The diagnosis of listeriosis is difficult to make on clinical presentation alone and therefore requires isolation of the bacteria from otherwise sterile sites such as the blood and cerebrospinal fluid (CSF). Identification can be challenging, however, as *Listeria* can look like cocci, diplococci, or diphtheroids under the microscope, often misleading the laboratory technician. Gram staining is only positive in approximately 30% patients. The organisms can be grown on selective media or using the cold enrichment technique and show a narrow zone of hemolysis. Rapid detection monoclonal antibody tests are available.

Unlike the name implies, infection in humans rarely leads to monocytosis. Instead, leukocytosis is more common with a predominance of polymorphonuclear cells. When meningitis is present, the CSF will usually be purulent with white blood cell counts ranging from 100 to 10,000 cells per mcL. The glucose levels are low in only 40% of the cases while protein levels are usually elevated.

Differential Diagnosis

Other neonatal sources of infection should be considered such as bacterial infections including group B streptococcus, *Escherichia coli*, and *Haemophilus influenza*. Other diagnoses may include disseminated herpes simplex virus, cytomegalovirus, rubella, or toxoplasmosis.

Treatment

While the diagnosis of maternofetal listeriosis is often missed due to the nonspecific symptoms associated with maternal infection, antimicrobial treatment of the mother during pregnancy can also treat the fetus and lead to a healthy newborn. Treatment of the neonate consists of supportive care in combination with antimicrobial therapy. High dose intravenous aminopenicillins such as ampicillin in combination with an aminoglycoside like gentamicin for synergy is the recommended treatment. Ampicillin alone is only weakly bactericidal and *Listeria* is resistant to all cephalosporins. An alternative in penicillin allergic patients is sulfamethazole-trimethoprim. Although there have been no randomized, controlled trials for the duration of therapy for listeriosis, the current recommendation is 10–14 days of IV therapy for invasive disease and 14–21 days for meningitis.

Prognosis

Twenty percent of *Listeria* infections during pregnancy will lead to stillbirth or spontaneous abortion while 68% of the surviving newborns will develop neonatal sepsis. Listeriosis has a 20–30% case fatality rate despite antimicrobial therapy. Non-neonatal cases who survive will have neurological sequelae in 30% of patients.

Prevention

There is no vaccine for *Listeria*. Avoidance of foods that are at high risk of being contaminated such as refrigerated deli meats, hot dogs/frankfurters, unpasteurized dairy products, and smoked fish is recommended in patients who are immunocompromised or pregnant. Other measures which may reduce the incidence of listeriosis include washing vegetables prior to consumption, keeping refrigerator temperature at 4.4°C or lower and freezer temperatures at −17.8°C or lower, and thoroughly heating all foods prior to consumption.

84 Lyme Disease

Michael P. Koster

Definition/Classification

Lyme disease, also known as Lyme borreliosis (LB), is a vector-borne, bacterial illness caused by the spirochete *Borrelia burgdorferi* sensu lato (*B. borgdorferi* in the general sense). Infection of the skin occurs first, but LB can disseminate to multiple organ systems.

Etiology

Historically, descriptions of dermatologic manifestations date back 100 years; however, LB was officially described in 1977 among an epidemiological cluster of patients with oligoarticular arthritis in Lyme, Connecticut, USA. In 1982, *B. burgdorferi* sensu stricto was detected and isolated in culture (see ❯ *Fig. 84.1*), and since then *B. garinii*, *B. afzelii* (both in Europe), and *B. spielmani* (Asia) species have been described with LB.

LB is transmitted to humans by infected *Ixodes* spp. ticks, which take blood meals from humans during their nymphal (more infective) and adult life stages. It is not a simple bite, but prolonged attachment (∼48 h) that transmits disease, as *Borrelia* spp. are found in the tick gut, and engorgement is associated with higher transmission rates.

Epidemiology

LB has a worldwide distribution, but the majority of literature is from Europe and North America, where it is the most common vector-borne illness. The United States has adopted epidemiological definitions and national surveillance; reporting 29,959 confirmed and 8,509 probable cases in 2009, and an incidence of 13.4/100,000 persons (Delaware reports the highest at 111.2, followed by Connecticut at 78.2) with 5–10-year-old children comprising the largest affected group. In Europe, not all countries have universal reporting; however, in 2006 reported incidence in Slovenia was 155/100,000 persons, Austria 130, Sweden 80, Bulgaria 55, and Germany 25 (with highest reported total cases at 20,700). Asian countries including China, Indonesia, Japan, Korea, and Nepal also report LB.

Pathogenesis

Borrelia spp. regulate gene expression throughout the life cycle to adapt to different host and host defenses. Upregulation of plasmid-encoded outer-surface protein (Osp) C allows the spirochete to attach to tick salivary glands to facilitate transfer to the mammalian host. Another example is the antigenic variation of lipoprotein VlsE, which helps elude host immunity. Once transmitted to humans, *Borrelia* spp. infect the skin and the ensuing inflammation gives rise to the characteristic erythema migrans (EM) rash. *Borrelia* spp. bind many host receptors, including plasminogen and its activators, to help it spread through tissue matrices. Additionally, certain gene expressions of OspC have been associated with dissemination. Although it is not known what makes certain spirochetes more neurotropic or arthritogenic, ongoing investigations continue to elucidate the spirochete–host interplay.

Humans respond to infection through both innate (complement, chemokines, Toll-like receptors) and adaptive immune responses (opsonizing antibodies). There is evidence that LB can trigger autoimmune phenomena, exemplified in patients with certain HLA-DR allotypes who develop noninfectious, recalcitrant arthritis.

Pathology

Although not clinically indicated, skin biopsy of early erythema migrans (EM) lesion reveals a dense mononuclear infiltrate, mainly of T cells, plasma cells, and occasional macrophages. Two other skin manifestations, more common in Europe, often require biopsy (in conjunction with immunohistochemistry, culture, and PCR) to establish the diagnosis: borrelial lymphocytoma is characterized by B cell infiltration and observable germinal centers in the cutis and subcutis, and acrodermatitis chronica atrophicans (ACA) is associated with an inflammatory response of T cells and macrophages.

Disseminated disease occurs from direct bacterial invasion, as animal models demonstrate spirochetes within nervous, cardiac, and synovial tissue. In arthritis,

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_84,

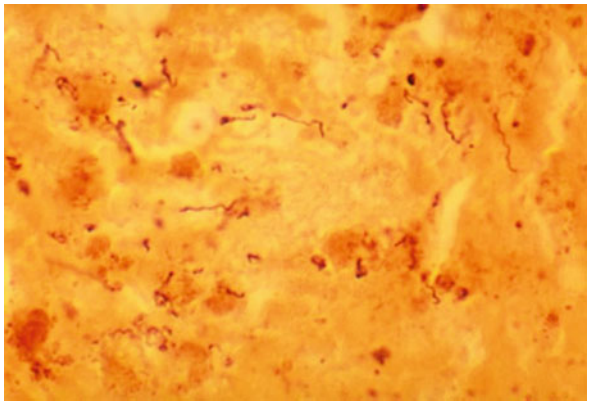

Figure 84.1
Histopathology showing *Borrelia burgdorferi* spirochetes in Lyme disease. Dieterle silver stain (Photo courtesy of CDC/Dr. Edwin P. Ewing, Jr. 1983)

joint aspiration will reveal a polynuclear leukocytosis. With meningeal involvement, cerebral spinal fluid will demonstrate a mild lymphocytic pleocytosis, moderately elevated protein, and typically normal glucose. Electrophysiological studies suggest that the bundle of His and AV node are the most commonly affected areas in cardiac disease associated with heart block.

Clinical Manifestations

Despite early and late clinical manifestations, symptoms do not necessarily present in a progressive linear fashion; however, the vast majority of patients (>90% in children) present with early localized disease, manifest by a single, circular, expanding (over days, at least 5 cm), macular, sometimes centrally-clearing (occasionally targetoid) lesion known as EM (see *Fig. 84.2*). EM typically occurs at the site of the tick bite approximately 10 days later (3–32 days), it can vary greatly in shape and infrequently can have a vesicular, scaly, or necrotic center. Careful examination is necessary as EM can be entirely within the hairline. Constitutional symptoms of myalgia, arthralgia, malaise, and/or headache can accompany EM or rarely be the only presenting symptoms. EM in Europe spreads slower, persists longer, and is associated with less symptoms of acute inflammation.

Multiple EM lesions are the most common presentation of early disseminated disease. Appearing days to weeks after a single EM in ~15–20% of cases, they are smaller, can

Figure 84.2
Erythema migrans rash with targetoid appearance (Photo courtesy of CDC/James Gathany 2007)

appear more linear, more often lack central clearing, and are often accompanied by constitutional symptoms. Neurological manifestations include isolated peripheral neuropathy, most commonly the facial nerve. Nuchal rigidity should prompt lumbar puncture for the evaluation of meningitis, but persistent and severe headaches are more typical. Increased intracranial pressure and papilledema, sometimes associated with abducens palsy, is well described in children with Lyme meningitis. Optic neuritis can also be seen. Cardiac involvement occurs in less than 1%, and presents as first-, second-, or third-degree heart block. Myocarditis can occur, but is less likely. An extremely rare and difficult to diagnose skin finding is borrelial lymphocytoma, which presents as a bluish-red swelling, mimicking a benign tumor, on the ear lobe or areola of the breast.

Arthritis, typically occurring months after infection, is the chief presentation of late disease and more common in North America (~10%). Monoarticular infection of the knee is most common; there is tremendous swelling with only mild-to-moderate pain and infrequently erythema overlies the joint. Occasionally, as described above, as a subset (~10%) of patients develop chronic arthritis. Polyneuropathy/ridiculoneuritis (Bannwarth syndrome)

is especially rare in children but should be suspected in endemic European areas when symptoms include muscle weakness, neuralgia, and/or paresthesias. Encephalomyelitis or encephalopathy (subtle cognitive dysfunction) is extremely rare in pediatrics, especially with better detection and earlier treatment. Also exceedingly rare (case reports in pediatrics), but historically important, ACA presents (typically in older women with *B. afzelii*) with a bluish-red lesion, atrophic skin, prominent vessels, and associated neuropathy.

Diagnosis

Serological testing is the mainstay for the diagnosis of LB. In North America, a two-tier testing system with excellent sensitivity and specificity has been adopted. Enzyme immunoassays (EIA) detect Lyme-specific antibodies quantitatively and if equivocal or positive (false positives occur), should be reflexed to a confirmatory Western immunoblot assay. The immunoblotting is considered positive if there are at least five of ten IgG bands or at least two of three IgM bands. Since immunoblotting can persist indefinitely after adequate treatment, a test which is positive by IgM alone would be considered false if symptoms had been present for longer than 1 month. Because of this, interpretation of testing can be very confusing, and testing should never be done for vague nonspecific symptoms, especially when the positive predictive value is low.

A clinical diagnosis of EM is pathognomonic for early localized disease, and serological testing should not be performed as it is unreliable at this stage.

Serological testing is invariably positive in early disseminated and late LB, although multiple EM is also specific enough to diagnose clinically. Especially in Europe where LB is more neurotropic, an antibody index or ratio of Lyme-specific immunoglobulins in the spinal fluid compared to the serum can elucidate neurological involvement.

Spirochete can be detected in affected sites by immunohistochemistry and culture, both with significant limitations to clinical practice. PCR has proven useful in diagnosing arthritis (not in meningitis).

Differential Diagnosis

The differential for EM includes, but is not limited to, other insect bites, granuloma annulare, nummular eczema, urticaria, pityriasis, tinea, drug eruption, erythema nodosum, and erythema multiforme. The expanding nature and persistence of EM, including the lack of scaliness and pruritus, help to distinguish it from the other rashes.

Lyme meningitis is indistinguishable from other forms of aseptic meningitis, but a larger percentage of monocytes in the spinal fluid, longer duration of symptoms, papilledema, and facial nerve palsy can be more telling.

Lyme arthritis can be mistaken for suppurative arthritis, reactive arthritis, juvenile idiopathic arthritis, rheumatic fever, or osteomyelitis with joint involvement. Ability to ambulate and only moderate pain, differentiate Lyme arthritis from suppurative arthritis, but serology (PCR if fluid is tapped) will decipher Lyme.

Coinfection (especially in North America) with other tick-borne illness like babesiosis should be considered in more severely ill-appearing patients and if leukopenia and thrombocytopenia are present ehrlichiosis should be suspected.

Treatment

Medication and duration are specific to the presenting symptoms of LB, best depicted in *Table 84.1*.

The use of macrolides (azithromycin 10 mg/kg/day (max 500 mg/day), clarithromycin 15 mg/kg/day in two divided doses (max 1,000 mg/day), erythromycin 50 mg/kg/day in 4 divided doses (max 2,000 mg/day)) should be reserved for those with true allergies to preferred regimens. Some patients may develop paradoxical worsening of symptoms soon after treatment begins that lasts about 24 h (Jarisch–Herxheimer). Few patients may have persistence of vague symptoms including fatigue, arthralgia, and headache that can last weeks to months after treatment. These post-Lyme syndromes are noninfectious, and should be treated supportively with nonsteroidal anti-inflammatory analgesic medications and reconditioning (there is no indication for prolonged antibiotics). For the few patients with recalcitrant arthritis, synovectomy or immune-modulating medications, like methotrexate, are treatment options.

Prognosis

LB has often been misdiagnosed, and has led to some confusion on treatment outcomes. Published data suggest that LB in children is completely treatable and outcomes for early and late disease are excellent.

Table 84.1
Treatment options based on symptomatology

Symptom	Drug	Duration
EM rash	1. Doxycycline[a] PO 4 mg/kg/day divided in two daily doses (max 200 mg/day) 2. Amoxicillin PO 50 mg/kg/day in three divided doses (max 1,500 mg/day) 3. Cefuroxime axetil PO 30 mg/kg/day in two divided doses (max 1,000 mg/day)	14 days (10–21 days)
Multiple EM rash	Same as for EM rash	21 days (21–28 days)
Borrelial lymphocytoma	Same as for EM rash	14 days (14–28 days)
Heart block/cardiac disease[b]	Same as for EM rash	21 days (21–28 days)
Isolated facial palsy	Same as for EM rash	28 days (14–28 days)
Meningitis,[c] polyneropathy, ridiculoneuritis, and other late neurological disease	1. Ceftriaxone 75–100 mg/kg/day IV once daily (max 2,000 mg/day) 2. Cefotaxime 150 mg/kg/day IV in three divided doses (max 6,000 mg/day) 3. Penicillin G 0.2–0.4 million units/kg/day in six divided doses (max 20 million units/day)	28 days (14–28 days)
Arthritis[d]	Same as for EM rash	28 days
ACA	Same as for EM rash	21 days

EM erythema migrans, PO per os, ACA acrodermatitis chonica atrohpicans
[a]Do not use in children <8 year and pregnant women due to teeth discoloration
[b]Third-degree heart block and severe cardiac disease requires hospitalization, sometimes pacing, and parenteral therapy initially
[c]Doxycycline has been studied extensively in Europe and can be used for acute uncomplicated neurological disease
[d]If arthritis needs to be re-treated some experts chose parenteral therapy

Prevention

The best way to prevent LB is to avoid tick-infested areas. In endemic residential areas, it is suggested to remove leaf litter and woodpiles, keep grass short, and apply pesticides. Using repellents such as DEET directly on the skin, and insecticides like permethrin on clothes, tents, and camping gear can be helpful. Also when anticipating exposure, wear long sleeves and tuck long pants into socks. Performing a careful skin inspection daily, when exposed, with prompt removal of ticks is most important as this dramatically decreases transmission rates (1–3%). Prophylaxis is not routinely recommended, only doxycycline has shown benefit in adults, and should be reserved for those who remove engorged ticks in endemic areas (children older than 8 years could take 4 mg/kg once, max 200 mg). Otherwise, patients who have been bitten should be monitored over the next month for the development of EM or constitutional symptoms and treated as needed.

85 Mycoplasma Infection

Manika Suryadevara · Leonard Weiner

Etiology

Mycoplasma pneumoniae, originally called the Eaton agent, was first isolated from a sputum culture in a patient with atypical pneumonia in 1944. Twenty years later, it was ultimately identified to be a *Mycoplasma* not a virus as once thought. Mycoplasmas are the smallest self-repliacting prokaryotes with a size of approximately 120–150 nm. These organisms cannot be seen by light microscopy nor do they produce visible turbidity in liquid growth media.

Like other bacteria in its Mollicutes class, Mycoplasmas lack the gene necessary to synthesize peptidoglycan cell walls. The absence of a cell wall explains its pleomorphic phenotype, inability to stain with Gram stain, and its resistance to antibiotics that interfere with cell-wall synthesis such as beta-lactams. While Mycoplasmas are found in many animals and plants, humans are the only known host for *M. pneumoniae* infection.

For many years, it was believed that *M. pneumoniae* infections were self-limited, confined to the respiratory tract, and involved only adolescents and young adults. Over time, much has been learned about this pathogen, its epidemiology, pathogenesis, and variety of clinical manifestations.

Epidemiology

M. pneumoniae, an exclusively human pathogen, is a frequent respiratory pathogen causing up to 40% of outpatient pediatric community-acquired pneumonia and 12–25% of lower respiratory-tract infections in hospitalized children. Once thought to infect primarily adolescents and young adults, recent literature suggests increasing infection in younger children. Worldwide, the incidence of *M. pneumoniae* infection is highest in children aged 5–9 years. However, a study of community-acquired pneumonia in children in Korea found that children less than 5 years accounted for over 44% of the 568 *M. pneumoniae* cases. Infants have also been documented to have *M. pneumoniae* infection, however, rarely.

M. pneumoniae occurs endemically and epidemically worldwide and throughout the year, with peaks in the summer and early fall months when the frequency of other respiratory pathogens is low. Community epidemic infections can be seen in 3–5 year cycles, with each epidemic lasting a few months. The 2–3 week incubation period in combination with asymptomatic nasopharyngeal carriage that persists for months beyond the initial infection likely contribute to these lengthy periods. During these epidemics, the frequency of infection can be 5–20 times greater than during the endemic periods. As *M. pneumoniae* is transmissible by respiratory droplets during close contact with a symptomatic person, these outbreaks tend to occur in closed populations such as military bases, colleges, and summer camps.

Mycoplasma infection elicits protective immunity; however, it is short lived, and reinfections throughout life are common. Naturally acquired infection in which pneumonia develops results in longer protective immunity than mild or asymptomatic infection.

Pathogenesis

Respiratory disease caused by *M. pneumoniae* is dependent on the close association between the host respiratory epithelium and the pathogen. This cytadherence process, considered a major virulence factor of this organism, is essential to colonization and infection as alteration of any of these proteins results in the organism's inability to cause infection. Subsequently, the immune response elicited, while responsible for much of the disease process, does not effectively clear the organism or produce long-term immunity.

M. pneumoniae enters the respiratory tract via inhalation of aerosolized droplets spread by symptomatic close contacts. The pathogen, with the help of P1 adhesion protein and accessory proteins, attaches to the ciliated epithelium and is thus protected from the host's mucociliary clearance mechanism. Close contact between host cell and pathogen allows for the pathogen's release of hydrogen peroxide and superoxide radicals directly onto

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_85,

the cell, which in combination with the toxic oxygen molecules produced by the host induces oxidative stress on the respiratory epithelium causing local disruption and cytotoxicity. Clinically, this damage to the respiratory tract manifests as a prolonged and irritating cough.

M. pneumoniae then reaches the base of a ciliated cell in the lower respiratory tract, where multiplication of organism occurs. Here, Mycoplasma is opsonized by complement and antibody and then phagocytosed by activated macrophages drawn to site of infection by chemotaxis, inducing a cytokine release. CD4+ T cells and B cells infiltrate the lung resulting in lymphocyte proliferation, antibody production, and further cytokine production, including interleukins, interferons, and tumor necrosis factor, and thus the development of pulmonary infiltrates seen on radiologic imaging. The stronger the immune response and cytokine production, the more severe the clinical picture develops.

Extrapulmonary manifestations of Mycoplasma infection occur by a variety of mechanisms, involving both immune-mediated processes (including autoimmunity, cytokine production, and the development of immune complexes) and direct invasion with dissemination. The presence of cross-reactive antibodies results in autoimmune reactions leading to neurological and hematologic presentations specifically encephalitis, Guillain–Barre syndrome (GBS), cranial and peripheral neuropathies, and autoimmune hemolytic anemia. Autoantibodies to ganglioside GM1 and galactrocerebroside have been implicated in the development of *M. pneumoniae* associated GBS, while those recognizing the I antigen of human red blood cells leads to development of cold agglutinins, previously used as a diagnostic tool in identifying Mycoplasma infection. These above-mentioned pathways are not exclusive and, as a result of the multiple pathogenic mechanisms, clinical presentation can be complex with or without respiratory symptoms.

Pathology

There are currently no cases describing histopathology of Mycoplasma infection in the pediatric population. Histopathologic examination has been reported in a few adult cases, animal models, and tracheal organ cultures, revealing lesions of the epithelial lining of the mucosal surfaces, ulceration, and destruction of the ciliated epithelium of the bronchi and bronchioles, bronchial and bronchiolar edema, and bronchiolar and alveolar infiltrates of macrophages, lymphocytes, neutrophils, plasma cells, and fibrin. Reports have also described Type II pneumocyte hyperplasia, diffuse alveolar damage, fibrinous exudates in the pleura, and lung abscesses. In fatal cases, desquamative interstitial pneumonia with focal alveolar disease and bronchiolitis obliterans have been seen.

Clinical Manifestations

Respiratory Tract

M. pneumoniae the most common pathogen causing an "atypical pneumonia," is known to infect both the upper and lower respiratory tract. The illness is usually gradual in progression over days to weeks, although sudden onset of dyspnea and cough has been reported. Three to ten percent of patients infected with *M. pneumoniae* go on to develop pneumonia.

Children present most commonly with fever and cough. The cough initially is dry and nonproductive but may develop into a mucopurulent cough, occasionally with blood streaked sputum. Children with Mycoplasma pneumonia are more likely to have a have a history prolonged fever that does not respond to beta-lactam antibiotics than those with pneumonia of other infectious etiology. Other symptoms include sore throat, headache, lethargy, chills, myalgias, rash, and a protracted cough which may become paroxysmal. Younger children tend to present with more rhinorrhea, wheezing, vomiting, and diarrhea, whereas older children and adolescents complain about sinus fullness and ear pain and are more likely to develop bronchopneumonia. The clinical presentation of Mycoplasma respiratory infection can mimic that of both respiratory viruses and/or pertussis making the diagnosis more difficult.

Physical-exam findings are dependent on the site of infection and, early in illness, can include non-exudative pharyngitis, myringitis, and cervical adenopathy. The etiology of bullous myringitis, thought to be pathognomonic of *M. pneumoniae*, has been shown to be a variety of organisms with Mycoplasma being only a rare cause. As the illness progresses over days to a week, the fever and upper respiratory symptoms resolve, and the lower respiratory findings become more prominent including tachypnea, scattered rales, ronchi, and/or wheeze on auscultation of the chest. The presenting symptoms usually resolve within 2 weeks; however, symptom resolution can take months.

Chest x-rays are usually abnormal in patients with Mycoplasma pneumonia; however, the findings are variable and not specific for *M. pneumoniae*. Lobar consolidation (typically unilateral and involving lower lobes) is a common finding as well as bilateral interstitial changes.

Hyperinflation, bronchial thickening, and hilar lymphadenopathy can also be seen. Parapneumonic effusions can be seen in 4–20% of patients. Improvement of radiographic findings lags behind clinical improvement by months.

Extrapulmonary Manifestations

While the respiratory tract may be the most common site infected by *M. pnueumoniae*, any organ system can be involved. Twenty five percent of hospitalized patients with Mycoplasma infection have extrapulmonary manifestations. These symptoms can occur before, during, after, or in the absence of respiratory symptoms. Although the pathogenesis of extrapulmonary manifestations is unclear, it is hypothesized to include direct invasion and/or autoimmune processes.

Table 85.1 lists the extrapulmonary complications associated with *M. pneumoniae* infection. The most common of the extrapulmonary manifestations are dermatologic, affecting 25% of infected patients, and neurologic, seen in 7–10% of hospitalized patients with Mycoplasma infection. The skin presentations can be, but are not limited to urticarial, vesicular, or maculopapular. *M. pneumoniae* is one of the most common infectious agents associated with Stevens–Johnson syndrome both with and without rash. Central nervous system (CNS) manifestations most commonly are encephalitis, meningoencephalitis, polyradiculitis, and aseptic meningitis. *M. pneumoniae* encephalitis is more frequent in children than in adults, and this pathogen should be on the differential diagnosis of patients with CNS disease, especially if associated with pneumonia.

Table 85.1
Extrapulmonary manifestation with *Mycoplasma pneumoniae* infection

Organ system	Clinical manifestation
Dermatologic	Urticarial or vesicular rash
	Erythematous maculopapular rash
	Stevens–Johnson syndrome
	Erythema multiforme
Central Nervous System	Encephalitis, Meningoencephalitis
	Aseptic meningitis
	Cerebellar ataxia
	Cranial and peripheral neuropathy
	Transverse myelitis
	Guillan–Barre syndrome
	Confusion
	Psychosis
Ocular	Optic neuritis
	Diplopia
	Conjunctivitis
	Retinitis
	Anterior uveitis
	Retinal hemorrhage
	Iritis
Hematologic	Hemolytic anemia
	Intravascular coagulation
Gastrointestinal	Vomiting
	Diarrhea
	Mild elevation of hepatic enzyme
	Pancreatitis
Cardiac	Heart failure
	Myocarditis
	Pericarditis
	Pericardial effusion
Renal	Glomerulonephritis
	IgA nephropathy
Bone/Joint/Muscle	Myalgias
	Arthralgias

Special Circumstances

Children with underlying conditions, such as sickle-cell disease, Down syndrome, and immunosuppression, are more likely to develop severe Mycoplasma infection with fulminant pneumonia and joint infection. *M. pneumoniae* infection has been associated with acute chest syndrome and multilobar infiltrates with large bilateral pleural effusions in patients with sickle-cell disease.

There is little published data describing *M. pneumoniae* infection in the pediatric HIV population. Recently, a study in India evaluated 90 HIV seropositive children who were hospitalized with acute respiratory symptoms. IgM antibodies specific for *M. pneumoniae* were seen in 32% of these children, with the majority of these patients between 6 and 9 years of age. Cough and fever were the most common presenting symptoms, in combination with headache, joint pain, dyspnea, sore throat, and hemoptysis. Almost all of these children were anemic and many had elevated hepatic enzymes, a side effect seen with many anti-retrovirals as well.

Diagnosis

Growing Mycoplasma in culture is difficult, labor intensive, and expensive. Special care is required to meet the complex nutritional needs to achieve growth, which can take up to 4 weeks. The sensitivity of culture is low at 61% when compared to PCR. As Mycoplasma can persist in the nasopharynx for months after the initial infection, isolation of the pathogen does not necessarily implicate it as the etiology of the current illness. Therefore, culture for Mycoplasma is not recommended for routine diagnosis.

Bedside testing of cold agglutinins was once the primary diagnostic tool for Mycoplasma infection. Cold agglutinins are an early nonspecific IgM antibody against the "I" antigen of the human erythrocyte. These autoantibodies are most active at 4°C. To test for cold agglutinins, the patient's blood would be drawn into a tube containing anticoagulant. The tube would be placed in ice water for 30 s to 5 min and then examined for agglutination. The strength of the agglutination correlates with the severity of disease. Cold agglutinins can be seen in half of patients infected with *M. pneumoniae*; however, false positives can be seen in children with lymphoproliferative disorder, infectious mononucleosis, influenza, and adenovirus infections. Lack of sensitivity, specificity, and standards render this method impractical in clinical situations.

There are several serological tests of *M. pneumoniae*, including complement fixation, passive agglutination, immunofluorescent antibody assays, and enzyme immunoassays (EIAs) which are the most commonly used. Complement fixation, the first serological method developed for *M. pneumoniae*, measures early IgM response without differentiating between the antibody classes. Since it is now known that Mycoplasma antibody can persist for months to years, this differentiating between antibody classes is important in distinguishing acute infection from old infection. EIAs have become more widely used for *M. pneumoniae* detection. The sensitivity of EIAs in *M. pneumoniae* detection is higher than that of culture and is even comparable to that of PCR.

Serologically, the diagnosis is made retrospectively with collection of acute and convalescent sera 2–4 weeks apart to show evidence of seroconversion. A fourfold increase in antibody titer between acute and convalescent titers or a single anti-Mycoplasma antibody titer of $>$1:128 is diagnostic of acute Mycoplasma infection. Similar to the time needed for culture, the need for acute and convalescent titers is a limitation in acute management, and empiric treatment should be given based on clinical suspicion.

New molecular-based testing such as PCR has been increasingly used in Mycoplasma detection. PCR allows for same day results and detection of Mycoplasma from body fluids, such as blood and CSF. While PCR has high sensitivity, a positive PCR result from a patient with a negative culture without respiratory disease is difficult to interpret since this may represent persistence of pathogen without infection or asymptomatic carriage.

Differential Diagnosis

Respiratory infection caused by *M. pneumoniae* commonly shares clinical features with respiratory viruses such as influenza, adenovirus, parainfluenza virus, respiratory syncytial virus, and human metapneumovirus. Similarly, other bacteria and atypical organisms should be considered in the differential diagnosis, including *Streptococcus pneumoniae*, *Haemophilus influenzae, Staphylococcus aureus*, and *Chlamidyophila pneumoniae.* In patients who present with protracted, paroxysmal cough, the diagnosis of pertussis should be considered.

Treatment

When *M. pneumoniae* infections were first described, antibiotic therapy was thought to be unnecessary as these illnesses were mild and self-limiting. Over time, antibiotics have been shown to decrease duration of both fever and respiratory symptoms. As it is difficult to obtain a microbiologic result at the time of the patient visit, empiric therapy should be started with clinical suspicion of Mycoplasma associated lower respiratory tract infection.

Beta-lactams and glycopeptides, commonly used to treat community-acquired pneumonia, are ineffective against Mycoplasma since this organism lacks a cell wall. Macrolides are currently the recommended treatment of choice for infection with *M. pneumoniae*. Azithromycin and clarithromcyin are clinically as effective as erythromycin and are better tolerated, given only once or twice a day, and require shorter treatment duration in the case of azithromycin. Fluoroquinolones and tetracyclines are also effective antimicrobial agents and, unlike macrolides, there have been no reported Mycoplasma resistance to these classes. However, due to the significant toxicities associated with these medications in the pediatric population, macrolides remain the drugs of choice. While antibiotic therapy may decrease clinical symptoms, they do not eradicate the organism and asymptomatic carriage may persist and subsequent reinfection may occur.

Macrolide resistant strains of Mycoplasma contain a mutation in the 23S rRNA gene decreasing the affinity of these medications for the ribosomes. First described in Europe, clinical resistance to macrolides has been increasing worldwide over the past decade. Rates of macrolide resistance have ranged from a few case series in the United States to 3% in Germany and 13% in Japan to 69% in a study in China. Children with macrolide resistant Mycoplasma infection were found to have longer fever duration than those with infection with a susceptible organism.

There is little data available regarding the treatment of extrapulmonary manifestations of *M. pneumoniae*. The pathogenesis of these clinical presentations is unclear and thought to be due to direct invasion and dissemination and/or an autoimmune response. Therefore, treatments have included antibiotics, steroids, as well as plasmapheresis and intravenous immunoglobulin. There currently have been no controlled studies evaluating these treatment options with extrapulmonary systems and no consistent studies showing any benefit. It is reasonable, since Mycoplasma can cause severe disseminated disease, to start antibiotics in patients with central nervous system disease, hemolysis, or cardiac disease when infection with *M. pneumoniae* is suspected.

86 Neisseria Infections

Melissa Ketunuti · Matthew P. Kronman

Definition and Classification

Neisseria are aerobic, gram-negative, oxidase-positive coccoid bacteria, and most species are found in pairs (diplococci) on examination of the Gram stain. Two main pathogenic species exist, *N. meningitidis* (commonly referred to as meningococcus) and *N. gonorrhoeae* (commonly referred to as gonococcus). This chapter will focus on *N. meningitidis* and manifestations of *N. gonorrhoeae* outside the urogenital tract. For a detailed discussion of genitourinary infections caused by *N. gonorrhoeae*, please see Chap. 71, "Sexually Transmitted Diseases".

Other *Neisseria* species commonly colonize the human upper respiratory and female urogenital tracts, and can be distinguished from the more pathogenic *Neisseria* species on the basis of carbohydrate utilization and biochemical testing. These other species include *N. sicca*, *N. subflava*, *N. cinerea*, *N. lactamica*, *N. mucosa*, *N. flavescens*, *N. weaveri*, *N. polysaccharea*, and *N. elongata*.

Epidemiology

Annually, *N. meningitidis* causes disease in approximately 2,500 people in the United States, and 500,000 people worldwide, resulting in an estimated 50,000 deaths. Despite advances in therapy, the 10% mortality rate has remained unchanged in the last 20 years. Two incidence peaks exist for meningococcal infection: the first peak occurs in children less than 5 years of age, and the second peak in people 15–24 years of age. Although the vast majority of meningococcal cases (95%) are endemic, epidemic outbreaks have occurred in association with daycare centers, college dorms, and military barracks. Crowded living conditions promote the spread of the organism, placing those of low socioeconomic status at higher risk of meningococcal disease. In addition, tobacco smoke exposure and upper respiratory viral infections increase the risk of disease, likely through diminishing mucous membrane integrity. Meningococcal cases are reported more frequent in the winter months following influenza virus infections.

There are 13 identified *N. meningitidis* serogroups as determined by differences in the bacterial polysaccharide capsule. The serogroups have varying epidemiological features and are responsible for different disease manifestations. For example, serogroup C usually causes meningitis and septicemia, whereas serogroup W-135 also causes arthritis and pneumonia. Current meningococcal vaccines target specific serogroups and are likely going to change the epidemiology of disease in the future as vaccination rates increase.

Serogroups B, C, Y, and W-135 are the most common causes of endemic meningococcal disease in the United States. Of these, serogroups B and C are the most prevalent serogroups causing disease, but serogroup Y is emerging as a more common entity, causing up to a third of endemic cases in certain areas. Serogroup W-135 previously caused 20% of meningococcal cases but is now responsible for only 4% of cases in the United States.

Worldwide, the majority of endemic meningococcal cases are caused by serogroups A, B, and C. Serogroups B and C cause disease in Europe and the Americas, while serogroups A and C cause disease in Asia and Africa.

Although all serogroups have the potential to cause epidemic disease, certain serogroups have caused recurrent outbreaks. In the United States, the majority of these outbreaks are due to serogroup C, and more recently, due to serogroup Y. Although the frequency of epidemics has been increasing since the 1990s, epidemics in the United States typically account for only 2–3% of meningococcal cases.

Worldwide, serogroup A is the most common agent responsible for epidemics of meningococcal meningitis. Serogroup A causes outbreaks in the sub-Saharan "meningitis belt," which extends from Ethiopia to Senegal. In this region, serogroup A is responsible for both endemic meningococcal disease as well as recurrent epidemics occurring approximately every 7–10 years. Other serogroups that have caused epidemic disease include serogroup W-135, which was responsible for the Hajj epidemic in 2000, and serogroup B, which caused an epidemic in Oregon and Washington in 1990.

Overall, the incidence of gonococcal infections remains high, with an estimated 60 million cases annually

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_86,

worldwide, including approximately 300,000 annually in the United States. Disseminated gonococcal infection, however, is less common, with fewer than 5% of patients experiencing disseminated disease. Rates of disease in the United States have remained stable since the mid-1990s. Gonococcal infections are more common among those with lower socioeconomic status and earlier onset of sexual activity.

Resistance to multiple antibiotic classes has begun to develop among *Neisseria* species worldwide. In part, horizontal gene transfer between nonpathogenic colonizing *Neisseria* species and pathogenic *Neisseria* species is responsible for these increasing resistance patterns. Emerging resistance to penicillins, extended-spectrum cephalosporins, and fluoroquinolones has been documented.

Pathogenesis

Five to ten percent of adults are asymptomatic carriers of *N. meningitidis*. The organisms colonize the nasopharynx and are spread through secretions of aerosolized particles. Disease occurs when the epithelial cells engulf the bacteria, which then gain access to the bloodstream. For reasons that are still unclear, invasive disease tends to occur within 1 week of a new exposure to *N. meningitidis*.

People with deficiencies in antibody-dependent immunity are more susceptible to meningococcal disease. The specific immune deficiencies associated with meningococcal infection include infants with waning maternal antibodies, those with functional or anatomical asplenia, and those with terminal complement deficiencies. Terminal complement deficiencies are estimated to cause a 10,000-fold increased risk of acquiring meningococcal disease. However, the majority of meningococcal disease does not occur in people with intrinsic risk factors.

Clinical Manifestations

The common and uncommon clinical presentations of *N. meningitidis* and *N. gonorrhoeae* are presented in Table 86.1. *N. meningitidis* most commonly causes meningitis and meningococcal sepsis (meningococcemia), but can also cause less common infections such as arthritis, pneumonia, otitis media, conjunctivitis, epiglottitis, urethritis, pericarditis, and osteomyelitis.

Meningococcal sepsis manifests as an abrupt onset of fever and a characteristic petechial or purpuric rash. The rash that typically presents in meningococcemia is known as purpura fulminans and is a diffuse, non-blanching petechial or purpuric rash over the trunk and extremities. Progression of sepsis leads to hypotension and disseminated intravascular coagulation with end-organ failure. End-organ failure in meningococcal sepsis often involves the kidneys, lungs, and adrenal glands. Waterhouse–Friderichsen syndrome is an acute adrenal hemorrhage often seen in meningococcal sepsis, which leads to a subsequent cortisol deficiency.

Table 86.1
Clinical presentations *of Neisseria meningitidis and Neisseria gonorrhoeae* infections

Neisseria meningitidis	*Neisseria gonorrhoeae*
Most common	
Meningitis	Neonatal conjunctivitis
Bacteremia	Urethritis
Septic arthritis	Endocervicitis
	Salpingitis
Uncommon	
Otitis media	Septic arthritis
Pneumonia	Arthritis-dermatitis
Conjunctivitis	Bacteremia
Epiglottitis	Meningitis
Urethritis	Endocarditis
Pericarditis	
Vasculitis	
Osteomyelitis	

Chronic meningococcemia is a rare clinical manifestation of *N. meningitidis* and is defined as meningococcal sepsis of at least 1 week duration without meningeal symptoms. It is characterized by recurrent fevers, rash, migratory arthralgias, and headaches. The pathophysiology of chronic meningococcemia remains unclear.

The hematogenous spread of *N. meningitidis* can lead to meningitis, which is the most common presentation of invasive meningococcal disease (see Chap. 69, "Meningitis"). About 60% of patients with meningococcal meningitis present without septic shock. Clinical signs of meningococcal meningitis are typical of those of other causes of bacterial meningitis and include meningismus, headache, increased intracranial pressure, and mental status changes. In infants, meningitis can often present as poor feeding or lethargy without any focal signs.

N. meningitidis also causes arthritis. Two different types of arthritis result following infection: septic arthritis or an immune-complex-mediated arthritis. Septic

arthritis can occur as an isolated meningococcal infection, but it most commonly presents as a complication of meningococcemia or meningitis. Septic arthritis complicates approximately 10% of meningococcemia and is frequently preceded by an upper respiratory tract infection. It is usually monoarthritic, particularly affecting the knees, and is more common in men. The immune-mediated form of arthritis, which also primarily affects the large joints, results from the deposition of immune complexes in the joint space, and presents as a sterile effusion. The frequency of immune-mediated arthritis complicating acute meningococcal infection ranges from 4% to 50%.

N. meningitidis, particularly serogroup Y, can cause pneumonia as an isolated infection or concurrently with meningococcemia or meningitis. Meningococcal pneumonia occurs in approximately 5–15% of invasive meningococcal disease. Diagnosis of meningococcal pneumonia is challenging given that isolation of the organism in the sputum cannot distinguish between colonization and infection. Blood or pleural cultures that yield *N. meningitidis* can assist with the diagnosis.

Other meningococcal infections such as otitis media infections, epiglottitis, pericarditis, urethritis, and osteomyelitis are rare and may require consultation with an infectious diseases specialist.

Gonococcus is a common cause of neonatal conjunctivitis, also known as ophthalmia neonatorum. Neonates acquire the organism after exposure to maternal colonization; symptoms typically begin within 2–5 days after birth, though can arise in the first 3 weeks of life. Clinical features include prominent eyelid edema and significant mucopurulent discharge, often bilaterally. Rarely invasive gonococcal disease can occur with the microbial entry to the bloodstream via the conjunctivae.

Disseminated infections due to *N. gonorrhoeae* outside the genitourinary tract are uncommon, typically occurring in fewer than 5% of patients. The more common manifestations of disseminated gonococcal infection include bacteremia, septic arthritis, tenosynovitis, and an arthritis-dermatitis syndrome including multiple skin lesions with polyarthralgias. As with meningococcus, when septic arthritis is present, typically single large distal joints are affected, such as knees, wrists or ankles, but multiple joints and small joints (such as interphalangeal joints) can be affected. Likewise, arthritis in patients with gonococcal infections can also be immunologically mediated and sterile in nature. The skin lesions seen with disseminated gonococcal infections can be quite varied, including papules, pustules, and bullae. Gonococcal infections in children outside the neonatal period should prompt a consideration of sexual abuse; see Chap. 71, "Sexually Transmitted Diseases".

The other *Neisseria* species are typically nonpathogenic, but have been associated with bacteremia, meningitis, endocarditis, septic arthritis, and other invasive infections, most typically in immunocompromised hosts or after surgical procedures, but occasionally reported in previously healthy individuals. *N. cinerea* has been specifically linked to ocular infections in neonates. Because these *Neisseria* species are commensal oral flora, they have also occasionally been identified in bite wounds.

Diagnosis

Diagnosing meningococcal infection relies on recognition of clinical signs and symptoms and on isolating the organism from the appropriate body site. Gram stain and culture of blood, cerebrospinal fluid (CSF), and tissue remain the gold standard. In suspected meningococcal meningitis, diagnosis is made by performing a lumbar puncture and obtaining CSF for analysis. Typical CSF findings include an elevated opening pressure, a pleocytosis with a neutrophil predominance, an elevated protein level, and a low glucose level. While meningococcal meningitis can be diagnosed using an antigen test on the CSF, the antigen test is rapid but has poor sensitivity and is not commonly used. Narrowing empiric therapy based on the results of a rapid antigen test alone is therefore not recommended. Nucleic acid testing for *N. meningitidis*, although not commercially available in the United States, is being developed and used in other parts of the world.

Diagnosis of meningococcemia can be more challenging as typical clinical symptoms do not always manifest initially. Gram stain and culture of blood and skin lesions are most helpful in making the diagnosis. Diagnosis of septic arthritis should include joint aspiration with synovial fluid analysis for Gram stain and culture.

The diagnosis of meningococcal pneumonia is challenging as *N. meningitidis* isolated in the sputum cannot differentiate infection from colonization. Blood cultures positive for *N. meningitidis* support the diagnosis, but a pleural effusion sample or pleural biopsy confirms it.

Diagnosis of gonococcal infections can likewise be made in several ways. Diagnosis of genitourinary infections can be made rapidly using nucleic acid amplification methods on urine specimens (see Chap. 69, "Meningitis"). Blood cultures should be obtained if gonococcal bacteremia is suspected, and culture of synovial fluid is routinely indicated and may be positive in up to half of patients with gonococcal septic arthritis.

Differential Diagnosis

For a differential diagnosis of organisms that may cause a specific infectious syndrome (e.g., meningitis, septic arthritis, etc.), please refer to the appropriate chapter. Other gram-negative organisms that can appear coccoid upon microscopic examination include *Moraxella* species (formerly *Branhamella*) and *Kingella* species.

Treatment

The initial treatment of meningococcal disease depends on the severity of the presenting infection. If a patient presents with shock, disseminated intravascular coagulation, and increased intracranial pressure, resuscitation and supportive intensive care should be initiated. If septic shock or meningitis is the presenting illness and *N. meningitidis* is suspected, broad-spectrum antibiotics such as third-generation cephalosporins (cefotaxime or ceftriaxone) should be administered (see Chap. 69, "Meningitis"). Fluoroquinolones are not routinely recommended for empiric treatment of suspected invasive meningococcal disease due to reports of emerging resistance.

Once *N. meningitidis* has been identified on culture from a sterile site (such as blood, spinal fluid, or synovial fluid), antibiotics can be narrowed based on the susceptibility profile. Treatment of chronic meningococcemia is identical to that for acute meningococcemia. The majority of *N. meningitidis* isolates continue to be susceptible to penicillin, which is the preferred treatment. Treatment of meningococcemia for 5–7 days with penicillin is appropriate, although shorter antibiotic courses are being explored. However, cases of *N. meningitidis* infection with reduced susceptibility to penicillin have been documented in certain serogroups (W-135 and C) outside the United States. Alternative treatments in the case of penicillin-resistance or penicillin allergy include cefotaxime, ceftriaxone, and ampicillin. In the low-resource setting, a one-time intramuscular dose of chloramphenicol has also been shown to be effective.

If antibiotics are administered prior to obtaining CSF, interpretation of CSF analysis cannot be relied upon as *N. meningitidis* is killed within 3–4 h of antibiotic administration. Although a CSF pleocytosis may be seen, it is unlikely that culture will yield an organism. The benefit of corticosteroids in meningococcal meningitis has not been established.

In cases of less severe illness such as conjunctivitis, susceptibility testing is not always necessary and empiric treatment is recommended. Susceptibility testing should be initiated only in cases of treatment failures.

Recommended empiric treatment of disseminated gonococcal infections outside the central nervous system includes a third-generation cephalosporin (cefotaxime or ceftriaxone) for 7 days, and should be extended to 10–14 days if meningitis is confirmed or suspected. Antimicrobial treatment can be tailored when culture results are available.

Prognosis

Severe meningococcal disease such as meningitis and sepsis causes sequelae in up to 20% of survivors, including hearing loss, limb loss and skin scarring, seizures, and neurologic disabilities. Untreated neonatal conjunctivitis can progress to corneal ulceration and ultimately blindness, and was formerly a leading cause of blindness worldwide. Other *Neisseria* infections typically resolve without significant sequelae if diagnosed and treated in a timely manner.

Prevention

The quadrivalent conjugate meningococcal vaccine (MCV4) was licensed in 2005 and includes the four most common meningococcal serogroups encountered in the United States (serogroups A, C, Y, and W-135). Most meningococcal disease is caused by these four strains as well as serogroup B, which is not covered in any vaccine. More than 50% of disease in younger children is caused by serogroup B. The meningococcal vaccine is recommended routinely for adolescents 11–18 years of age, for children >2 years of age with risk factors (including terminal complement deficiencies and asplenia), children living in high-risk endemic areas, military recruits, and those living in college dormitories who were not previously vaccinated. A new, more affordably produced conjugate meningococcal vaccine against serogroup A was introduced to sub-Saharan Africa in late 2010 with a goal of widespread immunization to prevent epidemics of meningitis caused by *N. meningitidis* serogroup A. No vaccine is currently available for *N. gonorrhoeae.*

Close contacts of patients with invasive meningococcal disease are considered high risk and chemoprophylaxis is recommended. This includes all household members, persons sleeping in the same dwelling within 7 days of the index case, and all attendees of a daycare or preschool present within 7 days of the index case. Persons who

Table 86.2
Recommended chemoprophylaxis for exposed persons

Infants	Rifampin (2 days)
Children	Rifampin (2 days) or ceftriaxone (single dose)
Adolescents	Rifampin (2 days) or ceftriaxone (single dose) or azithromycin (single dose)
Adults	Rifampin (2 days) or ceftriaxone (single dose) or ciprofloxacin (single dose) or azithromycin (single dose)

came into contact with any secretions from the infected person, such as health care workers taking oral or nasal samples, or health care workers involved in airway management should receive chemoprophylaxis. Chemoprophylaxis is not necessary for health care workers coming into contact with secretions more than 24 h following antibiotic initiation. Persons seated next to the index case on a plane or confined space for more than 8 h should also receive chemoprophylaxis. All chemoprophylaxis should be initiated within 24 h of contact.

Rifampin should be used as chemoprophylaxis in children and rifampin, ceftriaxone, ciprofloxacin, or azithromycin can be used in older children and adults (*Table 86.2*). Chemoprophylaxis is also recommended in children treated for meningococcemia with penicillin or chloramphenicol as these antibiotics do not eradicate nasal carriage. Prophylaxis to prevent neonatal conjunctivitis is routinely and universally indicated, by applying either 1% tetracycline ophthalmic ointment or 0.5% erythromycin ointment to both eyes immediately after birth.

87 Pertussis

Mohammad Al-Shaalan

Pertussis is an acute respiratory tract infection affecting all age groups. Pre-vaccine era witnessed a high prevalence of disease with a significant morbidity and mortality. Introduction of vaccine resulted in a significant decrease of the disease in children; however, because of waning immunity following natural disease in 7–14 years or vaccination in 4–12 years and because there is no booster vaccination after 7 years of age, the disease incidence increased in the adolescents and adults resulting in a pool of patients who remained a source for infecting others especially young infants who are not yet vaccinated or have received only one dose of the vaccine.

Because of these factors, the disease remained endemic in most of the countries with 50 million cases occurring annually resulting in 400,000 deaths. Most of the morbidity and mortality occur in young infants. However, the number of global reported cases is less than the estimated one (◉ *Fig. 87.1*).

The affected adolescents and adults usually present with a typical presentation of prolonged cough without classis whoop and therefore remain infectious for a long period.

Organism

Pertussis is mainly caused by *Bordetella pertussis* and *Bordetella parapertussis*. Bordetella is a Gram-negative fastidious aerobic, nonmotile bacillus. Therefore, it requires special media for its growth. The first media introduced was Bordet–Gengou agar. Bordet–Gengou medium is composed of potato, glycerol, and cephalexine. Recently, Regan–Lowe medium is being introduced. It is composed of charcoal agar, defibrinated horse blood, cephalexine, and amphoterecin B. In addition, there is a semisolid transport media of Regan–Lowe formula in case there is anticipated delay in culturing the specimen. Both media have similar yield although some studies showed Regan–Lowe to be superior. *B. pertussis* has also been shown to grow in some other media like buffered charcoal, yeast extract agar, and cyclodextrin solid medium.

Bordetella genus include other related species that may cause human disease but milder than that of *B. pertussis*. These species include:

- *Bordetella bronchoseptica*, which is primarily a pathogen in animals. It occasionally causes mild disease in humans.
- *Bordetella homesii* and *Bordetella hinzii* may be isolated from blood in patients with chronic illnesses. *B. henzii* has also been isolated from the respiratory tract of cystic fibrosis patients.
- *Bordetella trematum* is rarely isolated from wound and ear infections.
- *Bordetella petrii* has been isolated from patient with cystic fibrosis.

Pathogenesis

B. pertussis is acquired by inhalation of infected droplets. Once in the nasopharynx, they may invade the lower part of respiratory tract. It has a high preference for respiratory epithelium without systemic invasion. The attachment to respiratory epithelium is mediated by pertussis toxin and lymphocytosis promoting factor. The local damage is mediated by multiple factors that include in addition to pertussis toxin, tracheal cytotoxin, heat labile toxin, and other toxins. Adenylate cyclase and pertussis toxin inhibit the host immune response both by retarding chemotoxis and preventing phagocytosis and intracellular killing.

Clinical Features

After an incubation period of 7–10 days the symptoms start. The disease proceeds through three stages: catarrhal, paroxysmal, and convalescent.

Catarrhal Stage

In this stage, the child has nonspecific symptoms of fever, runny nose, conjunctivitis, and mild cough. This stage lasts for 1–2 weeks and it is usually very difficult to differentiate from symptoms of other respiratory infections.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_87,

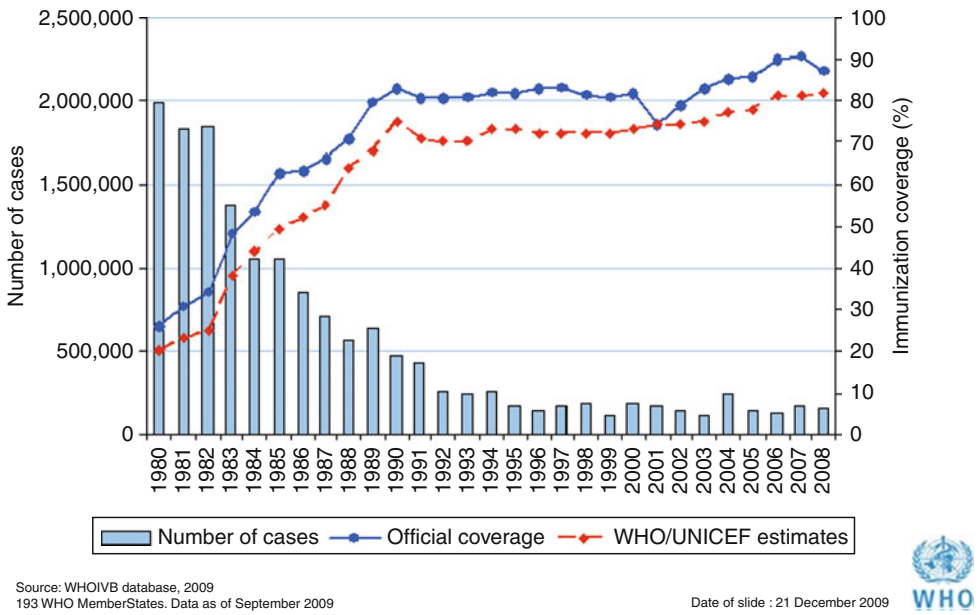

Figure 87.1
Pertussis global annual reported cases and DTP3 coverage, 1980–2008

Paroxysmal Stage

During this stage, the cough evolves into the characteristic pattern of paroxysms. Each paroxysm consists of 10–20 successive coughs that end by deep inspiration that may be associated with whoop due to forceful passage of air through narrow epiglottic opening. Young infants are less likely to have whoop; however, they are prone to develop apneic spells that may be prolonged and result in cyanosis and hypoxia. It is during this stage that hypoxemic insults may result. Such hypoxia may adversely affect brain and thus cause encephalopathy or seizure attacks.

Convalescent Stage

The cough decreases in its intensity; however, the child may remain to have episodes of cough that usually are not in paroxysm. This stage usually lasts for 1–2 weeks but it may persist for months. Recurrence of brief paroxysmal cough during this stage may occur but rare.

Complications

Pertussis is an acute disease that causes significant morbidity and mortality. Pneumonia whether primary or secondary is the most common complication and the most common cause of death among patients with pertussis. Pertussis results in atelectasis and bronchopneumonia in significant number of patients; however, long-term pulmonary sequelae are rare. Secondary bacterial pneumonia is common and therefore therapy directed for these pneumonias in addition to that of pertussis is required. Most common bacterial cases of pneumonia in such patients are *S. pneumoniae, H. ifluenzae*, and *S. aureus*.

Encephalopathy occurs in 8/1,000 and seizure occurs in 3% of affected patients. The presumed cause of these brain insults is hypoxia, toxins produced by *B. pertussis*, and intracerebral hemorrhage. Other complications include otitis media, sinusitis, subconjunctival hemorrhage, epistaxis, subdural hemorrhage, and melena.

Diagnosis

Culture, PCR, and serology are different methods of diagnosis but each has its limitation.

Culture

B. pertussis is fastidious organism that requires special growth media. Therefore in suspected cases, laboratory should be informed to prepare the appropriate media. Culture requires a collection of nasopharyngeal specimen

with a Dacron or calcium alginate swab and sending it immediately to the laboratory in a specific transport media, to be cultured in Regan–Lowe or Bordet–Gengou medium.

There are a number of factors which decrease the sensitivity of the culture:

1. Culture obtained after 7 days of illness.
2. Previous antibiotic usage.
3. Poor specimen collection or poor transportation or media contamination in the laboratory.
4. Previous immunization as the organism load is usually low.

Therefore, having a negative culture does not necessarily exclude the diagnosis:

PCR

A new modality for the diagnosis with a better sensitivity. It has the advantage of ability to be positive even if collected later in the disease course; however, sensitivity decreases after the 14th day of illness.

Serology

EIISA for IgG, IgA, and IgM against pertussis antigens can be done. The best antigen to be used is pertussis toxin. Previous immunization may result in positive test. Recent vaccination usually results in positive IgM and IgG. In acute infection IgA is usually positive; however, it is better to collect acute and convalescent sera for both IgA and IgG. A twofold rise is suggestive of acute infection. In adolescents and adults, a single IgG more than 100 unit/ml is highly suggestive of acute infection.

Antigen Detection Test

Direct fluorescent antibody (DFA) test is a rapid test that has 95% specificity but it is less sensitive 60%. The advantage of DFA is being rapid with result available in 2–4 h. Other experimental rapid tests are DNA hybridization and PCR-based tests but they are not yet widely used.

Treatment

Treatment of pertussis consists of nonspecific supportive measures and directed antibiotic therapy. Supportive measures include maintaining good nutrition, providing oxygen and supporting ventilation if needed. Nonspecific therapy with steroids and salbutamol has been used in few nonrandomized studies with some benefit; however, it cannot be recommended as a standard of therapy as it is not supported by controlled randomized studies. Young infants with severe leukocytosis exceeding 100,000/mm^3 may suffer from severe respiratory distress and pulmonary hypertension leading to respiratory and circulatory failure. Autopsy of such infants has shown obstruction of small- and medium-sized pulmonary arteries with lymphocytes without thrombosis. In such infants, there is some anecdotal report of some benefit from exchange transfusion to reduce the number of leukocytes. Specific antibiotic therapy is recommended in all patients with proven or suspected pertussis. Erythromycin especially the estolate form is very effective against *Bordetella*. The recommended dosage is 40–50 mg/kg/day in four divided doses. The new macrolides (azithromycin and clarithromycin) have been shown to be of equal efficacy with better tolerance. Use of antibiotic in the catarrhal stage (within 2 weeks of illness onset) may abort or ameliorate the progression of the disease. However, if it is not introduced until the paroxysmal stage is started, then there is no efficacy on the disease course; however, it will accelerate the eradication of the organism and thus its contagiousness. The recommended duration of therapy is 14 days; however, new studies have shown 7 days of therapy is equivalent to the longer duration and this has led many authorities to recommend the shorter course of therapy.

Resistance to erythromycin has been reported in occasional cases. Patients who do not tolerate erythromycin should be treated with cortimoxazol at a dosage of 8 mg of trimethoprim 40 mg of sulfamethoxazole/kg/day in two divided doses for 14 days.

Prevention

Isolation

Children suspected to have pertussis should be isolated if hospitalized until the culture is available or the patient is being treated for 5 days with appropriate antibiotics. They should also be prevented from school or day care attendance until they are 5 days on therapy.

Prophylaxis

Household contacts should be prophylaxed with erythromycin 40 mg/kg/day qid for 14 days.

Immunization

Killed whole cell vaccine has proven to be effective in decreasing the prevalence of pertussis and should be given to all infants. Recently, acellular pertussis vaccine with less side effects is being introduced and it may be the recommended future vaccine (see section on immunization).

88 Pneumococcal Infections

Mahmoud M. Mustafa

The pneumococcus *Streptococcus pneumoniae* continues to be a leading cause of morbidity and mortality in all age groups. In children, *S. pneumoniae* is the most common cause of community-acquired pneumonia, otitis media, and recently meningitis, due to the control of *Haemophilus influenzae* infection, which used to be the most common cause of bacterial meningitis, by the effective polysaccharide–protein conjugate vaccines. The significance of *Pneumococcus* is further accentuated because of the recent emergence of penicillin- and multidrug-resistant strains in many countries. The continued frequency and severity of pneumococcal disease, the emergence of penicillin resistance, and the fact that antimicrobial agents do not invariably prevent illness or death underscore the need for better understanding of pneumococcal infections and the development and use of appropriate vaccines.

Etiology

Streptococcus pneumoniae is a gram-positive, lancet-shaped, encapsulated diplococcus. There are 84 different serotypes that are identified by their type-specific capsular polysaccharides. Only smooth, encapsulated strains are pathogenic for humans. Capsular size varies considerably, with types 3, 8, and 37 having very thick capsules. Virulence is related in part to the size of the capsule. Capsular material impedes phagocytosis; therefore, fully encapsulated strains (e.g., type 3) are extraordinarily virulent.

Pneumococci are facultative anaerobes. On solid media, they form unpigmented colonies with α-hemolysis. Immediate and accurate identification can be made by exposing the pneumococcus to homologous type-specific antisera that combine with their respective capsular polysaccharides, thus rendering the capsule refractile (quelling reaction). Pneumococci also can be identified by rapid lysis after exposure to a 10% solution of bile salts.

In contrast to antibodies directed against the capsular polysaccharides, which are protective by promoting opsonization and phagocytosis, antibodies to various cell wall antigens such as C, R, and M antigens confer negligible immunity.

Epidemiology

Pneumococci normally reside in the pharynges of healthy people in all parts of the world. They spread from person to person in droplets of respiratory secretions, and infection of the upper respiratory tract aids spread. Therefore, both colonization and disease are more common in winter and spring. The colonization rate depends on age, exposure to young children, and the specific population studied. Maximum colonization rates occur in young children in institutions. Most children are colonized at some time during the course of a year. More than 90% of children between 6 months and 5 years carry *Pneumococcus* at some time. Adults with no contact with young children have a low colonization rate of 5%. Approximately 85% of infections are caused by serotypes 1, 4, 6, 9, 11, 14, 15, 18, 19, and 23, and 50% are caused by serotypes 6, 19, and 23.

Streptococcus pneumoniae is the most common cause of bacterial meningitis, otitis media, and pneumonia, with peak incidence at 3–6 months, 6–12 months, and 12–18 months, respectively. The increased susceptibility of children younger than 2 years of age to pneumococcal infection may be due at least in part to the inability of these infants to mount an antibody response to polysaccharide capsule antigens. In addition to young age, the frequency and severity of pneumococcal infections are increased in patients with sickle cell disease, asplenia, B-cell immune deficiencies, the acquired immunodeficiency syndrome, complement deficiencies, and underlying malignancy.

Pathogenesis

Pneumococci reach their target by direct extension from colonized mucosal surfaces or by hematogenous spread. Thus, most cases of otitis media result from extension of *Pneumococci* from the nasopharynx to the middle ear through the Eustachian tube, and most pneumococcal pneumonia cases spread from aspiration of pharyngeal secretions. Pneumococcal meningitis, in contrast, follows pneumococcal bacteremia except in the occasional case of

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_88,

direct spread to the meninges via a basilar or temporal skull fracture. It is believed that a preceding viral infection may enhance pneumococcal growth and invasion by producing mucosal damage, diminishing epithelial ciliary activity, and depressing the function of alveolar macrophages. In these tissues, *Pneumococci* can spread directly or invade the lymphatics and bloodstream.

Once *Pneumococci* reach the target tissue and multiply, severe inflammation ensues. Contrary to capsular polysaccharides, which have been shown to be nontoxic, cell wall active components of *Pneumococci* have been shown recently to induce severe inflammation in experimental animals. Exposure of tissues to such components has been associated with production of mediators of inflammation such as tumor necrosis factor and interleukins, among many others. These cytokines have been detected in high concentrations in body fluids infected with *Pneumococci*. Destruction of tissues results from direct bacterial invasion and the host inflammatory response incited by cell wall active components. (For details of pathogenesis at each site of infection [pneumonia, meningitis, otitis media], please refer to the respective chapter.) Severity of and survival from pneumococcal disease depends on the site of infection, underlying disease, and age of the patient. Infants and the elderly and patients with underlying immunodeficiency usually have severe disease and are more likely to have sequelae.

Deficiency of the terminal components of complement (C3 through C9) has been associated with recurrent pyogenic infections, including those caused by *Pneumococcus*. Splenectomized patients or patients with diseases that interfere with splenic functions are at an increased risk for severe pneumococcal infection, presumably related to deficient opsonization and the absent/decreased filtering functions of the spleen on circulating bacteria. In patients with sickle cell anemia, the greatest risk is in infants younger than 2 years of age. With advancing age, patients with sickle cell disease are able to mount an anticapsular antibody response, thereby reducing but not eliminating the risk of overwhelming pneumococcal sepsis.

Clinical Manifestations

The symptoms and signs of pneumococcal infections are related to the site of infection. Although *Pneumococci* most commonly cause bacteremia, otitis media, pneumonia, and meningitis, they can produce disease in virtually any organ. (Please refer to chapters addressing each specific site for detailed clinical presentation.)

Diagnosis

Isolation of *Pneumococci* from certain body fluids establishes a firm diagnosis. Examination of a Gram-stained smear offers prompt suggestive information, but both α-hemolytic streptococci and group B streptococci may closely mimic the appearance of *Pneumococci*. The quelling reaction is a helpful and rapid method in serotyping the bacteria. Blood cultures should be obtained in infants younger than 2 years of age who present without focal infection but who are toxic and not consolable, or have leukocytosis. Patients with focal infections such as pneumonia, arthritis, meningitis, and osteomyelitis should have blood cultures obtained before initiating antibiotic therapy.

Recently, the latex particle agglutination test has been shown to be helpful in establishing the diagnosis rapidly in patients with meningitis and bacteremic focal infections. The test is not sensitive enough in nonbacteremic pneumonia and otitis media. Although pneumococcal infections are associated with elevated erythrocyte sedimentation rate and leukocytosis, these findings are not specific.

Treatment

Penicillin has been the treatment of choice for pneumococcal infections. However, penicillin resistance among strains of *S. pneumoniae* has become a problem of international proportions. In certain areas of the world, most pneumococcal strains are either relatively or completely resistant to penicillin. Penicillin-resistant *Pneumococci* are not only resistant to other β-lactams but also to erythromycin, trimethoprim-sulfamethoxazole (TMP-SMX), tetracycline, and, in some countries, rifampin.

Acute otitis media and meningitis caused by penicillin- and cephalosporin-resistant pneumococci have been especially difficult for pediatricians to treat because traditional empirical therapy with β-lactams is often ineffective. Concentrations of the penicillins and cephalosporins in cerebrospinal fluid (CSF) and middle ear fluid are inadequate to achieve prompt eradication of some intermediate (minimal inhibitory concentration [MIC] 0.1–1.0 μg/mL) and most highly (MIC ≥2.0 μg/mL) penicillin-resistant pneumococcal strains. Therefore, unconventional therapeutic agents such as clindamycin and ceftriaxone for acute otitis media and vancomycin plus ceftriaxone or rifampin for meningitis might be necessary in these patients.

Penicillin G is the drug of choice for penicillin-susceptible strains. Oral penicillin V (50–100 mg/kg/day) for minor infections, intravenous penicillin G (200,000–250,000 U/kg/day) for bacteremia or pneumonia, and intravenous penicillin G (300,000 U/kg/day) for meningitis are recommended. Vancomycin (60 mg/kg/day) is effective in treatment of relatively or completely resistant pneumococcal strains. In areas with high or increasing incidence of penicillin-resistant *Pneumococci*, vancomycin should be the initial therapy for suspected pneumococcal meningitis or severe infections. For patients who are allergic to penicillin and do not have meningitis, erythromycin, cephalosporins, TMP/SMX, and chloramphenicol provide effective alternatives for susceptible strains.

Prevention

The presently available nonconjugated pneumococcal vaccine has proved to be immunologic and associated with few untoward reactions. However, responsiveness is unpredictable in children younger than 2 years of age, where the peak incidence of pneumococcal disease occurs. An effective protein-conjugate pneumococcal vaccine that can be given at 2, 4, and 6 months of age is now being evaluated.

Immunization with the available nonconjugated vaccine is recommended for children over 2 years of age who have sickle cell disease, functional or anatomic asplenia, nephrotic syndrome, or CSF leaks and children with human immunodeficiency virus infection. Reimmunization might be given to certain high-risk patients. Immunization does not completely prevent pneumococcal infections. Therefore, penicillin prophylaxis is still indicated in the high-risk patients. Recent data suggest that penicillin prophylaxis is not warranted in sickle cell anemia patients beyond 5 years of age.

Prognosis

Morbidity and mortality after pneumococcal infections is variable depending on the site of infection, the virulence of pneumococcus, host defense factors, and the adequacy of treatment (see chapters on specific diseases for details).

89 Rickettsial Infections

Stephanie H. Stovall · Richard F. Jacobs

Definition

Rickettsiae are pleomorphic intracellular bacteria causing a variety of human diseases in all parts of the world. These organisms are transmitted by arthropod vectors and the mammals on which they feed. The prevalence of these infections is largely dependent upon the particular vectors that transmit them. The Rickettsiae are divided into the spotted fever group (SFG) and typhus groups. Rocky Mountain Spotted Fever (RMSF) is the most recognized rickettsial disease infecting humans in the United States, while Mediterranean Spotted Fever (MSF), which is also known as African tick-bite fever or Boutonnese Fever, is common in Europe and Africa. The typhus group is most known for endemic typhus and epidemic typhus. While it is not of the genus Rickettsia, scrub typhus (caused by *Orientia tsutsugamushi*) is a disease similar to the other typhus group diseases and will not be discussed in this chapter.

Etiology

Rickettsiae are obligate intracellular pleomorphic organisms that live inside eukaryotic cells and stain weakly Gram negative. Common agents in the SFG include *R. rickettsii* (RMSF), *R. akari* (Rickettsialpox), and *R. conorii* complex (MSF). Typhus group organisms include: *R. prowazekii* (epidemic), *R. felis* (endemic), and *R. typhi* (endemic). Scrub typhus is caused by *Orientia tsutsugamushi*.

Epidemiology

Diseases from the spotted fever group have been found in virtually all parts of the world.

Geography. RMSF is found primarily in the United States, but has also been found in Canada and Mexico and some parts of central/South America. The CDC reports the annual incidence of RMSF in the US is 2.2 cases per million persons with five states (North Carolina, South Carolina, Arkansas, Oklahoma, and Tennessee) reporting half the cases. Mediterranean Spotted Fever has been described in Europe and Africa with highest rates described in areas surrounding the Mediterranean. Incidence rates are reported around 50/100,000 persons per year in the Mediterranean region; however, the disease is not reportable in many European countries, so estimates may far underestimate true incidence. Both RMSF and MSF are more commonly diagnosed in the summer seasons corresponding with the highest tick burden. In the last decade there have been five other similar spotted fever diseases emerging caused by subspecies of *R. conorii*. Rickettsialpox is found in highly populated metropolitan cities of Asia and South Africa. Epidemic typhus (caused by *R. prowazekii*) is more prominent in periods of crowding, poverty, and poor hygiene. Historically it is thought to be the cause of massive numbers of deaths during times of war and famine. Most recently, it has been associated with outbreaks occurring in the late 1990s in sub-Saharan Africa and South America. Endemic (or murine) typhus is reported worldwide and is specifically associated with areas of high rodent burden, particularly near seaports and coastal regions.

Age, Sex. Approximately two thirds of reported cases of RMSF are in children under the age of 16, with the largest group 5–9 years. MSF occurs in all age-groups and both sexes. It is common for patients with MSF to have had contact with dogs. There are no age or sex discrepancies among the typhus group.

Vectors. *R. rickettsii* is transmitted to humans during the feeding process of several species of ticks found in North America including Dermacentor variabilis (American dog tick), Dermacentor andersonii (Rocky Mountain wood tick), and others. *R. conorii* is transmitted via the Rhipicephalus sanguineus (brown dog tick). Epidemic typhus is transmitted between people through bites from the human body louse. The louse becomes infected when feeding on an acutely infected person and then dies within 2 weeks. Unfortunately, *R. prowazekii* can persist even in the dead louse and serve as infectious material to those exposed. The rickettsiae are deposited in the louse feces during feeding and then are introduced into the bite, the conjunctiva or mucosa. Endemic typhus is transmitted by fleas that feed off rats. The fleas become

infected for life and transovarially infect their progeny. These fleas deposit rickettsia in feces that are introduced into the bite wound or through the conjunctiva.

Table 89.1 provides additional epidemiologic information.

Pathogenesis

Rickettsiae infect endothelial cells producing a small vessel vasculitis. They can multiply in the cytosol or nucleus of the cells.

Rocky Mountain Spotted Fever. *R. rickettsii* is inoculated into the human skin by the tick vector. The organism attaches to endothelial cells of the host by means of a rickettsial outer membrane protein which triggers endocytosis. Release of the organism from the endosome and subsequent replication triggers polymerization of actin in the host cell which allows intracellular movement of rickettsia. Oxidative injury to host cells causes irreversible damage to infected cells leading to diffuse endothelial injury and vascular leak. This vasculitis causes multisystem disease manifesting in a variety of clinical signs and symptoms affecting potentially ever organ system.

Mediterranean spotted fever. A dark eschar forms as a result of mononuclear infiltration at the site of the bite causing the classic tache noire lesion. These lesions are more commonly found on the head of children and the extremities of adults. Similar to RMSF, a diffuse vasculitis results, involving endothelial cells of blood vessels throughout the body. Any organ can be involved with a wide variety of symptoms and signs including but not limited to: phlebitis, pericarditis, myocarditis, pleuritis, ARDS, nephritis, conjunctivitis, delirium, elevation of transaminases, and mild hepatomegaly.

Epidemic typhus. *R. prowazekii* infect endothelial cells preferentially using a rickettsial adhesion protein and can multiply in the cytoplasm. After killing of the host cell, these rickettsia are released and must infect other endothelial cells in order to continue to replicate. Vasculitis can be complicated by intravascular clotting or even gangrene.

Endemic typhus. *R. typhi* behaves similar to *R. prowazekii*; however, it can polymerize intracellular actin allowing some organisms to escape before cell death.

Pathology

The small vessel vasculitis caused by the offending Rickettsiae may produce various rashes that may be macular or petechial in nature. This vasculitis may also cause significant capillary leak and hypotension. Vasculitis of end organs (i.e., lungs or brain) may lead to respiratory failure or death.

Some rickettsial diseases (scrub typhus) commonly cause an eschar with perivascular inflammation at the site of inoculation.

Clinical Manifestations: Symptoms, Signs

Multisystem involvement particularly with rash, fever, and headache should trigger the clinician to consider rickettsial diseases. Many also exhibit an eschar at the site of inoculation.

Rocky Mountain Spotted Fever typically begins with fever, myalgia, and headache starting approximately 1 week after infection. In the United States it is frequently referred to as the "summertime flu" because the early symptoms are often "flu-like." Around the second to fourth day a rash begins to develop. Early on it appears macular and later progressing to petechial. It classically begins at the ankles and/or wrists with progression centrally and distally including the palms and soles. The full evolution of the rash may take 5 days. Most patients will present with ambulatory mild symptoms; however, untreated, many will progress to septic shock with or without respiratory failure. Many patients with RMSF will exhibit signs of central nervous system involvement which may be as mild as headache or as severe as seizures and coma. *Table 89.2* shows clinical and laboratory signs and relative frequency of occurrence. In the first 3 days of the illness, most patients have minimal symptoms that can easily be mistaken for a viral prodrome. In fact, many patients who seek medical care within the first few days of RMSF are treated symptomatically for viral illnesses. Few patients present for care with the classic triad of "fever, rash, and history of a tick bite." Less than half of patients with proven RMSF report a history of a tick bite even in retrospect. The characteristic rash of RMSF is seldom present at the onset of illness typically beginning around day 3 of symptoms; however, up to 20% of patients never develop a rash. Many adolescent and adult patients complain of an unremitting headache but young children are unlikely to verbalize this complaint. Of the three most common complaints recognized with RMSF (fever, headache, and rash), less that 60% of patients exhibit all three simultaneously. Absence of the classic triad should never be cause for delaying or avoiding therapy if RMSF is suspected because once the diagnosis is confirmed; the patient may well have developed severe morbidity or succumbed to the disease. The vasculitis of RMSF can involve any organ or system and frequently involves more than one system at the time of presentation, though early signs may be mild. Common signs may include nausea or vomiting (up to 70%), elevations of transaminases, pulmonary edema, or infiltrates sometimes severe enough to cause acute respiratory distress syndrome (ARDS), congestive heart failure, cardiac arrhythmia, mild CSF lymphocytosis, alteration of mental status, retinitis, conjunctival suffusion, and nephritis with resulting renal failure.

Table 89.2
Clinical signs and symptoms of RMSF in pediatric patients described in the published literature

Fever >39°C	>95%
Headache	~60%
Rash	80–95%
Myalgia	<50%
Respiratory symptoms	10–40%
Altered level of consciousness	~33%
History of tick bite	<50%
Thrombocytopenia $<150 \times 10^3$	~60%
Hyponatemia (<137)	>50%

http://www.cdc.gov/ticks/avoid/index.html
http://www.cdc.gov/ticks/removing_a_tick.html

Laboratory studies that support a diagnosis of RMSF are also highly variable. For instance depending on the stage of disease, the patient may have a normal, elevated, or low serum white blood cell count. Findings of hyponatremia and hypoalbuminemia often reflect the degree of vascular permeability. Thrombocytopenia is common, occurring in approximately 60% of pediatric patients.

Mediterranean Spotted Fever. Approximately 1 week after inoculation, the symptoms start abruptly with fever (>93%), myalgia, maculopapular rash (>94%), and headache. The rash typically involves the entire body including the palms and soles. Many patients (>60%) will also have a characteristic eschar at the site of inoculation (taché noire).

Epidemic typhus. High grade fever, severe headache, and rash occur 1–2 weeks after inoculation. The rash typically starts as macular and blanching on the trunk and spreads to extremities (sparing the palms and soles) while becoming fixed and sometimes purpuric or hemorrhagic. In extremely dark-skinned individuals the rash may not be appreciated, but evidence of vasculitis can sometimes be seen on the soft palate. Many will develop

constipation, dry cough, and jaundice. Neurologic abnormalities ranging from drowsiness to delirium or meningoencephalitic syndrome resulting in deafness or coma can occur. Patients have persistent symptoms until treatment or recovery. Prompt treatment relieves symptoms rapidly, typically without sequelae. Patients may have recrudescent symptoms up to many years later (Brill-Zinser disease). Recrudescent disease is similar but often less severe. Untreated, mortality rates are as high as 10–50%, with highest rates in those with malnutrition or chronic illnesses.

Endemic typhus. The initial symptoms of infection with *R. typhi* include fever, headache, and rash occurring approximately 5–10 days after inoculation. The headache and fever are usually milder than that found in epidemic typhus and symptoms resolve without treatment after 2–3 weeks. Treated patients will recover within 3 days. Mortality rate is <1%.

Diagnosis

The diagnosis of any rickettsial infection requires the clinician to consider the possibility or probability of exposure to the vectors which transmit these diseases. None of the rickettsial diseases can be reliably detected by commercially available rapid diagnostic tests during the acute phase of illness and many of the diseases left untreated will incur significant increases in morbidity and mortality.

Rocky Mountain Spotted Fever. Many patients seeking care for RMSF will be misdiagnosed early in the course due to nonspecific symptoms. Early laboratory findings may include hyponatremia and thrombocytopenia, but these are only found in about half of pediatric patients. Antibody-based testing through latex agglutination, indirect immunofluorescent antibody (IFA), enzyme immunoassay (EIA), or complement fixation can be helpful if positive, but are typically only positive after the first week of illness. A definitive diagnosis can be made by acute and convalescent serologic testing 2–3 weeks apart demonstrating a fourfold rise in titers. PCR testing is not commercially available, but is available through the Centers for Disease Control and Prevention. Sensitivity and specificity of Weil-Felix testing is poor and should not be used for diagnosis of RMSF.

Epidemic typhus. A fourfold rise between acute and convalescent serology (2–3 weeks apart) by IFA, EIA, or latex agglutination can establish the diagnosis. Likewise, testing is available though the CDC by immunohistochemistry or PCR of tissues.

Endemic typhus. A fourfold rise between acute and convalescent serology (2–3 weeks apart) by IFA, EIA, complement fixation, or latex agglutination confirms the diagnosis, and specific IgM by EIA can distinguish endemic and epidemic typhus if necessary. PCR or immunohistochemistry staining of tissues is available through the CDC.

Differential Diagnosis

Contact and exposure history is necessary to assess the likelihood of rickettsial diseases in patients presenting with symptoms of fever and rash.

Diseases causing fever and rash in childhood that can mimic the symptoms of RMSF include: meningococcemia, enteroviral sepsis, pneumococcal sepsis, typhoid fever, leptospirosis, secondary syphilis, rubella, scarlet fever, ricketsialpox, murine typhus, or ehrlichiosis.

After the rash of MSF appears it can look similar to measles, meningococcemia, secondary syphilis, or other rickettsial spotted fever group infections, particularly in cases where the tache noire is absent.

The progression of rash in patients infected with epidemic typhus is opposite to that of RMSF as it appears on the trunk and spreads peripherally and uncommonly involves palms and soles. Endemic typhus is usually mild with an evanescent rash without petechial character and may be mistaken for a viral exanthem.

Treatment

General Care. Patients presenting with shock should be volume resuscitated aggressively. Electrolyte abnormalities rarely require replacement once perfusion has normalized. Treatment for other infectious causes of septic shock should be administered simultaneously until certain diagnoses are excluded (i.e., meningococcemia, pneumococcal sepsis).

Rocky Mountain Spotted Fever. The treatment of choice for RMSF is doxycycline at 2.2 mg/kg/dose given twice daily (adult maximum dose: 200 mg/day). Administration of doxycycline is dependent upon the patient's clinical condition. Many ambulatory patients and those hospitalized for hydration and febrile illness of undetermined significance can receive doxycycline orally. Patients with septic shock, severe dehydration, vomiting, or significantly altered mental status should receive doxycycline orally to assure adequate absorption. Length of

therapy is dependent upon duration of fever. Doxycycline should be given at least 3 days beyond clinical improvement. Most patients will require 5–7 days of total therapy. Tetracycline antimicrobials have been associated with staining of permanent teeth. For this reason, they are not routinely recommended for children under 8 years of age while the enamel of permanent teeth is developing. However, because RMSF is a life-threatening infection and there is no evidence of tooth staining in patients treated with a single course of doxycycline, it is preferred treatment for this disease in all age-groups. One study shows that it requires more than six courses of tetracycline therapy in patients with developing teeth to cause significantly recognizable tooth staining. The only other potential therapeutic agent is chloramphenicol which is currently unavailable in the United States. Chloramphenicol has been associated with poorer outcomes compared to tetracyclines and is inferior treatment for Ehrlichiosis and Anaplasmosis which can occur in similar geographic areas and are often clinically indistinguishable from RMSF. Coupled with these findings and the high risk of aplastic anemia associated with chloramphenicol administration, doxycycline is the mainstay of treatment for RMSF in the United States.

Mediterranean Spotted Fever. The treatment of choice for MSF is doxycycline (same dose as RMSF); however, alternatives include chloramphenicol, ciprofloxacin, clarithromycin, or azithromycin.

Epidemic typhus. Effective treatment includes doxycycline (2.2 mg/kg/dose) twice daily for 7–10 days or chloramphenicol (12.5 mg/kg/dose) every 6 h for 7–10 days. Like in RMSF, use of chloramphenicol is associated with worse outcomes in children compared with tetracycline therapy. Single dose therapy for adults has been used for control in outbreak situations.

Endemic typhus. Like epidemic typhus, the treatment of choice is doxycycycline; chloramphenicol treatment increases the risk of relapse. Ciprofloxacin has been used successfully in adults. There appears to be no advantage to combination therapy.

Prognosis

Rocky Mountain Spotted Fever. Prior to the widespread use of anti-rickettsial therapy, the mortality rate of RMSF was 10–30% with surviving, untreated patients recovering after 2–3 weeks of illness. The majority of patients treated within the first 5 days of symptoms will recover completely without sequelae; however, even with treatment, approximately 3–5% of infected patients die usually within the first week of illness. Kirkland et al. noted the increased risk of death in patients treated beyond 5 days of initial symptoms (22.9%) compared with those treated within the first 5 days of symptoms (6.5%).

Mediterranean Spotted Fever. Fatality rates are up to 2.5%; however some studies have suggested an increase in severe disease and higher prevalence of sequelae in the last decade, some of which is likely related to particular subtypes of R. conorii (e.g., Israeli subtype). Patients who have renal failure are more likely to have a fatal outcome, and those with significant neurologic involvement have high rates of persistent neurologic sequelae.

Epidemic typhus. Untreated, 10–50% of infected people will die. Patients severely affected may have persistent neurologic sequelae including transverse myelitis, hemiparesis, or neuropathy. Recovered patients may also develop recrudescent disease, sometimes even decades later. Patients treated early in the course of illness typically recover uneventfully without lasting sequelae.

Endemic typhus. Untreated, mortality rates are approximately 4%, but with treatment fatalities are minimal. Elderly patients or those with underlying diseases affecting the liver or kidneys have more severe disease when infected with R. typhi.

Patients with Glucose-6-Phosphate Deficieny (G-6PD) are at increased risk of morbidity and mortality if they become infected with any rickettsial disease.

Prevention

Rocky Mountain Spotted Fever, Mediterranean Spotted Fever, and other tick-borne rickettsioses. Use of DEET during activities likely to encounter ticks, inspection for ticks after outdoor exposure, and environmental control of ticks is effective at preventing tick-borne spotted fever group rickettisioses. There is no vaccine available to prevent infection with *R. rickettsii* or *R conorii.* Removal of attached ticks should be done with tweezers or similar device by grasping the tick gently, close to the attachment point and pulling straight upward evenly while avoiding crushing the body.

Epidemic typhus. Insecticides containing pyrethrin to treat areas of infestation, decontamination of body louse infested clothing, and treatment of people infested with body lice are necessary to prevent epidemic typhus. There is currently no vaccine available to prevent epidemic typhus.

Endemic typhus. Prevention of endemic typhus includes avoidance of rodent infested surroundings and flea and rodent control programs. There is no vaccine to prevent endemic typhus.

90 *Salmonella* Infections

Mohammad Al-Shaalan

Salmonella is a gram-negative bacillus that results in a myriad of human diseases ranging from mild gastroenteritis to severe typhoid fever. Non-typhoidal *Salmonella* infections are a major cause of diarrheal disease in children accounting for 20% of the two million death that occur annually due to diarrheal illnesses especially in developing world. Typhoid or enteric fever is still endemic in many of the developing countries, particularly south central and southeastern Asia. Worldwide, almost 21 million cases of typhoid fever occur every year, resulting in 217,000 deaths. *Salmonella paratyphi* is increasing in incidence in many of Asian countries as a cause of enteric fever.

Microbiology

Salmonella is a gram-negative, motile, flagellated, and encapsulated bacillus that belongs to Enterobacteriaceae family. It is non-lactose fermenter. It grows in most artificial culture media; however, selective media are used to inhibit the other bacteria and allow *Salmonella* to grow in pure culture so it can be identified.

Salmonella nomenclature is confusing; however, the last agreement was to divide *Salmonella* into three species: *Salmonella enterica*, *Salmonella bongari*, and *Salmonella subterraned*. Each species has a number of subspecies, and each subspecies has a number of serotypes or serovars Table 90.1. Most cases of gastroenteritis are caused by *S. enteritides* group, whereas enteric fever is caused by *S. typhi, S. paratyphi A, B, and* C.

Pathogenesis

Salmonella reaches the gastrointestinal tract after ingesting contaminated foods or drinks, especially poultry or dairy products. The infecting dose is usually 10^5–10^6 organisms; however, lower doses produce illness in more vulnerable hosts like young infants, immunocompromised patients, patients with hemoglobinopathies, elderly patients, and patients with achlorohydria or who have gastrectomy.

Once in the intestine, it adheres to the mucosa and then passes to the lamina propria where they proliferate and stimulate an inflammatory response which is mainly of polymorphonuclear cells in cases of gastroenteritis and mononuclear cells in cases of enteric fever. Polymorphonuclear cells stimulate production of prostaglandins which in turn stimulate fluid secretion and diarrhea. In cases of enteric fever, mononuclear cells travel from lamina propria via lymphatics into local lymphoid tissue in the Peyer's patches and then via thoracic duct into systemic circulation (primary bacteremia) where they then disseminate into the reticuloendothelial tissues in the liver, spleen, and bone marrow. From there, they then invade blood, causing secondary bacteremia with resultant dissemination to different organs.

Clinical Features

Non-typhoidal Salmonellosis

Almost all species of *Salmonella* can cause human diseases mostly in the form of enteritis. However the most common serovars belong to *Salmonella enterica*. The acquisition of infection occurs through eating contaminated foods or water. Most of culprit foods are those of poultry origin, specifically eggs. Many outbreaks have been attributed to eating contaminated eggs. Other sources include contact with infected animals, especially birds and reptiles.

Gastroenteritis

Gastroenteritis is the most common presentation of *Salmonella* infections. After an incubation period of 6–48 h, the patient starts to have diarrhea which is usually watery and associated with blood in some occasions. In contrast to shigellosis, there is not much mucoid secretion with diarrhea. Other symptoms of fever, abdominal pain, and dehydration are usually present. The symptoms persist for 2–7 days and then resolve spontaneously.

From Su L-H, Chiu C-H (2007) *Salmonella:* clinical importance and evolution of nomenclature. Chang Gung Med J 30(3):210–219

Bacteremia

Five percent to 10% of patients with *Salmonella* infections may develop bacteremia. This might have been preceded by diarrhea, or it may arise without any preceding gastrointestinal symptoms. In immunocompetent children, it is rare and usually transient and benign. However, invasive disease in association with bacteremia is more common in certain groups of hosts, including those who are 3 months old or younger and immunocompromised hosts. Affected patients usually present with fever, lethargy, loss of weight, and headache. Most of the patients have isolated bacteremia; however, 10% may have their bacteremia complicated by local suppuration which most commonly involves meninges, bones, or lungs. Other organs may be involved like joints, liver, kidneys, prostate, testicles, pericardium, or endocardium. A rare complication that is more common in adults is aortitis. This complication is associated with high mortality. Recurrent bacteremia is an indication of an underlying immunodeficiency status, especially interleukin-12 deficiency.

Illustrative case:

A 2-year-old girl presented with history of fever and diarrhea. Blood culture grew *Salmonella enteritidis*. There was no evidence of any focal infection. Her symptoms recovered after receiving appropriate antibiotic. Two weeks after discharge, she presented with fever. Blood culture grew again *Salmonella enteritidis*. She was treated with antibiotic and responded well. She was investigated for possible focal lesion, including CT scan of brain, which came to be normal. CSF analysis was normal, and CSF culture was negative. Bone scan was negative. She was discharged home after treatment completion. Again she came back 2 weeks later with fever and blood culture grew *Salmonella enteritidis*. At this point, immunological work up was done and came to be normal. Interleukin 12 assay was done and came to be deficient. She was placed on cotrimoxazole prophylaxis after completion of therapy and continued to do well.

Enteric Fever

S. typhi and *S. paratyphi* A, B, or C may result in a severe form of infection, called enteric fever. Enteric fever is a syndrome characterized by insidious onset of lethargy, myalgia, headache, loss of appetite and loss of weight, and fever. It is still a major cause of morbidity and mortality in developing countries, especially Asian ones. In year 2000, almost 21 million cases of *Salmonella typhi* and five million of *Salmonella paratyphi* occurred worldwide. Endemic persistence in these countries is attributed to poor sanitarian conditions. Although there has been success with use of typhoid vaccine, paratyphi is becoming more in frequency. The other concern about enteric fever endemicity is increasing incidence of resistance to fluoroquinolones and third-generation cephalosporins. The main clinical feature of enteric fever is the presence of fever which follows a stepladder pattern starting to increase gradually until it reaches a maximum of 40–41°C in 5–7 days. Some patients present with fulminant illness with high fever, drowsiness, anemia, and shock, but this is rare. During the first week of illness, most patients are constipated; however, by the second week, diarrhea

develops. Rose spot rashes usually appear by end of the first week as faint blanching macular erythematous or rose-colored lesions over the chest and upper abdomen. They last for 2–3 days and then disappear.

Complications of enteric fever occur in up to 3–5% of patients and include intestinal hemorrhage and perforation (the most common) occurring by the second to third week of illness. Other complications include arthritis, osteomyelitis, pneumonia, meningitis, pyelonephritis, hepatitis, cholecystitis, orchitis, parotitis, tonsillitis, and lymphadenitis.

Diagnosis

The gold standard method of diagnosis is isolating the organism from infected specimens. In cases of gastroenteritis, stool can be cultured on Xylose-Lysine-Deoxycholate (XLD) medium or Hekton enteric medium. These media are used to prevent the growth of other normal flora of the intestine.

Specimens from sterile body sites can be cultured on blood or chocolate agar, and the organism can be identified by microscan or ABI-20 identification system. In addition, biochemical characters of *Salmonella* can help in identification.

These include ability to ferment glucose but not lactose. On TSI or KIA tube, they form alkaline slant and acid butt with gas and H_2S production. *S. typhi* produces only a scant amount of H_2S.

In cases of enteric fever, *Salmonella* can be isolated from blood during the first week and from stool or urine by the second week of illness. However, bone marrow remains the most sensitive specimen for isolating the organism even if the patient has been pretreated with antibiotics.

Other diagnostic aids include WBC, which is usually low in count and is associated with neutropenia and bandemia. Liver transaminases, alkaline phosphatase, and LDH are usually elevated. Serology remains shorthanded in diagnosing *Salmonella*. The standard test is Widal test; however, it lacks sensitivity and specificity and cannot be relied upon in diagnosing *Salmonella* infections.

New serology test for detecting antibodies and antigens are in progress. Currently, there is latex agglutination slide test which is used to identify organism isolated in the culture media therefore shortening the period of identifying the organism.

Treatment

Antibiotic therapy of *Salmonella* infections is indicated in the following situations:

1. Gastroenteritis in infants <3 months of age, in immunocompromised hosts, in patients with hemoglobinopathies, in patients who are toxic and moribund, and in those with associated bacteremia
2. Any patients with bacteremia
3. Enteric fever
4. Patient with focal suppuration like meningitis, osteomyelitis, etc.

Over the last two decades, there has been increasing emergence of multiresistant *Salmonella,* especially *S. typhi,* which renders therapy difficult. Therefore, therapy should be directed by local sensitivity pattern of the organism. Based on available data, a significant portion of *S. typhi* is resistant to chloramphenicol, amoxicillin, and trimethoprim/sulfamethoxazole in most of the developing countries. The available alternative includes third-generation cephalosporins (cefotaxime or ceftriaxone) and fluoroquinolones which are not recommended in children. Recently, there is an increasing report of some *Salmonella* strains that have reduced susceptibility to fluoroquinolones. These strains have an MIC between 0.25–1 mg/L. In addition these strains are usually resistant to nalidexic acid. Therefore strains that are resistant to nalidexic acid should be checked for reduced susceptibility to flouroquinolones. The empiric therapy of strains suspected to have reduced susceptibility to flouroquinolones is usually cefotaxime or ceftriaxone. Azithromycin may be an alternative therapy for multi-drug resistance strains.

Aminoglycosides, tetracyclines, and first- and second-generation cephalosporins should not be used in treating enteric fever, even if in vitro sensitivity showed them to be effective as they are ineffective in vivo. Chronic carriers are better treated by cholecystectomy preceded and followed by antibiotics therapy with either ampicillin or fluoroquinolones. Chloramphenicol should be avoided in treatment of chronic carrier status.

Prevention

Hygiene, improved sanitation, improved food (poultry) processing are the most important methods in decreasing the infection rate. Surveillance of food handlers and removing those who are infected from contact with foods is also important.

91 Shigellosis

Mohammad Al-shaalan

Shigella is not uncommon cause of bacterial enteritis in children. It is a Gram-negative non-lactose fermenter rod. Worldwide, 90 million cases are reported annually, 89 million of which occur in developing countries. Almost 70% of cases occur in children under 5 years of age. Every year 110,000 death occurs due to shigellosis, 65% of which occur in children below 5 years of age. The main clinical presentation is that of enteritis: vomiting and diarrhea.

Microbiology

Shigella is a Gram-negative, nonmotile bacillus. There are around 36 serotypes of *Shigella* which are divided into four groups: *S. dysenteriae* (group A) including 13 serotypes, *S. flexneri* (group B) including 13 serotypes, *S. boydii* (group C) including 18 serotypes, and *S. sonnei* (group D) with one serotype. The most pathogenic type is *S. dysenteriae*, which cause a significant proportion of shigellosis in developing countries; however, it is rare in developed countries. *Shigella* can be grown on MacConkey, xylose lysine deoxycholate (XLD), and Hektoen enteric media. It is identified by its inability to ferment lactose, inability to produce H_2S, and being urease negative. Most of the cases are caused by *Shigella sonnei* (*Table 91.1*).

Pathogenesis

Shigellosis is transmitted from humans to humans by the fecal–oral route via contaminated food and water or through person-to-person contact. Few organisms 10–100 are enough to cause infections. This in addition to its ability to withstand the stomach acidity makes it easy to establish infection. After passing from the stomach, they start to multiply in the small intestine to a large number that pass to the colon where they enter the mucosal cells by induced macropinocytosis, escape from the macropinocytic vacuole, multiply and spread within the cytoplasm, and pass into adjacent cells by way of fingerlike protrusions from the cell surface. Additional pathogenic factors include elaboration of three distinct enterotoxins: members of all four species produce the virulence plasmid-encoded ShET2, strains of *S. flexneri* 2a produce the chromosomally encoded ShET1, and *S. dysenteriae* 1 produce Shiga toxin (Stx). All of these enterotoxins are able to promote the secretion of solutes and water. However, they are not the only cause of the disease due to Shigella, as non-toxigenic strains cause similar disease. *Shigella dysenteriae* 1 is able to produce a shiga toxin similar to that produced by enterohemorrhagic *Escherichia coli* O157:H7 and thus may cause hemolytic uremic syndrome.

Recently, a 110-kDa heat and trypsin-labile cytotoxin was identified and implicated to be the cause of seizure and encephalopathy that associate shigellosis.

Clinical Features

Gastrointestinal Manifestations

Shigellosis is an enteric bacterial disease that commonly manifests with diarrhea. The incubation period is usually 2–4 days ranging from 1 to 7 days. Initially, the diarrhea is watery and of large amount due to involvement of small intestine. 24–48 h later, the disease progresses to involve large intestine with the production of small frequent bowel motions that are bloody and mucoid and associated with abdominal cramps and tenesmus (bacillary dysentery). The disease is usually self-limiting and lasts for 1–2 weeks. Most of the affected children have other systemic manifestations that include fever, vomiting, and dehydration (*Table 91.2*).

Extraintestinal Manifestation of Shigellosis

Ten to 40% of patients with shigellosis may manifest seizure activity. Other CNS symptoms include headache, drowsiness, and lethargy. Bacteremia and septicemia are rare in children; however, it occurs more commonly in young infants. Vaginitis and cystitis may occur in some patients. Conjunctivitis and keratitis are also rare complications. Reactive arthritis and Rieter's disease may occur in some patients, especially in sexually active patients.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_91,

Table 91.1
Isolated *Shigella* species from a stool culture of children at King Fahad National Guard Hospital

Shigella species	Number (%)
Shigella dysenteriae	4 (1%)
Non-speciated	22 (5%)
S. boydii	45 (9%)
S. flexneri	193 (41%)
S. sonnei	207 (44%)

Table 91.2
Clinical features due to Shigellosis

Clinical feature	Number (%)
Diarrhea	432 (92%)
Fever	393 (83%)
Vomiting	311 (66%)
Bloody stool	147 (31%)
Abdominal pain	112 (24%)
Seizure	50 (11%)

Ekiri syndrome is characterized by a fulminant course with severe dysentery, hypoperfusion, hyperpyrexia, and central nervous symptoms of convulsion and sensory impairment that progress rapidly to death. This syndrome has been described initially in Japan. Although it is rare it is being reported from other countries. Hemolytic uremic syndrome is rare and occurs mainly with *S. dysenteriae* infections and rarely with *S. flexneri* infection.

Diagnosis

The diagnostic method of choice of shigellosis is stool culture; however, stool culture is not justified in all children with diarrhea. Therefore, it should be limited to those with bloody stools or those with positive stool for leukocytes in toxic patients. Rapid test using latex agglutination test to identify *Shigella* spp. grown in the culture media is commercially available. Other diagnostic aids include leukopenia or leukocytosis with bandemia. In cases with seizures, CSF is usually normal although minority may have mild lymphoid pleocytosis. EEG is usually normal.

Treatment

Antibiotic therapy should be offered to all patients with symptomatic shigellosis. Treatment will decrease the duration of illness and also will shorten the period of organism shedding and thus will reduce secondary cases. The pattern of antimicrobial susceptibility of shigellosis is changing overtime. An increasing resistance of shigellosis to ampicillin and trimethoprim/sulfamethoxazole has been observed. Studies have shown a resistance rate of 40–80% to ampicillin and trimethoprim/sulfamethoxazole. Resistance to flouroquinolones and third-generation cephalosporins are still low in the range of 1–2%; however, regularly updated local or regional antibiotic sensitivity patterns to different species and strains of *Shigella* are required to guide empiric therapy. Empirical therapy for patient admitted with moderate or severe disease is usually by ceftriaxone until antibiotic susceptibility is available. Alternative therapy is ciprofloxacin which should not be used unless the organism is proven to be resistant to ceftriaxone. For oral therapy, cefixime and azithromycin have a good coverage in the range of 80–90%. Nalidexic acid is also a good choice but resistance is increasing.

Prevention

Hospitalized patient should be enterically isolated and hand washing should be emphasized in all contacts. No vaccine is available yet.

92 Staphylococcal Infections

Mohammad Al-Shaalan

In spite of the availability of adequate antibiotics, *Staphylococci* continue to challenge the treating physicians. New disease entities, new emerging species, and the changing spectrum of antibiotic susceptibility are examples of such challenges. Early in this century and before the advent of antibiotics, *Staphylococcus* was a major cause of morbidity and mortality. With the discovery of penicillin, it was thought that an upper hand had been achieved; however, *Staphylococcus aureus* (*S. aureus*) escaped this threat by producing b lactamase that renders them resistant to penicillin. This stimulated the research for an alternative antibiotic, penicillinase-resistant penicillin, namely, cloxacillin and others. Again *Staphylococci* start to have some resistance, methicillin-resistant *Staphylococcus aureus* (MRSA) which is now one of the major problems in health-care facilities. In addition, coagulase-negative *Staphylococci* are becoming important pathogens in many situations including neonates, immunocompromised host, and patient with implanted prosthetic devices.

Organism

Staphylococci are Gram-positive cocci that are catalase positive and non-spore forming. Staphylococcus genus includes a number of species that are classified to coagulase positive and coagulase negative according to production of a coagulation enzyme that aggregate sheep RBC.

The coagulase-positive staphylococcus is *Staphylococcus aureus. Staphylococcus aureus* is the commonest cause of human infections. It produces a variety of diseases that could be severe or mild. When antibiotics were initially introduced in the 1940s, *S. aureus* was sensitive to penicillin, and then it quickly became resistant which led to the introduction of b lactamase–resistant b lactam (methicillin, cloxacillin, and others). In the last 2 decades, methicillin-resistant *S. aureus* (MRSA) emerged as an important pathogen, initially in health-care settings, but recently it is becoming common in community-acquired infections. MRSA carry a chromosomally mediated gene that mediates resistance through alteration of penicillin-binding proteins (PBP). MRSA is one of the major problems in hospital-acquired infections, especially in hospitals with burn and intensive care units. Many epidemics due to MRSA have been reported in NICU, PICU, and burn units. MRSA is not more virulent than methicillin-sensitive *S. aureus*; however, it is difficult to treat because of its nature of being multiply resistant to many antibiotics including cephalosporins and aminoglycosides. They are usually susceptible to vancomycin, teicoplanin, linezolide, and daptomycin. Most of the hospital-associated MRSA strains are also resistant to other antibiotics like clindamycin, TMP/SMX, rifampin, and fluoroquinolones. Community-associated MRSA (CA-MRSA) are less resistant and it tends to be sensitive to clindamycin, cotrimoxazole, erythromycin, and tetracycline. However, attention should be paid that some of CA-MRSA is also multidrug resistant. When an MRSA is sensitive to clindamycin

The approach to treating patients with MRSA infection relies on a comprehensive surveillance for such organism in patients in the high-risk areas like burn unit and PICU. Patients who are colonized with MRSA but have no disease should be isolated in private rooms and barrier precaution are applied. Treatment of such patients has failed to eradicate colonization. If epidemics arise due to MRSA, a trial to eradicate infection by treating all colonized patients with TMP/SMX combined with rifampin or ciprofloxacin may be beneficial. Patients who develop diseases due to MRSA should be treated with vancomycin and if they have intravascular devices attempts to remove such devices is advisable. Application of mupirocin cream locally to the colonized areas has shown some success in eradicating infection.

There are almost 39 species of coagulase-negative *Staphylococcus* (CONS), the most important of which are *S. epidermidis*, *S. heminis*, *S. hemolyticus*, *S. werneri*, *S. lugodensis,* and *S. saprophyticus. Staphylococci* are facultative, nonfastidious organisms which can be cultured in ordinary media like blood or chocolate agars. Both *S. aureus* and some species of CONS are normal commensal of human skin.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_92,

Staphylococcus aureus

S. aureus is a primary human pathogen that is a major cause of human disease. In the 1960s, it was the commonest cause of neonatal sepsis. Nowadays, it is the major cause of nosocomial and community-associated infections. *Staphylococcus aureus* causes a variety of illnesses which are divided into:

(a) Skin and soft tissue infections
(b) Deep-seated infections
(c) Bacteremia and sepsis

Cutaneous Infections

Impetigo

Ten to twenty percent of impetigo is caused by *S. aureus*. In another 10–20% of cases of impetigo, the causative agents are *S. aureus* and Group A *Streptococci* (GAS). The remainder is caused by GAS. Impetigo is a skin disease that starts as a macular erythematous lesion which changes soon to pustule that then form a honey-colored crust. Any part of the body surface can be involved and the patient may infect himself at multiple sites by self-inoculation of the organism through scratching. Other siblings in the family may be affected. *S. aureus* is the main cause of bullous impetigo. In recent years, spiderlike or herpeslike lesions may be the presentation of staphylococcal skin infections. This presentation is being attributed to a staphylococcus that produces Panton–Valentine leukocidin (PVL).

Illustrated Case

A 13-month-old girl was admitted because of fever and skin lesions. The lesions were erythematous papule with necrotic center (spider like lesions). It was thought to be herpetic lesion and she was given intravenous acyclovir. Twelve hours later she started to be hypotensive and was in respiratory distress. Chest radiography showed bilateral patchy consolidation and pleural effusion. She was transferred to intensive care unit and was started on vancomycin and ceftriaxone. She required ventilation and chest tube insertion. Pleural fluid was bloody. Blood and pleural fluid cultures grew methicillin-sensitive *S. aureus*. She required pleural decortication and her condition improved.

Cellulitis

Rarely, *S. aureus* may cause cellulitis especially in young children. However, GAS is the commonest cause of cellulitis. Treatment can be achieved by using penicillinase-resistant penicillin like cloxacillin.

Folliculitis

Folliculitis is a mild superficial skin infection that appears as small yellowish pimples. They are self-limiting and can be treated by using a topical disinfectant.

Furunculosis or Boils

This is a staphylococcal infection of hair follicle. It starts as erythematous lesion which then becomes pus-containing vesicle. Treatment can be achieved by evacuation and topical antibiotics.

Carbuncles

Carbuncle is defined as infection of multiple hair follicles which usually coalesce and form large abscess with multiple draining sinuses. This type of infection is more common in patients who have phagocytic impairment either quantitatively or qualitatively. Local debridement and systemic cloxacillin are the therapies of choice.

Tracheitis

Although not common in children, it is a life-threatening condition that usually presents with high fever, toxic appearance, inspiratory stridor, drooling, and cough that is productive of tenacious sputum and retrosternal pain. In addition to *S. aureus*, GAS and other *Streptococci* are other causes. Tracheitis may arise without any preceding illness; however, it may complicate a preceding viral illness like varicella or influenza virus infections. Diagnosis can be achieved by obtaining sputum for culture. Intravenous therapy with an antibiotic agent that is effective against *S. aureus* and *Streptococci* should be instituted promptly. Cefuroxime or cloxacillin is appropriate. In patients with tracheostomy and thought to have tracheitis

Enterobacteriaceae like *E. coli*, *Klebsiella pneumoniae* and *Enterocobacter* as well as *Pseudomonas* may be involved as causative agents and this should be considered in the antibiotic coverage. In these cases, adding aminoglycoside or ceftazidime is recommended.

Pneumonia

In infants, *S. aureus* is one of the major causes of bacterial pneumonia and it is only preceded by *S. pneumoniae* and *H. influenzae*. However, *H. influenzae* is decreasing in frequency with the introduction of the conjugate Hib vaccine. Staphylococcal pneumonia is usually severe with complicating pleural effusions and empyema occurring in 30–50% of the cases. Diagnosis is achieved by positive blood culture, pleural fluid, or specimens obtained by bronchoscope. In addition to supportive therapy with oxygen and artificial ventilation if needed, intravenous antibiotics with cloxacillin or nafcillin should be used.

Chest tube drainage of pleural effusion may not be effective because of early loculations; therefore, the trend now is to use antibiotic therapy and observe the patient. If there is no response to this therapy within 7–10 days, then decortication may be needed after a trial of chest tube drainage.

Bacteremia

S. aureus is one of the major causes of nosocomial infections. Bacteremia is the third commonest cause of nosocomial infection in pediatric hospitals and the *S. aureus* is the commonest cause of nosocomial bacteremia. In addition, *S. aureus* can cause community-acquired bacteremia, but this is rare. Any patient with staphylococcal bacteremia should be investigated for an underlying focal infection like osteomyelitis, endocarditis, or deep abscess. Recently, fulminant sepsis that can be fatal is being reported.

Illustrated Case

An 8-year-old healthy boy brought to emergency room by his father after complaining of being tired and unable to walk for few hours. He was very well until around 15:00 same day of presentation; at which time he started to have generalized malaise and not feeling well and at around 19:00 he was unable to walk and therefore he was brought to ER. Upon arrival to ER, he was conscious and alert; however, he looks sick. His vital signs showed a temperature of 36.7°C, pulse rate 150 beats/min, respiratory rate 30/min, blood pressure 117/70, and pulse oximetry 98% in room air. He has normal chest and cardiovascular examination. His abdomen was soft. He has ice cold extremities with mottled skin and delayed capillary refill of around 6 s. He was judged to be in compensated shock likely of sepsis origin. Two boluses of intravenous normal saline at 20 ml/kg were given as well as a shot of ceftriaxone and vancomycin. His condition was worsening gradually with increasing work of breathing and desaturation. Arterial blood gas was done and showed pH 7.12, PCO2 52, PO2 28, HCO3 17, and base access 12.2 and therefore oxygen 5 L/min by face mask was given and he was continued on intravenous maintenance fluid. His initial laboratory workup revealed WBC 1,000/mm3, hemoglobin 95 g/L, platelet 41,000/mm3, CPK 9,315 U/L, lactic acid 12.9 mmol/L, CRP 330 mg/L, and D-dimer 2,279 mcg/L. By 23:45, he started to desaturate in spite of being on 10 L/min and therefore he was intubated and mechanically ventilated. His condition deteriorated farther with drop in blood pressure and increasing difficulty in ventilating him. Chest x-ray showed white out lungs suggestive of ARDS. He was started on dopamine, dobutamine, and norepinephrine but his blood pressure remained low and his heart rate started to drop and became asystolic and not responding to resuscitation. He died by 3:30 next morning. Two bottles of blood culture was positive for gram-positive cocci in clusters, which was identified as *S. aureus*; methicillin resistant based on MicroScan result which was confirmed by cefoxitin diffusion disk as well as positive PBP. Bacterial isolate underwent molecular characterization using multilocus sequence typing, staphylococcal cassette chromosome mec (SCCmec) typing, and PCR for the presence of the genes encoding Panton–Valentine leukocidin (PVL) and confirm a positive PVL.

Endocarditis

S. aureus is the second commonest cause of endocarditis; however, it is the commonest cause of endocarditis in patients with drug abuse.

Osteomyelitis and Septic Arthritis

S. aureus is the commonest cause of skeletal infection in all age groups. Although sicklemic patients have an increased susceptibility to *Salmonella* osteomyelitis, *S. aureus* is still common cause of osteoarticular infection.

Meningitis

S. aureus is a very rare cause of meningitis, but it is one of the major causes of brain abscess.

Therapy of Staphylococcal Infections

Soft Tissue and Skin Infections

Impetigo

Most of the time, topical therapy is enough; however, if there is systemic manifestation, then an oral antibiotic with a drug that is effective against both *Staphylococcus aureus* and *Streptococcus pyogenes* is needed. Usually, a first-generation cephalosporin like cephalexin is enough. However, if MRSA prevalence in the community is high, ≥10%, then clindamycin is advised.

Folliculitis

Topical antibiotic is usually effective.

Furunculosis, Carbuncles, and Abscesses

If there is fluctuation and there are no systemic symptoms, then drainage is usually enough. If there is systemic manifestation like fever, then oral antibiotics like first-generation cephalosporin is added to the drainage.

Cellulitis

Cellulitis is usually associated with some systemic manifestations. Antibiotic therapy is needed. Because both streptococcus and staphylococcus can cause cellulitis, TMP/sulfisoxazole is not adequate. Other antibiotic like first-generation cephalosporin is recommended. In community where community-associated methicillin-resistant *S. aureus* (CA-MRSA) prevalence is high (>10%), clindamycin is advised. In some area, clindamycin resistance is high and in such areas other antibiotics like vancomycin, linezolid, and daptomycin can be used. It is always recommended that local susceptibility pattern of the CA-MRSA should be checked and antibiotics should be advised accordingly (Table 92.1).

Deep-Seated Infection

When having deep-seated infection due to staphylococcal infection, some consideration should be taken into account:

1. Prevalence of CA-MRSA
2. Severe systemic manifestations
3. Comorbid conditions

As eluted to in the chapter about musculoskeletal infection, the recommended initial therapy is usually parenteral penicillinase-resistant penicillin like cloxacillin (Tables 92.2 and 92.3).

However, in areas where CA-MRSA prevalence is high, other antibiotic is usually recommended like clindamycin if the clindamycin resistance is not high or vancomycin if clindamycin resistance is high.

Table 92.1
Skin and soft tissue infections

Disease	Management	
	No systemic signs	Systemic signs
Impetigo	Topical therapy	
Folliculitis	Topical therapy	
Furunculosis	Drainage	Add first-generation cephalosporin or clindamycin
Carbuncles	Drainage	Add first-generation cephalosporin or clindamycin
Abscess	Drainage	Add first-generation cephalosporin or clindamycin
Cellulitis		First-generation cephalosporin or clindamycin

Table 92.2
Treatment of noncomplicated invasive infections

Treatment	Antibiotic
Empiric treatment	
Low CA-MRSA prev and low C-R prev	Cloxacillin[a]
High CA-MRSA prev and low C-R prev	Cloxacillin + clindamycin
High CA-MRSA prev and high C-R prev	Cloxacillin + linezolid
Directed treatment	
CA-MSSA PVL-negative	Cloxacillin[a]
CA-MSSA PVL-positive	Clindamycin
CA-MRSA PVL-negative	Clindamycin
CA-MRSA PVL-positive	Clindamycin
CA-MRSA PVL-negative C-R	Linezolid
CA-MRSA PVL-positive C-R	Linezolid

[a]Cloxacillin could be changed with a first-generation cephalosporin such as cephazolin. *CA-MRSA* community-associated methicillin-resistant *S. aureus, CA-MSSA* community-associated methicillin-susceptible *S. aureus, C-R* clindamycin resistant, *Prev* prevalence, *PVL* Panton–Valentine leukocidin
Source: Rojo P et al. (2010) Community-associated *Staphylococcus aureus* infections in children. Expert Rev Anti Infect Ther 8(5):541–554

In cases when severe systemic manifestations are present, a combination of cloxacillin and vancomycin is recommended until the susceptibility result is available.

Bacteremia

Most of the staphylococcal bacteremia has a predisposing factor like musculoskeletal infections, implanted devices, or endocarditis.

When bacteremia is isolated and no focal infection is identified, then a suitable parenteral antibiotic should be given for 10 days. In community where CA-MRSA is rare, cloxacillin or similar drugs can be used. In areas where CA-MRSA prevalence is high, the choice will be either clindamycin if clindamycin resistance is low or vancomycin if clindamycin resistance is high. Other agents like linezolid and daptomycin may be used.

When bacteremia is associated with a central line, then the duration should be expanded to 14 days besides that blood culture is cleared promptly and the central line is removed.

Table 92.3
Treatment of severe invasive infections

Treatment	Antibiotic
Empiric treatment	
Vancomycin + clindamycin ± rifampin ± IVIG	
Directed treatment	
CA-MSSA PVL-negative	Cloxacillin[a]
CA-MSSA PVL-positive	Cloxacillin[a] + clindamycin + IVIG
CA-MRSA PVL-negative	Clindamycin

Bacteremia associated with infective endocarditis requires a minimum of 4 weeks of parenteral therapy.

Coagulase-Negative Staphylococci (CONS)

CONS have emerged as a major cause of nosocomial infections. There are more than 39 species, the most common of which are *S. epidermidis*, *S. homonis*, *S. hemolyticus*, *S. werneri*, *S. lugodensis*, and *S. saprophyticus*. Most of the infections due to CONS occur in patients who have underlying predisposing factors like those who are immunocompromised and those who have implanted prosthesis. Other susceptible patients are neonates who are born prematurely and being cared for in NICU with a number of invasive procedures.

Neonatal Infections

Many reports have shown that CONS are becoming the most common cause of nosocomial infection in NICU, especially among premature neonates. Many factors predispose premature neonates to CONS infections including

prolonged hospitalization, intravascular devices, and TPN infusion. Varied presentations occur among infected neonates, the most common of which is bacteremia.

Bacteremia

Premature neonates are found to be more prone to bacteremia due to CONS. Some epidemiologic studies have shown that 10–25% of nosocomial neonatal bacteremia to be caused by CONS. The bacteremia due to CONS is usually indolent in its presentation with main manifestations including feeding intolerance, lethargy, apnea, bradycardia, decreased perfusion, hypotension, and temperature instability. Laboratory tests that frequently associate bacteremia include increased immature neutrophils, hyperglycemia, thrombocytopenia, and increased C-reactive protein. The major difficulty in diagnosing CONS bacteremia is the differentiation between true infection and contamination. However, in the presence of clinical signs, isolation of CONS indicates true infection.

Central Line Infection

Umbilical arterial catheter (UAC), umbilical vein catheter (UVC), or central lines can be colonized with CONS and become the cause of bacteremia. Polyvinyl catheters are more susceptible to be colonized than silastic catheter. TPN especially with intralipid infusion increases the susceptibility to infection. Diagnosis is by isolating CONS from blood that is drawn from the central line. Some quantitative estimates of the number of CONS colonies can help in differentiating colonization from infection. This can be done by semiquantitative method in which the intravascular tip of the catheter is rolled over the culture media.

If the number of colonies grown is more than 15 colonies then it indicates significant growth. If the line cannot be removed then comparing the colonies count of blood drawn from central line with that drawn from peripheral vein will give an idea of the source of infection. If the central count is more than peripheral one then this is likely to be central line infection. However, these methods are not standardized and cumbersome to do. Treatment requires removal of the central line and administration of appropriate antibiotics; however, in cases where removal of the line is not feasible, a trial of antibiotic therapy may result in cure although the failure rate is more common. The recommended therapy is vancomycin given through the central line for 10–14 days. Blood culture should be repeated in 24–48 h after starting the antibiotics. If the culture remained positive then central line should be removed.

Pneumonia

Reports of pneumonia caused by CONS have been increasing, especially congenital pneumonia and pneumonia in intubated neonates. Congenital pneumonia has been confirmed by isolating only CONS from placenta or from lung at autopsy.

Meningitis

CONS rarely causes meningitis; however, a number of cases have been reported. Characteristically, meningitis occurs in premature babies who have intraventricular hemorrhage. Meningitis due to CONS is characterized by minimal or absent abnormalities in CSF cell count, protein, and glucose. It is presumed that CONS are of low virulence and thus elicit minimal inflammatory response in CSF.

Enterocolitis

Narcotizing enterocolitis (NEC) is not uncommon in premature babies. Although the disease has been characterized and its pathology is known, its cause remains enigmatic. Delta toxin produced by CONS has been claimed to be a factor that may precipitate NEC.

Wound Infections

Surgical wound infection and local skin infections may be caused by CONS. In NICU and PICU, CONS share with *S. aureus* the cause of such infections.

Endocarditis

Few cases of endocarditis have been reported in neonates who have UVC inserted in the right atrium. The endocarditis involves mainly the right side of the heart with the tricuspid valve being commonly involved. Such patients usually present with persistent bacteremia associated with thrombocytopenia.

Bacteremia

CONS has emerged as a major cause of nosocomial bacteremia in children's hospitals. 20–30% of all nosocomial bacteremias are attributed to CONS.

CONS bacteremia is usually a disease of patients who have underlying predisposing factors, especially patients with malignancies or those who have undergone bone marrow transplant. Not all patients with CONS bacteremia have central lines or indwelling catheters. It is assumed that gastrointestinal tract may be the port of entry of CONS in the cases that have no indwelling catheters.

Urinary Tract Infection

S. saprophyticus is one of the principal causes of UTI in sexually active adolescent girls; however, it can cause UTI at any age group. *S. saprophyticus* has a specific adhesion that has higher affinity to attach to urogenital epithelium. Other CONS species can cause UTI. Because of their low virulence, even low colonies count may indicate a true infection rather than contaminant. Isolation of CONS species from urine in patients who are at risk of developing invasive disease may indicate the presence of bacteremia.

Endocarditis

Commonly arise following heart surgery especially during the first 3 months postsurgery. However, native value endocarditis may be caused by CONS. In one study, 26% of native valve endocarditis was caused by CONS.

Infection of Intravascular Catheters and Related Devices

Central Venous Catheter

CONS is the major cause of central line–related bacteremia. CONS is also the major cause of other central line–related infections like exit site or tunnel infections. Diagnosis of central line–related bacteremia is difficult. The comparison of central and peripheral blood cultures may be useful with the presence of five- to tenfold higher colonies in blood drawn from central line indicating central line infection. However, not all laboratories perform quantitative cultures. If the line is removed then culturing the tip of the catheter by rolling it over a blood agar plate and then counting the colonies may give a clue to the source of infection. Count that are >15 colonies indicate that the central line is the likely cause of bacteremia.

Ventriculoperitoneal Shunt Infection

Ventriculoperitoneal (VP) shunt infection can occur in 3–40% of the cases. Most of the infections are caused by CONS and most of them occur in the first 2 months after insertion. Diagnosis of shunt infection depends on isolation of the organism from CSF obtained by shunt-tapping. The changes in the CSF parameters may be minimal, but the culture usually yields the organism. Clinical presentations of shunt infection are variable, but mostly present with signs of shunt malfunction and increased intracranial pressure including headache, vomiting, and fever. Some patients may have associated signs of peritonitis. Treatment of VP shunt infection has been controversial. The recommended treatment is shunt removal with systemic antibiotics administration. Alternatively, success has been achieved with externalizing the peritoneal end of the shunt and systemic antibiotics administration until the CSF culture is negative in 3 consecutive days then reimplantation of the shunt and continuation of systemic antibiotics for 10–14 days. Intraventricular administration of antibiotics has shown some contradictory results; however, most of the studies show no additional benefit of such therapy.

Peritonitis

CONS is the major cause of peritonitis in patients undergoing peritoneal dialysis. Affected patients usually present with symptoms and signs of peritonitis: fever, abdominal pain, and vomiting, as well as changes in the color of peritoneal dialysate. Most cases of the peritonitis are associated with peritoneal fluid white cell count of more than 100; however, some have reported peritonitis with lower cell count. Treatment can be achieved by administering appropriate antibiotics with the peritoneal dialysate for 10–14 days. Removal of the catheter is unnecessary unless the infection cannot be controlled by antibiotics.

Other Prosthetic Devices Infections

CONS has been reported as causing infections in almost any implanted devices including implanted lens, pacemaker, and joint and vascular grafts.

93 Streptococcal Infections

Mahmoud M. Mustafa

Streptococci are among the most common pathogenic bacteria isolated from children. They are associated with a wide variety of disease states. In this chapter, diseases that are caused by group A and group B β-hemolytic streptococci are discussed.

Bacteriology

Streptococci are gram-positive cocci that form either short or long chains. They are classified according to their ability to hemolyze red blood cells when grown on sheep blood agar plates. They may produce complete hemolysis (β-hemolytic), resulting in a clear zone around the colonies; partial hemolysis (β-hemolytic), resulting in a green color around the colonies, hence the name *viridans*; or no hemolysis (γ-hemolysis).

Streptococci are further separated according to differences of carbohydrate components of the cell wall; so far, they have been divided into groups A through H and K through V. Therefore, there are group A β-hemolytic streptococci, group B β-hemolytic streptococci, and so on. Group A streptococci can be divided into more than 81 different types on the basis of a series of serologically distinct surface proteins, the M proteins. M proteins are components of the outer portion of the streptococcal cell wall. M antigen renders group A streptococci resistant to phagocytosis and is the major virulence factor. Other virulence factors include lipoteichoic acid and hyaluronic acid.

Streptococci produce and release into the surrounding medium a large number of biologically active extracellular products, many of which are of clinical significance. Pyrogenic exotoxins A, B, and C are responsible for the rash of scarlet fever and the shock in the toxic shock syndromes. Both streptolysin O and S injure cell membranes, not only lysing red blood cells but also damaging neutrophils and platelets. Streptolysin O is antigenic while streptolysin S is not. Many of the streptococcal extracellular products are digestive enzymes such as streptokinase, hyaluronidase, amylase, esterase, and proteinase that liquefy pus and facilitate rapid spread through tissue planes. The latter enzyme is associated with tissue destruction of severe invasive streptococcal disease. Other products include nicotinamide adenine dinucleotidase (NADase) and deoxyribonuclease (DNAse A, B, C, and D); both are antigenic. Measuring antibodies to the antigenic substances (e.g., antistreptolysin O [ASO], anti-DNAse, and antistreptokinase) can be clinically useful. M-type–specific antibodies are detectable 4–8 weeks after infection; antibiotic therapy ablates this response.

Group A Streptococci

Epidemiology

Group A streptococci are identified most frequently in humans and are rarely found in other species. They are normal inhabitants of the nasopharynx. The colonization rate varies from 15% to 20% of children. There are different epidemiologic features of streptococcal skin and throat infections. Streptococcal impetigo occurs frequently in preschool children, whereas streptococcal pharyngitis is predominantly a disease of school-age children. Streptococcal disease is uncommon in children younger than 3 years of age; however, outbreaks of streptococcal respiratory tract infections have been observed in day care centers. Streptococcal tonsillitis and pharyngitis are common in temperate and cold climates, whereas streptococcal impetigo or pyoderma occur with greater frequency in hot or tropical climates.

Transmission of group A β-hemolytic streptococci, from one person to another and from one body site to another varies according to the clinical type of infection. Infection may be spread by droplets or by contact with skin lesions or transmitted by water, milk, and food. Nasal and pharyngeal carriers are effective disseminators. Crowding is the most important factor that helps spread the disease, particularly in schools, homes, military installations, and sleeping quarters. Acquisition of streptococci from an infected individual is most common during the acute illness and decreases during colonization stage. Once acquired, group A β-hemolytic streptococci readily establish infection of the intact epithelial surface of the upper respiratory tract. In contrast, the production of streptococcal impetigo or pyoderma requires disruption of the

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_93,

cutaneous epithelium by trauma, insect bites, or a preexisting skin condition.

Infection as well as a carrier state may produce type-specific immunity. As immunity to different streptococcal strains develops after repeated exposures, the risk of streptococcal infection diminishes during adult life.

Pathogenesis

After acquisition of streptococci, the first step in disease pathogenesis is attachment to the mucous membranes of the upper respiratory tract or the skin. The reason(s) why certain M types produce pharyngitis or tonsillitis and others produce impetigo or pyoderma is not known. Invasion of tissues by group A streptococci is facilitated by damage to leukocytes and fixed tissue cells by release of extracellular digestive enzymes. Spread of infection to adjacent tissues is enhanced by enzymes such as streptokinase, DNAase, hyaluronidase, and proteinase, producing such complications as retropharyngeal or peritonsillar abscesses, sinusitis, lymphadenitis, and otitis media. Access of streptococci to the bloodstream can result in septicemia, pneumonia, and osteomyelitis.

The rash and toxic manifestations of scarlet fever are due to the development of hypersensitivity to pyrogenic toxins (A through C). The toxic manifestations of streptococcal toxic shock-like syndrome are attributed to direct influence of pyrogenic toxins such as tumor necrosis factor. The exact pathogenetic mechanism of rheumatic fever and glomerulonephritis is not known, but most theories invoke immunologic processes in one way or another.

Clinical Manifestations

The most common suppurative complications of group A β-hemolytic streptococci involve the respiratory tract, skin, soft tissues, and blood. The nonsuppurative complications, acute rheumatic fever and glomerulonephritis, are discussed in Chaps. 196, "Short Bowel Syndrome" and 249, "Cyanotic Heart Disease", respectively.

Respiratory Tract

Streptococcal pharyngitis or tonsillitis (*Fig. 93.1*) is an acute, suppurative, short-term illness with an incubation period of 12 h to 4 days. Its severity is greatly variable. In 30–50% of infections the disease is subclinical. Severe toxicity with high fever, nausea, vomiting, and collapse occurs in 10% of infections and is particularly more frequent in epidemic situations. Typically the onset of illness is acute and characterized by fever, sore throat, headache, and abdominal pain. The pharynx or the tonsils typically appear congested but may appear pale in the presence of marked edema. In 50–90% of the cases, exudate is present and usually appears by the second day. The exudate is typically whitish yellow and discrete but may become confluent the second day. Cervical lymphadenitis occurs in almost half of the cases. Unless complicated by otitis media, sinusitis, or peritonsillar abscess, the symptoms and signs disappear in 3–5 days. The average latent periods for glomerulonephritis and acute rheumatic fever are 10 and 18 days, respectively, during which the patient appears well.

Figure 93.1
Inflammation with tonsillar exudate in a patient with streptococcal tonsillitis. Note the white-coated tongue

In infants, group A streptococcal infection may take the form of persistent mucoserous nasal discharge, generalized lymphadenopathy, and chronic low-grade fever with little or no inflammation in the pharynx or tonsils. This form of disease is called streptococcal fever. Other infections associated with the upper respiratory tract that may be caused by group A streptococci include otitis media, sinusitis, mastoiditis, pneumonia, and empyema. Subpectoral abscess and pleural effusion may develop as complications of streptococcal infections of the thumb through lymphatic drainage.

Skin

Impetigo (superficial pyoderma) is the most common form of streptococcal skin infection. Colonization of intact skin precedes impetigo by approximately 10 days. The infection is frequently painless and the patient is afebrile. The initial lesion is a superficial vesicle with little

surrounding erythema that progresses rapidly to a pustule and then forms a thick, honey-colored crust; this stage may last for a few days to several weeks. The lesions are most common on the lower extremities and do not leave permanent scars. Impetigo may be superimposed upon scabies, eczema, burns, insect bites, and wounds.

Streptococcal cellulitis, an infection of skin and subcutaneous tissues, frequently complicates varicella skin infection and may develop into severe necrotizing fasciitis or myositis. Lymphatic spread to draining nodes is common. Ecthyma is a chronic and more deep-seated infection than impetigo; it is found predominantly in tropical areas.

Erysipelas is streptococcal infection involving the skin and sometimes the adjacent mucous membranes. The skin is erythematous and indurated with elevated margins. Erysipelas most often involves the face, but extremities and other parts of the body can be involved. The onset is acute and often accompanied by systemic manifestations. The lesion may last a few days to several weeks and relapses are rather common.

Scarlet fever results from infection by streptococci that elaborate pyrogenic exotoxins. The primary site of infection is usually the pharyngeal area, but it may follow infections of wounds or burns or other skin infections. The average incubation period is 3 days (range, 1–7 days), and the onset is sudden, with fever, headache, chills, sore throat, and vomiting. The typical rash appears within 24–48 h. Physical signs include signs of primary site of infection (pharyngitis or skin infection) in addition to the characteristic mouth and skin findings. During the early phase of illness the tongue has a white coat through which red, hypertrophied papillae project (white strawberry tongue) (*Fig. 93.2*). Several days later the white coat desquamates, leaving a red tongue with hypertrophied papillae (red strawberry tongue). The palate may show petechiae. The characteristic rash is red and finely punctate and may be palpated more readily than seen, having the texture of sandpaper. It appears initially on the trunk or axillae, groin, and neck but rapidly spreads to cover all the body. The rash fades on pressure and typically leads to desquamation toward the end of the first week of illness. Desquamation starts on the face and ends on the hands and feet. Other characteristic signs include circumoral pallor, pastia lines (areas of hyperpigmentation and petechiae appear in the deep creases, particularly the antecubital fossa), and, in severe cases, miliary sudamina (small vesicular lesions over the abdomen, hands, and feet).

The differential diagnoses of scarlet fever include measles, rubella, infectious mononucleosis, enteroviral infections, and roseola infantum. Severe forms of scarlet fever that are associated with marked toxicity, bacteremia, jaundice, arthritis, and hydrops of the gallbladder occur infrequently. Streptococcal toxic shock-like syndrome has been well described.

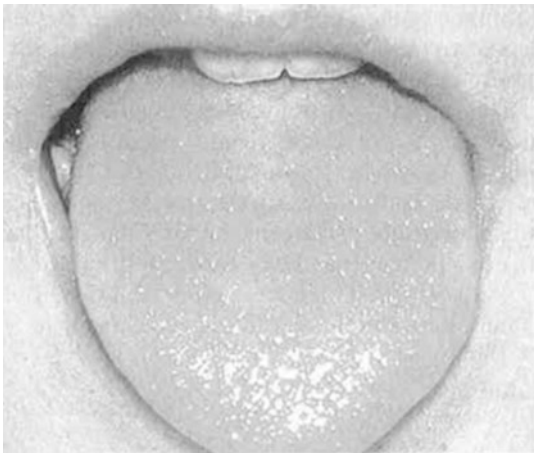

Figure 93.2
Strawberry tongue in a patient with scarlet fever

Bacteremia

Streptococcal bacteremia is usually secondary to a localized infection. However, primary streptococcal bacteremia has been described. The disease is severe and usually rapidly progressive, leading to severe systemic symptoms and organ dysfunction. Metastatic foci may complicate the course of infection, resulting in bacterial meningitis, osteomyelitis, arthritis, pneumonia, and endocarditis.

Diagnosis

Pharyngitis caused by group A streptococci is clinically indistinguishable from that caused by a variety of other etiologic agents, such as Epstein–Barr virus, *Corynebacterium diphtheriae*, *Arcanobacterium hemolyticum*, *Mycoplasma*, and groups C and G streptococci. Only 15% of children with pharyngitis and 25% of those with exudates have streptococcal infection; 10–50% of patients with streptococcal pharyngitis do not have tonsillary exudates. The diagnostic problem is especially difficult because group A streptococci can be found in the throats of normal children. Therefore, the pediatrician must rely on a combination of the clinical presentation, bacteriologic results, and epidemiologic findings to confirm the probability of streptococcal infection.

Isolation of the streptococci from the throat and evidence of host response are confirmatory of true

infection. Throat culture is the gold standard method for securing a safe diagnosis. However, isolation of group A streptococci from the pharynx of a child with pharyngeal infection does not necessarily indicate that the disease is caused by this organism. In recent years, a number of rapid techniques for direct identification of group A streptococci from the upper respiratory tract have become commercially available. Although they have relatively high specificity (~90%), they are not highly sensitive (50–90%). Therefore, rapid antigen detection tests are not sufficiently sensitive to be used without a backup culture.

Humoral antibodies to specific streptococcal extracellular products can be readily demonstrated by neutralizing assays. The ASO assay is the most commonly used. An increase in ASO titer to more than 166 Todd units is seen in more than 80% of untreated children with acute streptococcal pharyngitis within 3–6 weeks following infection. Early antibiotic treatment might diminish or abolish this response. It should be noted that, because streptolysin O is also produced by groups C and G streptococci, the test is not specific for group A infection. The ASO response can be feeble in patients with streptococcal pyoderma, and therefore its usefulness in this condition is limited. In contrast, the antideoxyribonuclease B (anti-DNAse B) and the antihyaluronidase responses are good after skin as well as throat infection. Titers start to rise 6–8 weeks after infection. Although the streptozyme agglutination slide test is inexpensive, simple, and fast to perform and detects antibody responses within 7–10 days, there are problems with standardization of its reagents, and it may not be specific for antibodies to extracellular products of group A streptococci. Furthermore, the test is not group-specific.

Changes in the peripheral white blood cell count, C-reactive protein, and erythrocyte sedimentation rate are nonspecific.

Treatment

Immediate antibiotic therapy is indicated to relieve symptoms and prevent suppurative, septic, and nonsuppurative complications. In patients with strong clinical epidemiologic evidence of streptococcal infection, therapy may be initiated before the results of throat culture are available. Although group A streptococci are generally susceptible to a number of antibiotics, penicillin remains the drug of choice except in those patients who have penicillin allergy. All strains of group A β-hemolytic streptococci are penicillin-sensitive. Although penicillin tolerance has been described, its clinical significance has not been defined. Penicillin V (125–250 mg three or four times per day) is the treatment of choice. Therapy must be continued for at least 10 days. If noncompliance is expected or the patient has nausea, vomiting, or diarrhea, we recommend a single intramuscular injection of a long-acting benzathine penicillin G (600,000 units for children less than 30 kg and 1.2 million units for children more than 30 kg). In patients with suspected allergy to penicillin, erythromycin (40 mg/kg/day), clindamycin (30 mg/kg/day), or cefadroxil monohydrate (15 mg/kg/day) may be used.

Repeating throat culture after a course of antibiotic therapy is indicated only in certain circumstances, such as patients with a history of rheumatic fever, a household member with rheumatic fever, and possibly when epidemic streptococcal disease is present in the community. Between 5% and 20% of children might have persistence of streptococci (treatment failure) after a complete course of penicillin. Treatment failures are more common with oral than intramuscular penicillin therapy or nonpenicillin antibiotic therapy. Treatment failure has not been adequately explained, but it may be due to poor compliance, presence in the throat of β-lactamase–producing organisms, tolerance to penicillin, reinfection, or presence of a carrier state. In these cases we recommend a second course of antibiotics, preferably an intramuscular penicillin preparation. Persistence of positive culture after a second course of antibiotics indicates a carrier state and need not be retreated.

Intravenous penicillin therapy should be used in patients with severe streptococcal infections such as pneumonia, deep soft tissue infections, meningitis, and toxic shock syndrome. For streptococcal impetigo, we recommend local hygienic measures plus oral antibiotics.

Prevention

Administration of antibiotics before the onset of symptoms is effective in preventing streptococcal disease. The best returns can be obtained from secondary prevention programs in patients with previously diagnosed rheumatic fever and perhaps from primary prevention programs in school-age children of low socioeconomic status and in institutional epidemics. For details of prevention of streptococcal infection in patients with rheumatic fever, see Chap. 196, "Short Bowel Syndrome".

In institutional epidemics and school exposure, the dose and duration of penicillin therapy is similar to that described under "Treatment" above. Management of the carrier state is controversial. Treatment with nonpenicillin antibiotics (erythromycin, a cephalosporin, or clindamycin) may be useful in eradicating the carrier state but should be reserved for the rare problem case.

Prognosis

Patients with streptococcal pharyngitis recover spontaneously. The prognosis for adequately treated patients is excellent. A few may develop suppurative complications, and an occasional patient may develop a nonsuppurative sequela. The risk of developing rheumatic fever after untreated streptococcal infection of the upper respiratory tract is about 3% after epidemic infections and 0.3% in endemic situations. However, 15–50% of patients who have had a previous attack of rheumatic fever might have a recurrence of acute rheumatic fever. There is no risk of rheumatic fever after skin streptococcal infection. The risk of poststreptococcal glomerulonephritis is dependent on whether the infection is caused by a nephrogenic strain or not. With a nephrogenic-strain throat or skin infection, up to 15% of patients can develop glomerulonephritis.

Group B Streptococci

Group B streptococcus is the most frequent bacterial pathogen responsible for neonatal sepsis in the United States and Western Europe. In other parts of the world, including the Middle East, the incidence of infection by this organism is lower, and in some countries it is rare. Besides neonatal infections, group B streptococci are occasionally responsible for other serious infections such as those in patients with malignancy, diabetic patients, obstetric patients, and patients with other chronic diseases. Asymptomatic bacteremia has been reported.

Group B streptococci are facultative, gram-positive, encapsulated, chain-forming β-hemolytic cocci. Based on type-specific capsular carbohydrates, together with C protein, most strains are classified into one of six relatively common serotypes, Ia, Ib, Ia/c, II, Iic, and III. Types IV and V are rare. The antiphagocytic polysaccharide capsule is the most important pathogenic factor. Increased capsular content of sialic acid has been associated with increased pathogenicity. Other virulence factors include C proteins, extracellular neuraminidase, and lipoteichoic acid.

Epidemiology

Group B streptococci have been recovered from birth canal cultures of 2–25% of pregnant and postpartum women. The majority (50–75%) of infants of culture-positive women are colonized in the first few days of life. In contrast, only 1–25% of infants born to culture-negative women have been shown to acquire group B streptococci. The transmission rate is increased in heavily colonized women. Cesarean section has little effect on transmission. Only 1–2% of colonized infants get systemic disease. The organism can also be transmitted to neonates after birth by health care providers; nosocomial nursery outbreaks have been reported.

Clinical Manifestations

The two most commonly encountered clinical presentations of group B streptococci in the neonate are early-onset and late-onset diseases. The clinical features of each are variable, and overlap is common. The early-onset disease is characterized by rapid-onset fulminant sepsis and pneumonia, typically associated with low birth weight, prolonged rupture of membranes, maternal peripartum fever, or difficult, traumatic delivery. Symptoms and signs begin within hours of birth and progress rapidly. The clinical and radiologic features are indistinguishable from those of hyaline membrane disease. Laboratory results may show leukopenia and gram-positive cocci in the tracheal aspirate. Mortality is approximately 50%. Group B streptococcal isolates from neonates with early-onset disease have been roughly even in their distribution among the major serotypes.

The late-onset disease, in contrast, is predominantly caused by type III group B streptococci. The disease is of slow onset and manifests as meningitis. The disease has a mortality of 10–15% and long-term neurologic morbidity of approximately 50%. Other presentations of late-onset disease include focal infections such as cellulitis, osteomyelitis, and arthritis.

Diagnosis

A high index of suspicion should always be maintained, and, when the diagnosis is considered, appropriate cultures should be obtained and prompt antibiotic therapy should be initiated. Infection is established by isolation of the organism from sterile body fluids. Antigen detection in these fluids using latex agglutination or counterimmunoelectrophoresis can be helpful. Changes in the complete blood count are not specific.

Treatment

Penicillin G is the antibiotic of choice for proven group B streptococcal disease. Intravenous penicillin should be administered in daily doses of 100,000–150,000 U/kg

(divided into two to three doses) in the first week of life and 150,000–200,000 U/kg (divided into three to four doses) thereafter. The dose should be doubled for meningitis. Duration of therapy should be 10–14 days for uncomplicated bacteremia, 2–3 weeks for meningitis and septic arthritis, and 3–4 weeks for osteomyelitis.

Ampicillin and gentamicin, commonly used for empirical treatment of infections in the neonate, is an effective combination. It may result in more rapid killing of streptococci in the blood and vascular tissues due to the synergistic activity of the two antibiotic agents against group B streptococci. Combination therapy should be continued for the first several days until a good clinical and bacteriologic response is obtained. Penicillin or ampicillin alone could then be used to complete the course of therapy.

Granulocyte-colony stimulating factor and streptococcal hyperimmune gammaglobulin have been used as adjuvant treatment to antibiotics with some promising results. More research is required before their routine use is recommended.

Prevention

Chemoprophylaxis and immunoprophylaxis have been tried to reduce neonatal infections, particularly in high-risk deliveries. The most successful chemoprophylactic approach is intrapartum administration of ampicillin to group B streptococcus-colonized mothers. Penicillin prophylaxis of an asymptomatic sibling of an infected twin may be justified. Because high levels of maternal type-specific antibody should protect full-term infants, the immunization of pregnant women with purified type-specific vaccine is a rational approach. The immunogenicity of capsular polysaccharide, however, has been low, with response rates of 40–80%. Protein conjugate vaccines are more immunogenic and might provide better protection. They are being investigated.

Group B streptococcal hyperimmune globulin has been used in some high-risk infants. Further studies are needed to confirm its efficacy.

94 Tetanus

Sulaiman Al Alola

Tetanus is an old disease that has been described vividly in medical history as far back as the second century AD.

Etiology and Pathogenesis

Tetanus is caused by the anaerobic, spore-forming, motile, gram-positive bacillus *Clostridium tetani*, which is present in soil and human and animal feces. This organism was isolated by Ketaset in 1889. The disease manifestation is not due to infection with *C. tetani* but rather is secondary to the specific neurotoxins produced by the vegetative form of *C. tetani* at the site of infection, which usually starts by the inoculation of the spore forms of the organism at the site of injury. The spores then turn into vegetative forms that flourish and multiply to produce the neurotoxins. *C. tetani* does not cause any tissue destruction nor inflammatory response.

There are two exotoxins produced by *C. tetani*, tetanolysin and tetanospasmin. Tetanolysin causes only hemolysis and has no role in the clinical manifestation of the disease. Tetanospasmin is the exotoxin responsible for the clinical features of the disease. It is a protein of 67,000 Da. It is a very potent toxin, next only to the poison produced by *Clostridium botulinum*. Humans are very susceptible to tetanospasmin, requiring only 1/2,500 and 1/35,000 of the dose fatal to cats and chickens, respectively, to show symptoms. Tetanospasmin inhibits release of acetylcholine in the neuromuscular junctions.

Clinical Features

The incubation period is usually 3–21 days, but it could be as short as 1 day or as long as several months. There is a direct relationship between the incubation period and the distance between the site of infection and the central nervous system. Tetanus may manifest in two forms, local or generalized. Tetanus diagnosis is totally clinical after excluding other causes of tetanic spasms, e.g., hypocalcemic tetany, phenothiazine reaction, strychnine poisoning and hysterical reactions.

Local Tetanus

This is an infrequent form of tetanus in which there is painful spasm of the muscles at the site of infection. It can be a precedent of the generalized form of tetanus. Cephalic tetanus is a variant of local tetanus. It usually follows the introduction of *C. tetani* in the course of injuries to the scalp, eye, face, ear or neck; chronic otitis media; or rarely tonsillectomy. The incubation period of this form of tetanus is usually 1–2 days. It is characterized by palsy of cranial nerves III, IV, VII, IX, X, and XII, singly or in any combination. Generally, the prognosis of cephalic tetanus is poor.

Generalized Tetanus

This is the most common presentation of tetanus. It usually follows deep penetrating injuries in which there is tissue damage, but, in the majority of cases, simple insignificant injury was the cause of the disease. Trismus, or spasm of the masseters muscles, is the hallmark of the disease. It may be unilateral early in the disease but becomes bilateral within a short time. In some cases, it may be absent during the entire course of the disease or appear only after other abnormalities have become apparent. Severe, unrelenting trismus leads to the development of a characteristic facial expression, the sardonic smile (risus sardonicus).

Generalized seizures (produced by tetanospasmin) usually start as sudden bursts of tonic contractions of all groups of muscles that lead to the development of opisthotonus, flexion and abduction of the arms, clenching of the fists on the chest, and extension of the legs. This tonic muscle contraction is very painful and is precipitated by the slightest noise or disturbance to the patient.

Neonatal Tetanus

Neonatal tetanus is still a major health problem in the developing world and is directly related to the local customs and handling of the birth process, particularly

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_94,

Table 94.1

≥3 doses of immunization given	No	No	No	No

cutting the umbilical cord and taking care of the umbilical stump. Neonatal tetanus is the cause of 45–75% of all deaths secondary to tetanus. The primary cause of death in neonatal tetanus is bronchopneumonia or hemorrhage in the lungs, singly or together. Among the nonpulmonary causes of death in neonatal tetanus are hepatitis, omphalitis, cerebral hemorrhage, and thrombosis and rupture of the renal vein.

Treatment

Treatment of generalized tetanus is directed to the following goals:

1. Neutralization of the circulating tetanospasmin before it gets attached to the nervous system by administration of antitoxin
2. Surgical débridement of the site of entry of the organism, when possible
3. Constant sedation and anticonvulsant treatment, or even complete paralysis of the patient, especially in neonatal tetanus, and mechanical ventilation, together with meticulous nursing care
4. Close monitoring of fluid, electrolyte, caloric, and acid–base balance
5. Intravenous or oral metronidazole (30 mg/kg/day) Q 6 hrs is the recommended first line treatment for 10–14 days. Penicillin given intravenously in a dose of 100,000 U/kg/day in four divided doses for 10 days to kill the vegetative forms of *C. tetani* at the site of injury is an alternative.

The antitoxin, human tetanus immunoglobulin (TIG), is given in a dose of 3,000–6,000 U intramuscularly (IM). If human TIG is not available, horse serum tetanus antitoxin is given in a dose of 100,000 U. Half of this dose is given IM after appropriate testing to rule out sensitivity to horse serum. If this dose is tolerated well, the other half is given intravenously (IV) slowly. Diazepam IV has proven very effective in controlling the tonic spasms of neonatal tetanus. Immune Globulin Intravenous (IGIV) can be given if TIG is not available. The IGIV dose recommended is 200–400 mg/kg.

Prevention

Tetanus is a preventable disease. Active immunization has proved to be very effective in decreasing the incidence of tetanus. In USA only 40 or fewer cases of tetanus have been reported annually since 1999. Tetanus is not tranmissble from person to person. After the initial basic course of tetanus immunization in children, a protective level of antitoxin is present in the serum for 5–10 years after the last dose of immunization. Prevention of neonatal tetanus can be accomplished by prenatal immunization of the previously unimmunized mother. The mother should be given two doses of tetanus toxoid at least 4 weeks apart, and the second dose should be given at least 2 weeks before delivery.

For the patient who recovers from tetanus, active immunization should be given because having tetanus does not confer lifelong immunity. The need for tetanus prophylaxis after receiving a wound is summarized in *Table 94.1*.

95 Tuberculosis

Suliman Al Jumaah

Etiology

Tuberculosis is caused by *Mycobacterium tuberculosis* (MTB) bacilli which are an aerobic nonmotile and nonspore-forming organism that range in size from 1 to 10 μm. These organisms do not take up usual stain for bacteria but rather stain strongly with special stains after treatment with acid and alcohol. Those characteristics are demonstrated by basic fuchsin stain technique (Ziehl–Neelsen and Kinyoun) or flourochrome method using auramine and rhodamine stains. Mycobacterium species include *Mycobacterium tuberculosis*, *Mycobaterium bovis*, and *Mycobacterium Africanum*.

Epidemiology

Tuberculosis is a major health problem worldwide. In 2009, WHO estimated 9.4 million incident cases of TB globally, accounting for an incidence of 137 per 100,000 with more than one million deaths. The global TB burden is falling slowly and the incidence rates have been declining since 2004 despite an increase in absolute TB cases due to population growth. There is a striking difference of TB among developed countries where incidence rate is generally less than 10/100,000 and low-income countries where incidence generally exceeds 100/100,000. In some regions like Africa, the incidence is still increasing. There is limited surveillance data that accurately quantify TB in pediatric population. In the year 2000, 884,019 (11%) of the estimated 8.3 million TB cases were in children, with 75% occurred in the 22 high-burden countries. The proportion of pediatric TB cases occurring in low-income countries is around 15% of total incident TB cases compared with 6% in the USA. In developed countries, like the USA, TB incidence is much less reduced. In 2009, the USA reported 11,545 total TB cases accounting for a rate of 3.8/100,000, representing 57% decline compared with 1992 resurgence peak. Six hundred and forty-six cases were among children, with an incidence rate of 1/100,000. Due to paucibacillary nature of TB disease in children, it is receiving less attention in TB control programs and most of the emphasis is directed toward the more infectious smear-positive TB. Recently, there has been an increased awareness regarding TB burden in children. In 2006, WHO compiled first guidance on the management of childhood TB and also requested all countries to include pediatric TB data in all future reports. In addition, in 2007, Global Drug Facility (GDF) made child-friendly TB drug formulation available for poor countries.

Infection with human immunodeficiency virus (HIV) is associated with tremendous risk of developing TB disease. Growing adult population coinfected with TB and HIV posed a major impact on TB incidence among their children due to more exposure and infection among those children. In addition, children infected with HIV and TB had a big impact on TB epidemiology in many countries, but no accurate data on actual burden.

Definitions

It is important to clarify some terminologies like TB exposure, latent TB infection (LTBI), and TB disease which are sometimes a source of confusions. Individuals who have been in contact with a case of tuberculosis but whose status is not clear because there is not enough time to rely on result of tuberculin skin test (TST) are defined as TB exposed. Asymptomatic individuals who have positive TST but no clinical or radiological finding of TB disease are referred to as latent TB infected. TB disease implies clinical or radiological findings consistent with Tuberculosis.

Pathogenesis

Mycobacterium tuberculosis is mostly acquired by inhalation of droplet nuclei containing the bacilli which reach the alveoli. Localized pneumonic process will form the primary (Ghon) focus. During the first 4–6 weeks, multiplication of bacilli within the primary focus will occur and bacilli will drain via lymphatic to regional lymph nodes. The upper lobes drain to ipsilateral–paratracheal nodes, whereas the rest of the lung drains to perihilar and subcarinal nodes, with dominant lymph flow from left to

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_95,

right. The Ghon complex (primary complex) is represented by both the Ghon focus, with or without some overlying pleural reaction, and the affected regional lymph nodes.

During this stage, occult dissemination occurs (primary bacillemia) to most of body organs including liver, spleen, bone marrow, and kidneys. This happens before cell-mediated immunity is reactivated. Most of this hematogenous spread is asymptomatic and few children progress to TB disease. After this primary dissemination, cell-mediated immune system is stimulated resulting in lymphocytic infiltration of the infected foci. Histologically, the infected foci become surrounded by lymphocytes and epitheloid cells, forming granuloma. In most of the situation, the immune system will control the disease which remains dormant as latent TB; however, this depends on various factors. Age and immune status are the most important factors determining disease progression. The risk of progression from tuberculosis (TB) infection to disease is generally small (5–10% lifetime risk) in immunocompetent older children and adults. However, in infants and children less than 2 years, the risk is increased to 40–50%. In untreated HIV-infected patients, there is 5–10% annual risk of disease progression. Risk is the lowest (2%) for children of 5–10 years of age. Fifty percent of disease progression occurs within the first 2 years.

Clinical Manifestations

Tuberculosis may involve any organ in the body. Pulmonary TB is the commonest form accounting for 60–80% of all cases. Extrapulmonary TB present with various forms with lymphadenopathy being the commonest (67%), followed by the central nervous system disease (13%), pleural disease (6%), miliary (5%), and skeletal (5%).

Pulmonary Tuberculosis

Inhalation of *Mycobacterium tuberculosis* bacilli results in Ghon complex causing parenchymal disease and intrathoracic adenopathy. The natural history of the disease illustrates that it either gets controlled by the immune system leading to LTBI or progress leading to primary parenchymal disease or progressive primary disease. LTBI may later reactivate leading to reactivation disease in adolescents or immunocompromised children.

Infants, young children, and adolescents are more likely to be symptomatic. Symptoms are usually vague with low-grade fever, malaise, cough, loss of appetite, and weight loss. Symptoms may result from enlarging lymph nodes compressing bronchus leading to collapse consolidation, hypoaeration, and segmental or lobar atelectasis. Progressive pulmonary tuberculosis results from poor containment of the initial infection, leading to tissue destruction and sometimes cavity formation (*Figs. 95.1* and *95.2*).

Reactivation form of the disease occurs usually in adolescents with fever, cough, and night sweats. It is not clear why adolescents are more prone to this form of disease. Radiological findings overlap with primary disease.

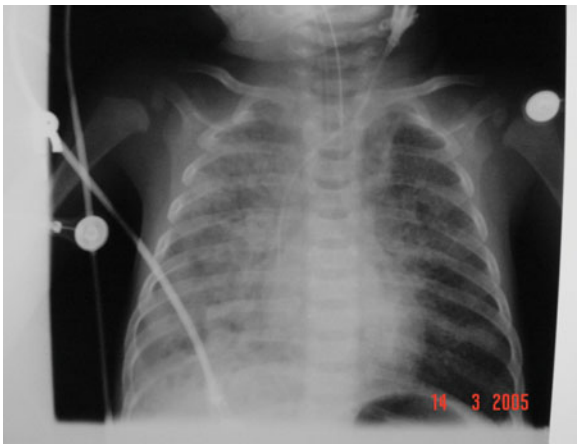

Figure 95.1
Chest radiograph of a 6-month-old infant with extensive consolidation, both gastric aspirate and tracheal aspirate grew *Mycobacterium tuberculosis*

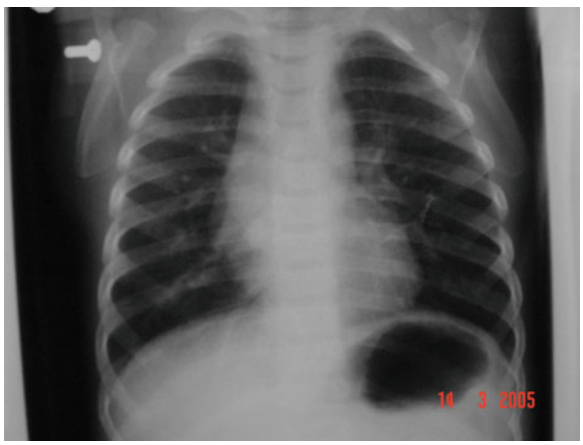

Figure 95.2
Chest radiograph of same infant showing marked improvement 6 months after therapy

The most common radiological finding is hilar, mediastinal adenopathy, followed by segment or lobar consolidation. Hilar adenopathy has been noted in about 50% of asymptomatic children as transient phenomenon which may be discovered in the context of contact tracing. However, this is conventionally treated as disease.

Pleural Disease

Pleural disease may result from primary infection or reactivation. In primary infection, there is direct invasion of pleural space after primary bacillemia, followed 6–12 weeks later by hypersensitivity reaction leading to pleural effusion. In reactivation form of the disease, there is usually parenchymal lung focus with secondary pleural involvement. Pleural TB occurs more in adolescents and rare in younger children.

Lymphatic Disease

Tuberculous lymphadenopathy occurs in 10–15% of children with TB and is the commonest form of extrapulmonary TB. Most cases of adenitis occur within 6–9 months of initial infection. Supraclavicular, anterior cervical, tonsillar, and submandibular nodes are involved secondary to extension of primary lesion of the upper lung fields or abdomen. Nodes are usually unilateral, firm, and non-tender. A primary pulmonary focus is visible in 30–70% of cases. Untreated lymph nodes can resolve but may also progress to caseating necrosis, capsule rupture with spread to adjacent nodes and overlying skin which will become shiny and red. If skin ruptures, this will lead to sinus formation. It is important to distinguish lymphadenitis due to *Mycobacterium tuberculosis* from that due to nontuberculous mycobacteria (NTM). Chest x-ray is usually normal in NTM adenitis and TST is negative or weakly positive and child is usually less than 3 years old with absence of systemic illness. History of contact in case of tuberculosis may be helpful, but generally excisional biopsy is required to confirm the diagnosis (*Fig. 95.3*).

Central Nervous System Tuberculosis

Central nervous system tuberculosis (CNSTB) is the most serious form of extrapulmonary TB, which is frequently fatal if untreated. CNSTB usually occurs within 6 months of primary infection, and 50% of patients are under 2 years. It complicates 0.5–2% of primary infection and 50% of military TB. The disease originates from caseous

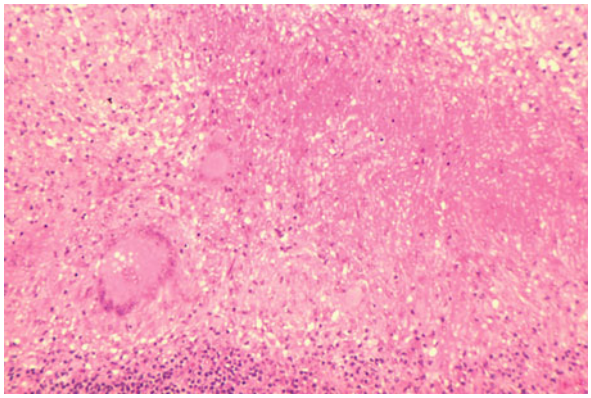

Figure 95.3
Lymph node biopsy from a child with tuberculosis lymphadenitis showing typical caseous necrosis

meningeal focus lesion in the cerebral cortex or meninges that were formed during the stage of hematogenous spread that release bacilli into subarachnoid space. The most common manifestation of CNSTB is meningitis in 95% and tuberculoma in 5%. The onset can be rapid but more often is insidious with nonspecific symptoms like fever, fussiness, and nausea. This is followed by cranial nerve palsy and meningeal irritation, and finally stupor and coma. CT scan of the brain frequently (>80%) shows hydrocephalus with basilar enhancement. Chest x-ray is abnormal in up to 90% and TST is positive in 30% of children. CSF shows high white cell count with lymphocyte predominance, low sugar, and high protein. AFB stain is positive in only 10–30% of patients, and culture is positive in 30–70% if enough CSF sample cultured (5–15 mL). Gastric aspirate is positive in about 10% of children.

Tuberculoma manifest as space-occupying lesion, which may involve any part of the brain but tend to be infratentorial in children (*Figs. 95.4* and *95.5*).

The most common symptoms are headache, fever, and convulsion. It needs to be differentiated from tumor and neurocysticercosis. The disease may be suspected on epidemiological ground, but biopsy is often needed for diagnosis. Tuberculoma may paradoxically increase in size or appear upon starting effective TB treatment. This phenomenon is probably immune mediated and does not signify failure of therapy.

Osteoarticular TB

Osteoarticular tuberculosis results from hematogenous seeding after primary infection. Interval between infection

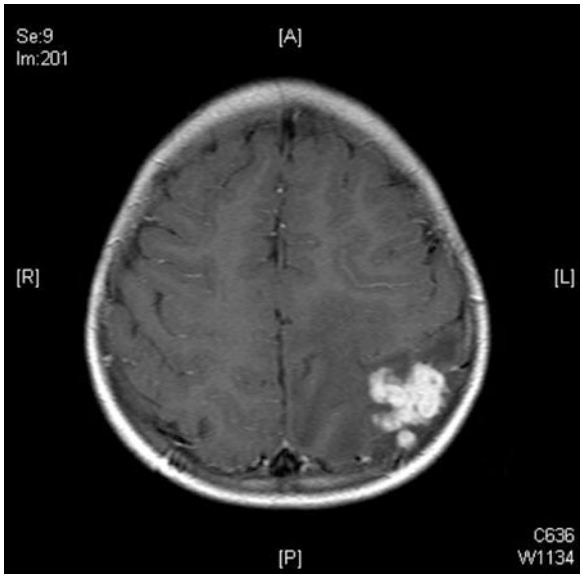

Figure 95.4
MRI brain, T1-weighted image of a child showing enhancing temporoparietal lesion proven by biopsy to be due *Mycobacterium tuberculosis*

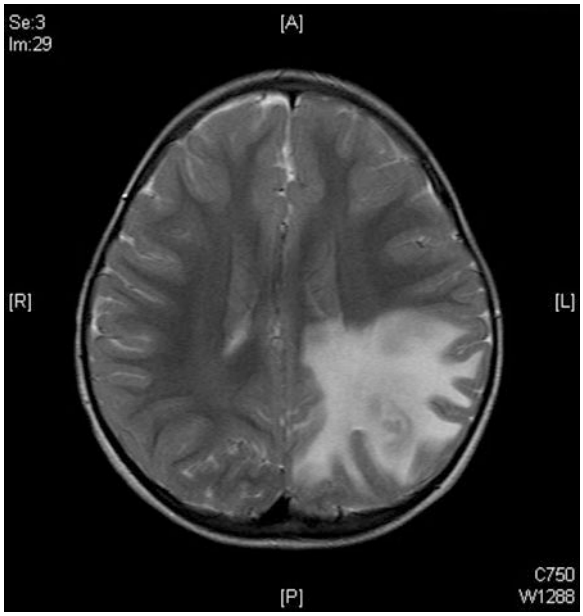

Figure 95.5
MRI brain, T2-weighted image of same child showing temporoparietal lesion with surrounding extensive edema

and clinical manifestation is usually several years but may be as short as 1 month like in tuberculous dactylitis in infants. Infection usually starts in the metaphysis of bone causing necrosis and caseation. Abscess formation and extension of infection to nearby joint complicate bone infection. Vertebrae are the most commonly affected bone, which is called Pott disease. It may affect any one or multiple vertebral bodies but mostly lower thoracic and upper lumbar. Wedging of the involved vertebrae results in Kyphosis and Gibbus deformity. Extension of infection to surrounding soft tissue causes paraspinal abscess, psoas abscess, or retropharyngeal abscess.

Vertebral diseases present with back pain, paraparesis, and parasthesia. CT and MRI will aid in diagnosis.

Other sites of involvement include knee, hip, elbow, and ankle. Involvement ranges from mild joint effusion to bone destruction with restriction of joint movement. TST is usually positive in 80–90%.

Other form of TB peculiar to infant is tuberculous dactylitits, which is present with swelling of hands, feet, and cystic bony lesions.

Miliary TB

Miliary TB results from lymphohematogenous spread with multiorgan involvement. It is commonly seen in infants and immuncompromised host including children with rheumatological disease receiving antitumor necrosis factors agent. Organisms seed many organs like lung, liver, spleen, meninges, bone marrow, and retina. Meningitis is seen in about 20–50% of cases.

Chest x-ray shows classic miliary pattern with multiple small nodules in 50%. There may also be airspace consolidation.

TST is usually negative due to anergy. AFB culture has a yield of 30–60%.

TB Diagnosis

Diagnosis of TB in children is a major challenge. Clinically, diagnosis is usually based on (1) known contact with an index case, (2) positive tuberculin skin test, (3) suggestive finding on chest radiograph.

In most situations, diagnosis of TB relies on clinical and epidemiological background. Unfortunately, there is no single test which could confirm the diagnosis in all situations. Bacteriological confirmation is possible in less than 50% of the cases.

Tuberculin Skin Test (TST)

TST using five tuberculin unit is the standard method. The antigens trigger delayed-type hypersensitivity reaction in persons previously exposed to TB. Induration is measured in millimeters after 48–72 h. Negative TST does not rule out TB since 10% of culture-confirmed TB cases have negative TST. False-negative results may be due to severe disease, debilitated children, malnutrition, immunosuppression, or if TST is done early after exposure. False-positive results are seen in infections due to NTM or previous vaccination with BCG. However, BCG vaccination is unlikely to give positive TST results after 3–5 years.

TST is interpreted taking in consideration risk of TB and immune status of the host. A cutoff of 5 mm or more is considered positive in persons with history of contact with TB case; chest radiograph is consistent with TB, HIV, and other immunosuppressive state. Ten millimeters or more is considered significant in health-care worker, population at risk, children in contact with adult at high risk. Fifteen millimeters is considered positive in low-risk group.

Mycobacterial Culture

Confirmation of TB in children is hampered by sampling difficulties since young children are not able to cough up the sputum. In addition, TB in children is paucibacilliary and AFB sputum smear is positive only in about 15–20% of cases. Early morning gastric aspirate yields positive culture in 37–45% which is better than bronchoalveolar lavage (yield 13–30%). Induced sputum has a yield of about 10%. Traditional solid culture medium (Lowenstein–Jensen medium and Middlebrook), takes 4–6 weeks to yield growth and in additional 2–4 weeks for susceptibility test. More recent fluid-based medium (radiometric and non-radiometric) has a better yield (10 days to 2 weeks). Other new method, microscopic observation susceptibility test (MODS) has median time of recovery of 7 days. It depends on direct inoculation of processed sputum into 24 well plates containing or not containing the drug. Growth is detected by examination under inverted microscope.

Nucleic Acid Amplification Methods

These tests are used to directly detect DNA on clinical samples. The principle is based on using high conserved segment to amplicate DNA. Polymerase chain reaction (PCR Amplicor, Roche) approved in the USA for adults with smear-positive sputum and Amplified *Mycobacterium Tuberculosis* Direct Test, Gene-probe (AMTD) is approved in adults for both smear positive and smear negative. These tests are very specific (95–98%), but sensitivity ranges from 35% to 75%. Limited studies in pediatric showed sensitivity of 25–83% in children with pulmonary TB. Those tests may help in diagnosis of TB in children but negative PCR does not exclude diagnosis of TB.

Interferon-γ Release Assays

These tests are based on in vitro stimulation of lymphocyte by specific mycobacterial antigen, early secretory antigen (ESAT), and culture filtrate protein (CFP). T cell of patients exposed to MTB will release interferon gamma. Released interferon gamma that reflects T-cell response will be measured.

Three tests are available: Quantiferon-TB Gold, Quantiferon-TB Gold in-tube (Cellestis, Victoria, Australia), and T-SPOT-TB (Oxford Immunotee, UK). Interferon gamma is measured by Elisa (Quantiferon) or by counting spot-forming T cells (T-SPOT-TB). Most of the studies were done on adults and there is limited data in pediatrics. Results of these tests are not influenced by previous receipt of BCG. Both tests are endorsed by FDA for diagnosis of LTBI and TB disease.

Recent meta-analysis of studies done on latent TB infection showed sensitivity of 70% for Quantiferon-TB Gold, 78% for Quantiferon-TB Gold in-tube, and 90% for T-SPOT-TB compared with 77% for TST. Both tests are fairly specific (96–99%) in both BCG vaccinated and non-vaccinated, but TST has specificity of 59% in BCG vaccinated and 97% in BCG non-vaccinated.

Both tests are promising but it is early to recommend their use in pediatrics.

Treatment of TB

One of the major problems with treating TB is the noncompliance which may lead to failure of therapy, relapse, and development of drug resistance which is already a growing problem worldwide. Adoption of directly observed therapy (DOT) is recommended for children and adolescents with tuberculosis. The American Academy of Pediatrics (AAP) recommends treatment of tuberculosis disease with 2 months of isoniazid, rifampin,

pyrazinamide, and ethambutol, followed by 4 months of isoniazid and rifampin. Some experts recommend starting three-drug regimens (isoniazid, rifampin, and pyrazinamide) as initial regimen if a source case is known to be sensitive or reside in low-resistance area. WHO recommends starting four-drug regimens if INH resistance is more than 4%. Majority of extrapulmonary TB is treated with same regimen as for pulmonary tuberculosis. Exceptions are children who have CNSTB, disseminated TB, or severe cavitory TB where treatment course is 9–12 months (*Tables 95.1* and *95.2*).

Corticosteroids have been used as an adjunctive therapy in some forms of TB to decrease damage caused by inflammatory response. Indication to use steroids includes CNSTB, pleural, severe miliary TB, pericarditis, endobronchial and abdominal TB. Dose is 2 mg/kg per day of prednisone for 4–6 weeks followed by tapering dose.

The rationale of using multiple chemotherapy is to ensure mycobacteriologic cure, because resistance to one of the antimycobacterial drugs occurs naturally (INH, 1 in 10^6; rifampin, 1 in 10^6; streptomycin, 1 in 10^5; and ethambutol, 1 in 10^6). Therefore, in lesions with high population size, such as the cavitary lesion, which contains 10^7–10^9 mycobacteria, there is a high chance of having colonies resistant to one of the drugs. However, the chance of having resistance to two drugs is 1 in 10^{13}–10^{17}. In children, tuberculosis is a result of primary infection, which usually results in small caseous lesions that contain a smaller number of mycobacteria (10^6–10^7), and therefore the cure rate is excellent. However, due to increasing incidence of multidrug-resistant (MDR) mycobacteria, attention should be paid to therapeutic response, and every effort should be made to obtain susceptibility testing.

Table 95.1
Treatment of tuberculosis in children

Infection or disease category	Regimen
Latent tuberculosis infection (positive TST)	
Isoniazid susceptible	9 months of isoniazid, once a day
Isoniazid resistant	6 months of rifampin, once a day
Pulmonary and extrapulmonary (except meningitis, disseminated disease, and severe cavitory TB)	2 months of isoniazid, rifampin, pyrazinamide, and streptomycin/ethambutol daily, followed by 4 months of isoniazid and rifampin by DOT for drug-susceptible *Mycobacterium tuberculosis*
Meningitis, disseminated disease, and severe cavitory TB	2 months of isoniazid, rifampin, pyrazinamide, and an aminoglycoside or ethambutol or ethionamide, once a day, followed by 7–10 months of isoniazid and rifampin once a day or twice a week (9–12 months total) for drug-susceptible *M tuberculosis*

Table 95.2
Commonly used drugs for treatment of tuberculosis in children

Drugs	Dosage forms	Daily dosage, mg/kg	Side effects
Isoniazid	Scored tablets 100 mg 300 mg Syrup 10 mg/mL	10–15	Mild hepatic enzyme elevation, hepatitis, peripheral neuritis, hypersensitivity Diarrhea and gastric irritation caused by vehicle in the syrup
Rifampin	Capsules 150 mg 300 mg Syrup formulated Capsules	10–20	Orange discoloration of secretions or urine, staining of contact lenses, vomiting, hepatitis, influenza-like reaction, thrombocytopenia, pruritus; oral contraceptives may be effective
Pyrazinamide	Scored tablets 500 mg	30–40	Hepatotoxic effect, hyperuricemia, arthralgia, gastrointestinal tract upset
Ethambutol	Tablets 100 mg 400 mg	20–25	Optic neuritis (usually reversible), decreased red-green color discrimination, gastrointestinal tract disturbances, hypersensitivity
Streptomycin	Vials 1 g 4 g	20–40 (IM)	Hearing loss Nephrotoxicity

Treatment of LTBI

Tracing contacts and treating individuals with LTBI is one of the most effective ways of controlling TB. INH therapy was shown to reduce TB disease by 94%. INH should be administered to all children (and adults) with positive TST. High-risk children (<5 years) and infants need to be started on INH therapy even initial TST is negative. TST should be repeated in 3 months and if still negative, INH may be discontinued.

Prevention of TB

BCG is the only available vaccine and still recommended by WHO in high-endemic countries. It is live attenuated vaccine derived from *M. bovis* strain that has been attenuated by serial passages. It has modest effect in preventing TB. Meta-analysis of randomized clinic trial showed an overall efficacy of 74%. Efficacy for disseminated TB was 78% and 64% for TB meningitis. Its main side effect is local adenitis. It may also cause fatal disseminated diseases in SCID patients and patient with gamma interferon axis defect.

Drug-Resistant TB

Drug-resistant TB is a growing concern all over the world. Resistant may be to single agent (like isozianizid) or resistant to multiple drugs. Multidrug resistance TB (IMDR) is defined as resistant to at least isoniazid and rifampin. Many factors had contributed to the increase in drug resistance, mostly noncompliance with medication, poor therapy, and epidemic of HIV. Prevalence of INH resistance or MDR is variable among different countries. In the USA, the prevalence of INH resistance among patients with pulmonary tuberculosis has increased from 2% to 9%.

Consideration of local drug resistance has major impact on choice of initial regimen and retreatment of tuberculosis. It is advised to start a four-drug regimen if local INH resistance >4% and a three-drug regimen if INH resistance is less than 4%. Prevalence of MDR is variable. A survey by WHO showed an overall prevalence 2.2% but 13% in retreated patients. The prevalence data in children are limited. MDR is always difficult to treat with approximately 50% failure rate. Therapy should include five- or six-drug regimens for 12–18 months. In these situations, second-line agents like ciprofloxacin, levofloxacin, ethionamide, amikacin, and cycloserine are used. However, those agents are generally less effective than first-line agents.

96 Fungal Infections

Ibrahim Bin-Hussain

Introduction

The number of patients at risk for fungal infection has increased dramatically over the last 3 decades. However, with the advances in medical technology and development of new antifungal agents, the diagnosis and treatment of fungal infections have been improved.

In the past, fungi were used by human in preparation of food, but over the last 3 decades the relation between fungi and human has been reversed with the emergence of new or previously rare fungal infections with an increased morbidity and mortality and development of drug-resistant strains.

In this chapter, the changing epidemiology of invasive fungal infections in pediatric patients is described, and the challenges with the diagnosis and treatment of fungal infections are discussed. The primary defense mechanisms against fungal infections are the skin and mucous membrane; these are fragile and easily colonized in children as well, as the functional immaturity of phagocytes and T lymphocytes put pediatric patients at higher risk for fungal infection. Interestingly, pediatric patients tolerate the intensive antifungal therapy much more than the adult patients.

Epidemiology

Fungi are present in the environment. The reservoirs for *Aspergillus* and *Zygomycetes* include unfiltered air-ventilation system, contaminated dust during construction. In contrast to candida, it is mostly acquired indigenously through prior colonization of the mouth, vagina, skin, and gastrointestinal tract, which can be transmitted to patient by the healthcare personnel; therefore, it is very important to practice infection control measures including hand hygiene to prevent transmission.

The systemic fungal infections are major causes of morbidity and mortality in the immuncompromised patients and the incidence of fungal infection is up to 40% in patient with acute leukemia and hematopoeitic stem cell transplant, 35% in patient with post heart transplant, up to 40% for post liver transplant, for other solid organ transplant is about 5% including kidney transplant.

Risk Factors

The most important defects that predispose to fungal Infections are neutrophil defects (either quantitative or qualitative) and defect in T-cell mediated immunity which are commonly seen in primary condition such as immunodeficiency either primary or secondary, leukemia, lymphoma, bone marrow transplant recipient, organ transplant, acquired immunodeficiency syndrome, primary immune disorder, gastrointestinal disease, severe burns, premature births, diabetes, and IV drug abuser. Other factors related to medical interventions (iatrogenic) include chemotherapy, immunosuppressive drugs, prolonged use of broad-spectrum antibiotics, breaks in skin or mucosa, indwelling catheters, peritoneal dialysis, prolonged hospitalizations, and total parenteral nutrition.

The classic risk factors for candidiasis include the use of multiple antibiotics, presence of central venous catheter, total parenteral nutrition, and colonization with candida. The specific risk factors in neonates, which are unique to this group, include low birth weight (90% of affected neonates) instrumentation like intubation and prolonged ventilation, prolonged use of third-generation cephalosporin, congenital malformation (frequently seen in infants with birth weight more than 2,500 g at birth with prolonged NICU hospitalization), gastrointestinal tract disease, necrotizing enterocolitis and anatomical abnormalities requiring surgery, and low Apgar score at 5 min.

In the invasive aspergillosis in children, the highest incidence are in patients post allogeneic bone marrow transplant, followed by patients with acute myloid leukemia (AML), congenital immunodeficiency; other groups at risks include aplastic anemia, acute lymphoblastic leukemia (ALL), lymphoma, autologous bone marrow transplant, and solid tumor. 74% of invasive

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_96,

Aspergillosis are related to oncological disorders both hematological and oncological malignancy and post bone marrow transplant.

Other predisposing factors for fungal infection include high dose and prolonged use of corticosteroid therapy. Other risk factors include Graft-versus-host disease, congenital immunodeficiency, and solid organ transplant. Interestingly, 90% of the patients have more than one of these risk factors.

Candidemia represent up to 15% of all bloodstream infections and is the third most common bloodstream isolate in the USA. The fungal sepsis is associated with second highest case fatality in children up to 13%. Comparing the pediatric patients and adult, the highest incidence per admission is in neonates up to 150 in 100,000 admissions, followed by children about 47 per 100,000 admissions and adult 30 per 100,000 admissions. The incidence in neonates increased with low birth weight and there is a reverse relationship between the birth weight and the incidence of fungal infection, mainly candidiasis.

In addition to fungal infection in high-risk patient, there is emerging fungal pathogen which can be varied from location to location. For example, in southern part of Saudi Arabia, there are pediatric patients reported with gastrointestinal basidiobolomycosis. Usually, these patients are present with huge abdominal mass that usually confuse with lymphoma or other solid organ tumor including rhabdomyosarcoma, and gastrointestinal tuberculosis. The clue for the diagnosis of gastrointestinal basidiobolomycosis is intense tissue eosinophilia surrounding the fungal structure (Splendore Hoeppli) phenomena and the special fungal stain (GMS) will show the fungal pathogen (*Fig. 96.1*).

Etiology

The predominant pathogen in immunocompromised patient is invasive candidiasis, followed by aspergillosis and mucormycosis. The candida species causing infection in immunocompromised patients are *candida albican*, which are most frequently isolated, but recently non-albicans candida species has emerged as a major pathogen including *Candida tropicales, Candida glabrata,* and *Candida parapsilosis*, in addition to other rarely isolated candida spp. including *Candida krusei* and *Candida lusitaniae*. The predominant aspergillus species is *Aspergillus fumigatos* in USA but other reported *Aspergillus flavus* is more frequently isolated.

Mortality in patients with invasive fungal infection is high. The mortality rate in patients post bone marrow transplant with invasive aspergillosis can exceed 70% and close to 30% in patients with candidemia.

The clinical manifestation of fungal infection varies depending on the immune status of the host. For example, Candida cause mucocutaneous candidiasis in neonate and patients or with prolonged use of broad-spectrum antibiotics. It is usually transient but if prolonged primary immunodeficiency should be looked at. Patients with polygandular endocrinopathy can present with recalcitrant mucocutaneous candidiasis.

Invasive candida infection involved wide spectrum of diseases from catheter-related candidemia to deep organ involvement. There are four forms of invasive candidiadis: candidemia usually catheter-related candidemia, acute disseminated candidiasis, chronic disseminated candidiasis, and deep organ candidiasis.

In aspergillosis, the targeted organs are lungs and paranasal sinuses. These patients can present with prolonged fever and neutropenia not responding to

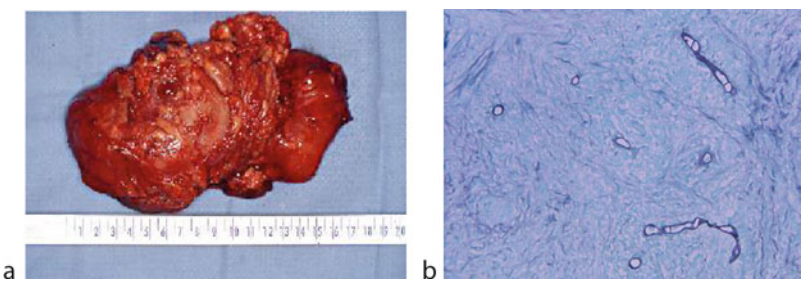

Figure 96.1
(a) Gross macroscopy of the mass after resection. (b) Silver stain showing branching septate hyphae of variable but generally wide diameter

broad-spectrum antiobiotics with few localizing signs. In adult series, the patient can have chest pain and hemoptysis but these are rare presentation in pediatric patient. Patient with paranasal sinusitis can present with localized facial swelling; with or without intracranial involvement.

Diagnosis

The diagnosis of fungal infection is a difficult task and it needs high index of clinical suspicion. Early diagnosis is very essential as the survival of patient often depends on the prompt initiation of appropriate therapeutic measure. Knowledge about spectrum of presentation is needed to predict the likely pathogen. Majority of these patients present with prolonged febrile neutropenia not responding to broad-spectrum antibacterial therapy. Few patients present with signs suggestive of fungal infection, for example, skin lesion, facial swelling, or necrotic lesion on hard palate. It is important to examine the patient thoroughly with good exposure to avoid missing an important clue for diagnosis. *Figure 96.2* shows patient presented with prolonged febrile and neutropenia, not responding to broad spectrum of antibiotic. This is the only clue for the diagnosis. If this patient is not exposed well, it will be easily missed as these lesions usually are asymptomatic and painless. It is also important to look in the oral cavity, for example, patient with acute lymphoplastic leukemia not responding to broad spectrum of antibiotic and with prolonged neutropenia, the examination for oral cavity can see the scar as shown in *Fig. 96.3* with necrotic ulcer in the hard palate.

Chest radiograph has low negative and positive predictive value in immunocompromised patients; therefore, it can be normal up to 25–50% of patient with invasive aspergillosis at the onset of the disease. The lesion in the chest x-ray can be patchy, peripheral, bilateral infiltrate, or solitary or multiple nodules. These lesions may progress over a period of days to weeks to form dense consolidated infiltrate or cavitation. Most of the patients who are at risk for fungal infection usually require high-resolution CT scan because it can give earlier and better assessment than chest radiograph. Findings from CT scan include halo sign, which is an early manifestation while the patient is neutropenic and usually appears as a rim of round glass–glass attenuation surrounding the nodule which usually corresponds to the rim of hemorrhage surrounding the pulmonary infarction. Other sign of invasive fungal infection includes air crescent sign. The problem in the air crescent sign is that the diagnostic usefulness is limited by the late occurrence which is usually seen about 1–3 weeks after the halo sign when neutropenia is resolved. This corresponds to the cavitations at the time of neutrophil recovery. In the recent publications in pediatrics, cavitation lessions is rarely manifested in pediatrics compared to adult. It is very difficult to depend on the air crescent sign and halo sign in pediatric patients. The difference in the manifestation radiologically between adult and pediatric is not understood.

Figure 96.2
12-year-old with ALL with small nodula shown on her right thigh culture from *C. albican*

Figure 96.3
14-year with AML with necrotic hand pilace session, biopsy showed fungal hyphere culture from *A. flavus*

The radiological diagnosis of chronic disseminated candidiasis, the lesion may not be detected early in the course while the patients are neutropenic because these patients are unable to mount immunological response. The MRI and CT are more sensitive than the ultrasound in diagnosing chronic disseminated candidiasis as both MRI and CT scan can detect characteristic lesion in about 90% of patients compared to 75% with ultrasound but the ultrasound is a suitable alternative for monitoring the progress of the lesion during therapy.

The blood culture is useful for the detection of candida blood stream infections. The yield of blood culture for candidemia is up to 50% but with the new advancement in the microbiology the detection rate increased up to 80%.

Because of the difficulty in the diagnosis of fungal infection, there is surrogate marker including new diagnostic test that can help in diagnosis. For example, for candidiasis, markers which can help diagnosing candidemia in the blood includes 1, 3 Beta D Glucan which is approved to help in diagnosing invasive fungal infections. Marker for Aspergillosis include aspergillus galactomannan, both in the blood, broncoalveolar lavage fluid and CSF in addition to 1,3 Beta D Glucan.

The Galactomannan assay performance in children is lower compared to adult. The reason for the high false-positive Galactomannan antigenemia in pediatrics is not clear but one postulation could be related to the dietary difference in dairy products. The performance of Galactomannan assay for primary immunodeficiency, non-neutropenic patients is poor compared to other patient population as studies have shown that Galactomannan antigenemia detected in only 4 out of 15 cases of chronic granulamatous disease (CGD) and hyper IgE syndrome versus 24 out of 30 cases of all other immunocompromised conditions with significant statistical difference.

Because the clinical and radiological manifestations of fungal infection are often nonspecific, definitive diagnosis of fungal infection requires the performance of procedures with some degree of invasiveness. These procedures will depend on the condition of the patients, the clinical finding, as well as the finding on the radiological evaluations. Lesions need to be biopsied to guide therapy. Specimens need to be sent to microbiology as well as histopathology laboratories for fungal staining and cultures. The presence of branching, septate hyphae on direct microscopy suggest Aspergillus spp. but need to be confirmed by culture. Gomori methenamine stain is helpful for better visualization of the fungal structure. Only microbiological culture can identify the pathogen with accuracy.

Management

There are three important factors to consider in caring for patient at risk of fungal infection: the environmental controls and the use of cytokines as immunomodulator and antifungal agents. For the environmental control, there are strategies to control infections and to reduce exposure to pathogen. The infection control measures in the hospital setting is paramount important to prevent the spread of nosocomial infection. Environmental control such as minimizing exposure to dust especially from building construction and the use of air filter are crucial to prevent acquisition of organisms such as aspergillus. Infection control measures, in particular, hand hygiene, can minimize the spread of indigenous organisms such as candida species. Suppression of colonization using antifungal agent such as nystatin, clotrimazole, and fluconazole has limited success. The deficiency in number on function of white cell counts is correlated with the degree of progression of the disease. Cytokines as an immune modulator act on both neutropenic and non-neutropenic patients. These cytokines including granulocyte colony-stimulating factor, granulocyte macrophage colony-stimulating factor show a promising adjunct therapy for proven fungal infection. Regarding reducing exposure to fungal pathogen, it is important to avoid area of construction or renovation. Nosocomial *Aspergillus* infections result primarily from inhalation of fungal conidia. Rooms for high-risk patients should be equipped with high-efficiency particulate air (HEPA) filters, high rates of air exchange, and positive pressure so that air from the patient's room flows into the hallway.

Most cases of invasive candidiasis are caused by endogenous *Candida* organisms colonizing the gastrointestinal tract. *Candida* species can be carried on the hands of health-care workers, who need to follow appropriate hand washing precautions to prevent the nosocomial spread of organisms.

Patients at high risk for infections should avoid food known to be frequently contaminated with fungi (e.g., teas, herbal medicines, nonprocessed peanuts) and avoid activities that would provide large exposures (e.g., gardening, construction).

Antifungal Therapy

Significant antifungal chemotherapy began in 1903, with the successful use of potassium iodide (KI) for the treatment of sporotrichosis. There was little progress for the next 50 years until nystatin, the first useful polyene, was introduced in 1951. This was soon followed by

amphotericin B in 1956, still the standard against which new systemic antifungals are compared. Except for the development of flucytosine (1964), there was little progress until early 1972 in the development of the azole drugs. The current era, which is characterized largely by the modifications of azole drugs, began with miconazole (1978) and ketoconazole (1981) and brought the agents fluconazole (1990) and itraconazole (1992), which can be given orally and have increasing potency, decreased toxicity, and a broader spectrum of activity. The development of lipid formulation ameliorate the well-known toxicities of the amphotericin B. But from 2000 onward, there is a plethora of antifungal agents including IV itraconazole in 2000, caspofungin in 2001, voriconazole in 2002, micafungin in 2005, posaconazole in 2006, and anidulafungin in 2006.

The Mechanism of Action of Antifungals

Polyenes including amphotericin bind to ergosterol in fungal cell membranes, resulting in altered permeability and cell death. The azole antifungals including itraconazole, fluconazole, and voriconazole inhibit CYP450-dependent 14-alpha-lanosterol demethylase required for ergosterol biosynthesis. The echinocandins including caspofungin, micafungin, and anidulafungin inhibit the synthesis of 1,3-beta-D-glucan synthesis complex, which is a major component of the fungal cell wall.

Amphotericin B

The amphotericin deoxycholate B has a broad spectrum of activity which is active against yeast and filamentous fungi but has low activity against *Aspergillus terreus*, *Candida lusitaniae*, *Trichosporon ashaii*, *Sedosporium prolificans*, and *Pseudoalisteria boydii* which are usually resistant. Other limitation is the toxicity both infusion toxicity and non-infusion related toxicity. The infusion toxicity includes fever, rigors, chills, anorexia, nausea, vomiting, phlebitis, and anaphylaxis. The non-infusion toxicity includes nephrotoxicity (leading to hypokalemia, hypomagnesemia, tubular acidosis) anemia, and thrombocytopenia. Nephrotoxicity can be ameliorated with good hydration. Majority of patients who are receiving regular amphotericin B require potassium supplement. Because of the broad spectrum of amphotericin B, it continues to be in use for a long period and continues to be the standard for antifungal therapy, but the disadvantage is the major side effect; therefore, the pharmaceutical company worked to modify structure to decrease the side effect of amphotericin B while keeping its efficacy. There are three lipid formulations of amphotericin B, which include amphotericin B lipid complex (ABLC), amphotericin B colloidal dispersion, and liposomal amphotericin B (amBisome). The advantage of the lipid formulation of amphotericin B is that the efficacy is similar to regular amphotericin B but less nephrotoxic than amphotericin B. The liposomal amphotericin B (amBisome) has the lowest infusion-related reactions and best pharmacokinetic properties. The amBisome has fewer breakthroughs in fungal infection in febrile neutropenic patients when compared to regular amphotericin B. The CNS penetration is better with amBisome compared to amphotericin B lipid complex or ABLC. The disadvantage of lipid formulations is the higher cost compared to amphotericin B deoxycholate.

The nephrotoxicity of amphotericin B is less severe in children compared to adults. The pharmacokinetic study of ambisome in children showed that there is no dose limiting trend in adverse events up to 10 mg/kg/day. ABLC was assessed in more than 540 children with similar efficacy of amphotericin deoxycholate in children and adults.

Azoles

The fluconazole has broad-spectrum activity against candidiasis, cryptococcosis, trichosporum spp., and dermatophytes. It has very good bioavailability with high urine concentration. The limitation of fluconazole is the Candida krusei, which is intrinsically resistant to fluconazole, and resistance can develop in candida glabrata. Fluconazole has no activity against filamentous fungi including aspergillosis. The clearance in children is more rapid compared to adult with lower half-life. Children more than 3 months require to double the daily dose up to 12 mg/kg/day; the neonate showed slow elimination of drug due to reduced hepatic enzyme and reduced GFR.

The second agent in this class is the itraconazole. It is active against yeast and filamentous fungi includes aspergillosis but the activity is limited against fusarium and zygomytes. The limitation of oral capsule of itraconazole is erratic absorption. Other formulation of itraconazole is itraconazole cyclodextrin oral suspension and IV formulation.

Because of the erratic absorption of itraconazole and the limited spectrum activity of fluconazole, there are new generation triazoles including voriconazole. The voriconazole is available both in IV and oral, and has better candida activity, has a very potent anti aspergillus activity

but it is not active against zygomyces. Voriconazole has been approved as the primary treatment for invasive aspergillosis. In adult, it follows a nonlinear pharmacokinetics but in pediatrics it is a linear pharmacokinetic with accelerated metabolic clearance in children, therefore it needs higher dose without loading dose. The bioavailability of oral voriconazole is less in children (65%) than in adults (96%). In certain patients who are failing to respond to voriconazole, consider therapeutic drug monitoring.

Posaconazole

Posaconazole was approved by European Union in 2005 and by FDA in 2006 and is active against yeast and filamentous fungi including zygomyces. Only oral formulation is present at the time being. There is very limited data in pediatric patients. The pharmacokinetics studies of posaconazole are similar in adults. The dose for pediatric patients for posaconazole is not yet established.

Echinocandins

The third class is echinocandins, which include caspofungin, anidulafungin, and micafungin. These agents are acting in the cell wall and the cell wall is an important structure element in the fungal cell which is not found in other eukaryotic cells and therefore fulfill the criteria for selective toxicity.

The indication of echinocandins includes systemic candidiasis, esophageal candidiasis, and refractory invasive aspergillosis. The pediatric caspofungin dosing should be based on body surface areas and not on weight as weight-based dosing results in suboptimal plasma concentration. 70 mg/m^2 loading is used, then 50 mg/m^2 daily for children more than 3 months of age, and 25 mg/m^2 daily for children younger than 3 months of age as well as neonate. The half-life of caspofungin is about one third less in children. The Food and Drug Administration approved the caspofungin in pediatrics in July 2008.

The micafungin has similar activities with caspofungin and has been licensed for prophylaxis and treatment of invasive candidiasis in children.

The anidulafungin is not well studied in pediatric. There were phase I and phase II dose escalations study that showed pediatric patients more than 2 years of age receiving 0.75 or 1.5 mg/kg/day have PK similar to adults receiving 50–100 mg/kg/day. Based from the limited data, anidulafungin can be dosed based on body weight area (*Table 96.1*).

Table 96.1
Antifungal dosing for children

Drug	Formulation	Pediatric dose
Conventional AB	IV	0.6–1.5mg/kg/day
LAB (Ambisome)	IV	1–5 mg/kg/ day
ABCD	IV	3–5 mg/ kg/day
ABLC	IV	5 mg/kg/day
Fluconazole	Capsule, suspension, IV	6–12 mg/kg/day
Itraconazole	Capsule, suspension, IV	2.5–5 mg/kg q12
Voriconazole	Capsule, suspension, IV	6–8 mg/kg q12
Posaconazole	Suspension	400–800 mg/day in 2–4 divided doses
Caspofungin	IV	50 mg/m^2 daily Neonate 2 mg/kg or 25 mg/m^2
Micafungin	IV	1–4 mg/kg/day
Anidulafungin	IV	1.5–3 mg/kg load d1 followed by 0.75–1.5 mg/kg/day

In Managing Fungal Invasive there are four antifungal therapeutic strategies:

Antifungal prophylaxis is based on the risk factors in the absence of infection.

Empirical antifungal therapy for patients with risk factors and signs of infection of unclear etiology and the possibility of fungal origin, prolonged febrile neutropenia.

Pre-emptive antifungal therapy for patients with risk factors and additional evidence for the presence of a fungal pathogen including abnormal CT scan and/or abnormal aspergillus Galactomannan assay or 1,3 D Beta Glucan.

Definite therapy is treatment of proven infection.

In definite therapy, the prognosis will be poor if one waits for immunocompromised patient to establish the diagnosis of fungal infection before the initiation of antifungal therapy. The best approach is better utilization of preemptive antifungal therapy with monitoring of surrogate marker for the fungal diagnosis. The prophylaxis and empiric antifungal therapy will expose large number of patients to antifungal therapy and there is a potential of side effects and emergence of resistance.

Treatment of neonatal candidiasis: The regular Amphotericin is still the drug of choice followed by lipid formulation amphotericin B, and then fluconazole. If the patient is not receiving prophylaxis, echinocandins can be used with caution in neonates. Usually, neonate with candidemia will be treated for 3 weeks but all neonates with candidemia need LP and CSF study to exclude meningitis. Patient also needs serial eye exam to exclude involvement of the eye.

In other patient population, the algorithm below, can be followed. The first question is the patient is hemodynamically unstable or neutropenic; if yes, strongly considered avoiding the use of fluconazole. If the answer is no, move to the second question "Is *Candida glabrata or Candida krusei* likely to be the cause?" A yes strongly considers avoiding the use of fluconazole but use of echinocandin or polyene is preferred; use of voriconazole is an alternative option. If the answer for both questions is "NO" considers use of fluconazole.

The current practice of treating candidemia is to continue the treatment for 2 weeks after the last negative blood culture with resolution of neutropenia and signs and symptoms of infections. Patients with extensive visceral involvement will require longer therapy till all lesions seen on radiology are resolved or calcified. Follow-up with oral fluconazole provides the opportunity to manage these patients on outpatient therapy if the isolate is susceptible; other option is to use voriconazole as outpatient therapy. Most of the studies indicate that the removal of central venous catheter is important factor to clear the infection and decrease the complication of candidiasis. The mortality of candidemia and the contributing factor will approach 40–50%.

In the treatment of aspergillosis or mold infection, the first question to ask is the infection is likely to be caused by voriconazole susceptibility strain; if yes, use voriconazole, if no (the patient is exposed to voriconazole or other azoles or high incidence of zygomycosis in the

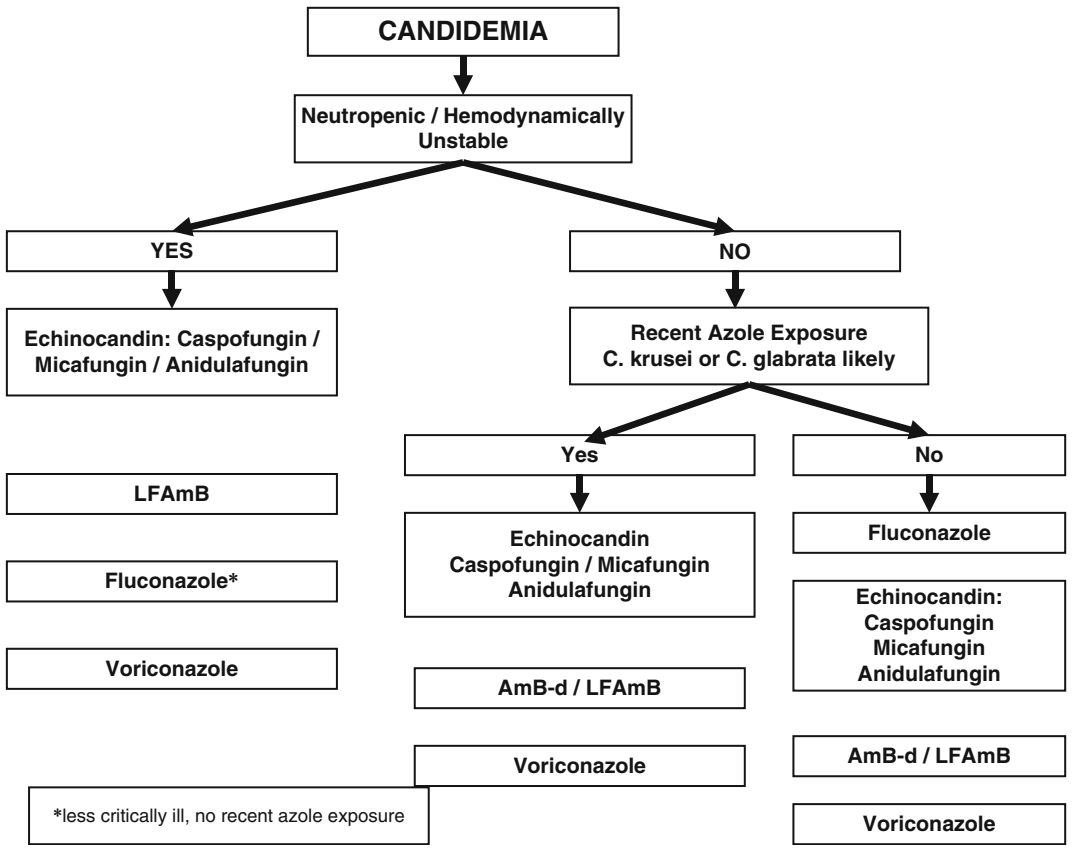

Fig 96.4
Approach to Patient with Candidemia

Table 96.2
Spectrum of activity of antifungal agents

Antifungal	Important clinical uses	Not/limited activity
Amphotericin B (including lipid formulation)	Cryptococcus neoformans, most candida species, aspergillus, mucoromycosis	Candida lusitaniae, scedosporium, fusarium, trichosporon
5-Fluorocytosine	Combination therapy yeasts	
Fluconazole	Most candida, C. neoformans	Candida krusei, candida glabrata, aspergillus
Itraconazole	Candida, aspergillus	
Voriconazole	Candida, aspergillus, fusarium, scedosporium	Mucormycosis caution: C. glabrata
Echinocandins	Candida, aspergillus	C. neoformans, fusarium, mucormycosis

center), use liposomal amphotericin B. Modification is guided by species identified response and tolerance.

The treatment must be started early and a definitive diagnosis must be pursued to exclude other pathogens. Once invasive aspergillosis is confirmed, the voriconazole is the treatment of choice. Variconazole has increased efficacy and improved survival when compared with amphotericin B as first-line therapy for invasive aspergillosis.

The echonicandins especially caspofungin have shown good efficacy and safety in patients with documented invasive aspergillosis not responding to or intolerant to other antifungal therapy.

Oral itraconazole can be used as chronic therapy but oral voriconazole is preferred.

The outcomes of invasive aspergillosis depend on the primary diseases, predisposing factors, as well as the location of the fungal infection. The highest mortality is in patient post bone marrow transplant followed by leukemia but if the CNS is involved in the immunocompromised patient the mortality is close to 95% and for non-immunocompromised patient with CNS involvement the mortality is much lower close to 13%.

The patient with invasive aspergillosis has higher hospital mortality rate than in patient with no invasive aspergillosis.

It is very important to know the susceptibility of the isolate before the selection of antifungal therapy. Aspergillosis is usually sensitive to voriconazole, itraconazole, amphotericin B, and echinocandins but aspergillosis terreus are usually resistant to amphotericin B. Voriconazole has no activity whereas posaconazole has some activity against zygomytes. Amphotericin B including the lipid formulation has limited activity against *Candida lusitaniae*, *Scedosporium*, *Fusarium*, and *Trichosporon*, but it is active against *Cryptococcus neoforms*, most Candida species, Aspergillus, and Mucoromycosis (*Table 96.2*).

The 5-flucytosine should not be used alone because development of resistant. Fluconazole is not active against *Candida krusei* as it is natively resistant to fluconazole no activity against aspergillus species but active against most of the candida and *Cryptococcus neoforms*. Itraconazole has activity against candida as well aspergillus but has limited activity zygomyces. Voriconazole is active against *Candida spp*, *Aspergillus spp*, *Fusarium spp*, and *Scedosporium spp* but has no activity against mucormycosis and caution has to be taken when the isolate is *Candida glabrata*. Echinocandins has activity against candida and aspergillus but has no activity against *Cryptococcus neoformans*, *Fusarium* and mucormycosis.

97 Intestinal Infections

Mohammad Al-Shaalan

Parasitic (protozoa and helminths) intestinal infections are common in children (*Fig. 97.1*, *Tables 97.1* and *97.2*). Many of the infections are asymptomatic; however, they play a major role in childhood morbidity. Some protozoa are not pathogenic. These include Iodameba buetschlii, Endolimax nana, Entameba nana, and Entameba hartmanii. Others are pathogenic but rare like Dientameba fragilis, Balantidium coli, and Entameba polecki.

Protozoal Infections

Giardiasis

Giardiasis is a protozoal intestinal disease caused by *Giardia lamblia*. It is probably the most common parasitic infection worldwide. Infection is acquired by drinking water or ingesting food contaminated with infectious cyst. Person-to-person transmission as well as infection through contaminated inanimate objects can occur.

Clinical Features

Asymptomatic infection is common accounting for 50% of cases. Symptomatic infection is varied in presentation. Some patients present with mild diarrhea that is self-limiting, others present with decreased appetite, loss of weight, and signs of malabsorption (large greasy stools and signs of vitamin A, vitamin B12, and protein deficiencies).

Extraintestinal symptoms are rare and include fever, urticaria, reactive arthritis, pancreatitis, mesenteric adenitis, erythema nodosum, peripheral neuropathy, iridocyclitis, and biliary tract disease.

Diagnosis

Stool microscopy is the golden standard of diagnosis. When three stool specimens are examined, 90% of infected patients will have positive test. The stool should be processed in three fractions. The first is fresh stool that can be prepared as wet mount or stained with iodine and examined for motile trophozoites or the presence of the cyst. The second should be preserved in polyvinyl alcohol and stained with trichrome or iron hematoxylin stain. The third fraction is concentrated by formalin-ethyl acetate or zinc sulfate floatation which may increase the yield of stool microscopy.

Other diagnostic modalities include serology, antigen detection, or DNA probing. Antigen detection in the stool using EIA or IFA techniques is very sensitive and specific; however, in areas where the incidence of mixed parasitic infection is high, this technique is not practical and will miss diagnosing mixed parasitic infection, therefore in such areas stool microscopy should be the primary diagnostic method.

Serology testing to detect IgM and IgG are useful, however they are epidemiological studies.

Treatment

Recently some controversy has been raised on whether all patients with Giardia infection should be treated.

Asymptomatic Cyst Passers

It is recommended that all infected patients be treated in order to prevent future complications; however, some argue against such strategy as reinfection is common in endemic areas and thus asymptomatic patients need not be treated. The recommended therapy is metronidazole 15 mg/kg/day in three divided doses for 5 days. Alternative therapy can be achieved with quinacrine 6 mg/kg/day in three divided doses for 5 days. Other effective therapies include furazolidone, tinidazole, and paromomycin.

Symptomatic Infection

All patients should be treated and cure should be proved by negative stool microscopy or antigen test. Both

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_97,

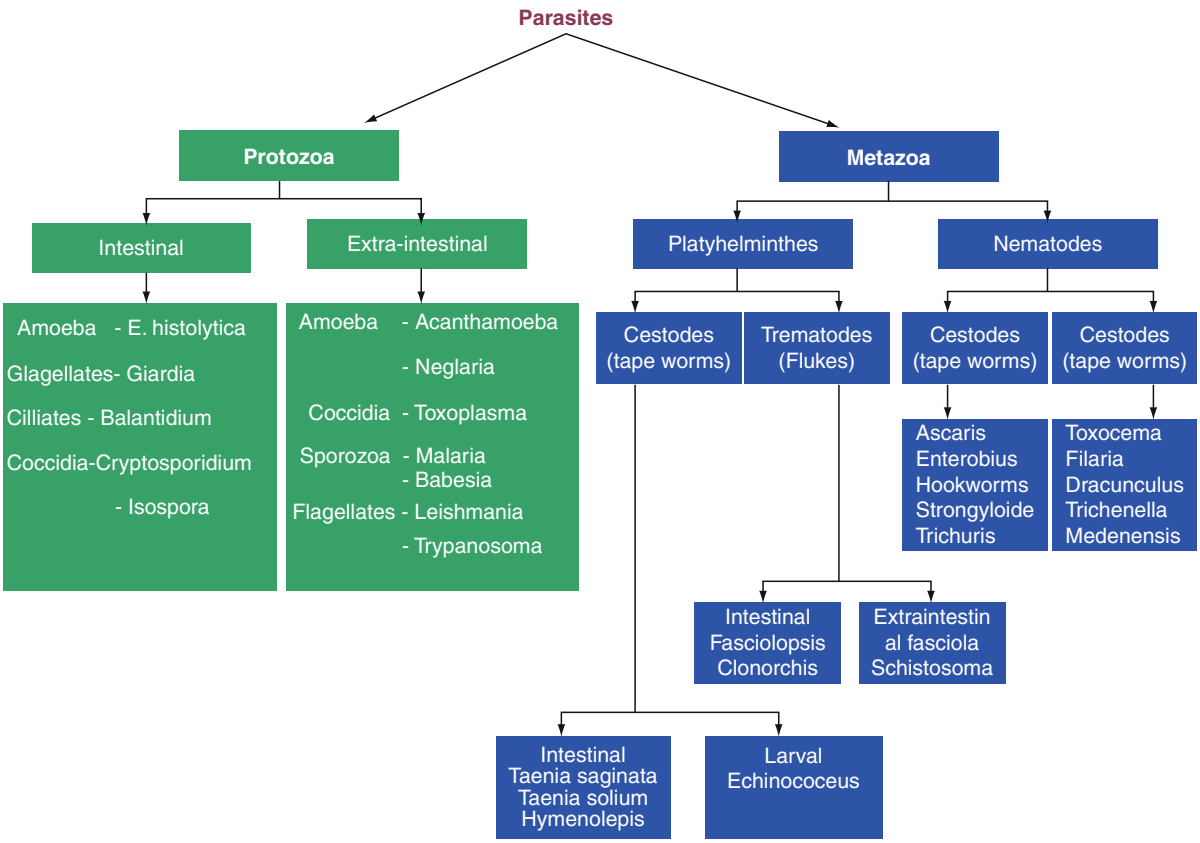

Figure 97.1
Simple classification of pathogenic parasites

quinacrine 2 mg/kg three times daily for 5 days or metronidazole 5 mg/kg three times daily for 5 days are equally effective; however, metronidazole is more widely used. Alternative drugs include furazolidone, mebendazole, albendazole, tinidazole, and paromomycin. Azithromycin has also shown to be effective against Giardia. Cases that fail to respond to therapy should be investigated for possibility of re-exposure and re-infection or whether the organism is resistant to therapy. In cases that are thought to be due to resistant organism, shifting to another drug is indicated. In those that remain resistant to therapy in spite of using different drug combinations, therapy with metronidazole and quinacrine is recommended.

Prevention

Assurance of water purity and sewage sanitation is of prime importance in decreasing the incidence of Giardia infection. Giardia is resistant to usual concentration of chlorine that is used to disinfect water. Therefore, Giardia is responsible for many outbreaks occurring in water recreation facilities. To increase the purity of water, it should be processed by sedimentation, filtration, and flocculation.

Preventing infected child from attending school or day care until he/she is cured was not proven effective. Personal hygiene remains the mainstay of protection.

Cryptosporidiasis

Cryptosporidium is a common cause of diarrhea especially in immunocompromised children. It is also a common cause of waterborne diarrheal illness in developed countries, and as a pathogen with long-term effect on childhood growth and development in impoverished areas.

Table 97.1
Protozoa

Protozoa	Diagnostic tests	Infection stage	Drug of choice	Alternative therapy
Giardia	• Cyst or trophozoite in the stool • Antigen detection in the stool using EIA	Cyst	Quinacrine 6 mg/kg/day in three divided doses for 5 days OR Metronidazole 15 mg/kg/day in three divided doses for 5 days	Tinidazole 50 mg/kg once Furazolidone 6 mg/kg/day in four divided doses for 7–10 days Paromomycin 25–30 mg/kg/day in three divided doses for 7 days
Amebiasis: Asymptomatic Carrier	• Cyst or trophozoite in the stool • Serology: IHA, ELISA	Cyst	Not recommended	Iodoquinol 30 mg/kg/day in three divided doses for 2 days or Paromomycin 30 mg/kg/day in three divided doses for 7 days
Symptomatic intestinal and hepatic			Metronidazole 35 mg/kg/day in three divided doses for 10 days OR Tinidazole 50 mg/kg/day once daily for 3 days Followed by carrier treatment	Dehydrocortine 1 mg/kg/day IM in two divided doses for 5 days
Dientameba fragilis	Trophozoite in the stool	Trophozoite	Iodoquinol 40 mg/kg/day in three divided doses for 20 days	Paromomycin 30 mg/kg/day in three divided doses for 7 days
Cryptosporidium	Oocyst in the stool by AFB stain IFA or EIA	Oocyst	Nitazoxanide: 1–3 years: 100 mg bid for 3 days 4–11 years: 200 mg bid for 3 days >12 years: 500 mg bid for 3 days	Azithromycin and paromomycin orally in AIDS patients
Balantidiasis	Cyst or trophozoite in the stool	Cyst	Iodoquinol 40 mg/kg/day in three divided doses for 20 days OR Metronidazole 35 mg/k/day in three divided doses for 5 days	
Blastocystis	Cyst in the stool	Cyst		
Isospora	Oocyst in the stool	Oocyst	TMP/SMX	

Causative Agent

Cryptosporidium is coccidian protozoa. Many species and subspecies are known; however, cryptosporidium parvum is the commonest cause. The oocyst is the infectious stage and it is sporulated and chlorine-resistant. After ingestion of the cyst, excystation occurs in the intestine. The released sporozoites penetrate the enterocytes of terminal jejunum and ileum and envelope themselves. They mature into type I meronts that release merozoites, which in turn invade the adjacent enterocytes. These merozoites mature into type I meronts (source of autoinfection) or type II meronts, which mature into micro- and macrogametocytes. Microgametocytes fuse with macrogametocytes and form zygotes that mature into cysts, which are passed with stool.

Epidemiology

Cryptosporidium is ubiquitous in both developed and developing countries. Serologic prevalence varies in different countries ranging from 10% to 80%. It constitutes 1–37% of diarrheal causes among Saudi children. Factors contributing to its high prevalence include small size of infectious oocyst, low infection dose, high chlorine resistance, and its ability to be transmitted from animals to humans.

Table 97.2
Helminthes

Parasite	Drug of choice	Alternative	Diagnostic method
Ascariasis	Mebendazole 100 mg PO bid × 3 days	Pyrantel pamoate 11 mg/kg once Albendazole 400 mg once	Ova in the stool and rarely in sputum
Trichuris	Mebendazole 100 mg bid × 3 days Pyrantel pamoate 11 mg/kg/ once	Albendazole 400 mg once	Ova in the stool
Enterobius Verimcularis	Mebendazole 100 mg single dose repeat in 2 weeks	Pyrantel pamoase 11 mg/kg/ once Albendazole 400 mg once (repeat in 2 weeks)	Ova seen on the Scotch tape or finger nail scraping
Strongyloides	Thiabendazole 50 mg/kg/day bid × 2 days	Ivermectin 200 mcg/kg/d for 1–2 days	Larva in the stool or duodenal aspirate Serology (ELISA)
Hookworms	Mebendazole 100 mg bid × 3 days	Pyrantel pamoate 11 mg/kg/d × 3 days Albendazole 400 mg once	Ova in the stool
Taeniasis	Praziquantel 5–10 mg/kg/once	Niclosamide 11–34 kg: single dose of two tablets >34 kg: single dose of three tables	Ova or gravid proglottid in the stool
Hymenolepis nana	Praziquantel 25 mg/kg once	Niclosamide	Ova in the stool
Diphyllobothrium latum	Praziquantel 25 mg/kg once	Niclosamide	Ova in the stool
Fasciolopsis buski	Praziquantel 25 mg/kg once		Ova in the stool
Toxocariasis	Diethylcarbamazine 2 mg/kg tid × 10 days	Albendazole 400 mg bid × 5 days Mebendazole 100 mg bid × 5 days	Serology
Trichinosis	Prednisone and mebendazole		Serology
Dracunculus Medinensis	Metronidaole 25 mg/kg/d in three doses × 10 days	Thiabendazole 50–75 mg/k/day in two doses × 3 days	Adult worm at the site of ulcer
Hydatid disease	Albendazole 15 mg/kg/d bid × 28 days, repeat as necessary		CT scan Serology (ELISA or HAI are sensitive and Immunoblot are specific) Skin test
Cysticercosis	Praziquantel 50 mg/kg/d in three doses for 15 days	Albendazole 15 mg/kg/day in three divided doses for 8 days	CT scan, serology (ELISA)
Schistosomiasis	Praziquantel 20 mg/kg q4h for two doses		Ova in stool or urine Serology
Opisthorchis	Praziquantel 25 mg/kg for three doses for 1 day		Ova in the stool
Fascioliasis	Bitgiomol 30 mg/kg on alternate days for 15 doses		Ova in the stool

Clinical Features

Cryptosporidiosis manifests as one of three patterns:

1. Self-limiting acute diarrheal illness: This is the presentation in immunocompetent hosts. It usually starts after an incubation period of 7 days with fever, diarrhea, abdominal cramps, and vomiting. This illness lasts 7–10 days and resolves spontaneously.
2. Chronic or recurrent diarrheal illness which occurs mainly in immunocompromised hosts, especially patients with AIDS. It is found that the disease is more severe with decreasing CD4 counts.
3. Growth deficit in impoverished children in developing countries.

Diagnosis

The widely available method of diagnosis is acid fast stain for stool specimen. However, this method is not sensitive or specific enough. Direct fluorescent antibody test and ELISA and PCR are now available. All of these tests have high sensitivity and specificity and will replace the standard acid fast staining in the future.

Treatment

Acute diarrhea in immunocompetent hosts is usually self-limiting and only supportive therapy with fluids is needed.

Non-HIV immunocompromised patients who are infected with *Cryptosporidium* pose a challenge to treating physicians as there is no effective therapy. Use of paromomycin and nitazoxanide, either singly or in combination, has some efficacy but not optimal.

Use of HAART in AIDS patients has resulted in decrease in infections with C*ryptosporidium* in these patients. Use of azithromycin and promomycin has shown some efficacy.

Amebiasis

Amebiasis represents a spectrum of diseases caused by *Entameba histolytica*, a protozoan parasite that is one of the major causes of morbidity and mortality especially in developing countries. More than 50 million people are infected annually with a mortality of around 1,00,000, ranking the second to malaria as the commonest cause of death from parasitic diseases.

The prevalence and incidence of E. histolytica cannot be precisely attained because of low sensitivity of stool microscopy, high proportion of asymptomatic infection, and inability to differentiate the pathogenic E. histolytica from nonpathogenic E. dispar and E. moshkovskii.

Pathogenesis

E. histolytica has three virulent factors: parasite surface protein (lectin), amebapore, and cytoproteins (cysteine proteases). Once ingested, cyst reaches the intestine, excystation occurs, releasing trophozoite. The trophozoite surface lectin recognizes the sugars galactose and *N*-acetylgalactosamine (GalNAc) on the host cell surface. If the lectin attaches to mucin galactose, noninvasive infection occurs and the trophozoite completes its life cycle and passes with the stool after encystations. However, if trophozoite penetrates the mucin layer and the lectin attaches to host cell surface GalNAc, then invasion ensues and the cascade of host cell death occurs with resultant ulceration and sometimes extraintestinal invasion. E. histolytica trophozoite has the ability to kill a wide variety of tissue cell lines including neutrophils, T. lymphocytes, and macrophages which explain the lack of inflammatory cells in the amebic ulcers.

Clinical Features

E. histolytica is acquired by ingesting infectious cyst with contaminated foods or water. Person-to-person fecal–oral transmission can occur. Incubation period ranges from few days to months or years. *Entameba* strains are classified as pathogenic or nonpathogenic according to specific pattern of isoenzymes (desmosomes) electrophoresis. Only 10% of infections are caused by the pathogenic *E. histolytica*, and only 10% of those develop symptomatic infection. Most of the positive stool microscopy will yield the cyst of nonpathogenic Entameba (E. dispar and E. moshkovskii).

Amebic Colitis

Amebic colitis usually presents as mild diarrhea that may be bloody. However, in some patients, the diarrhea may be severe, frequent, and associated with blood and mucus. There is usually no systemic manifestation of fever or lethargy. When colonoscopy is done, there are usually shallow flask-shaped ulcers that mostly involve the mucosa only. These pathologic lesions are produced as

a sequence of production of lysing enzymes that lyse not only mucus cells but also the macrophages and neutrophils. Therefore, on microscopic examination of scraping done from the edge of the ulcer, no neutrophils or other inflammatory cells are seen; however, most of the specimen will show trophozoites that may be containing RBC (hematophagous trophozoites).

Fulminating Enterocolitis

In some occasions, the disease may become severe enough that toxic megacolon or perforation may occur. Up to 75% of children with fulminant colitis develop perforation. The patient will present, in addition to dysentery, with diffuse abdominal pain and abdominal distention. The patient will be toxic and may be mistaken to have fulminant ulcerative colitis. In such patients, colonoscopy should be done with caution. The presence of trophozoites on biopsy will confirm amebiasis.

Ameboma

About 1% of patients with intestinal amebiasis will develop ameboma. It is a mass lesion that forms as a result of inflammatory and granulation tissue. It can be mistaken for malignant tumor.

Amebic Liver Abscess

Most commonly encountered in adults, but children may be affected. Patients usually present with abrupt onset of fever associated with right upper quadrant abdominal pain. The liver is usually diffusely enlarged, but in few occasions a single or multiple masses may be palpable. Pyogenic liver abscess may have similar presentation, but it usually has predisposing factors such as previous abdominal surgery or presence of intravascular devices. Ultrasound of the abdomen will show a single hypoechogenic lesion that usually involves the right lobe of the liver; however, multiple abscesses and involvement of other parts of liver may occur. Ultrasound may not detect small abscesses and in such cases, CT scan may be indicated. Echinococcal liver cyst may have similar appearance; however, such patients usually have no associated systemic manifestation of fever or toxicity. Diagnosis of amebic abscess can be confirmed by positive stool analysis for *E. histolytica* cyst and serology test that is positive in 90% of patients by day 7 of illness.

Diagnosis

Stool examination for Entameba cyst or trophozoite is the usual method of diagnosis; however, it lacks sensitivity and specificity. It will never be able to differentiate the pathogenic E. histolytica from the similarly appearing nonpathogenic E. dispar and E. moshkovskii. Therefore, depending solely on stool microscopy to decide about treating an asymptomatic patient who has Entameba cyst in the stool is not appropriate. Polymerase chain reaction, isoenzyme analysis, and monoclonal antibody-based antigen detection assays can differentiate E. histolytica, E. dispar, and E. moshkovskii. However, these tests are not available widely and therefore positive stool microscopy should be augmented by having clinical features suggestive of amebic infection to decide about initiating therapy.

Indirect hemagglutination (IHA) test has been replaced by enzyme immunoassay (EIA) test for routine serodiagnosis of amebiasis. EIA is 95% positive for extraintestinal amebiasis, 70% positive for active intestinal infections, and less than 10% for cyst passers. Aspiration of abscess under CT scan guidance may show the trophozoite and it is advisable in doubtful cases.

Treatment

Asymptomatic Cyst Passers

Treatment is not advisable.

Amebic Dysentery and Ameboma

Metronidazole 10 mg/kg three times daily for 10 days followed by luminal therapy with iodoquinol 30–40 mg/kg/day for 20 days or paromomycin for 7 days. In patients with microperforation, conservative therapy with antibiotics without surgical intervention is advisable. Nitazoxanide may be effective for mild to moderate intestinal infection.

Amebic Liver Abscesses

Metronidazole 10 mg/kg three times daily for 10 days followed by intraluminal therapy with iodoquinol 30–40 mg/kg/day for 20 days or paromomycin. Chloroquine phosphate may be used in combination with metronidazole for a better response. The cavity of the abscess may remain forever; therefore, there is no need to do any surgical intervention if the patient responds clinically to the treatment. When the abscess is large and risk of perforation is high, aspiration under ultrasound or CT scan guidance is advisable. It is also advisable to do aspiration when the response to medical therapy is poor.

Nematode Infections

More than one billion worldwide are infected with intestinal nematodes (round worm); most of them reside in developing countries. These infections play a major role in morbidity of infected persons as a major cause of anemia and malnutrition.

Ascariasis

Ascaris lumbricoides, the cause of ascariasis, is a 15–40 cm long round worm. It is pink-whitish in color and it is of smooth surface. The life cycle of this parasite starts by ingesting foods that are contaminated with the infectious ova. The ova pass to the duodenum and jejunum where they hatch into the rhabditiform larvae, which in turn penetrate the mucosa and travel by blood into the lung. They then pass into the alveoli and migrate upward through trachea into the pharynx and then pass into the intestine where they mature into adult form. The adult worm deposits 2,00,000 ova daily which pass with the stools and contaminate the soil or vegetations.

Clinical Features

Most of the ascaris infestations are asymptomatic; however, it tends to cause symptoms in children even with one worm.

The most common symptoms are abdominal pain and flatulence. In areas where recurrent infection is common, the number of parasites may be enormous to cause mechanical intestinal obstruction. In some occasions, the parasite may migrate through the ampulla of Vater and cause biliary symptoms, obstructive jaundice, cholangitis, or cholecystitis. In rare occasions, the pancreatic duct may get obstructed and pancreatitis may result.

During the initial passage of larva through the lungs, eosinophilic pneumonitis may occur especially when the infection is heavy. The patients usually have cough and shortness of breath. Chest x-ray may reveal some infiltrates.

Diagnosis

Clinical symptoms may not be helpful unless the patient has the complications. Most of the patients have moderate eosinophilia. Stool examination for ova and parasites is very sensitive.

Barium study may show the parasite in the intestinal lumen and ultrasound of the abdomen may show the parasite floating in the gallbladder. Endoscopic retrograde cholangiopancreaticography (ERCP) may show the parasite in the common bile duct.

Treatment

Ascaris is very sensitive to pyrantel pamoate, piperazine, or mebendazole. Patients who have intestinal or biliary complications need to be assessed by surgeons and gastroenterologist as they will need some surgical intervention. Patients with biliary ascariasis may develop cholangitis caused by the bacteria that migrate with worms and they should be treated with broad spectrum antibiotics like ampicillin, gentamicin, and metronidazole or third-generation cephalosporins.

Hookworm Infections

Necator americanus and *Anclyostoma duodenale* are common causes of intestinal parasitic infections. Infected persons are prone to develop anemia and hypoproteinemia.

Life Cycle

The infectious stage is filiform larvae which penetrate the skin and travel through the blood into the lung. From there, they migrate up to the trachea and then downward through pharynx and esophagus until they reside in the upper part of small intestine. There they mature into adult form which attach into the mucosa by their hooklets. *N. Americanus* and *A. duodenale* are 7–12 mm long.

Clinical Features

Heavy infections are usually associated with abdominal pain, diarrhea, anemia, and hypoproteinemia.

During the initial larva migration through the lungs, mild respiratory symptoms of cough occur. Eosinophilia is usually present.

Diagnosis

Microscopic stool examination will show the characteristic ova of the hookworms. Mild anemia and hypoproteinemia are usually present. Most of the patients will have eosinophilia.

Treatment

Mebendazole, pyrantel pamoate, and piperazidine are very effective in eradicating these infections. The response to therapy is associated with resolution of anemia and hypoproteinaemia. It also results in improvement of malnutrition and behavioral disturbances.

Trichuriasis "Whipworm Infection"

Common parasitic infection in developing countries. The causative parasite is *Trichuris trichura*, which is 30–50 mm long and resides in the cecum and colon. Most of the infections are asymptomatic; however, with severe infection, the worms may migrate into the rectum and cause rectal prolapse. Diagnosis can be made by finding ova in the stool. Mebendazole as a single dose is very effective in eradicating the infection.

Enterobiasis "Pinworm Infection"

The commonest parasitic infection with high incidence in developed and developing countries. It is caused by roundworm *Enterobius vermicularis*, which is 8–13 mm long and resides mainly in the cecum. The main presentation of the infection is pruritus ani which occurs as a result of migration of the parasite into the perianal area during the night time. In girls, vaginitis and peritoneal granuloma may occur on rare occasions.

Diagnosis does not depend on finding the parasite ova in the stool, but by applying scotch tape over the anal area and then adhesing it into a slide. The ova can be seen adhesing into the tape. The best time for applying the tape is early morning at a time when the parasite has laid many ova in the area.

Mebendazole given in two doses 2 weeks apart is very effective. In cases which are resistant to treatment, mass treatment of the whole family members with the same regime is advisable.

Strongyloidiasis

Strongyloides stercoralis is an intestinal nematode that is common in most of the developing countries. It gains more importance after emergence of HIV epidemics as a cause of disseminated and hyperinfectious disease.

Life Cycle

Strongyloides stercoralis has a distinctive life cycle with ability to produce autoinfection, intestinal multiplication, and free-living adult worms. The infectious stage is filiform larva which upon penetration of the skin travels with blood into the lungs. Then it passes into the alveoli and migrates along the trachea into the pharynx and then down to the upper intestine. It penetrates the mucosa and resides in the submucosa where it matures into adult form. In the submucosa, the female adult does not need male for fertilization and reproduces by parthenogenesis and lays ova in the submucosa. The ova hatch into rhabditiform larvae that pass into the lumen and pass with feces; however, some of these rhabditiform larvae mature into filiform larvae in the lumen before excretion. These filariform larvae are able to autoinfect the host by penetrating the intestine and passing with the blood into the lungs and then complete the cycle. The excreted rhabditiform larvae pursue one of two pathways of maturation: either maturing into an adult form or maturing into filiform larvae. The adult forms will lay ova in the soil that mature into filiform larvae.

Clinical Features

Immunocompetent Patients

The infection is mostly asymptomatic; however, when symptoms occur they consist of abdominal pain, diarrhea, urticaria, and loss of weight. Some patients may develop severe disease with severe abdominal pain, bloody diarrhea, protein enteropathy, and urticaria.

The disease may run a fluctuant course of symptomatic period followed by asymptomatic ones. During the initial stage of larva passage through the lungs, Loffler's pneumoniae may develop.

Immunocompromised patients may develop hyperinfection and/or disseminated disease. Because of the immunosuppression, the multiplication of the organism in the intestine goes unchecked which in turn results in heavy infection that is associated with severe enterocolitis, abdominal pain, protein-losing enteropathy, and intestinal bleeding. Lungs are involved frequently with parenchymal infiltrates that may be severe enough to cause adult respiratory distress syndrome. Filiform larvae may disseminate to other organs like liver, kidneys, and brain. Passage of gut flora with larva may result in septicemia and septic shock. Although HIV is one of the immunocompromised diseases, there was no noticed increased severity of strongyloides in such patients.

Diagnosis

Stool Microscopy

The main diagnostic method is finding rhabditiform larva in the stool, sputum, or duodenal aspirate. It is unusual to find adult forms or ova in the stool because these stages are located in the submucosa.

Serology

In endemic areas, it is of limited help because the available ELISA test does not differentiate between acute or chronic infection.

DNA Probe and PCR

Are still investigational but has some promises.

Treatment

The drug of choice is thiabendazole 25 mg/kg three times daily for 2 days. Recently, the efficacy of thiabendazole has been questioned; therefore, a more potent alternative has been sought. Albendazole 400 mg once daily for 3 days and ivermectin 200 mcg/kg/day for 2 days have shown very good activity in treating strongyloidiasis with efficacy of 80–90%. Cyclosporin has shown also to be very effective in spite of being immunosuppressive.

Toxocariaris

Toxocariaris is a zoonotic disease that is widely distributed all over the world. The causative agents are nematodes *Toxocara canis* and *Toxocara catti* that have their reservoir in the gut of dogs and cats, respectively. Infections commonly occur in children 3–10 years of age who have the habits of playing outdoors in areas that might be contaminated with dogs and cats excrete.

Life Cycle

Ova are produced with excreta of infected dog or cat. When a child encounters them during his play, they might be ingested orally if they remain on his hands at the time of eating or drinking. Other ways of acquiring infection is the ingestion of infectious ova with contaminated foods. Once the ova reach the intestine, they hatch and produce larvae. Larvae penetrate the intestine and reach the blood where they then may migrate to any organ including liver, eyes, brain, kidneys, lungs, and heart, however liver is the most commonly involved organ.

Clinical Features

Viscera Larva Migrans (VLM)

Most of the infections are asymptomatic. In symptomatic cases, symptoms depend on organ involved. However, general symptoms of malaise, urticaria, and gastrointestinal symptoms may occur. Liver may be enlarged and tender. Patients may present with respiratory symptoms of cough, wheezing, and shortness of breath with radiological appearance of lung infiltrations. Seizure may occur in patients who have encysted brain lesions. With severe infection, encephalitis may occur.

Ocular Larva Migrans (OLM)

Larvae may localize to any part of the eye and stimulate inflammatory response causing fibrosis, vitreous fibrosis, and retinal detachment. Ophthalmoscopy may reveal Leukocoria and may be difficult to differentiate from retinoblastoma.

Diagnosis

VLM diagnosis depends mainly on serological testing using fluorescent antibody test or ELISA. In infected tissue, larvae may be seen by histopathology examination. With invasive disease, eosinophilia is usually prominent. Western blot test is used for confirmation of infection because it is more specific.

In OLM, positive serum serology is usually negative or low. Therefore, confirmation of diagnosis requires estimation of antibody titer and eosinophilia in vitreous fluid.

Treatment

Asymptomatic patients require no therapy. However, those with symptoms need anti-helminthic therapy. Diethylcarbamazine 2 mg/kg three times daily for 10 days is the most effective therapy. Albendazole and thiabendazole are adequate alternatives although less effective. Adjunctive therapy with steroids in cases of severe systemic inflammatory response as in pulmonary, CNS, or cardiac disease may be life saving. In OLM, steroid therapy with prednisone 1 mg/kg/day for 2–4 weeks is the mainstay of therapy. Diethylcarbamazine is effective in eradicating the infection.

Cutaneous Larva Migrans (Creeping Eruption)
A zoonotic dermatologic disease that is caused by larvae of *Ancylostoma caninum* or *A. braziliensis*. Upon exposure, the larvae penetrate the skin and start migrating in the skin resulting in formation of serpiginous tracts. Each larvae form one tract and there may be many of them. The larva advance a few millimeters every day. The migration is associated with pruritus. Rarely, systemic invasion by larvae may occur. Treatment with single dose of albendazole 400 mg or ivermectin 150 mcg/kg is very effective and the migration stops within 48 h.

Trematodes

Intestinal Trematodes

Fasciolopsis buski is the commonest intestinal trematode infection. Infection is acquired by ingesting infectious metacercaria with contaminated water chestnuts. Most of the infection is asymptomatic. However, symptomatic cases may occur with presentation of abdominal pain, diarrhea, decreased appetite, and change in behavior. Treatment is achieved by giving one dose of praziquantel at a dose of 25 mg/kg.

Liver Flukes

Opisthorchiasis and Clonorchiasis

Both clonorchis and opisthorchis cause the same disease in humans and both are acquired by ingesting raw fish that is harboring the infecting metacercaria. In the intestine, the metacercaria mature into the adult form that migrate into the biliary system and reside mainly in the common bile duct. Adult worms lay ova there which in turn pass through the bile into the intestine and then are excreted with feces. They then mature into metacercaria which is the infection stage to humans. Opisthorchis is common in Southeast Asia where it is common to consume raw fish.

Clinical Features

In children, most of the infections are asymptomatic and are diagnosed by investigation for eosinophilia. However, some infections cause an acute illness that manifests with fever, abdominal pain, nausea, vomiting, loss of appetite, and loss of weight. With chronic infection, complications may arise; however, they require 15–30 years to develop, thus they are rare in children. Such complications include cholangitis, obstructive jaundice, biliary cirrhosis, and cholangiocarcinoma.

Diagnosis

Diagnosis can be achieved by finding the characteristic ova in the stool. Serology is limited in its application.

Treatment

Praziquantel 25 mg/kg/dose for three doses in 1 day is a very effective therapy. Response can be monitored by resolution of eosinophilia and if there are gallbladder changes on initial ultrasound of abdomen, this also can be followed sequentially, however it is very rare to see such changes in children.

Fascioliasis

Two species of Fasciola cause human diseases; *F. hepatica* and *F. gigantica*. Infection is acquired by ingesting the metacercaria with contaminated water plants. Some infection may occur after ingesting raw or undercooked sheep or goat liver which contains the adult form that may attach to the pharynx and cause laryngopharyngitis (Halzoun disease). Once in the intestine, the larva excyst the metacercaria and penetrate into the peritoneal cavity. From peritoneal cavity, it migrates through the liver capsule into the liver parenchyma. There are two stages of symptomatology. First stage lasts for 6–9 weeks and it coincides with the period of larva migration in the liver tissue. It is associated with fever, abdominal pain, hepatomegaly, and urticaria. The second stage coincides with the residence of the adult form in the biliary tree. Most of the patients have no symptoms in this stage unless the burden of the organism is high which may result in chronic biliary disease.

Diagnosis

Stool microscopy to visualize the characteristic ova is the gold standard of diagnosis. Most patients have an associated eosinophilia.

Treatment

Praziquantel 25 mg/kg three times daily for 6 days is the recommended therapy of choice.

Lung Fluke

Paragnomiasis

Paragnomiasis or lung fluke is a disease most commonly seen in Southeast Asia and Central and South America. It is acquired by eating raw fish that contain metacercaria. These metacercaria hatch into larvae and mature in the small intestine. From there, they pass through intestinal wall into the peritoneal cavity and then migrate through diaphragm into the lungs resulting in mass lesion that locate most commonly in the right lung. The mature worms lay ova in the lungs that can be expectorated or swallowed to be passed with stool.

Clinical Features

Some infections are asymptomatic. In others, the symptoms may be mild with cough, fever, chest pain, diarrhea, and urticaria. Some of these patients progress into a chronic disease and present with cough that is productive of rusty or golden-colored sputum, loss of weight, night sweating, and fever. The disease may have a prolonged course and mimic tuberculosis or aspergillosis.

Complications

Some patients develop local complications and in rare instances other distant organs may be involved. Local complications include bronchiectasis, fibrosis, pleural effusion and empyema. In rare instances, the adult forms and eggs may get access into the blood vessel and implant into various organs, most distinctly brain; however, other organs like liver, kidneys, testes, spleen, and skin may be invaded.

Diagnosis

Microscopy of the sputum or feces may show the ova of infecting organism; however, sensitivity may be limited. If surgical resection of the lesion is done, adult worms and ova may be seen in histopathology. ELISA and skin test are excellent in confirming diagnosis.

Treatment

Praziquantel 25 mg/kg three times daily for 3 days is very effective in curing the infection. Bithionol is an alternative therapy but more toxic.

Schistosomiasis

Schistosomal infection has its major burden in developing countries. Most of the cases in developed countries are imported with the exception of schistosomal dermatitis caused by avian schistosoma that has its vector in the lakes of Canada and USA.

It is estimated that 200 million people worldwide are infected with schistosoma with annual fatality of 2,00,000.

The various species of schistosoma are distributed among countries according to the availability of their intermediate snail host. *Schistosoma hematobium* (*S. hematobium*) infect 90 million persons and it is distributed in more than 50 countries in Africa, East Mediterranean and Southeast Asia. In Saudi Arabia, Jizan area in the south is the main endemic focus with a prevalence rate of 10–13%. Egypt also has a focus of infection mainly along Nile River with a prevalence of 10–15%. Currently, *S. hematobium* is the predominant species in Egypt due to the shift in the intermediate snail. *Schistosoma mansoni* (*S. mansoni*) infects 65 million people and causes 80,000 deaths annually. It has a prevalence of 1–7% in Saudi Arabia and mainly found in the western regions; however, an estimated prevalence in Riyadh is 7%, probably related to population movement to the capital from endemic areas. Nile delta is the main endemic focus for most of S. mansoni in Egypt. Other species are not common in Arab countries, *Schistosoma japonicum* (*S. japonicum*) is mainly found in Southeast and Far East Asian countries. *Schistosoma intercalatum* (*S. intercalatum*) is restricted to forest areas of Western and Central Africa. *Schistosoma mattheei* (*S. mattheei*) is reported in South Africa, Zaire, and Zimbabwe. *Schistosoma megoki* (*S. megoki*) is restricted to Cambodia and Laos.

Life Cycle

Humans and other mammals are the main reservoir for schistosoma species whereas different species of freshwater snails act as intermediate hosts. After being excreted with feces or urine into fresh water, the schistosomal ova hatch into mobile miracidia. The miracidia then enter a specific snail and mature into cercaria. The cercaria then is released into the water and upon encountering susceptible host, it penetrates through the skin. In subcutaneous tissue, cercaria matures into schistosomule which in turn passes with blood into the lungs. From the lungs, the schistosomule passes into their final residence in either mesenteric venous plexus in case of *S. mansoni* and vesical venous plexus in case of *S. hematobium*. In the venous

plexuses, the schistosomule mature into adult forms and start laying 200–300 ova/day.

Pathogenesis

The acute symptoms of schistosoma are related to local destruction of infected tissues as well as immune complex formation resulting in serum-sickness-like reactions. However, the main investigations were aimed at understanding the mechanism of chronic illness. It is thought that both parasite and host factors are responsible for the illness. The ova stimulate granuloma and fibrosis formation. The main contributing factor in such process is the release of cytokines, mainly alpha-TNF. In addition, T-cell subset Th1 has been shown to participate in the process of granuloma formation.

Some patients were found not to develop chronic disease and in these patients, it was found that they have some genetic constitution that makes them resistant to the infection.

Clinical Features

Acute Infection

In endemic areas, most of the infections are asymptomatic. At the time of skin penetration by cercaria, the patient may have itching and papular eruptions at the site of penetration. By 5–30 days after exposure, the patient starts to have symptoms of Katayama fever, which consists of fever, myalgia, arthralgia, and skin rashes that are usually papular and itchy. These symptoms last for 2–3 days and then resolve spontaneously. In cases of *S. mansoni*, *S. intercalatum*, *S. megonki*, and *S. japonicum*, the patients may have abdominal pain, diarrhea that is sometimes bloody and enlarged liver especially with heavy infection. *S. hematobium* may cause dysuria, frequency, and microscopic or gross terminal hematuria.

Chronic Infections

Without treatment, adult worms' life span is prolonged for 10–30 years. During this period, these worms lay a large number of eggs that usually remain in the venous channels and stimulate formation of granulomas and fibrous tissues.

S. hematobium results in formation of granulomas in the bladder. These granuloma cause bladder contracture and stricture of the ureter, which may lead to secondary hydronephrosis and obstructive nephropathy. Additional complications include vesical stone formation and bladder carcinoma.

S. mansoni, *S. japonicum*, *S. intercalatum* and *S. megonki* result in formation of fibroocclusive disease of the hepatic periportal areas resulting in presinusoidal portal hypertension with hepatomegaly, splenomegaly, and sequence of portosystemic shunting (esophageal varices, hemorrhoids, and ascites).

Swimmer's Itch

Some patients develop papular eruption following contact with cercaria especially those of avian schistosoma. History reveals a complaint of itching following a swimming in a freshwater lake. The itching evolves into papular eruption that is usually generalized. The symptoms resolve spontaneously in 2–3 days.

Diagnosis

Clinical suspicion should be the primary step in diagnosis of patients living in or returning from endemic areas. Laboratory diagnosis relies mainly on identifying the characteristic egg in the stool, urine, or infected tissue biopsies like rectal snip.

1. Stool microscopy: Ova of Schistosoma species other than *S. hematobium* can be identified in stool microscopy. *S. hematobium* ova can be seen in stool microscopy in rare occasions. Concentration of the stool is required to improve the yield of microscopy.
2. Urinalysis: For *S. hematobium*, urine microscopy will show the characteristic ova with terminal spike. It is recommended to collect urine between 10 a.m. and 2 p.m. as it is the best time when the ova concentration is high. In addition, filtration and sedimentation method is used to increase the yield of recovering the ova from the urine. *S. intercalatum* and *S. mansoni* ova can be seen in the urine microscopy in 10–15% of patients infected with these species.
3. Serology: HAI is the standard serology used in detecting IgG against Schistosoma. It is a genus specific and thus cannot differentiate between species. Also, it cannot differentiate between acute and chronic infection and thus it has limited role in diagnosing schistosomal infection in endemic areas. Other serological tests include EIA, RIA, IFA, and latex agglutination test. Using keyhole limpet hemocyanin, ELISA

can distinguish between acute and chronic infection but its use is restricted to research laboratories.

4. Antigen detection tests: Using EIA, two Schistosoma genus–specific antigens can be detected in the serum or urine. These two antigens are circulating anodic antigen (CAA) and circulating cathodic antigen (CCA). They are very sensitive and very specific but expensive and require special expertise and therefore not widely used.
5. Imaging studies: Plain radiography may be useful in showing bladder stones that could arise secondary to *S. hematobium* infection. Ultrasonography studies of liver are very specific and sensitive in showing periportal fibrosis that usually occurs with chronic *S. mansoni* infection. These changes also have been described rarely with *S. hematobium* infection. Ultrasound changes have been staged according to the severity of the infection and can be used to follow the response of therapy.
6. Supportive laboratory tests: Eosinophilia is present in most of the infected patients as well as leukocytosis. Urinalysis will show hematuria in those infected with *S. hematobium*. Stool may show hematochezia in *S. mansoni* infection. In chronic infection with fibroocclusive disease, there is raised bilirubin with normal liver transaminases. In fact, if liver transaminases are raised, then it is mandatory to rule out coexisting viral hepatitis.

Treatment

Treatment of Established Infections

Appropriate and very effective medication is available to treat Schistosomiasis. Praziquantel is effective against all human schistosomal infections. The recommended dosage is 30 mg/kg/dose in two doses given 4–6 h apart. Oxamniquine is effective against *S. mansoni*. Metriphonate is effective against *S. hematobium*. So far Schistosoma remain. Schistosoma responds to therapy very well with resultant resolution of acute symptoms, prevention of complication if used early, and halting the progression of the disease.

Response to therapy should be assessed by following stool and urine microscopy at 4–6 weeks and 3–6 months. Once antigen detection test is available, it will replace microscopy because it is more sensitive and specific.

Mass Therapy

In areas where schistosomal infection is endemic and involving a large proportion of population, mass therapy of the whole population proved to be effective in reducing the burden of infection. This can be achieved by giving praziquantel 40 mg/kg as a single dose.

Special Presentations of Schistosoma Infection

Central Nervous System Infections Schistosoma can infect both brain parenchyma and spinal cord. Encephalitis, meningoencephalitis, and focal brain lesions have been described in some cases of schistosoma infection especially *S. intercalatum*. Transverse myelitis and myelopathy can occur secondary to migration of schistosoma eggs into the spinal cord from the nearby venous plexuses. Early diagnosis and therapy may halt the infection and improve the outcome. Diagnosis can be achieved by myelography and finding schistosoma ova in the stool or urine. Steroid therapy in these cases is controversial but some showed it to be helpful.

Hepatitis B and C Infection Although incidence of hepatitis infection is reported to be high among patient with schistosoma infection, there is no scientific evidence that schistosoma infection increases host susceptibility to hepatitis.

Persistent Salmonella Bacteremia in Patients with Schistosoma Infection Salmonella bacteremia may be difficult to treat in patients with schistosoma infection as it may be kept hidden from antibiotics and host immunity in the tegument of schistosoma egg. Therefore, in such patients schistosoma should be treated in order to be able to eradicate schistosoma.

HIV and Schistosomiasis Again there is no proof that either infection predispose to the other.

Prevention This can be achieved through one of the following methods:

1. Immunization:

   Although there are efforts to find adequate vaccine, nothing yet comes in the surface. There is a need for vaccine because trials to decrease transmission have failed.
2. Decrease transmission:

   This can be tackled through the following methods:
   (a) Decrease the source of infectious eggs through mass therapy of all persons suspected to be infected.
   (b) Decrease the chance of encountering infectious ova by improving sanitation and decreasing the chance of having infected persons to contaminate water.
   (c) Decrease the loud of intermediate snails through using mollucicides.

Cestodes

Taeniasis

Taeniasis is a common intestinal cestode infection caused by either *Taenia saginata* or *Taenia solium*. Infection is acquired by ingestion of undercooked meat which is pork in case of *T. solium* and beef in case of *T saginata*. The infecting stage is cysticercus which upon reaching the stomach and small intestine degenerates to produce larva that mature to adult form. The adult forms are 8–12 m long (T. sagmata) or 4–8 m (T. solium) and contain many numbers of proglottids 1000–2000. The proglottids contain the reproductive system which upon fertilization, are replaced by gravid uterus that contain many eggs. These gravid proglottids then detach and pass with stool resulting in contamination of soil and vegetations. Beef and pork then ingest the eggs with their food which upon reaching intestine hatch to larvae that penetrate intestinal wall and travel to reside in the muscle to form cysticerci.

Clinical Features

Mostly asymptomatic and can stay so up to 25 years. When symptomatic, the manifestations include abdominal pain, vomiting, constipation or diarrhea, loss of appetite or increased appetite, and psychologic disturbances. The patient may give history of passing proglottids, which give a sensation of being passing a muscular tube that produces wave of movement upon passing through the rectum.

In few occasions, local complications may arise in the form of intestinal obstruction, pancreatitis, or biliary obstruction.

Diagnosis

In addition to clinical diagnosis, confirmation can be made by stool microscopy which sometimes may be negative because the proglottids release eggs upon passing through the rectum and in such cases perianal swab or scotch tape method may have a better yield.

Treatment

These patients respond very well to praziquantel 5–10 mg/kg as a single dose. Emetics should be avoided as gravid proglottid may be regurgitated and in this way may rupture and release the eggs in the intestine which in case of *T. solium* may result in cysticercosis.

Cysticercosis

Cysticercosis is a systemic parasitic disease that is caused by T. solium. In this disease, the human acts as an intermediate host who ingest eggs with contaminated foods or drinks. In the intestine, the egg hatches and produces larva that penetrates through the intestine and passes through blood to reside in any organs with particular predilection to the central nervous system.

Neurocysticercosis

Although not common in children, it can occur especially in the residents of endemic areas of Central and South America and some parts of Africa. The disease takes 3–5 years to develop and become symptomatic in 50% of the cases.

There are two types of neurocysticercosis, parenchymal and extraparenchymal. The parenchymal disease is localized in the brain tissue of cerebral cortex. The extraparenchymal disease may be intraventricular, subarachnoid, or spinal.

The symptoms associated with neurocysticercosis are variable and range from incidental finding of space-occupying lesion in the CT scan of the head, to a severe disease with meningoencephalitis that is manifested by fever, altered sensorium, headache, signs of increased intracranial pressure, and visual abnormalities. Majority of the affected patients present with epilepsy. Others may present with focal neurologic deficit.

Other Types of Cysticercosis

1. Muscular cysticercosis occurs in some patients but rare.
2. Cutaneous cystelcosis manifest by cutaneous nodules which may be calcified.
3. Eye cystelcosis which may involve any part of the eye.

Other organs: Any organ can be involved including heart, liver, kidneys, lungs, and spleen.

Diagnosis

Serology by ELISA is the mainstay of diagnosis in combination with compatible clinical signs and imaging studies. CT scan and MRI are very sensitive in elucidating the cerebral lesions which are variable in appearance from hypodense to isodense or hyperdense areas. Calcification may be present and usually indicates inactive disease. Brain biopsy is not indicated except in patients with negative serology in whom other causes of space-occupying lesions should be ruled out.

Treatment

In asymptomatic patients with calcified lesions, treatment may not be justified. Symptomatic patients should receive specific anti-helminthic therapy in addition to therapies to reduce the mass effects of the lesions such as steroids, mannitol, and diuretics as well as anticonvulsants. Specific anti-helminthics include praziquantel in a dose of 50 mg/kg/day for 15–28 days or albendazole 15 mg/kg/day in three divided doses for 28 days. Duration may need to be extended in cases that are not promptly responsive.

98 Actinomycosis

Rana AlMaghrabi · Ibrahim Bin-Hussain

The genus Actinomyces consists of a heterogeneous group of gram-positive, non-spore forming catalase-negative pleomorphic rods that form a significant component of the commensal microflora of the oral, gastrointestinal, and female genital tracts and that are generally of low pathogenicity. Actinomyces species may invade via damaged mucosa, leading to bacteremia and systemic infections in both healthy individuals and immunocompromised patients. Actinomycosis is a catalase-negative infection and important to consider in chronic granulomatous disease (CGD).

Etiology

Of the 14 human actinomyces species, six may cause disease in humans, including the facultative anaerobic A. israelli, A. naeslundii, A. odontolyticus, A. visosus, A. meyeri, and A. gerencseriae. Actinomyces are fastidious bacteria that require cultures enriched with brain-heart infusion media, may be aided in growth by an atmosphere of 6–10% ambient CO_2, and grow best at 37°C. Colonies may appear after 3–7 days of incubation, but for adequate detection of slow growth, cultures should be observed for $>$ 21 days. Characteristically, actinomyces species appear "molar-tooth" colonies on agar or as "breadcrumb" colonies suspended in broth media.

Epidemiology

Human actinomycosis was first described in 1878 by Israel, who along with Wolfe first isolated that causative agent in culture and defined the organism's anaerobic nature. Actinomycosis occurs worldwide, with likely higher prevalence rate in areas with low socioeconomic status and poor dental hygiene. Humans are themselves the natural reservoir of the Actinomycyes species that cause actinomycosis. No external environmental reservoir such as soil or straw had been documented. There is no person-to-person transmission of the pathogenic actinomyces species. Actinomycosis in cattle, horses, and other animals is caused by other species, usually actinomyces bovis.

Pathogenesis and Pathology

Four clinical forms of actimonmycosis, i.e., cervicofacial, thoracic, abdominopelvic, and cerebral, account for the majority of infections in humans. Actinomycosis usually occurs in immunocompetent persons but may occur in persons with diminished host defenses.

The portal of entry of Actinomyces species is typically a break in the mucosa or the gastrointestinal tract, anywhere from the mouth to the rectum; such a break may occur as a result of a dental procedure, overt or covert dental sepsis, bacterial suppuration, diverticulitis, appendicitis, surgery or trauma.

In tissues, infecting Actinomyces species grow in microscopic or macroscopic clusters of tangled filaments that are surrounded by polymorphonuclear neutrophils. Subacute or chronic inflammation with granulation tissue, extensive fibrosis, and sinus tract is present in the surrounding tissues, but giant cells and cassation necrosis are generally not seen. When grossly visible, clusters exude from the soft tissues through sinus tracts, are pale yellow in color, and are called sulfur granules. Sulfur granules are not unique to actinomycosis. They occur in case of nocordiosis, chromomycosis eumycetoma, and botryomycosis. The causative organism can be recognized by their particular morphological features and cultural characteristics. The absence of sulfur granules from any lesion, however, does not exclude the diagnosis of actinomycosis; culture-proven case of actinomycotic cerebral lesions lacks this feature.

Diagnosis

The diagnosis of *actinomycosis* is made most accurately by isolating *Actinomyces* species in cultures specimens. However, the demonstration of actinomycotic granules in exudates or in histological sections of tissues not connected to hollow organs is strongly supportive of the diagnosis. Whether the sulfur granules are microscopic or macroscopic, they consist of tangled filaments of *Actinomyces* species, which becomes apparent on microscopic examination of a gram-stained smear of a crushed granule.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_98,

Manifestations

Cervicofacial Actinomycosis

The face and neck are the most common sites of actinomycosis. The frequency of this location among cases of actinomycosis ranges from 11% to 96% with a mean frequency of 55%. Actinomyces species are normally present in high concentrations in the tonsillar crypts and gingivodental crevices, and many actinomycosis infections are odontogenic in origin. In addition to poor dentition and recent dental manipulation, chronic tonsillitis otitis and mastoiditis are important risk factors for these infections. External trauma may result in the introduction of Actinomyces species into the head and neck tissues.

Lesions are frequently located at the angle of the jaw or in the submandibular region. Cervicofacial actinomycosis may extend to the underlying mandible or facial bones, leading to the development of periostitis or osteomyelitis. Human cervicofacial actinomycoses can be diagnosed reliably only by adequate microbiological method. Histological procedures often do not provide conclusive result, because characteristic sulfur granules are often low in number and not always easy to identify or differentiate from granules of various other origins.

Thoracic Actinomycosis

Thoracic actimonmycosis accounts for 15–20% of cases and may involve the lungs, pleura mediastinum, or the chest wall. Routes of infection include aspiration of oropharyngeal secretions or gastric contents; direct extension of cervicofacial infraction in the mediastinum, along the deep facial planes of the neck; transdiaphagmatic or retroperitoneal spread from the abdomen; or rarely hematogenous dissemination. Infection in the lung usually leads to the development of chronic pneumonia with or without associated pleural effusion. The clinical picture of thoracic actinomycosis most often mimics that of tuberculosis or malignancy with findings of cough, low-grade fever, weight loss, and chest pain. Pulmonary actinomycosis presented as a mass-like consolidation. Response to antibiotics was facilitated by a removal of the airway plug through bronchoscopy. Airway obstruction may contribute to the prolonged medical treatment of pulmonary actinomycosis. The plug formation from fibrous material generated by the bacteria may obstruct bronchial orifices and account for the recurrence. Thus, periodic bronchoscopy to inspect and remove the airway plug may facilitate medical treatment.

Chest radiographs may reveal infiltrates suggestive of aspiration pneumonitis, firbronodular and cavitary parenchymal disease, or a mass in the lung. Contiguous extension from a chronic pulmonary focus may lead to empyema; vicinal destruction of the ribs, sternum, or shoulder girdle; involvement of the chest-wall muscles and soft tissues; and the formation of sinus tracts extending to the skin. Involvement of the mediastinal structures rarely leads to obstruction of the superior vena cava, formation of a trachoesophageal fistula, vertebral or paravertebral extension, or the development of pericarditis or myocarditis.

Abdominal and Pelvic Actinomycosis

Actinomycosis of the abdomen and pelvis accounts for 10–20% of reported cases. Actinomyces species are frequently part of the normal flora of the gastrointestinal and female genital tracts. Abdominal actinomycosis usually occurs following penetrating trauma, perforation of the gut, or surgical manipulation of the gastrointestinal tract. Abdominal actinomyocosis may be the most indolent and latent of all of the clinical forms of the disease; diagnosis may be delayed months or years after the inciting event. There is a predilection for involvement of the ileocecal region of the gut; thus, chronic abdominal actinomycosis may be confused with intestinal tuberculosis, ameboma, or chronic appendicitis.

Anorectal disease is not uncommon, and may present as rectal stricture, perirectal or ischiorectal abscess, or recurrent draining sinuses and fistulae. The primary site may be an anal crypt, or there may be direct extension from an intra-abdominal focus of infection. Gastric and perigastric, hepatic, splenic, and renal involvements are uncommon forms of abdominal actinomycosis. Actinomycosis species may reach these viscera through direct extension from the bowel or an intra-abdominal or intrathoracic site or via seeding through the portal vein or systemic circulation. Similar to intestinal infection, pelvic actinomycosis is typically insidious in its course and easily confused with other inflammatory or malignant pelvic disorders. Nonspecific symptoms of this form of the disease (lower quadrant abdominal pain and weight loss) and low-grade fever (or no fever) may persist for months to years. If pelvic actinomycosis is secondary to intestinal infection, the usual source is indolent ileocecal disease that extends to the right adnexa in 80% of cases. The ovary is most commonly affected, followed by the fallopian tubes, uterus, vulva, and cervix.

Central Nervous System

Actinomycosis of the CNS may present as a brain abscess, meningitis or meningoencephalitis, subdural empyema, actnomycoma, and spinal and cranial epidural abscess. Brain abscess accounts for almost 75% of all CNS lesions. Actinomycosis of the CNS is usually secondary to hematogenous spread from a primary infection in the lung, abdomen, or pelvis. However, extension form foci of infection in the ears, para nasal sinuses, and cervicofacial regions may proceed along the connective tissue planes or trough foramina at the base of the skull, causing focal infection of the CNS or diffuse basilar meningitis.

Actinomycotic cerebral abscesses are usually singular but may be multiple, unilocular, or multilocular, encapsulated or less frequently, un-encapsulated. The interval from the onset of symptoms to diagnosis is typically longer than that for pyogenic brain abscesses. There is a predilection for involvement of the temporal and frontal lobes. Cerebral actinomycosis may also be a component of disseminated disease that occurs in three or more noncontiguous body sites.

Involvement of the meninges results in basilar meningitis; the signs and symptoms mimic those of other chronic meningiticides. Because of the indolent nature of this form of the infection, frequent lack of acute toxicity, and findings in the CSF (e.g., mononuclear pleocytosis, an elevated protein concentration, and normal or low glucose concentrations), the disease is frequently misdiagnosed as tuberculous meningitis. Actinomycomas may occur at various sites within the CNS, i.e., as space-occupying lesions in the cerebral cortexes, as masses of the gasserian ganglion, or as lesions simulating tumors in the posterior or third ventricle.

Primary cutaneous actinomycosis is rare, and the diagnosis requires a high index of clinical suspicion.

Treatment and Prognosis

Actinomyces species are susceptible in vitro to several antimicrobials including penicillin G., chloramphenicol, the tetracyclines, erythromycin, clindamycin, imipenem, streptomycin, and the cephalosporins. Fluoroquinolones, aztreonam, fosfomycin, and other aminoglycosides generally have poor activity against *Actinomyces* species and *P.propionicus*. The clinical experience with actinomycosis has been extensive and supports the use of penicillin G as the drug of choice for all clinical forms of the disease. Mild cervicofacial infections maybe adequately managed with a 2-month course of peroral penicillin V or one of the tetracyclines (e.g., doxycycline, 100 mg given orally twice daily), without surgical intervention.

For other more complicated forms of actinomycoses, parenteral penicillin G, 10–20 million U/d divided every 6 h, should be administered for 4–6 weeks, followed by oral penicillin V, 2–4 g/d divided every 6 h, for 6–12 months. For penicillin-allergic patients, a tetracycline, erythromycin, clindamycin, and cephalosporins are suitable alternatives. Chloramphenicol, given orally or intravenously in a dosage of 50–60 mg/(kg/d) divided every 6 h, is probably the preferred agent for treating actinomycosis of the CNS in patients who are allergic to the penicillins. Risk factors significantly correlated with a poor outcome (death or relapse) for patients with CNS actinomycosis include the onset of disease $>$2 months before presentation, lack of antibiotic therapy or surgery, and the performance of needle aspiration drainage rather than open drainage or excision.

In light of the potential for relapse of actinomycosis, prolonged antibiotic treatment is prudent; the exact duration of therapy depends on the site and severity of disease. Prolonged observation of patients after treatment is necessary to detect recurrence.

Prevention

There are no specific measures for preventing actinomycosis; however, maintenance of good personal orodental hygiene, and in particular, removal of dental plaque, may reduce the density if not the incidence of colonization and low-grade periodontal infection with *Actinomyces* species.

99 Hydatid Disease

Mohammed El-Bali · Adetunji Adeyokunnu

Hydatid disease is a cosmopolitan infection of humans and certain other mammals caused by cestodes belonging to the genus *Echinococcus*. *Echinococcus granulosus* is the main infection, with infection with *E. multilocularis* occurring to some extent and *E. vogeli* occasionally; *E. oligarthrus* is very rarely known to cause disease in humans. Infection is acquired by ingestion of ova from feces of carnivorous definitive hosts. The larvae most frequently develop in the liver but may occur in many different tissues, such as the lungs, spleen, and other organ systems, including the brain, eye, heart, bone, and genitourinary system. Although the disease is often referred to as hydatid disease, it may also be designated according to the morphology of the larval stages: unilocular echinococcosis, caused by *E. granulosus*; multilocular or alveolar echinococcosis, caused by *E. multilocularis*; and polycystic echinococcosis, caused by *E. vogeli*.

Etiology

The life cycles of the main species of *Echinococcus* are similar, but significant differences occur in the geographical distribution, types of host, and morphology of the parasite. *E. granulosus*, the most common species found in human infections, is of two major strains: the domestic or pastoral strain and the sylvatic strain. The small adult worm lives in the intestine of dogs, the main definitive host, and related canids such as the fox and wolf. Infective eggs are passed in the feces of these animals and may be ingested by sheep, cattle, camels, goats, or humans, who are usually the intermediate hosts. The eggs hatch in the small intestine and the embryos (in a larval stage called oncosphere) burrow through the intestinal wall and gain access to the portal circulation. Many embryos are destroyed, but those that survive may develop in many tissues, most commonly the liver or lung, where they become the cystic larval structures called hydatid cysts. The cyst is made up of an outer laminated acellular membrane lined by a thin, cellular germinal membrane. Spherical structures called brood capsules grow from the germinal membrane. Protoscolices develop within the brood capsules. These structures contain suckers and hooks and become scolices of adult worms. The cycle is maintained when dogs or wolves eat carcasses of the intermediate hosts. Unilocular cysts, which may contain daughter cysts, develop most commonly in the liver, with the second most common site being the lungs. In children, pulmonary involvement may be more common than hepatic involvement.

E. multilocularis typically involves foxes as definitive hosts and mice as intermediate hosts. Because the cysts lack a containing capsule, they progressively invade involved tissues and produce honeycombed alveolar hydatid cysts. The larvae may invade contiguous structures and rarely may metastasize. When *E. vogeli* infection occurs in humans, the germinal membrane of the larval cyst grows externally to form additional cysts and also develops septa within the original cyst. This is the polycystic variety of hydatid disease.

Transmission

Humans acquire hydatid disease by ingestion of food or drink contaminated with feces from the infected definitive hosts, usually dogs. The eggs can be found on the dog's perianal hear, muzzle, and paws. Children become particularly susceptible because of their intimate contact with dogs. They may pick up eggs contaminating the animal's coat or ingest eggs from the dog's tongue after being licked. Flies may disseminate the eggs from dog feces. The practice of tanning leather with a mixture of water and dog feces might be responsible for the high prevalence of infection among shoemakers in Lebanon. Major differences between the human-dog parasite and cattle-dog organism have been detected, thus raising doubt about the infectivity of the cattle and camel strains to humans.

Epidemiology

E. granulosus is the most common species found to infect humans and has a global distribution, being endemic in sheep-rearing regions such as the Mediterranean basin, the Middle East, East Africa, Latin America, southwestern

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_99,

Canada, Australia, South America, and New Zealand. *E. multilocularis* is confined to the northern hemisphere, including Europe, Canada, Alaska, Japan, the north central United States, Russia, and Turkey. *E. vogeli* is found in South America, and *E. oligarthrus* was discovered in Central and South America, where it is a rare infection in humans.

Pathogenesis

The development of disease is related to compression or displacement of host tissue. Unilocular hydatid cysts, for example, enlarge concentrically, increasing in diameter by 1–5 cm a year. A cyst may exceed 35 cm in diameter in the abdominal cavity. When there is rupture of or leakage from a cyst, an allergic reaction caused by the antigenic cyst content usually occurs. Patients may experience bronchospasm, urticaria, or anaphylaxix. Blood eosinophilia is usual. Cysts may calcify after many years, signifying the death of the parasite. The cysts may form foci for secondary bacterial infection. Infection of the cyst can facilitate the development of liver abscesses and mechanic local complications, such as mass effect on bile duct and vessels that can induce cholestasis or portal hypertension.

Clinical Manifestation

Many cases of hydatid disease are silent. When symptoms occur, they are caused by pressure produced by the expanding cyst, and its location determines the clinical presentation. Thus recurrent fever, proxysmal cough, chest pain, and hemoptysis are common symptoms of pulmonary hydatidosis. When pulmonary cysts rupture into the bronchus, the patient may describe "coughing up grape skins." Constant or intermittent right upper quadrant abdominal pain, vomiting, hepatomegaly, and jaundice may indicate liver involvement. Lung disease is reported to be most common form of presentation. It is thought, because of the slowly growing nature of the liver and lung hydatid cysts, even when such infections are acquired in childhood, most cases become symptomatic and are diagnosed in adult ages, and only 10–20% of cases are diagnosed in patients younger than 16 years. But cysts located in other organs like the brain or an eye can cause clinical symptoms even when small; thus, most cases are diagnosed in children. Central nervous system involvement is also much more common in children than in adults. Intracranial localization produces symptoms indistinguishable from those of a tumor, seizures, personality changes, intellectual deterioration, signs of increased intracranial pressure, or neurologic abnormalities. Orbital cysts produce proptosis. Bone cysts, which may be seen in preschool children, are most common in the vertebral and long bones. Unlike cysts in other sites, bone hydatids are characteristically multilocular and contain little fluid. Bone pain and pathologic fractures have been reported. Vertebral hydatid disease causes spinal cord compression.

Serious morbidity is the consequence of enlargement, secondary infection, or a cyst rupture. Some children with hydatid disease also show retarded growth patterns. Sensitivity to cyst contents due to slow leak of fluid may develop, with resulting allergic symptoms, notably urticaria.

Diagnosis

Diagnosis of human equinococcosis is made by a combination of clinical, imaging, serological, and molecular techniques. Diagnosis of hydatid disease depends initially upon clinical awareness of the condition. This includes history of residence in endemic areas. Physical examination is rarely definitive. Certainly, hydatid cysts are most commonly found in the liver and lungs, but other locations have been reported and prevalently in children and young adults. A moderate eosinophilia is almost invariably present in childhood cases except during febrile illnesses. Only about 50% of patients with hepatic hydatids have abnormal liver function tests. Immunoglobulin E levels characteristically are elevated.

A noninvasive confirmation of the diagnosis can usually be accomplished with the combined use of radiologic imaging and immunodiagnostic techniques. Results of radiologic and imaging studies can strongly suggest the diagnosis of hydatidosis. Plain x-ray of the chest may suggest pulmonary cysts. It will not differentiate such cysts from pyogenic lung abscess, lung tumor, metastatic deposits, or cavitating tuberculosis. Such x-rays will not visualize cysts in other organs unless they are calcified, as often is seen in hepatic cysts. However, since calcification takes years to occur, this procedure is unhelpful in childhood hydatid disease. Ultrasound techniques (*Fig. 99.1*) can be used to differentiate fluid-filled cysts from solid tumors. The expanded use of ultrasonography has improved the potential of diagnostic techniques in cystic echinococcosis, and the availability of portable ultrasound units facilitates epidemiological screenings in remote endemic areas. World Health Organization

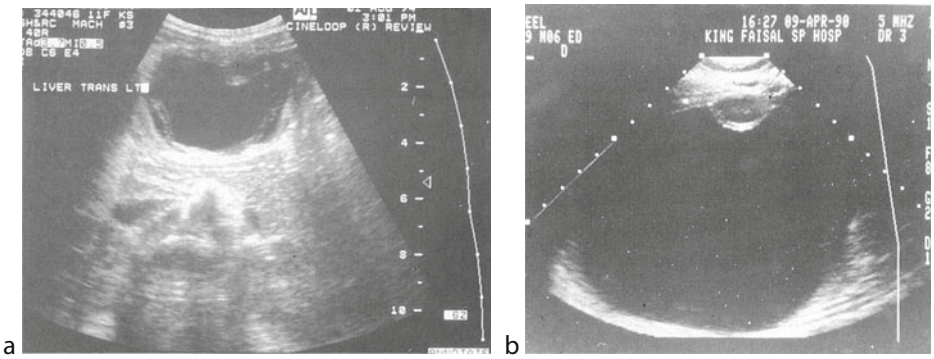

Figure 99.1
Ultrasonographs showing typical unilocular hydatid cysts of the liver. Notice the highly characteristic daughter cyst (b) and the double-layer lining (a)

developed a standardized classification system for hepatic hydatidosis cysts detected by ultrasonography. Briefly, this classification system includes the following types: CL, unilocular cyst(s) with uniform anechoic content, but no pathognomonic signs are detectable; CE1, active unilocular cyst with uniform anechoic content and cystic wall well visible; CE2, active multiseptated, rosette-like cyst with visible wall; CE3, cyst with anechoic content and inner floating detached membranes or daughter vesicles in solid matrix; CE4, inactive cysts with hypoechoic or hyperechoic degenerative content and no daughter cysts; and CE5, inactive cyst with wall calcification varying from partial to complete. A pathognomonic computerized tomography (CT) finding, in addition to the intact cyst (*Fig. 99.2*), is the presence of daughter cysts that are either free within the cyst or adherent to the inner germinal layer. Magnetic resonance imaging scans can add precision to equivocal results of CT scanning or ultrasonography.

Antibody assays are useful to confirm presumptive imaging diagnoses, although some patients do not demonstrate a detectable immune response. Intact cysts can elicit a minimally detectable response, whereas previously ruptured or leaking cysts are associated with strong responses. Several immunodiagnostic tests are available for detecting antibodies in the sera of patients with hydatid cysts. Casoni intradermal test has an accuracy of between 50% and 80%. However, sensitivity is variable, specificity is low, and false positives may be encountered in patients with schistosomiasis or neoplasia of the liver or lungs. The test may remain positive for several years after removal or death of the parasite. The complement fixation test (CFT) has an overall sensitivity of 70%. False positivity has been recorded in patients suffering from pancreatic or lung cancers or sarcomas. Results of the CFT revert to negative more quickly than those of agglutination reactions following surgical removal of hydatid cyst from the body. It is, however, a reliable method for monitoring continued infection and detecting reinfection. The indirect hemagglutination test and enzyme linked immunosorbent assay can be performed first in acute cases to record a presumptive diagnosis of hydatidosis. Both tests are simple, highly sensitive, and amenable to automation, but, because of the possibility of false-positive results produced by cross-reacting helminthic infections, specificity must be confirmed using the immunoassays with Arc-5 antigen, which so far is considered by

many to be the only absolutely specific serologic test available for hydatidosis. Em2, a species-specific native antigen isolated from the metacestode of *E. multilocularis* has been used successfully over a long period for immunodiagnosis of alveolar echinococcosis in ELISA format with a sensitivity ranging between 77% and 92%.

Even with these assays, 5–25% of patients with neurocysticercosis have false-positive results. Conversely, negative tests do not exclude the diagnosis because about 50% of patients with isolated pulmonary cysts and 10–15% of those with hepatic cysts lack detectable antiechinococcal antibodies. In seronegative individuals, a presumptive diagnosis can be confirmed by the demonstration of protoscolices or hydatid membranes in the aspirates obtained by percutaneous aspiration of the cyst, preferably guided by ultrasonography and under anthelmintic coverage.

Treatment

The definitive therapy for echinococcosis has been surgical excision. Success depends upon the size and location of cysts and the skill of the surgeon for removal of *E. granulosus* cysts and resection of tissues containing *E. multilocularis* cysts. In all cases, care must be taken during surgery to avoid spilling the cyst contents, which carries an immediate risk of anaphylaxis, spread of infection, and delayed risk of disseminated echinococcosis. Before excision, the cyst may be aspirated and scolicidal solutions such as hypertonic saline or ethanol cetrimide instilled into the cavity. Fear has been expressed that such a precautionary procedure may produce its own problems, such as hypernatremia, alcohol intoxication, and, with communicating hepatic lesions, sclerosing cholangitis. Albendazol has been used during surgery in the hope of reducing the risk of secondary spread of infection. Medical treatment before, during, and after surgery may be beneficial in some cases. For inoperable lesions, or when there is no consent for surgery, percutaneous cyst drainage followed by alcohol injection and reaspiration can be carried out with ultrasound guidance. The mortality from surgery is around 3–5%.

Chemotherapeutic agents are no substitute for surgery as their effect on available evidence seems to be palliative rather than curative. When surgery is not feasible because of poor general condition of the patient, the disease is too widespread to permit curative surgery, or the location of the cyst makes it technically inaccessible, then one of the two available agents, mebendazole or albendazole, may be used.

Mebendazol is a synthetic benzimidazol derivative. It was the first drug to be tried against echinococcal infection in humans. It is larvicidal to *E. granulosus* and *E. multilocularis* by limiting their cellular glucose uptake. It is also known to kill the germinative membrane of peritoneal hydatid cysts in experimental animals. A dose of 50 mg/kg body weight per day in three divided doses taken orally with meals for 3 months is probably the minimum effective dose for treating *E. granulosus* infection. Low-grade fever, pruritus, urticaria, exfoliative dermatitis, bone marrow toxicity and neutropenia, transient liver toxicity, and glomerulonephritis have been recorded complications. The initial abdominal discomfort and nausea can be lessened if the drug is taken with meals. Albendazole, another benzimidazole carbonate, was meant to be an improvement over mebendazole. The drug seems to induce degeneration of the germinal layer of the hydatid cysts and to kill protoscolices. The dose is 5–7 mg/kg twice daily to be taken at mealtimes. The treatment should be in the form of 30-day courses separated by 2-week intervals.

Response to chemotherapeutic agents can be monitored using ultrasonography and serial CT to detect changes in the size and contour of soft tissue cysts. Serial chest x-rays may also be helpful in monitoring pulmonary cysts. Serologic tests should also be employed to monitor disease activity during treatment. The prognosis of hydatid disease is widely variable. In 25% of cases, hepatic cysts may undergo spontaneous death and calcification, but, once patients become symptomatic, the prognosis without intervention is very poor.

Prevention

There are currently no effective drug treatments or vaccines to protect humans against the disease. Prevention of the disease requires elimination of infection in dogs, the main definitive host. This can be achieved by regular treatment of dogs with an effective teniafuge, such as praziquantel or mebendazole, at least twice yearly. Also, dogs should not be allowed to have access to carcasses of intermediate hosts like sheep. Control and prohibition of farm and home slaughter were key features in successful programs of eradication in countries like Iceland, New Zealand, and Tasmania.

Populations need constant education and to be alert to the possibility of infected eggs contaminating their foods, greens, and water, and they should be encouraged to take effective measures.

100 Leishmaniasis

Mohammed El-Bali · Adetunji Adeyokunnu

Leishmaniasis refers to a group of parasitic diseases caused by protozoan flagellates of the genus *Leishmania*. The infection is transmitted to humans through the bite of *phlebotomine* sandflies that have fed on an infected host. The pattern of disease produced varies from innocuous self-limiting cutaneous lesions to potentially lethal visceral leishmaniasis depending on the infecting species of *Leishmania* and the host's immune response to infection. The disease is endemic in large areas of the tropics, subtropics, and the Mediterranean basin.

Etiology

Leishmaniasis is mainly a zoonosis, where human beings are incidental hosts of infection, and other mammals, such as rodents and canines, are reservoir hosts, although in certain areas of the world, it is primarily anthroponotic, with human–vector–human transmission (e.g., anthroponotic visceral leishmaniasis due to *L. donovani* and anthroponotic cutaneous leishmaniasis due to *L. tropica*).

Leishmania parasites are transmitted to humans predominantly through biting sandflies vectors of several species and subspecies of *Phlebotomus* in the Old World and *Lutzomyia* in the New World. The disease can also be transmitted by close contact with a contaminated bite wound, blood transfusions, congenitally from mother to infant and by shared blood-contaminated syringes among intravenous drug users, though; these are rare modes of contracting the disease.

The protozoal parasite *Leishmania* exists in two distinct morphologic forms: flagellated promastigotes, which replicate extracellularly within the sandfly vector gut and also in axenic cultures, and aflagellated amastigotes, which are obligate intracellular parasites of mononuclear phagocytes in mammalian hosts. When the vector, a sandfly, feeds on an infected host, it may ingest an infected cell from blood or tissue. The amastigotes are liberated in the fly's midgut and, within a few hours, transformation to the promastigote occurs. Binary fission then begins, and large numbers of promastigotes are produced that gradually move forward to the buccal cavity and mouth parts of the fly. The organisms may remain in the fly's mouth parts for between 1 and 3 weeks before dislodging into the bite wound when the fly next takes a blood meal.

Once inoculated, many of the promastigotes do not survive because vertebrate host tissue fluids contain cytolytic substances. On the other hand, the organisms that are phagocytized transform to amastigotes and initiate replication. They are round to oval bodies about 2–4 μm in diameter that possess a single nucleus and kinetoplast; they lack free flagellum. They are also referred to as Leishman–Donovan bodies. The organism can be seen readily in tissues or smears by light microscopy, especially with Giemsa staining.

Epidemiology

Leishmaniasis is found in all continents and is endemic in the tropical and subtropical regions of 88 countries. There is an overall prevalence of 12 million cases worldwide, and 350 million people are considered at risk. Each year, about 1.5–2 million new cases of cutaneous leishmaniasis occur, 90% of them registered in Afghanistan, Algeria, Brazil, Iran, Peru, Saudi Arabia, and Sudan, and some 500,000 new cases of visceral leishmaniasis, mostly in Bangladesh, Brazil, India, Nepal, and Sudan. In visceral leishmaniasis endemic areas, children and young adults are especially affected. Visceral leishmaniasis is also prone to large-scale epidemics with high fatality rates.

The number of leishmaniasis cases is increasing, mostly because of climate change, mass population movements, exposure of people who are not immune, deterioration of living conditions in outlying urban areas, and malnutrition. *Leishmania*/HIV coinfection has emerged as a result of the increasing overlap between both diseases. Visceral leishmaniasis is the clinical form most frequently associated with HIV/AIDS. Although, some coinfection cases with cutaneous forms have been reported.

Clinical Manifestations

Leishmania infection can in general manifest in three broad clinical forms: visceral, cutaneous, and mucocutaneous. These depend on the tissue tropism of the

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_100,

leishmanial species and the host's immune response, principally the cell-mediated component of immunity. Other variants of the disease are also well known, namely, post-kala-azar dermal leishmaniasis, diffuse cutaneous leishmaniasis, and recidivans cutaneous leishmaniasis.

Visceral Leishmaniasis

Certain *Leishmania* species show exaggerated viscerotropism in humans and cause the potentially lethal kala azar or visceral leishmaniasis. These organisms are grouped under the *L. donovani* complex and comprise the subtypes *L. donovani* and *L. infantum* in the Old World, and *L. chagasi* in the New World. In *L. infantum*, children are involved almost entirely and dogs or foxes are among the extrahuman vertebrate hosts, and *L. chagasi* is similar epidemiologically. In infections with *L. donovani*, adults tend to be involved more, and there is no extrahuman vertebrate. Few cases of visceral leishmaniasis caused by *L. tropica* have been also reported.

Typically, symptoms appear between 2 and 6 months following sandfly bite, although incubation periods of up to 3 years have been reported. Lesions at the inoculation site are rarely observed when the patient first comes to medical attention. In infants, an acute onset is associated usually with high fever, sometimes vomiting, and occasionally rigors. In younger infants, mild to moderate toxemia is commonly seen. Temperature is variable, irregular remittent, or intermittent, sometimes showing double or even triple peaks in 24 h. Congenital kala azar, though very rare, has been reported in infants whose mothers were affected with the disease during pregnancy.

In older children, the onset of disease is usually insidious, with low-grade fever that is also irregular, remittent, intermittent, or continuous with an uneven plateau. Apyrexial periods may intervene during the pyrexial course of the disease. During the early course of the disease, children may remain ambulatory with temperatures of 40°C and appear less ill than the height of the temperatures would suggest. Nonspecific complaints include vomiting, diarrhea, anorexia, and unproductive cough. Thereafter, the fever may recede, and the patient becomes weak and complains of symptoms due to an enlarged spleen, such as abdominal discomfort and early satiety. Physical examination will reveal splenomegaly. The spleen may so enlarge as to expand to the iliac fossa, but splenomegaly is an invariable finding. Hepatomegaly and less frequently lymphadenopathy are associated features. Well-established cases are characterized by pallor and later by ashen gray skin color.

Kala azar means "black poison," a terminology derived from the increased skin pigmentation in the malar region, the temples, and around the mouth that can be seen in dark-skinned races. There is wasting and drying of the skin; sparseness of the hair, which becomes thin and brittle; and varying degrees of abdominal protuberance due to gross splenic enlargement (*Fig. 100.1*). Petechiae, ecchymoses, and mild edema appear. Jaundice and ascites are rare. Anemia, leukopenia, and thrombocytopenia are common.

Kala azar should be suspected in any patient from an endemic area presenting with fever, splenomegaly, pancytopenia, hypoalbuminemia, and hyperglobulinemia. The disease may simulate malaria, salmonellosis, brucellosis, miliary tuberculosis, subacute bacterial endocarditis, and leptospirosis in general, as well as schistosomiasis, leukemia, reticulosis, glucagon storage disorder, tropical splenomegaly syndrome, and histoplasmosis with respect to the splenomegaly particularly.

Post-kala-azar dermal leishmaniasis is a complication of visceral leishmaniasis. A varying proportion of recovered visceral cases may evolve into a cutaneous form characterized by a macular, maculopapular, and nodular rash starting usually around the mouth and spreading to other parts of the body. It is mainly seen in East Africa (Sudan and Kenya) where usually it appears within the first 6 months post treatment, and in Indian subcontinent where most patients present after 2–3 years. Post-kala-azar dermal leishmaniasis cases are highly infectious because the nodular lesions contain many parasites. The post-kala-azar dermal leishmaniasis, although not as deadly as visceral leishmaniasis, requires a lengthy expensive treatment program.

Cutaneous Leishmaniasis

This type of infection is traditionally divided into Old World and New World cutaneous leishmaniasis. Old World (the Mediterranean basin, Africa, India, China, the former Soviet Union, the Middle East, and Asia Minor) cutaneous leishmaniasis is caused by three species of *Leishmania* that belong to the *L. tropica* complex: *L. tropica* is present in the Middle East and the Mediterranean littoral; *L. major* is found in the Middle East, Arabia, the former Soviet Union, India, and sub-Saharan Africa; and *L. aethiopica* is found principally in Ethiopia and Kenya. New World (primarily Central and South America) cutaneous leishmanasis arises from infection with parasites belonging to the *L. mexicana* or the *L. braziliensis* complexes. In most geographic areas, these parasites are maintained by transmission in nonhuman reservoirs, usually rodents, but person–vector–person transmission can also occur. The differential diagnosis of cutaneous leishmaniasis includes yaws, syphilis, leprosy, tuberculosis, basal cell carcinoma, sarcoid, and fungal infections.

The characteristic skin lesion begins as an erythematous papule or macule that may ulcerate after several weeks (*Fig. 100.2*). The lesions are generally painless, nontender, and nonpruritic unless superinfection with bacteria has occurred, in which case there may be regional lymphadenopathy. The lesions are often solitary, but multiple bites can produce several concurrent lesions. Satellite lesions containing parasites may form adjacent to the primary one. In Old World cutaneous leishmaniasis, spontaneous healing usually occurs over a period of months.

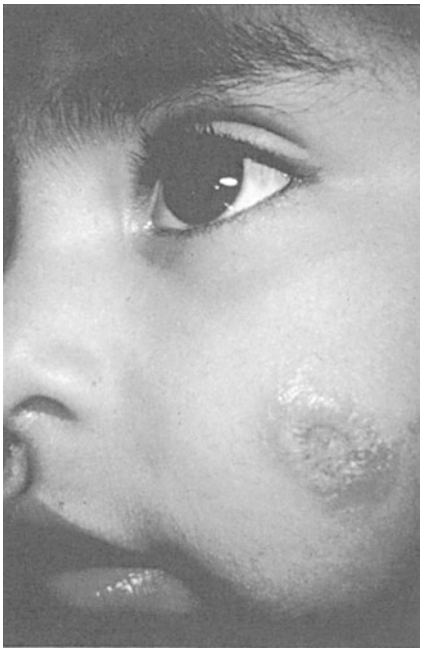

Figure 100.2
Cutaneous leishmaniasis. Note the raised edges and central ulcer (Courtesy of Haysam Tufenkeji, FAAP)

In humans, infection with *L. tropica* usually produces self-limited skin ulcers in which amastigotes can be found situated in macrophages in and about the lesions. However, military personnel in the Middle East have acquired cutaneous leishmaniasis with *L. major* as well as viscerotropic infection with *L. tropica*. It should be noted that, in the wet form of cutaneous leishmaniasis caused by *L. major*, the incubation period is short, rapid healing ensues, and few parasites are found in the skin; various rodents, for example, the fat gerbil (*Psommosys obesus*), are the main reservoir.

Cutaneous leishmaniasis, depending on the species of the causal agent, may evolve into diffuse cutaneous leishmaniasis, recidivans leishmaniasis, or mucocutaneous leishmaniasis.

Diffuse Cutaneous Leishmaniasis

Diffuse cutaneous leishmaniasis occurs most often in Ethiopia, Brazil, Dominican Republic, and Venezuela. It is an anergic form of cutaneous leishmaniasis in which neither cellular nor humoral immune responses are functional. This form of leishmaniasis is characterized by disseminated and chronic skin lesions very similar to those of localized cutaneous leishmaniasis and those of lepromatous leprosy. It occurs with extensive and widespread proliferation of parasites in the skin but without apparent inflammation or tendency for visceralization. The disease is usually refractory to treatment.

Recidivans Cutaneous Leishmaniasis

Leishmaniasis recidivans, also known as lupoid or tuberculoid leishmaniasis, is a chronic form of anthroponotic cutaneous leishmaniasis that may occur years after a localized cutaneous lesion has healed and lasts for many years. The lesions, commonly presenting on the face and exposed areas, form over the edge of the old scar. Untreated, the disease is destructive and disfiguring. Parasites are few or not detectable, but they may be isolated by culture.

Mucocutaneous Leishmaniasis

Infections with strains of *L. braziliensis* and *L. panamensis*, which are endemic in various areas of South America, mostly in Bolivia, Brazil, and Peru, cause cutaneous leishmaniasis, which may result in later development of mucocutaneous leishmaniasis. Such mucocutaneous disease (also known as espundia) involves the nasal or oropharyngeal mucosa or both, causing gross mutilation of the nose and palate. Lesions, almost never heal spontaneously and are usually seen months or years after a first episode of cutaneous leishmaniasis. Secondary bacterial infections are frequent and the disease may prove fatal.

In the Old World, mucosal lesions are rarely seen, but any species of *Leishmania* can cause them. Patients with anthroponotic visceral leishmaniasis, post-kala-azar dermal leishmaniasis or HIV coinfection, may develop lesions in the mouth or nose.

Diagnosis

Definitive laboratory diagnosis of *Leishmania* infection requires demonstration of the parasite in smears, in biopsies, or by isolation in culture media or in experimental animals. Histochemical and immunohistochemical methods for the demonstration of the parasite are also available. Different serologic methods for detecting the presence of antibodies against *Leishmania* parasites are available. Other laboratory methods, such as antigen detection by latex agglutination test and specific DNA detection by molecular techniques, have also been described for the diagnosis of leishmaniasis.

When kala azar is suspected based on the observation of a patient with fever, hepatosplenomegaly, and a history of exposure in endemic areas in addition to laboratory findings of anemia, leucopenia, thrombocytopenia, marked polyclonal hypergammaglobulinemia, and hypoalbuminemia, diagnosis can be confirmed by spleen or bone marrow aspiration looking for amastigotes in stained samples (*Fig. 100.3*). Tissue specimens can also be obtained from lymph nodes aspiration and liver biopsy. Microscopy shows high specificity, but its sensitivity varies. Although, splenic aspirates have been found to have the highest yields (93–99%), they are not without risk. The procedure should be avoided in individuals with a bleeding diathesis. Other contraindications include a soft or diffluent, acutely enlarging spleen; low platelets; and/or prolonged prothrombin time. In children younger than 5 years of age, splenic aspiration should be performed only by a fully experienced physician. Aspiration of lymph nodes has provided diagnosis in patients with kala azar and significant lymphadenopathy. Aspirated or homogenized biopsy material should be cultured for up to 4 weeks on specialized media (NNN or other medium).

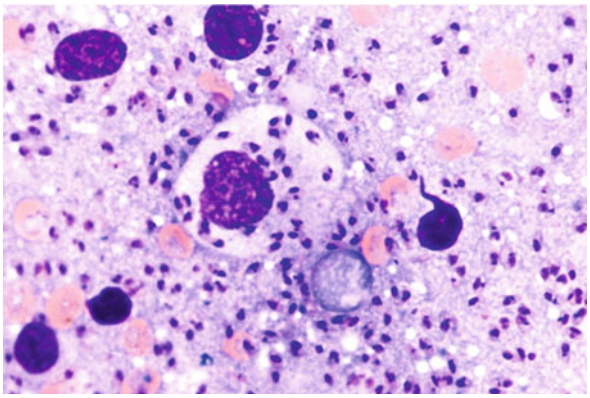

Figure 100.3
Stained spleen aspirate smear showing *Leishmania donovani* amastigotes

Several serological tests have been developed for the diagnosis of visceral leishmaniasis. These include antibody-detection tests, such as complement fixation (CF), indirect fluorescent antibody test (IFAT), indirect hemagglutination (IHA), enzyme-linked immunosorbent assay (ELISA) tests, direct agglutination test (DAT), and an immunochromatographic test (rK39-ICT). These last two tests are specifically adapted for field use. The DAT is a semiquantitative test using freeze-dried stained *Leishmania* promastigotes to detect and quantify specific anti-*Leishmania* antibodies in serially diluted sera of suspected individuals. Results are obtained after 18 h incubation, and positive reactions are visible with the naked eye. Sensitivity and specificity of the DAT were estimated about 95% and 97%, respectively. A rapid diagnostic test in format of dipstick or ICT using a recombinant *Leishmania* antigen (rK39) showed excellent sensitivity 93.9% and specificity 95.3% in several studies. rK39-ICT is proven to have a crucial importance for early diagnosis of visceral leishmaniasis cases in remote areas of endemic countries.

The leishmanin skin test (LST) or Montenegro test, like the tuberculin test, measures delayed type hypersensitivity (DTH) to leishmanial antigen, an important feature of cutaneous forms of leishmaniasis. The test is performed by injecting a suspension of killed promastigotes intradermally. A positive result is a palpable area of induration of at least 5 mm in diameter in 48–72 h. Particularly, the

delayed-type hypersensitivity to leishmanial antigens is associated with cutaneous, mucocutaneous, post-kala-azar dermal and cured visceral forms of the disease. The diagnosis of cutaneous leishmaniasis is best achieved by skin biopsy from the raised edge of a lesion.

Molecular techniques, such as PCR, developed for diagnosis of leishmaniasis using different specimens, are more sensitive and accurate, but these assays remain restricted to equipped centers and hospitals.

Treatment

Specific treatment of visceral leishmaniasis involves the use of chemotherapeutic agents. The pentavalent antimony compounds, sodium stibogluconate (Pentostam) and meglumine antimonate (Glucantime), have been the mainstays of antileishmanial therapy. The pediatric dose of Pentostam is 20 mg/kg/day intravenously or intramuscularly (maximum dose 800 mg). There is no unanimity of opinion as to how long it should be given. In most centers, 20 days appear sufficient. Pentamidine and amphotericin B, classical alternatives to antimonials, were relegated to second line because they were considered more likely to cause irreversible toxic effects, are now being resurrected particularly in antimony-resistant cases. Amphotericin B in a dose of 0.25 mg to 1 mg/kg by slow infusion daily or every 2 days for up to 8 weeks is proving effective in antimony-resistant cases. Commercial lipid formulations of amphotericin B are recommended for treatment of visceral leishmaniasis, but unfortunately, are too expensive for use in the countries where leishmaniasis is more prevalent.

Old World cutaneous leishmaniasis lesions are usually self-healing and confer immunity to people living in endemic areas. But, when complications or disfiguring scarring are expected, chemotherapy should be given. If there are only a small number of lesions, local infiltration of pentavalent antimonials can be employed. Cryotherapy and curettage can also be used in some cases of cutaneous leishmaniasis. Systemic treatment is recommended for cutaneous leishmaniasis cases with large and/or multiple lesions, with recidivans or disseminated cutaneous types, or with the risk of mucosal involvement.

Prognosis

Visceral leishmaniasis left untreated in childhood results in 75–85% mortality, but, properly treated at an early stage, 85–95% of cases can be cured. Patients with underlying malnutrition and acquired immunodeficiency syndrome and those who develop pancytopenia or bleeding diathesis or who fail to develop a delayed hypersensitivity skin reaction fare badly.

Prevention

Any meaningful prevention of *Leishmania* infection of humans will depend upon a detailed knowledge of the ecology of the reservoirs and vectors of the various forms of leishmaniasis. Transmission can be reduced by treating cases, decreasing human contact with vectors, destroying animal reservoirs, and eliminating the vectors. Insect repellents and insecticide-impregnated bednets can decrease exposure to sandflies. Travelers to endemic areas should be advised not to camp openly in close proximity farmland or naturally vegetated areas, which provide a habitat for rodents and thus an environment for the rodent–sandfly life cycle of the different forms of *Leishmania*. Sandflies are tiny (2–3 mm long) and their mobility is limited by wind speed. As wind speed increase with height, they do not fly high; they stay close to the ground. Thus, where situations permit, people should sleep in upper floors of their houses.

No chemoprophylactic agents are available. Although, Leishmanization, by intradermal inoculation of live virulent *L. major* promastigotes harvested from fresh culture has been practiced intermittently for many years in certain countries, such as the former Soviet Union, Israel, and Iran in large-scale vaccination trials. The procedure has its drawbacks. It may induce severe cutaneous lesions and should not be used under normal conditions, and in the case of American leishmaniasis, delayed sequelae such as mucocutaneous lesions are distinct deterrents for its use. The observation that curing an infection appears to impart protection against reinfection with homologous parasite species rekindled hope for the development of an effective safe vaccine in the future.

101 Malaria

Shireesha Dhanireddy · John B. Lynch

Case

A 3-year-old child is brought into clinic with 3 days of headache, vomiting, and fever. On exam, he is coughing, tachypneic, and somnolent. Retinal exam shows retinal whitening and hemorrhages accompanied by papilledema (Fig. 101.1).

Initial laboratories return with a hemoglobin of 45 g/L a serum glucose of 2.0 mmol/L and a metabolic acidosis. As you evaluate the labs, the child has a seizure. As part of the work-up, a *Plasmodium falciparum* specific rapid diagnostic test is positive and antimalarial therapy with intravenous artesunate is started in addition to blood transfusion and treatment for hypoglycemia. Within 24 h of initiating therapy and careful monitoring of vital signs and serum glucose, the patient is awake and interactive. She goes on to make an uneventful recovery after completing a course of oral artemether-lumefantrine.

Introduction

For clinicians living and working in malaria endemic regions, the enormous scope of the problems associated with these infections is unfortunately all too well known. In a world with individuals and populations traveling across country lines and between continents in such large numbers, malaria also has the potential to affect children living in non-endemic areas, such as those emigrating from and traveling to endemic areas. Families traveling with children need to be aware of these risks and to know how to minimize them. Clinicians also need to be ready to recognize the symptoms and signs of malaria in any at-risk child. Malaria remains a major global threat that continues to preferentially injure and kill children and, as a result, the clinician must remain vigilant to this infection.

Epidemiology

Malaria continues to disproportionately affect the young, particularly those under 5 years of age. Of the estimated 1–2 million deaths each year due to malaria, greater than 80% are in children under 5 years, most of who live in sub-Saharan Africa. In the pediatric population, however, the effects of malaria extend well beyond mortality. Infection is associated with anemia, poor growth and development, intrauterine growth restriction, low birth weight, and school absenteeism, all of which have profound effects on child health. Taken as a whole, "at risk" African children on average have two to five episodes of malarial fever per year. Given this environment the United Nations Children's Fund (UNICEF) includes malaria prevention and control interventions as integral parts of the high-impact interventions to improve maternal and child survival.

As of 2010, there are five species that cause malaria in humans, all belonging to the genus plasmodium: *P. falciparum, P. ovale, P. vivax, P. malariae,* and *P. knowlesi. Plasmodium knowlesi*, which also infects macaques (*Macaca fascicularis)*, is the only zoonotic species known to infect humans, with the first published reports in 2004. Although *P. vivax* infections occur over a greater geographic area and affect a similar number of people, *P. falciparum* is responsible for the majority of deaths globally. It is important to recognize, however, that in many parts of the world, the attributable morbidity of *P. vivax* infections remains substantial.

The habitable parts of the planet can be separated into three general areas based on malaria risk due to the activity of the mosquito vector: little to no risk (e.g., Europe), unstable (seasonal) risk (e.g., South Africa and much of South America), and stable (year round) risk (e.g., The Gambia). The level of endemicity (variation in the level of the disease) is the result of a number of factors, including the level of specific immunity in the population, the presence of gametocytes in that population, and an environment suitable to anopheline mosquitoes (the vector). Endemicity is influenced by the *entomological inoculation rate* (EIR = mosquito biting rate × proportion of mosquitoes carrying sporozoites), which can range from <1 to $>1{,}000$ infectious bites per person per year. In high EIR areas, mortality is mainly clustered in children under a year old due to cerebral malaria, and adults with malaria in these areas are commonly found to be anemic. In low

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_101,

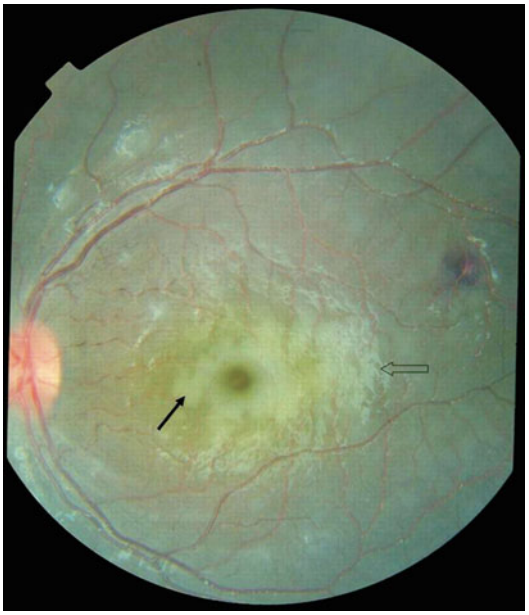

Figure 101.1
Retinal exam (Image from Beare, Tayler, Harding, Lewallen and Molyneaux, Trop Med Hygeine, 2006, p. 790)

EIR areas, the highest mortality rates are seen in children less than 5 years of age, again due to cerebral malaria.

Although *Anopheles* mosquito species are limited by temperature (18–29°C) and altitude (<6,000 ft above sea level), much of the rural and urban parts of the planet remain quite hospitable to these insects. As a result of this geography, between 3.3 and 5 billion individuals (over half the world's population) in ~100 countries are at risk of infection with *Plasmodium* species. Most (~70%) at-risk individuals live in areas of unstable transmission, where transmission intensity varies with the seasons and weather. As a result of this unstable transmission pattern, these populations do not develop the same level of acquired immunity as those living in highly endemic settings and tend to present with more severe disease, such as cerebral malaria. Similarly, individuals living in areas where malaria has been eliminated (both native born and migrant) have no immunity, putting them at high risk for progressive infection when exposed in endemic settings. These latter individuals without any immunity have benefited from programs that used a combination of approaches under the umbrella of the World Health Organization (WHO) Global Malaria Eradication Program (1955–1969) that successfully eliminated malaria from much of Europe and North America, notably in the absence of a vaccine. Due to increased awareness and new technologies, a similar, multifaceted approach to malaria elimination appears to be a realistic goal in over 20 of the more heavily affected countries of the world. Although the pursuit of an effective vaccine faces significant barriers due to the incredible complexity of the parasite's life cycle, a number of candidates are undergoing testing in humans, including one in phase III studies in African children.

The number of cases of malaria imported from endemic to non-endemic settings has risen dramatically over the last 30 years, with children accounting for 15–20% of all cases, although this may be an underestimate. In a 2009 study that reviewed cases of imported malaria in children between 1992 and 2002, over 17,000 cases were reported in 11 countries (predominantly France, UK, and USA). The children at highest risk were those returning to visit friends and relatives. Given the inappropriately high level of incorrect chemoprophylactic recommendations and issues with adherence, it is critical that children visiting endemic regions undergo appropriate pre-travel counseling and receive active chemoprophylaxis, with or without subsidies, in order to prevent infection.

Pathogenesis/Pathology

Anopheles mosquitoes serve as the only organism in which sexual reproduction occurs for the *Plasmodium* species that cause human disease. Humans act as "intermediaries" between mosquitoes in which a sexual reproduction of the parasites takes place as part of an amazingly complex life cycle (*Fig. 101.2*).

Following a mosquito blood meal, sporozoites are delivered from the salivary glands of the mosquito into the skin of the human, where they may remain for up to 2 h, postulated by some as the "skin stage" of infection. These sporozoites enter the blood stream, where they are rapidly cleared (<30 min) and circulate to the liver sinusoids where they infect hepatocytes (the pre- or exoerythrocytic cycle). In the liver cells, the sporozoites develop into liver stage schizonts containing haploid merozoites. Within 7–14 days, these merozoites are released in plumes from the infected liver cells back into the circulation where they can infect red blood cells (the erythrocytic stage of infection). Both *P. ovale* and *P. vivax* can also remain in quiescent hypnozoites in the liver, which can rupture and release merozoites months or years later, leading to relapses. The merozoites enter red blood cells by binding specific cell surface receptors, fusing with the cell membrane and vacuolization. Following red blood cell invasion, the parasites mature into trophozoites and undergo asexual reproduction to generate blood stage

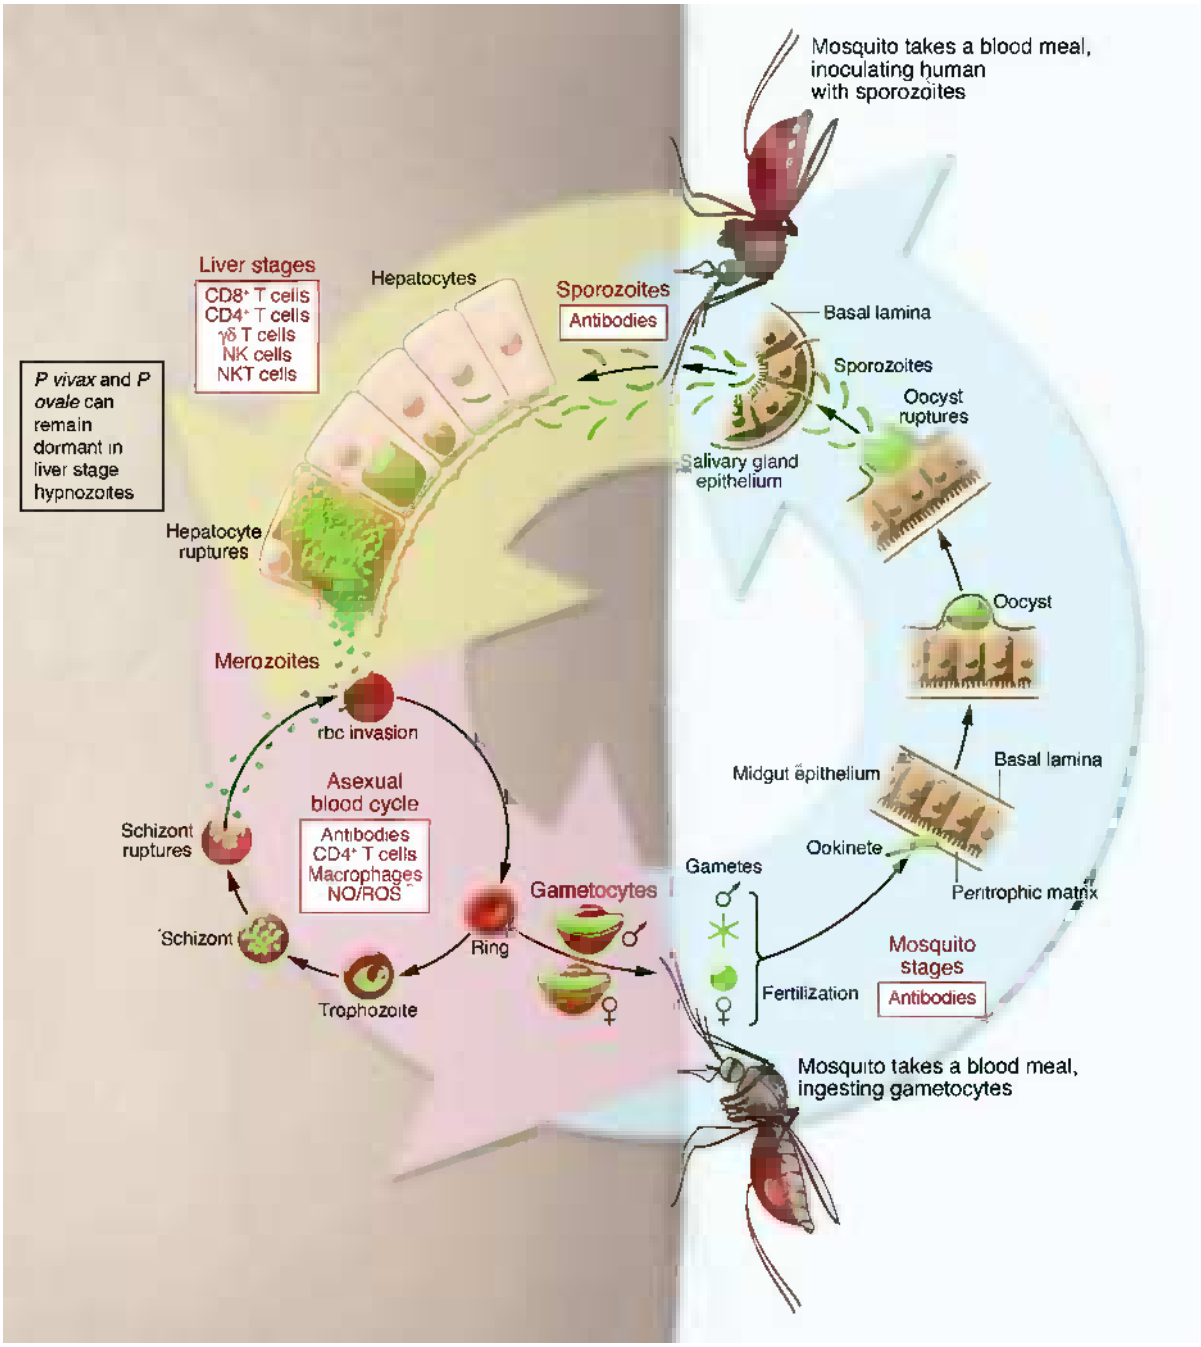

Figure 101.2
Life cycle. *Plasmodium* life cycle (Modified from Crompton PD, et al. (2010) J Clin Invest. (Modification is the addition of the box just to the left of "Hepatocyte ruptures")

schizonts followed by rupture of the red blood cell and release of blood stage merozoites. These merozoites are free to infect more red blood cells, creating more and more merozoites. With each cycle of asexual reproduction, the parasite burden increases, producing the classic recrudescent symptoms of malaria: fevers, chills, headache, nausea, and diaphoresis. The timing of the rupture of blood stage schizonts is the etiology of the various fever patterns

attributed to each species (subtertian, q36–48 h, *P. falciparum*; tertian, q48h, *P. ovale* and *P. vivax*; and quartan, q72h, *P. malariae*). Importantly, microscopy, the classic method of malaria diagnosis, detects only the erythrocytic (clinically active) stages of infection. Mixed infections are not uncommon, but what impact each species has on the other and how this changes the course of disease remains unclear.

Some blood stage merozoites develop into male or female gametocytes that are ready to be taken up by the next mosquito bite and undergo sexual reproduction (sporogenic cycle) in the gut to generate more sporozoites and complete the cycle.

The key pathophysiological feature of malaria is the effect that infection has on red blood cells. Once the merozoites enter the cells, they become adherent to the endothelial lining of the blood vessels and fixed in place. Given a sufficient density of infected cells, small vessels can become obstructed, leading to ischemia and destruction of the vessel itself. The signs and symptoms of infection are the result of the anatomical areas affected by the clogged vessel. As the blood stage schizonts mature and rupture the red blood cells, anemia results, and with advanced infection, hyponatremia and hypoglycemia. Infected cells are taken up by the reticuloendothelial system, leading to splenomegaly and hepatomegaly.

The severity of anemia is strongly influenced by the specific red cell stages targeted by the different *Plasmodium spp. P. falciparum* is able to enter erythrocytes of all stages, hence its ability to achieve the highest parasite densities (over 50%). *P. vivax* and *P. ovale* are only able to infect reticulocytes and so uncommonly can infect more than 2–5% of circulating erythrocytes. *P. malariae* infects senescent red cells and rarely exceeds a parasite count greater than 2%. This can lead to clinically latent infection and late (decades) manifestation of disease.

The coexistence of *Plasmodium* species and humans has led to a high degree of selective pressure on the human genome and, as a result, a spectrum of susceptibility and disease. A number of erythrocyte gene disorders offer some benefit to individuals, most often in the heterozygous state (e.g., alpha- and beta-thalassemia, elliptocytosis, G6PD deficiency), as well as the ability to generate potent, specific immune responses (e.g., HLA-B53, Fc-gamma receptors, and toll-like receptor 4).

While many factors influence the population prevalence of each of the five species of disease-causing *Plasmodium* species, the presence of a specific human Duffy blood group antigen gene (the Fy (a-b-) silent allele) in western and southern SSA populations appears to be a dominant factor, at least for *P. vivax*. This protein serves as the only red cell receptor for *P. vivax*, and in these populations there is very low to no expressed antigen on the surface of red blood cells, thus markedly limiting the spread of this species in that area. *P. ovale* is very similar to *P. vivax* in biology and microscopic appearance, but does not need the Duffy antigen. As a result, it is much more prevalent than *P. vivax* in Africa. Conversely, *P. vivax* is found throughout much of Asia and Latin America. *P. knowlesi*, a zoonosis also found in macaques, appears to be limited to Southeast Asia.

Clinical Manifestations

The clinical features of malaria vary depending on the endemicity (or EIR) in the geographic area as well as the species of malaria. Children less than 5 years of age are susceptible to more severe forms of disease and suffer a higher mortality rate, particularly in areas with low transmission rates. The incubation period, which is the time from infection with sporozoites to onset of symptoms, varies depending on species: 12 days for *P. falciparum*; 12–17 days for *P. vivax* and *P. ovale*; and 30 days for *P. malariae*.

A common feature of all types of malaria is paroxysms of fever, occurring every 48–72 h, which coincide with rupture of schizonts from the erythrocyte. In the early stages of the disease, pyrexial episodes may be somewhat irregular in occurrence, but later they tend to settle to the 48-h pattern of *P. vivax* infection or the 72-h pattern of *P. malariae* infection. Other characteristic features of malaria include headache, nausea, vomiting, abdominal pain, diarrhea, and myalgias. These paroxysms may be less apparent in young children. Children can also present with lethargy and decreased level of consciousness, organomegaly, and cytopenias.

In young nonimmune children, symptoms may consist of fever, listlessness, restlessness or drowsiness, vomiting, diarrhea with watery, dark green, mucous-containing stools, and seizures. In nonimmune older children, in addition to the above signs and symptoms, children may complain of headache, nausea, generalized aching, as well as abdominal pain as a result of splenomegaly.

In areas of stable malaria, infected children may die early as a result of overwhelming infection or may develop ill-defined subacute symptoms, possibly as a result of natural immunity. By 5 years of age, children in highly endemic regions have typically developed immunity to malaria that significantly modifies the clinical manifestations of the

disease. Heavy parasitemia may exist in children of school age without any symptoms. When symptoms do occur, they may be mild in severity, such as low-grade fevers, moderate degree of anemia, and hepatosplenomegaly.

Disease from *P. falciparum* is associated with higher degrees of parasitemia, as this species can infect all stages of erythrocytes, and is therefore associated with higher mortality, up to 30% in nonimmune infants. Disease caused by *P. vivax*, *P. ovale*, or *P. malariae* is typically less severe as these species generally result in <2% parasitemia. In addition, *P. vivax* and *P. ovale* can also result in recrudescence of symptoms months to even years later as they can remain as quiescent hypnozoites.

Human disease from *P. knowlesi* has only recently been described and mostly in adults in Southeast Asia. Most patients with disease from this species may present with a nonspecific febrile illness associated with thrombocytopenia, but approximately 10% can develop severe complications such as respiratory distress, renal failure, and hypotension. *P. knowlesi* has only a 24-h erythrocytic cycle, unlike the other known species to cause human disease which have longer cycles, which may explain the significant rates of severe disease that have been reported. Given that *P. knowlesi* appears nearly identical to *P. malariae* based on microscopic appearance, epidemiologic clues such as travel or residence in Southeast Asia, particularly near forested regions, are important in making the diagnosis.

Most of the severe complications of malaria result from infection with *P. falciparum*, given the potential for higher levels of parasitemia. Cerebral malaria is most common among children less than 5 years of age and can present with altered mental status, delirium, or even coma and carries a morality rate of up to 40%. Typically, children present with high fevers, seizures, and/or focal neurologic deficits. Cerebrospinal fluid analysis is generally unrevealing, but opening pressure is typically elevated. Despite the severe symptoms at presentation and high mortality, children who survive do not classically have residual neurologic deficits.

Hypoglycemia is another complication, which is associated with a poor prognosis in children with malaria, particularly in sub-Saharan Africa. Renal failure from malaria occurs as a result of several mechanisms, including decreased renal perfusion, acute tubular necrosis, hemoglobin deposition in tubules, or from antibody-mediated hemolysis. The latter results in a rare syndrome called blackwater fever, which is characterized by renal failure and severe hemolytic anemia. Other complications include thrombocytopenia, splenic rupture, pulmonary edema, and septic shock (algid malaria).

Diagnosis

The WHO recommends diagnostic testing of all cases of suspected malaria prior to treatment. This is a significant change from the prior recommendation to treat all febrile children in endemic areas for presumptive malaria. The new recommendations are in response to data from increased surveillance and testing, which revealed that other common causes of fever were not being diagnosed or treated.

The signs and symptoms of malaria in a child are nonspecific: fever, rigors, nausea, vomiting, headache, and listlessness, and as a result are not sufficient for diagnosis. A parasitological diagnosis should always be pursued if at all possible. In high resource, usually non-endemic, settings, the major barrier to diagnosis is considering malaria as a potential disease process. Once considered, however, testing for the presence of parasites should be pursued, often using a combination of technologies. For suspected cases, thick and thin blood smears should be sent in addition to blood cultures (to evaluate for other sources of fever), liver enzymes, complete blood count, blood urea nitrogen, and creatinine. Care must be given to not miss an alternative or concurrent infection, even when the clinical picture is consistent with malaria. This approach is also appropriate in low resource settings where the disease is seen much more commonly. Testing of suspect cases, preferably within 2 h of presentation, should be sought unless none are available. In the absence of a parasitological diagnosis, the clinician has to depend on the clinical exam and history, which, like all tests, depends on the prevalence of the test in the population. Where the risk of malaria is low, the diagnosis of malaria should meet stricter criteria (e.g., exposure, fever in last 3 days, signs of advanced illness, no other obvious disease processes such as rhinorrhea or measles). In higher prevalence settings, fever within the last 24 h and supporting findings, such as anemia or stiff neck, support the clinical diagnosis and indicate initiation of treatment. The WHO/UNICEF provides a guided approach to assist the Integrated Management of Childhood Illness (IMCI), a guide for the assessment and treatment of children 5 years of age and younger (http://www.who.int/child_adolescent_health/documents/IMCI_chartbooklet/en/index.html). It is critical to remember that other diseases, including other infections, can present in a manner similar to malaria in children. Continued testing and treatment for other disease are appropriate in the absence of a laboratory diagnosis. In non-endemic settings the diagnosis of malaria in children either emigrating from an endemic

area or returning from travel to such an area are likely underestimated. The infection might be missed on microscopy due to any number of issues, but most commonly is missed due to failure to consider the diagnosis.

Microscopy remains the gold standard for the diagnosis of malaria, but requires training and quality control (http://www.searo.who.int/LinkFiles/Malaria_malaria_microscopy_Learners_guide2010.pdf). Definitive diagnosis relies upon the *identification of the parasite on stained blood films.* For diagnosis, both thick and thin films of the blood should be prepared using a Romanovsky-type stain (most commonly Giemsa), with initially negative samples repeated every 12–24 h for a total of three samples, looking for parasite forms within erythrocytes. The concentrated, thick film allows for greater sensitivity, even with fairly low parasite density. Thin films are more useful for species identification and quantification. The percentage of infected red blood cells on a thin film can be used as a marker of illness severity and can contribute to species identification (e.g., *P. falciparum* is the only species able to infect up to 50% of erythrocytes). Alternatives to microscopy include molecular assays, serology, and immunochromatography. The utility of microscopy also has the potential to be improved with adjunctive techniques, such as the addition of fluorescent agents.

Given the challenges to the diagnosis of malaria, the use of rapid diagnostic tests (RDTs) is replacing microscopy, even in areas where the latter is available. The WHO currently lists over 40 different RDTs on its procurement list, with many undergoing large-scale testing of efficacy and effectiveness. These tests are antigen detection assays that use specific monoclonal antibodies to bind histidine-rich protein 2 (HRP-2, specific to *P. falciparum*), parasite lactate dehydrogenase (LDH, depending on antibody used can detect *P. falciparum* or mixed infections), or aldolase (used to determine non-*P. falciparum* infection versus mixed infection) in blood. LDH is only found with active infection, whereas HRP-2 can be found for weeks after effective treatment. This latter fact increases the false positivity rate. Whether to use an RDT or microscopy depends on many factors, including cost, availability of electricity, and technical support. RDTs are often more expensive, but offer the ability to test affected children in a much wider set of circumstances. With rapidly developing and spreading drug resistance, testing at the point of care has the potential to both improve treatment for the individual and prevent the increase of drug resistance in the community. Ultimately, the availability of microscopy or RDTs is usually made at a country or district level.

Molecular methods, including PCR and NAAT, are commonly used for a number of pathogens, but require high-level laboratory capabilities. Newer molecular assays, such as loop-mediated isothermal amplification (LAMP), exist that do not require temperature changes to amplify genes, overcoming a significant hurdle to use in very limited resource settings. Serological assays continue to have problems with cross-reactivity and can remain persistently positive long after primary infection. They remain useful for surveillance, but not necessarily for diagnosis of an acute infection.

Treatment

The primary goal of treatment of malaria is to avoid mortality. In the case of uncomplicated malaria, the goal is cure to prevent disease progression, whereas in severe malaria, the main goal is to maintain life. The widespread emergence of resistance, to all classes of antimalarials, has made treatment challenging. Another challenge in the pediatric population is the limited data about safety and proper dosing, particularly in children aged <12 months.

The WHO released new treatment guidelines in 2010 (*Table 101.1*), in response to increasing resistance and availability of newer drugs. The new strategy for treatment involves combination therapy with two or more antimalarials with different mechanisms of action to effectively treat malaria by overcoming resistance possibly present as well as preventing the development of resistance.

The approach to treatment of malaria is based on the severity of disease as well as suspected species. For uncomplicated malaria due to confirmed or suspected *P. falciparum*, which typically manifests as a febrile illness without organ dysfunction or hemodynamic instability, artemisinin-based combination therapy (ACT) is preferred. The benefits of ACTs include rapid clearance of parasitemia, leading to faster resolution of system, as well as reduction of gametocyte carriage, which can lead to decreased malaria transmission. Several ACT options are available, including artemether plus lumefantrine (pediatric formulation available), artesunate plus amodiaquine, artesunate plus mefloquine, artesunate plus sulfadoxine-pyrimethamine, and dihydroartemisinin plus piperaquine. Unfortunately, sufficient data about safety and dosing are lacking for any of the ACT options for children less than 5 kg.

Dosing is ideally based on body surface area but can also be weight-based. Given the lack of pediatric formulations readily available for most medications, adult tablets are often divided, which can lead to inaccurate dosing. For children unable to take oral medications due to nausea, the WHO does recommend a single dose of rectal

Table 101.1
WHO malaria treatment recommendations

Uncomplicated *P. falciparum* or species unknown malaria		
Preferred/first line	**Alternative options**	**Not recommended for use**
Artemether + lumefantrine (pediatric formulation available) OR Artesunate + amodiaquine OR Artesunate + mefloquine OR Artesunate + sulfadoxine-pyrimethamine OR Dihydroartemisinin + piperaquine	If child cannot take po and medical facility >6 h away, rectal artesunate (10 mg/kg) can be given Artesunate + (doxycyline or tetracycline or clindamycin) – should be reserved for treatment failures and only in the hospital setting	Tetracyclines should be avoided throughout infancy and in children <8 years of age Sulfadoxine-pyrimethamine should be avoided in first 2 weeks of life
Uncomplicated *P. vivax* or *P. ovale* malaria		
Chloroquine 10 mg/kg po, followed by 5 mg/kg at 6 h, 24 h, and 48 h (total dose 25 mg/kg) + primaquine 0.5 mg/kg po qday x 14 days *In areas of chloroquine-resistant P vivax* DHA-PPQ + primaquine		In patients with mild-to-moderate G6PD deficiency, primaquine dose should be reduced to 0.75 mg/kg once a week for 8 weeks. Primaquine should be avoided in patients with severe G6PD deficiency and in children < 4 years of age.
Uncomplicated *P. malariae* or *P. knowlesi* malaria		
Chloroquine 10 mg/kg po, followed by 5 mg/kg at 6 h, 24 h, and 48 h (total dose 25 mg/kg)		
Severe *P. falciparum* malaria		
Preferred/first line	**Alternative options**	**Comments**
Artesunate 2.4 mg/kg IV or IM on admission, then at 12h and 24h, then once a day OR Quinine 20 mg salt/kg IV infusion or divided IM infection on admission, then 10 mg/kg q8h	If child cannot take po and medical facility > 6 h away, rectal artesunate (10 mg/kg) can be given Artemether 3.2 mg/kg IM on admission, then 1.5 mg/kg qday (absorption is variable)	Parenteral therapy should be continued for at least 24 h and then consider changing to oral ACT regimen when clinically improved and able to take po

artesunate until the child can present to a medical facility for further care and appropriate treatment.

Treatment with ACTs has been shown to be generally well tolerated but severe nausea has been reported in children treated with mefloquine. Sulfadoxine-pyrimethamine can lead to neonatal hyperbilirubinemia and should be avoided for the first few weeks of life. Primaquine should also be avoided in the first month of life as well as in children with G6PD deficiency. Tetracyclines should be avoided by all children under 8 years of age due to its effects on bone development.

Treatment of uncomplicated *P. vivax* and *P. ovale* malaria is generally with chloroquine as these species remain susceptible to this drug in most areas of the world. In certain areas where chloroquine-resistant *P. vivax* exists, such as Indonesia, treatment with ACTs such as dihydroartemisinin plus piperaquine is recommended. Effective treatment of these species also requires treatment of the liver forms to prevent relapse of disease known as radical cure. Primaquine is the drug of choice for radical cure, but its use is limited to children greater than 4 years of age due to risk of hemolysis. Also,

primaquine is contraindicated in children with severe G6PD deficiency, and dose adjusted is recommended in children with mild to moderate G6PD deficiency.

The mainstay for the treatment of severe malaria had been quinine therapy, which is derived from the bark of the Cinchona tree. However, the availability of artemisinin-based therapies has changed the treatment paradigm for severe malaria. A systematic review of 12 trials comparing artemisinin derivatives and quinine in children with severe malaria found no difference in mortality or long-term morbidity. More recently, a large open-label, randomized trial of artesunate versus quinine in African children with severe malaria demonstrated that artesunate led to a significant reduction in mortality compared to standard quinine therapy. Artesunate was also shown to be well tolerated without serious adverse effects. These data were not available when the latest WHO guidelines were published. Unfortunately, parenteral artesunate is not readily available in many countries at this time. Treatment with parenteral chloroquine or sulfadoxine-pyrimethamine is no longer recommended due to significant resistance worldwide.

The effect of nutritional status on antimalarial absorption, distribution, metabolism, and elimination has been evaluated in mostly small studies, and studies are ongoing to determine the extent of this effect. In general, dose adjustment for protein-calorie malnutrition is not recommended.

In addition to antimalarial therapy, patients with severe malaria need intensive supportive care of symptoms and potential complications. Treatment with antipyretics for fever, glucose infusions for hypoglycemia, transfusions for anemia, and hemodialysis for renal failure may be necessary. In addition, children with altered mental status and seizures require airway management and anticonvulsant therapy.

Prevention

No single control strategy is sufficient to prevent malaria infection from occurring in individuals or populations. Conversely, combination approaches to prevention can have profound impacts on individual child and population morbidity and mortality.

Malaria remains a disease that disproportionally affects the poor, and poverty acts as a barrier to treatment and prevention. Most travelers do not avail themselves of appropriate malaria risk–reduction measures. This is especially true for children of immigrants returning to endemic areas to visit friends and family.

Tried and true basic advice continues to hold true. Children should wear loose clothing with long sleeves and pants. Exposed skin can be treated with N,N-diethyl-meta-toluamide (DEET) in concentrations not exceeding 35%. The choice of chemoprophylaxis should be a considered one made with a specialist in this area if possible. A growing number of drugs are available, tolerable and safe for use in the pediatric population. (*Table 101.2*)

Insecticide-treated bed nets (ITNs) and long-lasting insecticidal nets (LLINs) are a proven method of preventing childhood malaria and can last for between 6 months (ITNs) and 5 years (LLINs) depending on the handling and type of net. The materials used for these nets are usually impregnated with pyrethroids such as permethrin or deltamethrin, commonly used insecticides. Unfortunately, a growing number of *Anopheles* species are now resistant to this chemical. Nets also have been shown to act in a manner analogous to the herd immunity provided by vaccinations. When coverage with bed nets is high enough in a community (greater than 80%), even those without nets appear to benefit from some level of protection. In Eritrea, there was a significant drop in malaria cases following the distribution of free ITNs. For families and children traveling to at-risk regions, impregnated nets can be purchased before departing and used during the entire trip, especially if sleeping in non-air-conditioned spaces.

Indoor residual spraying (IRS) of insecticide is, according to WHO recommendations, the most effective method of quickly reducing mosquito density. Once applied, preferably to at least 80% of the premises, the residual spray appears to be effective for between 3 and 12 months depending on the chemical used. The only caveat is increasing resistance to the commonly used insecticides, such as DDT and the pyrethroids, especially in Africa.

There are two methods of intermittent preventative treatments (IPT) that affect the pediatric populations: IPT prenatal (IPTp) and IPT infant (IPTi). IPTp provides at least two doses of the antimalarial drug sulphadoxine-pyrimethamine (SP) at each scheduled antenatal visit after the first trimester. This intervention substantially reduces the risk of anemia and low birth weight. IPTi is an inexpensive and cost-effective intervention, costing between USD $0.13–$0.23 per child, and appears to be effective in reducing anemia and clinically apparent malaria in young children. In a study carried out in four African countries over 9 years, IPTi reduced malaria cases in infants by 30% and reduced all-cause hospital mortality. IPTi with SP is recommended in areas of moderate to high levels of transmission and low to moderate levels of parasite resistance.

Table 101.2
Prevention

Mediation	Restrictions	Common doses	Advantages	Disadvantages/ side effects	Resistance	Affected phase of the *plasmodium* life cycle
Chloroquine	All ages, all weights	5 mg/kg PO once per week, start 1–2 week prior to arrival and continue for 4 weeks after departing from endemic area	Inexpensive, weekly dosing	Resistance is common	Common	Erythrocytic
Doxycycline	>7 years, all weights	2 mg/kg PO daily (max 100 mg PO daily, starting 1–2 days before arrival and continuing for 4 weeks after departing endemic area)	Inexpensive	Age restriction, nausea, sun sensitivity, daily dosing		Erythrocytic
Atovaquone/ Proguanil	>10 kg	11–20 kg – 62.5 mg/25 mg PO daily 21–30 kg – 125 mg/50 PO daily 31–40 kg – 187.5 mg/75 mg PO daily >40 kg 250 mg/100 mg PO daily Start 1–2 days prior to arrival and continue for 7 days after departing	Shortest length of therapy, pediatric tablets available	Expensive, daily dosing		Exoerythrocytic, not including hypnozoites
Mefloquine	>3 months, >4 kg Seizure disorders Cardiac arrhythmias Psychiatric history	>3 months, 5–45 kg- 5 mg/kg PO once per week >45 kg – 250 mg PO once per week, start 1–2 weeks prior to arrival and for 4 weeks after departing	Weekly dosing	More nausea in children, neuropsychiatric effects	Border areas shared by Thailand, Myanmar and Cambodia	Erythrocytic
Primaquine	Normal G6PD status Rarely used, but best drug for prophylaxis in areas with predominantly *P vivax*	0.6 mg/kg PO daily × 14 days concurrent or following chloroquine treatment to prevent relapse	Inexpensive, prevents late relapses with *P ovale* and *P vivax* Daily dosing	Requires G6PD testing, daily dosing		Exoerythrocytic, including hypnozoites

An effective vaccine in the near future remains a possibility. Although correlates of immunity remain unknown, clinical immunity that improves with exposure time (age) appears to be commonplace and effective (unlike HIV). In vivo studies dating back to the 1960s documented high-level sterilizing protection (>90%) afforded by vaccination by irradiated sporozoites, indicating a role for the immune response prior to the clinically latent stage. Unfortunately, this method of vaccination has proven to be a technological barrier thus far, leading to an emphasis on vaccines that focus on other, later stages of infection. Currently, a large number of candidate vaccines

are currently being tested in humans (www.who.int/index.html) including one in phase III study in African children. Some level of protection can be achieved by passive transfer of hyperimmune immunoglobulin, implicating a role for antibodies in protection. There is likely a role for the innate immune system in early infection and T cells in clearance, but these responses have yet to be characterized. It is likely that any vaccine that goes into use will do so with an incomplete understanding of the immunology of malaria-host response.

102 Nocardiosis

Rana AlMaghrabi · Ibrahim Bin-Hussain

Introduction

Nocardia, also called as nocardiosis, is a bacterial infection which tends to strike the lungs, brain, and skin, particularly in people with an impaired immune system. Majority of the cases of nocardiosis involves lung infection, brain abscess, or disseminated disease from nocardia. The cases are localized to the skin and cause cellulitis or skin infection.

The most common symptoms with the pulmonary form of nocardiosis are fever, cough, and chest pain. The symptoms of brain nocardiosis are usually headache, lethargy, confusion, seizures, and sudden onset of neurologic problems.

Epidemiology

Nocardia species have been identified in house dust, garden soil, beach sand, and swimming pools. Pathogenic species usually arise from direct inoculation of the skin or by inhalation. Underlying pulmonary dysfunction with decreased bronchobiliary clearance mechanisms is predisposed to colonization. This is the most common nocardial infection reported from tropical regions of southern United States.

Incidence estimates vary in immunocompromised populations. In patients who undergo renal transplant, the incidence rate is 0.20%. In patients who undergo bone marrow transplant the incidence rate is 0.3% and that is marginally associated with increased mortality among long-term survivors of allergenic marrow transplantation. In patients with systemic lupus erythematosus, the incidence rate is 2.8%. Nocardiosis is an uncommon cause of morbidity in heart-lung transplant recipients.

The risk factors for nocardial infection in transplanted patients show that high-dose steroids, CMV disease, and high levels of calcineurin inhibitors are independent risk factors. Nocardia infections in patients with CGD are not usually fatal if treated properly, and prophylaxis with IFN-y and sulfonamide may protect against dissemination.

Pathogenesis

Inhalation of *Nocardia* spp. can lead to primary pulmonary disease. Disseminated infection occurs via haematogenous spread from respiratory tract, especially immunocompromised hosts. Primary cutaneous infections usually result from trauma with soil contamination of the wound keratitis, either posttraumatic or associated with lens use. Patients with deficient host defenses are at high risk of invasive nocardiosis. Chronic lung disease and alcoholism are additional risk factors for pulmonary nocardiosis.

Clinical Manifestations

Pulmonary Manifestations

The most common clinical manifestation of nocardiosis is pulmonary disease occurring in more than two-thirds of the cases. Almost 90% of cases are caused by members of the *N. asteroides* complex. Pulmonary infection can present through cough or dyspnea as a well as nonspecific symptoms such as anorexia and weight loss. Chest radiographic findings are variable which include bronchopneumonia, alveolar infiltrates, interstitial reticular infiltrates, and abscesses. Complications such as empyema, mediastinitis, and pericarditis can occur following contagious spread from lung, pleural, or cutaneous focus.

Superficial Infection and Mycetoma

Skin manifestation includes cellulites. Subcutaneous abscesses and mycetoma (a glaucomatous mass associated with nodules, sinuses, and granules) can occur from days to months after inoculation and typically located distally on the limbs.

Disseminated Disease

CNS involvement was recognized in more than 44% of the cases, the hallmark of CNS nocardiosis is formation of

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_102,

parenchymal abscess that can occur in any region of the brain. The disease frequently progresses over months to years and causes a broad range of neurologic deficits. The most commonly involved sites, other than pulmonary, CNS, and cutaneous, are bone, heart, eye, kidneys, joints, spleen, and liver.

Laboratory Diagnosis

A definitive diagnosis of nocardiosis requires the isolation and identification of the organism from a clinical specimen. Direct smear from the specimens typically show gram-positive, beaded fine right-angled branching filaments that are usually acid fast. Nocardia species will grow on most nonselective media; growth of *Nocardia* species may take 48 h to several weeks. It appears as either buff or pigmented, waxy cerebriform colonies.

PCR provides a more accurate and rapid molecular identification of *Nocardia* species than conventional methods. Clinical laboratory performance of susceptibility testing on *Nocardia* spp. has been standardized and micro-broth dilution methods are used.

Treatment

Sulfonamide is the treatment of choice for nocardiosis since the 1940s in conjunction with appropriate surgical drainage or excision of empyema or large abscesses. The efficacy of sulfonamides and TMP-SMX is maximal against *N. brasiliensis*, *N. nova*, and *N. transvalensis*, variable against *N. farcinica*, but poor against *N. otitidiscaviarum*. Combination therapy, with a carbapenem or third-generation cephalosporin with or without amikacin, is usually recommended for severely ill patients or for those with CNS involvement.

Minocycline has excellent activity in vitro against many strains and is considered a reliable alternative to the sulfonamide in adults. Amikacin and imipenem, followed by cefotaxime and ceftriaxone, are the most active parental agents against the largest percentage of nocardia isolates, although *N. farcinica* and *N. transvalences* are usually resistant to imipenem and the cephalosporins. Meropenem has been shown to be more active than imipenem in vitro against *N. otitidiscaviarum* and *N. brasiliensis*.

Amoxicillin-clavulanate is active against most strains of Nocardia with the exception of *N. nova*, *N. otitidiscaviarum*, and *N. transvalensis*, which are resistant to the medication. Linezolid appears to be an effective alternative for the treatment of nocardiosis.

Because there are no optimal recommendations for all nocardia and the increasing in vitro sulfa resistance is associated with worsening the patient's outcomes, physicians should use empirical combination therapy until susceptibility results are available.

Duration of therapy for nocardial infection depends on the site of infection and the immune status of the host. For primary cutaneous nocardiosis, a course of 6–12 weeks of sulfonamide therapy is appropriate. For individuals with isolated pulmonary disease, 6–12 months of therapy is preferred. Brain abscesses or meningitis require longer therapy with a duration of at least 12 months in most cases.

103 Schistosomiasis

Elizabeth M. Keating · Andrea P. Summer · Philip R. Fischer

Definition/Classification

Schistosomiasis is a chronic disease caused by parasites of the genus *Schistosoma*. More than 207 million individuals are infected with it worldwide, while 700 million are at risk of infection due to exposure from agricultural, domestic, and recreational activities. Symptomatology is variable and ranges from subclinical infection to severe disease with potentially fatal portal hypertension, urinary tract involvement, renal failure, and bladder cancer.

Hygiene and play habits make children especially susceptible to infection, so in endemic areas initial infection occurs most often during childhood. Schistosomiasis usually peaks in the teen years and most of the morbidity occurs in adults. However, symptomatic disease does develop in millions of children.

Etiology and Epidemiology

There is historical evidence of schistosomiasis occurrence as early as 2000 BCE. In fact, schistosoma eggs have been found in mummies from the 20th dynasty in ancient Egypt and ancient China. The etiology of schistosomiasis in humans was first discovered in 1851 by Theodore Bilharz who identified the parasitic cause of endemic hematuria to be *Schistosoma haematobium*. Consequently, clinical human disease caused by schistosomes was initially referred to as bilharziasis. During the same time period, the association between acute infection with schistosoma parasites and Katayama fever was recognized in Japan.

In the first decades of the twentieth century, the complete life cycle of the schistosoma parasite was identified. Until the development of effective curative medication in the 1970s, schistosomiasis was considered to be the "most dreadful of the remaining plagues of Egypt." Efforts to control this disease continue and eradication measures are still in the early stages of implementation.

Schistosomiasis is caused by helminths of the class Trematoda. Unlike other human flukes, schistosomes can invade through the skin and live in the vascular system. Additionally, they have separate male and female sexes. Humans are definitive hosts for five different species within the *Schistosoma* genus: *Schistosoma haematobium, Schistosoma japonicum, Schistosoma mansoni, Schistosoma mekongi, and Schistosoma intercalatum*. All of these species infect the intestinal vasculature except *S. haematobium,* which is the cause of urinary schistosomiasis. *S. japonicum* and *S. mansoni* have a global distribution, while *Schistosoma mekongi* and *Schistosoma intercalatum* are more restricted geographically. There are also avian species of schistosomes, but these are not able to penetrate fully through the human skin and thus cause a non-definitive pruritic rash, more commonly known as swimmer's itch.

Each of the aforementioned species uses freshwater snails as obligate intermediate hosts. The geographic distribution of each species is limited by the habitat of the snails. *S. japonicum* lives in *Oncomelania* snails, which inhabit moist soil along slow-flowing streams and irrigation canals limited to parts of China, the Philippines, and Indonesia. For its host, *S. haematobium* uses *Bulinus* snails that live in shaded, slow-flowing, shallow water primarily in tropical Africa, along the Nile River, and in the Middle East. The *Bulinus* snail is also a host to *S. intercalatum*, which occurs only in Cameroon and the Democratic Republic of the Congo. *S. mansoni,* on the other hand, inhabits *Biomphalaria* snails that live in shaded, slow-flowing, shallow water across tropical Africa, along the Atlantic Coast of South America, and on some Caribbean islands. The *Tricula* snail is the host for *S. mekongi*, and is limited to the Mekong River in Laos and Cambodia. In the United States, infection is seen only in immigrants and travelers from endemic regions. There is no transmission within the United States.

Most schistosomiasis infections in humans originate during childhood, when children come into direct contact with freshwater streams, rivers, or lakes that house infected snails. This contact occurs during everyday activities such as bathing, fishing, irrigating fields, or obtaining water for household use. Exposure to freshwater sources that harbor the parasite is greatest in boys aged 5–10 years. However, infection is seen in children of all ages and has been observed in infants as young as 6 months. In some African villages along Lake Victoria (shown to have heavy

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_103,

parasite loads), nearly half the children are infected with schistosomiasis within the first 7 years of life. The peak intensity of infection, which is measured by counting egg excretion, occurs in children as young as 8–12 years of age in heavily infected areas and in the teenage years in lightly infected areas. Males are more often infected because of their increased recreational exposure to water. After the adolescent years the incidence and intensity of egg excretion decreases, possibly due to hormonal changes during puberty that are associated with increased resistance to infection.

Pathogenesis and Pathology

Upon contact, the fork-tailed schistosomal cercariae penetrate the skin using secreted serine proteases (Fig. 103.1). Once they have penetrated, the cercariae lose their tails and modify their tegument to form the schistosomula stage. The schistosomulae then enter the bloodstream and travel to the lungs, where they exit the pulmonary arterial system and enter the venous circulation. From here, the schistosomulae travel through the systemic system until they reach the splanchnic vessels and gain access to the portal system.

Over a period of a few weeks, the parasites live in the portal system maturing and developing into male and female adults that mate persistently. Adult schistosoma worms can be from 1 to 3 cm long, and live for 3–7 years. As mentioned above, the Schistosoma species differ in the locations of the body that they infect. *S. haematobium* infects the venules of the urinary bladder, while *S. japonicum* and *S. mansoni* infect the mesenteric vessels (*S. japonicum* superior and *S. mansoni* inferior). Thus, the pregnant mature female parasites migrate up the bloodstream to lay eggs near either the bladder or the

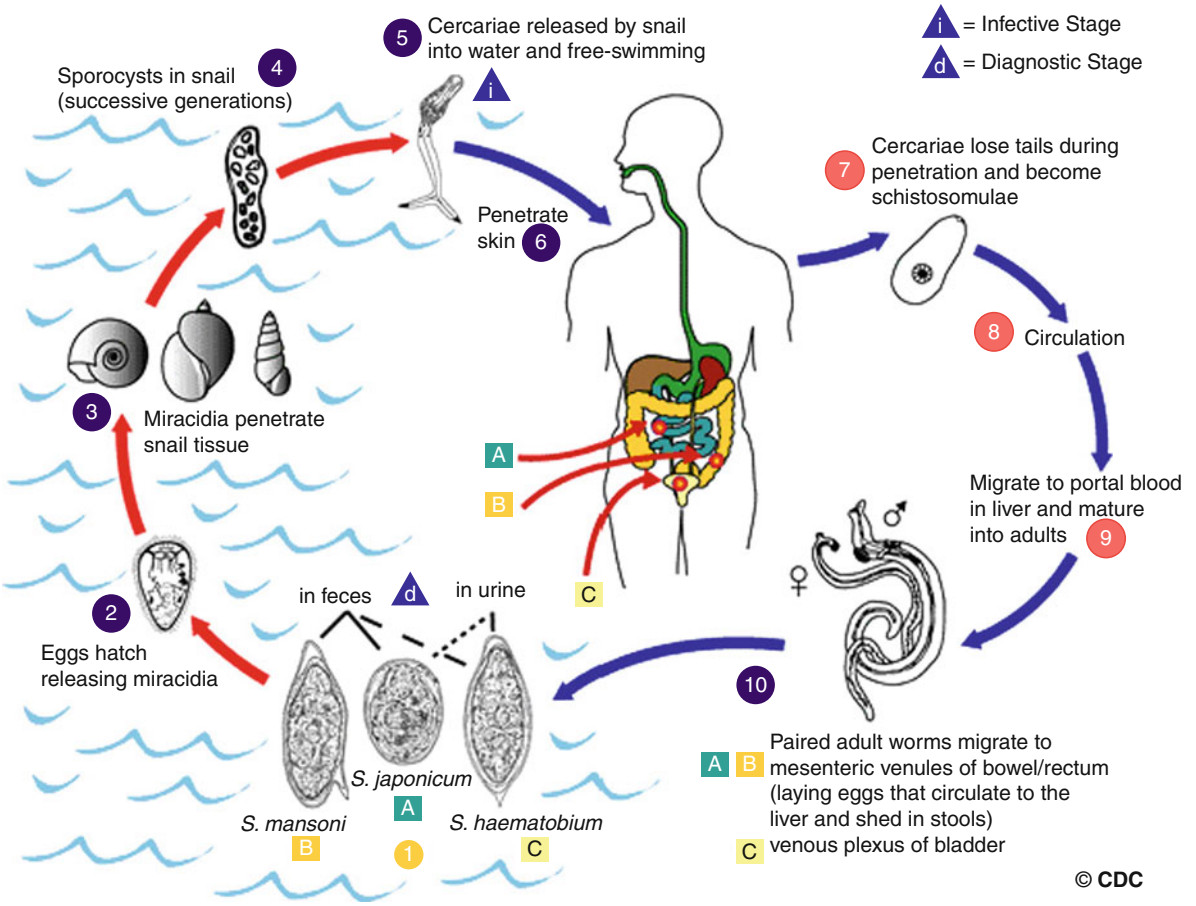

Figure 103.1
Life cycle of *Schistosoma* parasites

intestines, depending on the species. These females can lay up to hundreds of thousands of eggs per day.

Once they are laid, the parasitic eggs become embedded in the vessel walls causing reaction and disease. Additionally, some eggs can flow down the bloodstream and cause reactions at other sites. A localized granulomatous response allows the eggs to travel through the wall of the bladder (with *S. haematobium*) or the intestine (other *Schistosoma* species) and be released into the urine or stool. A week after being laid, the eggs mature and hatch, releasing miracidia. When released into freshwater sources, the miracidia are then able to reinfect their host snails to begin their life cycle once again. In the snails, they mature into hundreds of cercariae that can affect humans, and the cycle continues.

Initial Reaction

Within hours of penetration of the skin by the Schistosoma parasite, local erythema and inflammation may result from activation of parasite proteases. These papules are caused by infiltration of the dermis or epidermis with mononuclear cells and eosinophils, and is commonly referred to as swimmer's itch. Most often, swimmer's itch is associated with avian schistosomes, which are unable to penetrate fully through human skin into the circulation and consequently die in human tissue. If the person infected has been previously sensitized to the parasite, a delayed immune reaction can cause papular or vesicular lesions on the skin that may last for 7–10 days.

When the schistosomula initially infect the lungs from the bloodstream, they may migrate through unnoticed. If the person is heavily infected, fever, pneumonitis, pulmonary infiltrates, and eosinophilia may develop. However, these symptoms most often resolve with no intervention.

Acute Schistosomiasis (Katayama Fever)

Four to eight weeks after exposure, acute schistosomiasis may occur as the female parasites begin to produce eggs. This condition resembles serum sickness and is more often associated with *S. japonicum* infection than with *S. mansoni*, and rarely with *S. haematobium*. During acute schistosomiasis, patients have marked eosinophilia and immune complex deposition. This leads to the clinical manifestations of fever, myalgia, urticarial rash, and bloody diarrhea, which is commonly called Katayama fever. Severity of these clinical manifestations is determined by cercarial burden and the host immune response to parasite antigens. Pulmonary nodules and infiltrates may also be noted. In addition, acute infection can be complicated by ectopic egg production, and patients with acute *S. mansoni* or *S. haematobium* infection occasionally can have neurologic involvement. Interestingly, acute disease rarely occurs in endemic populations, possibly because the immune response is desensitized to parasite antigens from exposure in utero. In nonimmune travelers, on the other hand, acute disease is more common, with studies estimating rates of 39–100%.

Chronic Schistosomiasis

Chronic schistosomiasis is possible due to the evasion tactics of adult worms living in the bloodstream, which enable them to cause little host response. Their parasite surface incorporates blood group glycoproteins and downregulates expression of its own surface proteins, which may help them evade immune system attack. Chronic infection is caused by localized granulomata surrounding the parasite eggs. The granulomata form in order to protect the host from the injury caused by the egg antigens, which are cytotoxic to host cells. The granulomata also facilitate transfer of eggs into the stool and urine.

The two principal disease patterns observed in chronic schistosomiasis are gastrointestinal and urinary due to the egg-laying preferences of schistosome species. Other chronic manifestations may occur because of embolic egg deposition or heavy worm burdens.

When the egg count is high enough, eggs may stay in the venous vasculature and migrate back to the liver. Once here, granulomata form around the eggs and the liver becomes congested. This can eventually lead to hepatosplenic disease and portal hypertension.

In children with advanced hepatosplenic schistosomiasis and portal hypertension, eggs can bypass the liver and flow from the abdominal and pelvic veins in the small lung vessels. Localized granulomata form around the eggs lodged in the lungs, and after time children can develop fatigue, cough, and right-sided heart failure, cor pulmonale. Although medical therapy will stop the progression of cor pulmonale and decrease the ongoing inflammatory responses, right-heart failure is not fully reversible once it is established.

Urinary Schistosomiasis

Genital and urinary schistosomiasis is also the result of granuloma formation. Granulomata can form in the

ureters and bladder wall, blocking ureteral emptying and thus causing abnormal ureteral flow, dilatation, and hydronephrosis. Eventually, scarring and calcifications form and can be associated with chronic hydronephrosis, even with cured or light chronic infection. This chronic hydronephrosis and urinary stasis often predisposes patients to chronic bacteriuria and urinary tract infections. Other common complications in *S. haematobium* infection are glomerulonephritis from immune complex depositions in the patients' glomeruli, nephrotic syndrome, and amyloid deposition in the kidneys.

Squamous cell carcinoma of the bladder, although normally rare, is a common occurrence in areas of heavy infection with *S. haematobium*. It is thought that the prolonged irritation of the bladder epithelium by schistosome eggs and the resulting immune response triggers hyperplasia in the bladder and subsequent malignant disease.

Schistosomiasis in the Central Nervous System

The involvement of the central nervous system in schistosomiasis results in neurologic manifestations that are rare, yet often dramatic. Schistosomiasis worms do not always follow the usual routes described for urinary and intestinal schistosomiasis. Sometimes, worms migrate instead to the cerebral blood vessels and produce eggs there. This production can lead to seizures and headaches in children. On occasion, localized space-occupying inflammatory reactions that develop around the worms or eggs seem to result in optical field defects and dysarthria. Due to the space-occupying lesions, spinal fluid pressure may be elevated, and protein concentrations and lymphocyte counts in spinal fluid may both be increased. Cerebral schistosomiasis occurs more commonly with *S. japonicum* infection and is thought to develop in as many as 2% of children infected with this parasite.

S. mansoni infection and, even rarer, *S. haematobium* infection can produce eggs that embolize to the spinal cord. The eggs or associated granulomata can then cause transverse myelitis. Initially, paraplegia along with urinary and fecal incontinence are common problems in children with spinal schistosomiasis infection.

Clinical Manifestations

The main clinical manifestations of schistosomiasis vary greatly both with the stage of the life cycle and the species of parasite. Many patients are asymptomatic and can be identified during community screening programs in endemic areas, in immigrant or returned traveler evaluations in nonendemic areas, or when diagnostic tests such as urine or stool analysis are done to analyze other seemingly unrelated symptoms. Only a minority of children with heavy infections are likely to develop early symptoms, and these children are at greatest risk for major health complications.

Pruritus

After cercarial penetration through the skin, some children develop pruritus, or swimmer's itch. This response is more common in nonimmune travelers than in those indigenous residents of endemic areas. Additionally, the response is more pronounced upon repeated exposures. Pruritus occurs after contact with any human Schistosoma species, but more commonly results after contact with avian schistosomes. The rash that develops is erythematous and sometime papular, and usually disappears during a period of 2–10 days without scarring whether or not treatment is given.

Acute Schistosomiasis (Katayama Fever)

Acute schistosomiasis, on the other hand, is a more serious infection. It is sometimes referred to as Katayama fever, and begins 4–8 weeks after exposure upon egg production by the female worms. Clinical manifestations of acute schistosomiasis are high fever, chills, myalgia, headache, and general ill appearance. Additionally, urticarial rash and diffuse lymphadenopathy may be seen. In the lungs, cough, rales, and pulmonary infiltrates may be noticed, even without fever. Further, gastrointestinal symptoms of anorexia, abdominal pain, and loose stools may sometimes be noted. With heavy infections of *S. japonicum* and *S. mansoni,* which both infect the intestinal vasculature, bloody diarrhea can be seen acutely. In approximately 30% of children with Katayama fever, hepatomegaly and mild splenomegaly develop. A number of reports suggest that myelopathies are also a common partner to schistosomiasis. Genital symptoms and marked eosinophilia are also often seen with acute schistosomiasis.

Urinary Schistosomiasis

The classic finding of *S. haematobium* infection is painless hematuria. In fact, in some highly endemic areas, it is

considered abnormal for boys nearing puberty to *not* display this sign of "male menstruation." In urinary schistosomiasis, the hematuria results from the release of blood from irritated and inflamed areas about the granulomata in the bladder wall as the bladder contracts during micturition. Thus, there is typically "terminal hematuria," in which blood is most obvious at the end of the urine stream when bladder contraction is greatest. Although the hematuria is painless, it is sometimes accompanied by dysuria. In children who are either not treated or reinfected, chronic infection can develop and lead to obstructive uropathy. In fact, in community surveys completed in endemic areas, 40% of children were found to have significant renal or uretal abnormalities (often both). Hematuria and dysuria are found more often in children than adults, possibly due to the higher parasite loads in children. However, hydronephrosis is seen more often in adults, likely due to its chronic development.

Another complication that can develop as a result of urinary schistosomiasis is bacterial urinary tract infection. This complication is most likely secondary to urinary obstruction. The bacteriuria is sometimes caused by unusual urinary pathogens including Salmonella, which has been shown to cause recurrent Salmonella bacteremia. Chronic urinary infection can also lead to eventual renal failure. Additionally, obstructive uropathy can lead to a loss of renal function whether or not urinary tract infections are involved. Children with schistosomiasis can also have glomerulonephritis and nephrotic syndrome, and bladder cancer can occur in the context of untreated, heavy chronic urinary schistosomiasis.

Genital Schistosomiasis

Many studies have also identified the genital tract as an important site of schistosomiasis infection in both males and females. In women, granulomata can form around eggs in the cervix, uterus, or fallopian tubes. These granulomata can cause irritation, ulceration, vaginal bleeding, infertility, or ectopic pregnancy. Often, genital schistosomiasis is confused with cancer. In males, the prostate and seminal vesicles can become involved, especially in adolescent boys. Eggs were noted in the semen from 43% of men in an area endemic for *S. haematobium*. The main clinical finding of genital schistosomiasis is haematospermia, which may occur with either acute or chronic disease. In Africa, genital schistosomiasis may be an important cofactor in transmission of human immunodeficiency virus infection.

Intestinal Schistosomiasis

Most children with intestinal schistosomiasis do not present with intestinal symptoms. Thus, even finding eggs in the stool does not mean that symptoms are necessarily from a schistosomiasis infection. However, in some instances schistosomiasis can involve both the small and large intestines. Irritation of the bowel wall from inflammatory reactions induced by the eggs may cause diarrhea that can contain blood or mucus. Bowel wall granulomas can serve as the lead point for intussusceptions. Anorectal disease including abscesses and fistulas has also been described. Further, crampy abdominal pain and generalized malaise may occur. When endoscopy is performed, it can show granular inflammation with hyperemic areas, ulceration, hemorrhage, or polyps. Polyps can develop around the granulomata and can also be identified by contrast radiography. Protein-losing enteropathy and blood loss can cause malnutrition and iron deficiency, especially in cases with significant coexisting bowel disease. The role of schistosomiasis in malnutrition was illustrated by studies of mass chemotherapy, which resulted in improved nutrition and a lower prevalence of anemia.

Hepatosplenic Manifestations

Hepatosplenic disease can be caused by *S. japonicum* and *S. mansoni*, and can result in life-threatening complications. These complications are the result of eggs that stay in the venous vasculature and migrate back to the liver. The greatest predictor of hepatic involvement seems to be the total egg count, but some link with HLA type has been suggested.

Children with hepatosplenic disease that is compensated initially may show few symptoms, which may include anorexia, malaise, and abdominal fullness. These children exhibit hepatosplenomegaly even without significant portal hypertension. The enlarged liver is firm with fine nodules and either minimally tender or nontender. Splenic enlargement may be seen and can be massive. Liver function is affected only late in the course of hepatic schistosomiasis, so jaundice and liver enzyme elevations are unusual. As fibrosis develops over time around the eggs in the liver, portal hypertension occurs. Ascites develops slowly over a number of years, and the spleen may become very large. In the beginning stages of the disease, liver function usually remains sufficient. During the late adolescent and early adult years, however, worsening esophageal varices can cause death. Thus, bleeding

esophageal varices are a common cause of death in patients who had heavy schistosomiasis infections during childhood. Such individuals may come to medical attention due to the related symptoms of melena or hematemesis. Initial episodes are most often not serious, but with progressive liver decompensation variceal bleeding can be fatal. Additionally, children with severe hepatosplenic schistosomiasis often do not grow as well as other children.

Larval Pneumonitis

Occasionally, children have initial low-grade fever and cough as the schistosome larvae migrate through their lungs. This can occur with either an initial heavy infection, in which eggs will not yet be detectable, or in a heavy reinfection, when eggs will be detectable in urine or stool from the previous infection. This larval pneumonitis can be noted on lung examination as basilar rales and wheezing. Radiographic images may show basilar mottling in the lung fields. This condition usually resolves in 2–4 weeks, even without treatment. Similar symptoms also may be seen as a reactive pneumonitis when treatment of patients with heavy parasite burdens occurs.

Salmonellosis Coinfection

In endemic areas, some children have both salmonellosis and schistosomiasis at the same time. These children present with chronic low-grade fever, fatigue, malaise, and poor growth. Blood cultures frequently demonstrate *Salmonella* bacteremia, but stool does not always contain these bacteria. Some children have chronic *Salmonella* bacteriuria, yet despite the persistent bacterial infections are seldom affected with sepsis and mortality. Relapse of the *Salmonella* infection occurs commonly unless the coexisting schistosomiasis is treated. Bacteria apparently hide within the parasitic worms, evading host defenses since antibiotic penetration is poor within the worms.

Diagnosis

A clinical diagnosis of schistosomiasis should be given in the presence of the typical clinical findings and features. These features might be obvious, as with a painless hematuria in a child in a region endemic for *S. haematobium*, or less so, as with portal hypertension noted late in the second decade of life in an otherwise healthy adolescent from an area endemic for *S. mansoni* or *S. japonicum*. The other clinical findings described should also prompt the clinician to consider a diagnosis of schistosomiasis when the child has resided in or traveled through a *Schistosoma*-endemic area. In traveling children, the level of suspicion should be particularly high because patients may be asymptomatic or have atypical symptoms, they may not have a clear history of exposure to contaminated water, and parasitologic examination findings are often negative.

Reinfection is not typical outside endemic areas. Thus, a reasonable approach would be to test all children, including asymptomatic children, who have returned or emigrated from an endemic area where they had potential exposure to fresh water. This testing would involve all travelers who sat in, waded in, or even touched suspicious water, and it could involve immigrants who have spent time in endemic areas. Definitely, any child outside an endemic area who has even remote history of having had possible contact with cercariae along with clinical findings suggestive of any form of schistosomiasis should be tested. Testing is appropriate even at a later stage because even late therapy can have benefit to the course and outcome of schistosomiasis. In some highly endemic areas, diagnostic testing has limited feasibility or questionable reliability – or both – and curative medications are readily available. In these cases, establishing a proven diagnosis might not be completely necessary. For example, in a highly endemic setting, a simple urine paper strip test result positive for hematuria could provide sufficient suspicion of infection to justify administration of specific antischistosomal therapy. In populations with known high rates of infection, mass treatment without expensive diagnostic testing is reasonable and efficient.

In non-acute heavy infections, eggs can usually be found easily on microscopic examination of urine or stool. Urine samples collected between 10 am and 2 pm are more likely to be positive because this is when peak excretion of schistosome eggs tends to occur. For lighter infections, urine concentrating techniques may be necessary and useful. To do this, urine can be centrifuged and filtered to increase the yield of eggs. The result of a urine examination is most likely to be positive when urine is collected at midday and at the end of the urine stream. When infection is suspected and urine findings are negative, a bladder wall biopsy can be performed. The procedure is usually not necessary, however, because urine microscopy is usually positive, especially with concentrated or filtered samples. Additionally, in the instance of negative urine findings, multiple samples can be collected and examined to increase the egg yield.

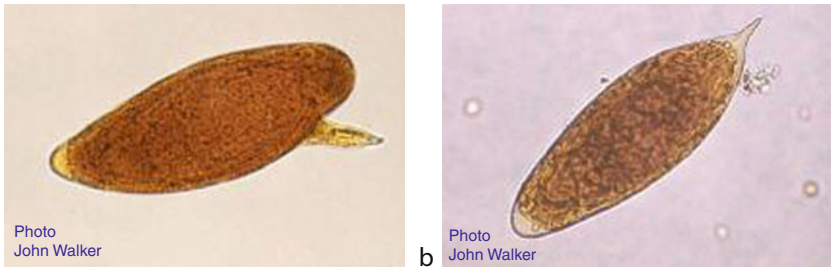

Figure 103.2
Eggs of *Schistosoma mansoni* and *S. haematobium*

Determination of the species of infection can be done by examining the yielded eggs microscopically. The eggs of *S. haematobium* and *S. mansoni* are approximately 90 mm in diameter, while the eggs of *S. japonicum* and *S. mekongi* are slightly smaller. As demonstrated in *Fig. 103.2*, identification of the specific species can be done by examining the spine, which is small for *S. japonicum* and *S. mekongi*, on only one end for *S. haematobium*, lateral for *S. mansoni*, and broad at each end for *S. intercalatum*. Additionally, plain radiographs of the bladder may show some calcification in the bladder wall around chronic granulomata. If cystoscopy is performed, it can reveal bladder wall hyperemia and consequent nodular lesions and fibrosis that give rise to "sandy patches" on the bladder wall. Granulomata can protrude from the bladder wall into the lumen and, along with edema, can cause obstruction of uretal orifices.

In light or acute infections, examination of urine or stool samples may not show eggs due to intermittent or low-volume shedding. Thus, negative stool or urine test results do not necessarily rule out schistosomiasis. When stools are repeatedly negative for ova, a rectal biopsy may be done. This can be performed by random punch biopsy, but the yield is increased when samples are taken from inflamed sites under direct visualization. Eggs are detected most often in unstained smears made by placing the tissue sample between a glass slide and a coverslip, but eggs can also be seen with standard histologic stains.

After successful treatment, nonviable eggs can be excreted for months or even years. With good medical treatment, eggs usually are inviable within a week of initiating therapy. However, with ineffective treatment or re-infection, viable eggs may continue to be passed. On microscopic examination, living ova contain transparent miracidia within the egg, which are often motile. To further prove their viability, the eggs may be hatched by placing them in freshwater exposed to light for 20 min. Afterward, observation with a hand lens can reveal swimming miracidia.

Since acute infections may occur before eggs are excreted or with eggs in ectopic locations, serologic tests may be needed for diagnosis since they are more sensitive and specific. For travelers with limited exposure and the likelihood of having either an acute or a limited chronic infection, serology is the principle diagnostic tool, even if it does not provide information about worm burden or clinical status. Delaying serology in asymptomatic but exposed individuals until 3 months after the exposures seems to be ideal to prevent pre-seroconversion false negative findings. Currently, the most common screening serologic test is the FAST-ELISA (the Falcon assay screening test-enzyme-linked immunosorbent assay) using *S. mansoni* adult worm microsomal antigen. It also cross-reacts with *S. haematobium* but is less sensitive for *S. japonicum* or *S. mekongi* infection. Species can be confirmed by the use of an immunoblot assay (enzyme-linked immunotransfer blot). This technique is also available for S. japonicum. Antigen-detection assays may be helpful, but they are not available in the United States.

A potential future option for diagnosis that, like serologic tests, does not rely on high egg yields is in vivo imaging using positron emission tomography (PET). This technique has been performed in mice and utilizes the *S. mansoni* species' high metabolic demand for glucose by measuring uptake of radiolabeled glucose with PET. Although still in the development states, in vivo imaging with PET based on animal data has been predicted to possibly better assess disease burden, improve the management of schistosomiasis, and enhance study of the parasite's biology.

The main imaging technique used in schistosomiasis is ultrasonography. This is because it is able to document involvement of the portal and urinary tracts and, in certain cases, can be diagnostic of schistosomiasis. Ultrasonography can identify bladder polyps, ureteral dilatation, hydronephrosis, and calcifications within the urinary tract. When possible, any child found to be infected with

S. haematobium should have an ultrasound evaluation of the urinary tract done. For older adolescents with persistent urinary symptoms such as dysuria, suprapubic pain, or hematuria despite having received good medical treatment, a cystoscopy could be considered to screen for bladder cancer. Other radiographs and tests of renal function and excretion are usually not performed unless the ultrasound evaluation shows significant urologic disease.

With hepatic involvement, portal ultrasonography is the imaging study of choice. The presence of periportal fibrosis with thickening of the portal tracts and vein walls correlates with parasite burden and hepatic disease. Experienced clinicians are able to distinguish schistosomiasis from cirrhosis and other chronic liver diseases.

Differential Diagnosis

Pruritis

When considering the pruritic rash that occurs upon schistosomal cercariae penetration, it is important to consider penetration by avian trematode cercariae, visceral leishmaniasis (kala-azar), and visceral larva migrans (toxocariasis and other common forms of dermatitis).

Acute Schistosomiasis

The differential diagnosis for acute schistosomiasis includes amebiasis, bacterial dysentery caused by Shigella or Salmonella, viral hepatitis, typhoid fever, malaria, fever of undetermined origin, or visceral larva migrans (toxocariasis).

Chronic Schistosomiasis

Chronic schistosomiasis, on the other hand, can present like visceral leishmaniasis (kala-azar), lymphoma, amebiasis, portal hypertension due to cirrhosis or portal vein thrombosis, tuberculosis, or trichinellosis infection. Additionally, chronic schistosomiasis can sometimes hide infection with *S. typhi* and is unrecognized until investigation is undertaken for recurrent typhoid fever.

Urinary Schistosomiasis

Schistosomiasis with urinary tract involvement presents with hematuria, which could also be due to a urinary tract infection, nephritis, or renal cell carcinoma.

Genital Schistosomiasis

Some types of genital schistosomiasis, such as *S. haematobium,* cause genital itch and vaginal discharge also common in irritant and infectious vulvovaginitis and with sexually transmitted diseases.

Intestinal Schistosomiasis

Since schistosomiasis in the intestine can present with diarrhea and abdominal discomfort, there is a large number of possible differential diagnoses for these symptoms. They include irritable bowel syndrome, Celiac disease, lactose intolerance, inflammatory bowel disease, chronic infections such as Whipple's Disease, or other parasitic infections.

Hepatosplenic Manifestations

The hepatosplenomegaly manifestations of schistosomiasis could also be due to Gaucher's disease, liver abscesses, or chronic heart failure causing hepatosplenomegaly.

Treatment

The optimal treatment of schistosomiasis depends on the stage of the disease. For the early stage of cercarial dermatitis, no antiparasitic treatment is necessary; it resolves on its own. However, oral antihistamine agents can be given for severe itching. When the human schistosomes gain access to the bloodstream and cause schistosomiasis infection, medical therapy has been shown to be effective and well tolerated without significant complications. Thus, there is no good medical reason to allow schistosomiasis to go untreated. However, the cost of treatment is a limiting factor in resource-poor areas of the world. If they can be obtained, several different medications can be considered to cure schistosomiasis.

The most effective agent against each of the five human schistosome species is praziquantel, a broad-spectrum oral anthelmintic agent. Praziquantel is a mixture of stereoisomers of pyrazinoisoquinoline ring structures, and is thought to unmask parasite antigens with subsequent killing by the host immune response. However, patients with acquired immunodeficiency syndrome respond well to praziquantel, raising questions about other concurrent mechanisms of action.

Praziquantel is given as full curative treatment in divided doses on a single day. For infection with *S. haematobium, S. mansoni,* and *S. intercalatum*, the dose is 40 mg/kg in two divided doses given on the same day. For infections with *S. japonicum* or *S. mekongi*, the dose is 60 mg/kg in three divided doses given the same day. Heavily infected children can sometimes experience nausea, vomiting, and abdominal cramping with praziquantel treatment. Rare side effects such as headache, pruritus, bloody stools, and fever are brief and resolve 1–2 days after treatment initiation. Since praziquantel mainly kills mature adult worms, a second course is recommended for the treatment of acute infection. Praziquantel has been shown to be effective in more than 90% of treated children. Unfortunately, some studies suggest that resistance may be emerging. However, these studies were performed in areas where there is frequent reinfection and high parasite burden, so the poor response may be due to the fact that young worm forms are not as susceptible to praziquantel. On the other hand, studies from nonendemic areas continue to demonstrate superb efficacy. In addition to curing schistosome infection, treatment with praziquantel has been linked with improved growth and a reduction in anemia. In endemic areas with high rates of infection, school-based and community-based treatment strategies without confirmatory diagnostic testing are effective, yet expensive. Due to this, cost issues raise concerns for program sustainability.

Oxamniquine, a tetrahydroquinoline compound, is an alternative treatment effective only against *S. mansoni.* Like praziquantel, the mechanism of this agent is unknown. The effective dose varies with the geographic origin of the schistosomal infection, and some resistance has been reported. Current recommendations are that children treated with oxamniquine be given 40–60 mg/kg divided into two doses administered on 1 day or four doses given over 2 days. Treatment can result in mild side effects including nausea, headache, and fever. Seizures are a rare side effect of treatment with oxamniquine, so children with seizure disorders should not receive this medication. Cure rates of more than 90% have been reported with oxamniquine.

Another treatment option is metrifonate, an organophosphate compound that causes paralysis of the schistosome parasite. It has been shown to be 70–80% effective against *S. haematobium* when it is used at a dose of 10 mg/kg orally once every 2 weeks for a total of 6 weeks. It decreases the child's own plasma and erythrocyte cholinesterase activity, yet actual cholinergic symptoms seldom occur. This medication is less expensive than the other two options mentioned, but it generally is not used when praziquantel is available.

When treatment is given, there is clear improvement in the patient's disease burden. In fact, even established uropathy and portal hypertension are often reversible. Surgical procedures usually are only done in children with complications related to long-term infection, such as persistent portal hypertension. Propranolol prophylaxis and sclerotherapy or banding can reduce rebleeding from esophageal varices. In addition, some cases require surgical decompression of portal hypertension. One way to do this is by using a splenorenal shunt, but these are associated with high rates of hepatic encephalopathy. However, comparative studies suggest that as long as a clinician is experienced enough, esophagogastric devascularization with splenectomy is the procedure of choice.

In severely ill children with Katayama fever or severe larval pneumonitis, systemic steroids may be useful. They may also be helpful in cases with granulomata in the central nervous system. However, corticosteroids have not been proven effective treatments in other forms of the disease, and thus should be restricted to use in patient with systemic complications of acute schistosomiasis.

Prognosis

Early medical treatment is most often effective for children with schistosomiasis infection, even with advanced disease. Thus, children with schistosomiasis have an excellent chance for full recovery. Recent studies have shown cure rates for children treated for schistosomias infection ranging from 70% to 100%. The remaining children who were not cured often showed persistent infection. This persistent infection is likely due to reinfection since it is common in endemic areas. Factors that affect prognosis are severity of schistosomiasis disease and the presence of comorbidities, which are fortunately not as common in children.

Prevention

The first step to prevention is limiting the risk of initial cercarial penetration. This can be done by applying *N*, *N*-Diethyl-meta-toluamide (DEET) to the skin when it is available. However, it is not always available in endemic countries.

Additionally, prevention can include travelers and emigrants in endemic areas limiting exposure to infectious fresh water. While in an endemic area, these people should avoid swimming in freshwater streams and lakes. Additionally, the cercaria can be eliminated by chlorination

or by allowing water to settle for 24 h before using it to bathe or wash.

The use of effective medical therapy combined with improved urine and stool hygiene has the potential to eradicate schistosomiasis from endemic areas. Elimination of the snails that serve as intermediate hosts would also be effective, but implementation of such elimination programs has been unsuccessful to date. In the past, national control programs in China focusing on snail control, sanitation, and improved water supplies have led to sustained reductions in infection rates, even apart from the influence of chemotherapy. For specific endemic populations, health education can lead to significant beneficial changes in knowledge about the illness, water-exposure activities, and reinfection rates in school-age children. In recent years, control efforts have focused on mass chemotherapy, with particular emphasis on school-based therapy. Treatment programs in which the entire school-age population is treated, typically with praziquantel, have resulted in an overall improvement in the levels of nutrition and in reducing the prevalence of anemia. However, in areas where reinfection occurs often, the effects of mass treatment programs are of limited duration, and treatment must be repeated every 6 months to a year. Sustainability of national control programs and of favorable outcomes thus remains challenging in Africa.

Artemisinin derivatives can prevent development of infection and decrease the worm burden in those exposed to both *S. mansoni* and *S. japonicum*. They are less effective for chemotherapy than praziquantel, however, probably because antiparasitic activity is limited to the juvenile forms of the parasite. Further, the public health role of chemoprophylaxis in preventing infection has not been established.

Prevention of experimental schistosomiasis can be achieved via immunization of experimental animals with irradiated cercariae. Thus, development of a vaccine to prevent humans against schistosomiasis is theoretically possible. Several potentially protective antigens have been identified on schistosomes, and they are being used as targets for vaccine development. However, the associates of protective immunity in humans are not well defined. Currently, vaccines using combinations of antigens are being studied for *S. mansoni*. Early stage clinical trials have been performed for *S. haematobium* glutathione S-transferase-containing vaccines. Very recently, the genomes of *S. mansoni* and *S. japonicum* were published, taking the world a step closer to the identification of key protective molecules and the development and implementation of effective anti-schistosome vaccines. Indeed, numerous proteins that play a role in *S. japonicum* parasite development and pathogenesis have been identified as possible new drug targets or vaccine candidates. It is uncertain whether development of a vaccine to prevent schistosomiasis infection in humans is a real possibility, and it is unlikely that any vaccine will be ready for clinical use in the very near future.

The best options for schistosomiasis control are multifaceted, integrated control programs that incorporate praziquantel treatment with transmission reduction through additional control measures such as the use of molluscicides, environmental modification, health education, and improved sanitation. Continued various avenues of schistosomiasis research should include vaccine development and the search for alternative drugs to praziquantel, because resistance against the drug in the future cannot be ruled out. Even if only partially effective, anti-schistosome vaccines that are incorporated as part of an integrated control strategy will be needed to hasten efforts to eliminate a disease that has existed for thousands of years. This combined-approach model has the potential to improve the health of a billion of the world's poorest people and its effect cannot and should not be underestimated.

104 Hemorrhagic Fevers Including Dengue Fever

Richard J. Whitley

Introduction

Viral hemorrhagic fevers (VHFs) refer to a group of illnesses that are caused by one of four distinct families of viruses. The phrase viral hemorrhagic fever descriptively defines the clinical findings in patients who suffer from these illnesses. Generally, the integrity of the vascular system is compromised, resulting in hemorrhage and, potentially, life-threatening disease. These agents are broadly distributed across the globe.

Etiology

Viral hemorrhagic fevers are caused by four families of viruses: arenaviruses, filoviruses, bunyaviruses, and flaviviruses. Each of these viruses is zoonotic, being totally dependent upon an animal reservoir or arthropod vector for replication. Rodents and arthropods are, for the most part, the main reservoirs for viruses that cause VHFs.

All members of these four viral families are RNA viruses that have a lipid envelope. Because they are zoonotic, these viruses are restricted to the host range. Each of these four families will be considered separately.

Arenaviruses

Old World arenaviruses including lassa virus, the cause of lassa fever, a disease that occurs in West Africa, and lymphocytic choriomeningitis virus, cause less severe infections than the major New World arenavirus hemorrhagic fevers. Argentine hemorrhagic fever is caused by junin virus, Bolivian hemorrhagic fever is the consequence of machupo virus, and Venezuelan hemorrhagic fever is the consequence of guanarito virus. The first arenavirus isolated was lymphocytic choriomeningitis virus in 1933. Of note, new arenaviruses are identified at regular intervals.

The virus particles are spherical with an average diameter of 110–130 nm. Their name is derived from Latin which means "sandy."

Epidemiology and Pathogenesis

Arenaviruses are maintained in nature in rodent hosts in which chronic viremia persists. Infection of humans is the consequence of inhalation or contact of virus with mucus membranes and abraded skin. All arenaviruses can be transmitted by an airborne route. Of these agents, Argentine hemorrhagic fever was the most common, accounting for a few hundred cases annually, until a vaccine was developed. Disease caused by the remainder of this family of viruses is sporadic.

Clinical Manifestations

Following an incubation period of 6–17 days, illness can range from a mild, acute febrile infection to severe, life-threatening illness associated with multiorgan dysfunction and a bleeding diathesis. With all infections, fever, myalgia, headache, abdominal pain, and bleeding, particularly of the conjunctiva, are all common.

Diagnosis of Arenavirus Infections

Currently the standard diagnostic approach is the detection of virus-specific antibodies directed against either IgM or IgG. In addition, polymerase chain reaction will detect evidence of viral RNA. Virus can be recovered from the blood and transmitted to uninfected individuals. Thus, tissues and body fluids obtained from patients suspected to have an arenavirus infection should only be evaluated in Biosafety Level IV conditions.

Treatment of Arenavirus Infections

Intravenous ribavirin has been reported to decrease mortality in patients with severe lassa fever. However, no data are available regarding its use in the treatment of other

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_104,

arenavirus hemorrhagic fever infections. The role of immune globulin in preventing hemorrhagic fevers of arenavirus etiology is unclear.

Other Considerations

Patients with suspect arenavirus infections should be managed in an isolation room with careful attention to infection control procedures. A negative pressure room is recommended for these individuals. For Argentine hemorrhagic fever, a vaccine is available in South America, but is not licensed in North America. Zoonotic control, particularly reduction of the rodent community, has contributed significantly to the reduction of Argentine hemorrhagic fever and Venezuelan hemorrhagic fever.

Bunyaviridae Hemorrhagic Fevers

Etiology

Three syndromes are associated with bunyavirus infections: hemorrhagic fever with renal syndrome (HFRS), Crimean-Congo hemorrhagic fever (CCHF), and Rift Valley fever (RVF). HFRS is caused by hantaviruses and includes Korean hemorrhagic fever, epidemic hemorrhagic fever, and nephropathia epidemica. Crimean-Congo hemorrhagic fever is caused by a tick-borne nairovirus, a member of the *Bunyaviridae* family. Rift Valley fever is attributed to phlebovirus.

Epidemiology and Pathogenesis

All of the viruses that cause viral hemorrhagic fevers are associated with arthropod vectors except hantaviruses, which are associated with exposure to infected rodents. Hemorrhagic fever with renal syndrome accounts for approximately 100,000 cases annually in Asia and throughout Eastern and Western Europe. The incubation period ranges from 7 to 42 days. The vector for HFRS is the aedes mosquito.

Crimean-Congo hemorrhagic fever occurs through much of sub-Saharan Africa, the Middle East, Western and Central Asia, and the Balkans. It is transmitted by *Hyalomma* ticks. The incubation period ranges from 2 to 10 days.

Rift Valley fever occurs throughout sub-Saharan Africa and has caused epidemics in the Middle East, particularly Egypt, Saudi Arabia, Yemen, and Kenya. The virus is arthropod-borne and is transmitted from livestock to humans by mosquitos. It can also be transmitted by aerosol. Again, the incubation period is 2–10 days.

Clinical Manifestations

All three of these diseases are severe febrile illnesses that are associated with shock and bleeding. Multiple organs are usually involved. Of these three syndromes, HFRS and CCHF are the most severe as both involve vascular instability and varying degrees of renal insufficiency, accompanied by bleeding and fever. Additional findings include headache, myalgia, and hypotension. HFRS is associated with oliguria and renal insufficiency. Rift Valley fever is usually self-limited.

Diagnosis

While CCHF and RVF viruses are readily culturable from tissue and body fluids, working with such materials requires Biosafety Level 4 laboratories. Alternatively, enzyme immunoassays will detect viral antigen in blood and other body fluids. In addition, serum IgM and IgG virus-specific antibodies develop with convalescence and can be a useful retrospective diagnostic test. On the other hand, infections caused by HFRS are associated with the rapid clearance of virus, requiring the use of serologic assays for confirmation.

Treatment

There are reports that HFRS can be successfully treated with ribavirin. However, supportive care for all of these clinical illnesses is required, usually requiring management at a tertiary care facility in an intensive care unit.

Filoviruses

Introduction

Among the filoviruses, only Marburg virus and Ebola virus have been found to infect humans. Four species of Ebola virus have been identified and named according to the area of isolation, namely, Ivory Coast, Sudan, Zaire,

and Reston. Of these four viruses, Ebola-Reston does not cause severe disease in humans. These viruses exhibit pleomorphism upon replication, as characterized by both long and short filaments.

Etiology

Marburg hemorrhagic fever is a rare hemorrhagic fever that affects both humans and nonhuman primates. This virus was first isolated in 1967 when outbreaks occurred simultaneously in laboratories in Marburg and Frankfurt, Germany and in Yugoslavia. The most recent severe outbreaks occurred in the Democratic Republic of Congo (1998–2000), accounting for 154 cases with a mortality of 83%. Subsequently, in 2004–2005, an additional outbreak occurred in Angola, accounting for 252 cases with 227 deaths. Since then, cases have been sporadic.

Ebola virus was first identified in the mid-1970s when two outbreaks occurred in the current Democratic Republic of Congo and southern Sudan. The mortality of both outbreaks was exceedingly high. Since the mid-1970s, Ebola virus has appeared sporadically in Africa; however, large epidemics have occurred in Zaire and Uganda.

In the twenty-first century there have been ten outbreaks of Ebola, six of which have been attributed to Ebola-Zaire and two to Ebola-Reston. For the former strain, mortality has consistently exceeded 75% while with the latter strain, mortality remains about 50%.

Epidemiology and Pathogenesis

Transmission of Marburg virus to humans is unknown. Nevertheless, individuals with Marburg hemorrhagic fever can transmit infection to other humans. Similarly, persons who have handled infected monkeys have become infected. The natural reservoir of Ebola virus remains unknown. Thus, the mechanism by which humans become infected is also unknown. Nevertheless, people exposed to infected individuals and their bodily fluids can become infected. There has been documented spread of Ebola virus within the health care setting.

The incubation for Marburg virus hemorrhagic fever is approximately 5–10 days and disease is marked by the sudden onset of fever, chills, headache, and myalgia. A maculopapular rash involving the trunk appears approximately 5 days into the course of illness. As the disease progresses, multiorgan dysfunction becomes apparent.

In contrast, Ebola infection has an incubation period that appears to be longer, ranging from 2 to 21 days. The onset of illness is abrupt and characterized by fever, headache, myalgia, and weakness. A bleeding diathesis may occur.

Diagnosis

Specific laboratory diagnostic tests for Ebola and Marburg viruses include virus-specific antigen capture enzyme-linked immunosorbent assays (ELISA), and polymerase chain reaction detection of viral RNA. The detection of both IgM and IgG antibodies has been useful for both infections.

Treatment

There is no treatment for either Marburg virus or Ebola virus infections. The standard of care is supportive management.

Dengue

Introduction

There are four closely related dengue viruses, identified as dengue-1, dengue-2, dengue-3, and dengue-4. These viruses are transmitted to humans by the bite of infected mosquitoes. The dengue virus is a member of the *flavivirus* family and is considered an arbovirus since transmission occurs through a mosquito vector. The arthropod vector for transmission of virus to humans is most frequently by *Aedes aegypti.*

Epidemiology and Pathogenesis

Dengue viruses are transmitted by either *Aedes aegypti* or *Aedes albopictus.* The incubation period is usually 4–7 days and disease persists for 3–10 days. Dengue is endemic in many parts of the world, particularly in tropical and subtropical regions, especially during the rainy season when mosquitoes are breeding.

Approximately 40% of the world's population resides in areas at risk for dengue transmission. Dengue is endemic in at least 100 countries, causing between fifty and one hundred million infections annually. Dengue hemorrhagic fever accounts for approximately 500,000 cases. The mortality of dengue in children is approximately 22,000 deaths globally. Recently, dengue has been

detected in the continental USA. This is not surprising since *Aedes aegypti* is detected in these areas of the USA.

Clinical Manifestations

Dengue fever is characterized by what has been described as "bone-crushing" pain, rash, ocular pain, joint pain and mucosal bleeding. As noted above, the duration of disease is approximately 5–7 days. As illness ebbs, the patient is more likely to develop a capillary leak syndrome with bleeding diathesis, accounting for the hemorrhagic nature of the disease.

Diagnosis

The utilization of EIA-specific antibodies or polymerase chain reaction can be used to detect evidence of dengue virus.

Of note, infection with one dengue virus does not provide protection against the other three dengue virus strains. In fact, with infection caused by an additional strain, illness is reported to be more severe.

Treatment

Treatment is supportive. There is no specific therapy for dengue virus hemorrhagic fever.

Avoiding exposure to mosquitoes or the use of mosquito repellents in dengue virus endemic areas is of importance. In addition, the use of mosquito nets decreases the risk of acquisition of infection.

105 Hepatitis Viruses A Through G

Daniel P. Mallon

The Hepatitis viruses A, B, C, delta (D), E, and G comprise a group of viruses that infect humans and display hepatic tropism. Each virus has an individual disease profile ranging from asymptomatic, to self-resolving acute infection, to chronic infection and, in some cases, liver failure and death. The burden that viral hepatitis places on individuals and communities is great, and the worthwhile work of developing new therapies and prevention strategies to mitigate that burden is ongoing.

Hepatitis A

Definition/Classification

Hepatitis A virus is one of two primarily water-borne hepatitis viruses. It is a single-stranded ribonucleic acid (RNA), non-enveloped virus in the Picornaviridae family, which can withstand harsh extracorporeal environments. The hearty virus can withstand heat and common solvents, but is inactivated by autoclaving, UV radiation, chlorine, and concentrated formalin.

Pathogenesis

The virus is usually spread via a fecal–oral route through contaminated water and food. Once ingested, it infects and replicates in the oropharynx and small bowel epithelial cells. From here, the virus then enters the blood, resulting in transient viremia, before it infects the liver. There the virus elicits an inflammatory response that leads to hepatocellular necrosis. Occasionally, the virus is spread parenterally, owing to the transient viremia.

Epidemiology

Hepatitis A is ubiquitous around the world, but its prevalence varies widely, with seroprevalence of anti-HAV antibodies ranging from 15% to 100%. Low-income countries have the highest incidence and prevalence, whereas high-income countries and countries with better access to clean water have low prevalence. In addition to varying levels of endemicity throughout the world, Hepatitis A also commonly occurs in sporadic outbreaks.

In highly endemic areas, nearly all young children are exposed in early childhood and gain immunity, resulting in low rates of infection in older children and adults. In areas of low or intermediate endemicity, there is little immunity in older children and adults, except where vaccination programs are in place. For example, the virus is common in the United States, but yearly incidence has been declining steadily in the past 15 years, especially in Western states, Alaska Native and Native American populations, which were areas of intermediate endemicity in which routine vaccination was instituted. These populations, the incidence has fallen from over 25 cases/100,000 to about <5 cases/100,000, which matches the rest of the country.

Pathology

Histologic changes are consistent with acute inflammation of the liver parenchyma and include hepatocellular necrosis and regeneration, leukocyte invasion of the parenchyma and portal tracts, and proliferation of bile ducts and Kupffer cells. However, obtaining a biopsy is rarely indicated in the management of patients with Hepatitis A.

Clinical Manifestations

Clinical disease manifests in phases (*Fig. 105.1*). After exposure, the incubation period lasts 28 days on average. As with the other hepatitis virus disease courses, there is a prodromal phase that can include nausea, vomiting, malaise, abdominal pain, and fever. Many patients, especially young children in highly endemic areas, may be completely asymptomatic or have only the above nonspecific viral symptoms. About 10% of children under 6 years of age enter a 1–2 week icteric phase, during which they exhibit jaundice and often have tender hepatomegaly. Most patients then enter a convalescent phase during which their clinical symptoms and signs improve

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_105,

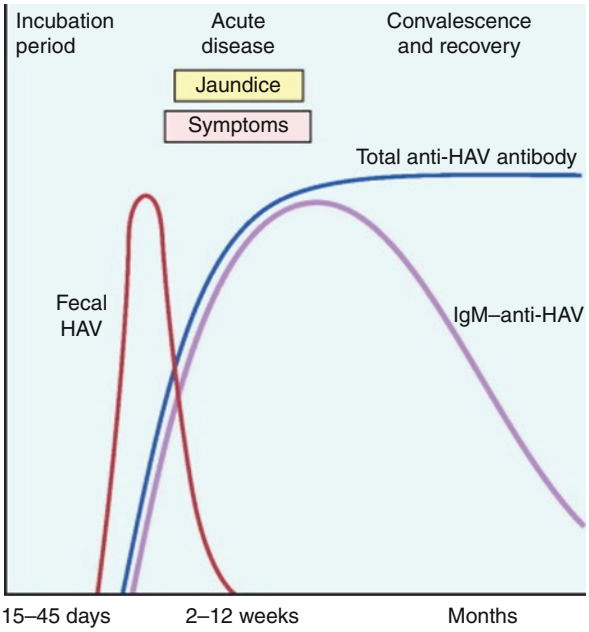

Figure 105.1
Serology and clinical manifestations of hepatitis A infection. *HAV* hepatitis A virus (Adapted from Crawford J, Liu C (2010) Liver and biliary tract. In: Kumar V et al (eds) Robbins and Cotran pathologic basis of disease, 8th edn. Saunders Elsevier, Philadelphia)

and resolve over 2–4 weeks. Occasionally, the acute signs and symptoms can abate and relapse over several weeks. Rarely (0.2% of icteric patients), they develop acute liver failure, and some progress to coma or death. The US mortality rate from Hepatitis A in children less than 14 years is 0.1%, while in adults it is 1.1%.

Diagnosis

Diagnosis begins with recognition of clinical signs of intestinal and hepatic disease and is aided by the measurement of markers of liver damage. Hepatic transaminases, alanine aminotransferase (ALT) and aspartate aminotransferase (AST) become markedly elevated up to 10–100-fold as a result of hepatocellular damage. They peak 3–10 days after the onset of clinical symptoms and can remain abnormal for 2–4 weeks. Hyperbilirubinemia and bilirubinuria is also seen in patients who become icteric.

Anti-HAV antibodies confirm exposure to the virus, with anti-HAV IgM confirming recent infection in symptomatic patients and IgG confirming exposure in the more remote past. Anti-HAV IgG persists and confers lifelong protection. Testing a patient's stool for HAV virus in culture or genetic material is often of little use because the virus is so common.

Differential Diagnosis

The symptoms and signs of the prodromal phase of infection are nonspecific and can be similar to those seen in acute viral gastroenteritis, bacterial or parasitic gastritis or enteritis, pancreatitis, abdominal trauma, ischemic bowel disease, intussusception, or small bowel obstruction. Hepatitis may be caused by other viruses like Epstein-Barr virus, herpes viruses, adenovirus, enterovirus, parvovirus B19, Lassa fever, Dengue, and Yellow Fever viruses. Similar symptoms and signs are also seen in bacterial, parasitic or fungal hepatitis or liver abscess, as well as biliary disease including cholangitis, cholecystitis, and cholelithiasis.

Therapy

Specific therapy against hepatitis A viral infection is not usually necessary, and treatment is supportive to prevent dehydration, malnutrition, and spread of disease. In the case of acute hepatic failure, more aggressive supportive therapy is necessary and may include parenteral nutrition, fluid management, repletion of coagulation factors, medical management of increased intracranial pressure, endotracheal intubation and mechanical ventilation, and sometimes liver transplantation.

Prevention

For areas of high endemicity, where almost all children are exposed to the virus, primary prevention aims at improved water sanitation, but immunoprophylaxis with vaccines is too costly to be recommended. In areas of intermediate endemicity, the World Health Organization (WHO) recommends consideration of large-scale vaccination programs with the caveat that cost-benefit calculations should consider the relative benefits of vaccination against other diseases like Haemophilus influenza or pneumococcal disease. In areas of low endemicity, the WHO recommends vaccination for high-risk groups such as intravenous drug users, men who have sex with men (MSM), certain ethnic groups and travelers to intermediate or high endemic areas. In the United States, the

Advisory Council for Immunization Practices and Centers for Disease Control and Prevention (CDC) currently recommend routine vaccination for all children ≥12 months of age, MSM, persons who are at risk of occupational exposure, use illicit drugs, have chronic liver disease or receive regular administration of clotting factors, and those traveling to endemic areas.

There are four commercially available vaccines, all of which are highly immunogenic and effective. Some are available as two-dose regimens given 6–18 months apart, and one that is a combination vaccine with recombinant Hepatitis B vaccine is given in a three-dose regimen on a 0, 1, and 6 months schedule. Exact recommended schedules vary by manufacturer; none are licensed for infants younger than 1 year of age.

Postexposure prophylaxis (PEP) in areas of low or intermediate endemicity can be given to certain individuals with possible HAV exposure to prevent symptoms and spread of the virus. Household and sexual contacts of any index case and regular caretakers of children with confirmed HAV infection should be considered for PEP. If an index case is a child who attends a day care where children wear diapers, staff, other attendees, and household contacts of attendees should also receive PEP. The Centers for Disease control and the UK Health Protection Agency suggest similar algorithms regarding who to treat and what agent(s) to choose. In general, monovalent anti-HAV vaccine is sufficient PEP for children and adults 12 months to 40–50 years of age. Anti-HAV immune globulin should be given to infants <12 months, adults over 40 years, and anyone who is immunocompromised, has chronic liver disease, or is allergic to the vaccine. Special consideration is given when the index case or exposed individual is a food handler, and those organizations offer detailed recommendations.

Hepatitis B

Definition

Hepatitis B virus (HBV) is a virus in the Hepadnaviridae family whose virion is small, only 42 nm in diameter, and consists of an envelope that includes the Hepatitis B surface antigen (HBsAg) protein, glycoproteins, and lipids. Within the envelope, there is a capsid containing Hepatitis B core antigen (HBcAg), a molecule of partially double-stranded deoxyribonucleic acid (DNA), DNA polymerase, protein kinase and the nonstructural, soluble Hepatitis B e antigen (HBeAg). The presence and absence of these specific antigenic proteins as well as the patient's antibodies to them provide important clinical information. The virus targets the liver primarily, replicating in hepatocytes, but some chronically infected patients may have detectable virus in their circulating mononuclear cells, polymorphonuclear leukocytes, bone marrow, pancreas, kidneys, spleen, and even skin.

Epidemiology

The incidence of hepatitis B infection varies across the world, but overall, the WHO estimates that over two billion people living today have been infected with hepatitis B. It is also estimated that about 350 million individuals are chronically infected and that 600,000 people die every year due to the virus. A person's risk of being infected is influenced by endemicity, vaccination, and certain behaviors.

Areas of high prevalence include Sub-Saharan Africa, Southeast Asia, Eastern Mediterranean countries, south and west Pacific Islands, Caribbean Islands, and Amazon basin countries. High prevalence is defined as having greater than 8% prevalence, but in some areas, up to 20% of the population may be chronically infected. In these areas, mother-to-child perinatal transmission, child-to-child transmission, and sexual contact are the major ways the virus is spread. In areas of low endemicity (<2% prevalence), like North America, Northern and Western Europe, Australia, and New Zealand, homosexual and heterosexual sex and use of contaminated needles, especially among intravenous drug users, are major modes of transmission.

Pathogenesis

Hepatitis B is spread via parenteral routes including transfusion, blood exposure, or via sexual contact and enter the liver through direct hematogenous spread. Acute infection includes intracellular viral replication and causes an inflammatory immune response, which causes varying amounts of hepatocellular necrosis and degeneration. Although uncommon, acute liver failure due to extensive liver necrosis can be fatal. While the apparent lack of symptoms despite continued viral replication observed in many chronically HBV-infected individuals suggests the virus is not directly cytotoxic, the possibility that overwhelming viral replication can exacerbate disease remains, and is observed in chronically infected persons with immune systems compromised by chemotherapy or other immunosuppressive agents.

Pathology

The histological changes and chemical markers of hepatic injury, like elevations of serum aminotransferases, seen in the acute hepatitis phase are indistinguishable between different hepatitis viruses. Chronic hepatitis, caused primarily by HBV, Hepatitis C and D viruses (HCV, HDV), is characterized by persistent elevations of liver aminotransferases, hyperbilirubinemia, and detectable viral antigens and genetic material. Histologically, chronically HBV-infected patients have livers that can appear normal after the initial inflammatory response, injury, and regeneration of hepatocytes. However, biopsy specimens often show cells that display evidence of accumulated viral antigens referred to as "ground glass" hepatocytes (*Fig. 105.2*). Ongoing inflammation with lymphocytic/mononuclear infiltrates in the parenchyma and portal tracts, or the spectrum of fibrotic changes of cirrhosis can also be seen.

Clinical Manifestations

The clinical course of infection with Hepatitis B is similar to that of the other hepatitis viruses in the acute phase (*Fig. 105.3*). The incubation period is variable, lasting 4–26 weeks before viral antigens appear in the serum. Clinical signs and symptoms of acute infection may be absent or may range from mild to severe. A prodromal phase may include headache, nausea, vomiting, abdominal pain, malaise, and fever. Rarely, patients may experience symptoms similar to serum-sickness with fever, arthralgia or arthritis, and an erythematous maculopapular rash. An icteric phase then follows and can include jaundice, pruritus (especially in infants), dark urine, and light-colored stool. The rash of Gianotti-Crosti syndrome, papular acrodermatitis, has a long-recognized association with Hepatitis B infection. Physical exam may show the above mentioned skin findings, scleral or buccal icterus, lymphadenopathy, jaundiced skin, a tender right upper quadrant, hepatomegaly and/or splenomegaly. Injury may subside and symptoms usually resolve over the course of 6–8 weeks.

Acute HBV infection may cause extrahepatic phenomena including urticarial rash, vasculitis, polyarteritis nodosa, pericarditis, serositis, Henoch–Schönlein Purpura, thrombocytopenia, cryoglobulinemia, and aplastic anemia. Multiple types of glomerulonephritis can occur in association with HBV, especially in the setting of chronic infection, the most common of which is membranous glomerulonephritis due to deposition of HBV antigen–antibody complexes in the basement membranes of glomerular capillaries.

Worldwide, acute liver failure occurs more often as a result of Hepatitis B viral infection than the other hepatitis viruses, affecting 0.1–0.5% of those infected. Coinfection with Hepatitis D virus increases a patient's risk of developing this serious complication.

Age, immune status, viral genotype, and the HBV infecting dose all affect the clinical outcome of HBV infection. Infection is more likely to become chronic with young age at exposure to the virus, occurring in up to 90% of exposed neonates. In contrast, 30% of children ages 1–5 years, and only 5–10% of immunocompetent adults develop chronic HBV infection. Most infections that

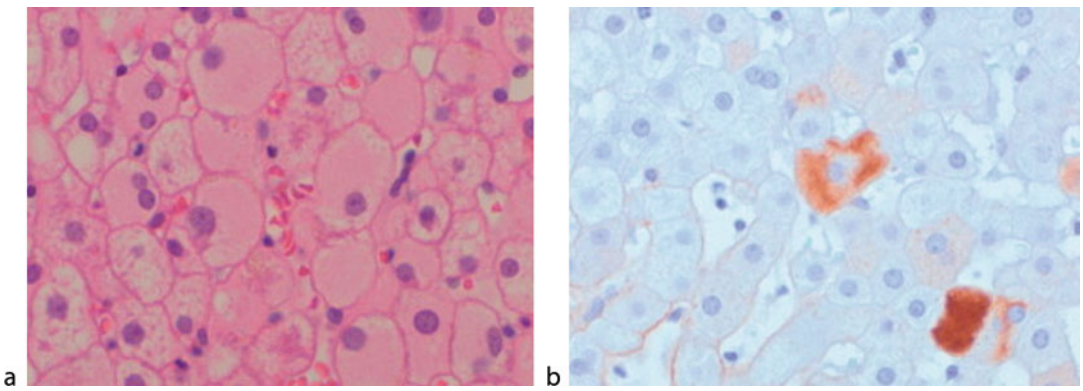

Figure 105.2
Chronic hepatitis B infection with "ground-glass" hepatocytes (a) and immunoperoxidase stain for hepatitis B surface antigen (b) showing cytoplasmic inclusions of viral particles (Adapted from Crawford J, Liu C (2010) Liver and biliary tract. Figure 105.3

Serology and clinical manifestations of acute (a) and chronic (b) hepatitis B infection. *HBV* hepatitis B virus, *HBc* hepatitis B core antigen, *HBsAg* hepatitis B surface antigen, *HBeAg* hepatitis B e antigen (Adapted from Crawford J, Liu C (2010) Liver and biliary tract. In: Kumar V et al (eds) Robbins and Cotran pathologic basis of disease, 8th edn. Saunders Elsevier, Philadelphia)

occur in the perinatal or young childhood period are asymptomatic in the acute period, and clinical signs of disease rarely arise before the second or third decade of life.

Those with chronic infection pass through four phases. (1) *Immune tolerance* is the first phase, during which the virus replicates relatively freely (HBeAg +, ↑ HBV DNA) without hepatic disease (normal ALT). This phase characterizes most infants and young children who were infected perinatally by vertical transmission. Available evidence suggests that immune tolerance may be induced by transplacental passage of HBeAg and fetal thymic restriction of T cells that would respond to these "self-antigens." (2) *HBeAg-positive chronic hepatitis* is defined by active viral replication (HBeAg+, ↑HBV DNA), high infectivity, and elevated liver transaminases. Seroconversion to HBeAg-negative/anti-HBe-positive status indicates host immune response, which can attenuate active disease and usher in the next stage. (3) *Inactive carriers* have positive HBsAg and normal aminotransferases, are asymptomatic, have low or undetectable levels of viremia (HBV DNA), and are not as infectious. Patients may remain in this stage for many years. (4) *HBeAg-negative chronic hepatitis* is present when patients remain HBeAg-negative, HBsAg positive, and develop elevated transaminases and higher levels of viremia (HBV DNA). Patients in the stages of chronic hepatitis are at higher risk of developing cirrhosis and hepatocellular carcinoma.

Diagnosis

Diagnosis and determination of chronicity and infectivity depend primarily on serology (*Table 105.1*). Detection of HBcAg or HBsAg in the absence of vaccination confirms infection. Presence of HBeAg suggests active viral replication and high infectivity. Seroconversion occurs with the production of antibodies to HBsAg, HBcAg and HBeAb, anti-HBs, anti-HBc and anti-HBe, respectively, but there exists a "window period" during which HBsAg may be negative before anti-HBs is detectable. Anti-HBc antibodies of the IgM type can be very helpful in diagnosing recent infection, whereas IgG antibodies to any of the antigens indicate past infection only. Advances in polymerase chain reaction (PCR) techniques allow detection of lower levels of HBV DNA.

Differential Diagnosis

The differential diagnosis of acute liver injury in Hepatitis B is similar to that of Hepatitis A. Hepatitis B is an important cause of chronic hepatitis in children, but it is important to consider other causes, including autoimmune hepatitis, which is the most common cause of chronic hepatitis in children. Other etiologies include Hepatitis C infection, alpha-1 antitrypsin deficiency, Wilson's disease, cystic fibrosis, and drug-induced

[a]Patients with HBeAg-negative chronic hepatitis may have significant liver damage, viremia with higher HBV DNA

hepatitis. Chronic hepatitis of many etiologies is often asymptomatic, with only elevated serum aminotransferases prompting evaluation.

Treatment

General Care

For those with confirmed acute infection, care is mostly supportive, as with Hepatitis A. Children diagnosed with acute or chronic infection with hepatitis B should be screened for HDV, which can coinfect persons with HBV, and be followed with regular monitoring of ALT and HBeAg for evidence of active liver disease and seroconversion. Abdominal ultrasound can be useful in evaluating for hepatocellular carcinoma. Liver biopsy gives definitive measure of inflammatory acuity and fibrosis, aids in prognosticating advancement of disease and need for therapy, and may help rule out other conditions.

Specific Treatment

Treatment options for children with chronic infection are limited, and optimal care is aided by referral to a pediatric liver specialist when possible. The goals of therapy are to reduce the morbidity and mortality of chronic infection and to slow or stop viral replication as evidenced by normalization of liver transaminases and clearance of HBV DNA and HBeAg. With the available treatment options, treatment is reserved for chronically infected children with active liver disease (↑ ALT) and active viral replication (↑ HBV DNA). However, children with cirrhosis, coinfection with HDV, rapidly deteriorating liver function, and those expected to begin immunosuppressive or cytotoxic chemotherapy should be considered for treatment regardless of ALT or DNA levels.

Currently, only a few drugs are approved for use in young children: interferon-α, which has an immune modulating as well as antiviral effect, and the antiviral nucleos(t)ide analogs lamivudine and adefovir. Interferon-α is modestly effective, yielding clearance of both HBV DNA and HBeAg in 23% of children versus 10% spontaneous clearance in controls. Important side effects include fever, malaise, and myelosuppression. A pegylated form may be better tolerated with its less frequent administration and is the subject of ongoing research.

Lamivudine is also effective, but is limited by viral resistance that frequently develops with prolonged use. Limited research of adefovir showed little efficacy in children under 12 years of age. Combination therapy of the above agents and promising new antivirals that have been used in adults are under pediatric study.

Prevention

Vaccines against Hepatitis B have been available since 1982, and have been very effective in preventing disease. Since 1992, when the WHO issued a global recommendation to routinely vaccinate all infants, the number of countries that have Hepatitis B vaccination programs increased fivefold, up to 164 countries in 2006. Such programs have taken prevalence levels in some countries from high to below 1%. Vaccination is also recommended for older

children and adults at high risk of exposure to or morbidity with HBV infection, including health care workers and those with occupational exposure to blood products, those who use injection drugs, persons with multiple sexual partners, and persons with chronic liver disease.

Currently, recombinant vaccines derived from modified yeast have mostly replaced plasma-derived vaccines. Both are equally effective and interchangeable within regimens. Preexposure immunization schedules are somewhat flexible, usually require three doses of vaccine, and individual doses vary by age and manufacturer. These can be initiated at birth, or for convenience, simultaneously with other vaccines (*Table 105.2*). The three-dose regimen is recommended for preexposure prophylaxis, and the four-dose regimen is recommended for use in immunocompromised patients or for older children as postexposure prophylaxis. Postvaccine testing and provision of booster doses are not routinely recommended, but may be appropriate in some cases, (e.g., immunocompromised patients).

Postexposure prophylaxis for infants born to chronically infected mothers should include administering a birth dose of hepatitis B vaccine and a dose of Hepatitis B immune globulin (HBIG), preferably within 24 h after delivery. Thereafter, the usual three-dose schedule of vaccine is recommended. Of note, the four-dose schedule without HBIG has been shown to be similarly effective in preventing vertical transmission, but is not currently recommended.

Two recent meta-analyses showed both lamivudine and HBIG to be individually effective in reducing the risk of mother to child transmission when administered to late-gestation HBsAg-positive mothers. Infants with mothers who are HBeAg-positive or have high serum levels of HBV DNA are at higher risk of vertical transmission, and these agents may augment prevention when added to HBIG and HBV vaccine regimen given to the infant at birth.

Hepatitis C

The hepatitis C virus is also transmitted parenterally and causes chronic infection and serious sequelae. Prior to its identification in 1989, it was the predominant cause of so-called non-A, non-B chronic hepatitis in the world. It is an enveloped, single-stranded RNA virus in the *Flaviviridae* family that is very heterogeneous genetically, with six separate genotypes and multiple subtypes that have diverse geographical distributions. Its ability to mutate rapidly allows it to elude host immune systems as well as scientists' efforts to develop an effective vaccine.

Epidemiology

Worldwide prevalence has been estimated at 3%, but ranges from 1.7% in the United States to 5.3% in Africa. Transfusions, while once a major source of HCV infections, are less risky due to widespread donor-blood screening for HCV. Now, vertical transmission is the most common way children acquire the infection, accounting for about 60% of cases of pediatric chronic infection. In contrast to vertical transmission rates seen with HBV, only about 5–7% of infants born to mothers with chronic HCV infection will acquire the infection themselves. Risk factors for vertical transmission include high levels of viremia, coinfection with HIV, prolonged or difficult delivery, and the use of internal fetal monitoring. Hepatitis C is also transmitted via other parenteral routes including sexual contact, use of contaminated needles, and via transfusion of donor blood products.

The different genotypes are clustered geographically around the globe. Genotypes 1–3 are prevalent worldwide. Genotype 1 is the most common in the United States and Europe. Genotype 2 accounts for less than 20% of all infections in all regions. Genotype 3 is most common in

Australia, South America and India, 4 in Egypt, the Middle East and central Africa, and 5 and 6 are most common in South Africa and southeast Asia.

Pathology

Histologic changes due to HCV infection do not necessarily correlate with liver aminotransferase levels, but are similar to those seen with the other hepatitis viruses. Chronic infection carries a high risk of development of cirrhosis. Hepatocellular carcinoma can also be seen in chronically infected persons.

Clinical Manifestations

Children with hepatitis C are generally asymptomatic, but may have mild nonspecific malaise, anorexia, or abdominal pain. Hepatomegaly is the most frequent sign of disease in young children. Acute hepatic failure has not been reported in children and is rare in adults. Clinical progression of disease in those with chronic HCV infection is often indolent, with fluctuating serum transaminases and recurrent or chronic evidence of inflammation, but leads to cirrhosis in up to 25% in that population (*Fig. 105.4*). Hepatocellular carcinoma is associated with chronic HCV infection, though the mechanism of oncogenesis is yet unclear.

Diagnosis

Diagnosis is based on detection of viral RNA, which can be done by PCR or other assays. Chronic infection is determined by detecting HCV RNA in serum twice, at least 6 months apart. Measuring anti-HCV antibodies is useful to screen for past exposure, but they may be absent in recent infection, and in infants, may represent maternally transmitted antibody up to 18 months of age. Spontaneous clearance of virus is uncommon, occurring in about 15% of patients, and is seen more often in transfusion-acquired infection and when initial ALT levels are >5 times the upper limit of normal.

Differential Diagnosis

The differential diagnosis of chronic hepatitis C seen in children is similar to that of Hepatitis B, discussed above.

Treatment

General Care

Management of patients with chronic hepatitis C infection aims to reduce the risk of morbidity and mortality due to long-term sequelae including cirrhosis, liver failure, and

hepatocellular carcinoma. Evaluation should include laboratory monitoring of liver aminotransferases and HCV RNA, since the course of progression can vary widely and viremia can sometimes recur even after a period of undetectability. Genotype determination can lend very helpful prognostic information, especially related to expected response to therapy. Liver biopsy can be helpful in evaluating degree of liver injury, but must be weighed against its invasiveness, risk of complication, and the likelihood of sustained response to therapy. Some centers prefer to obtain ultrasounds every 3–5 years to evaluate for changes in liver size, echotexture, and for hepatocellular carcinoma, though the latter is rare in childhood. The intervals at which laboratory studies, imaging, and histology should be monitored have not been codified in current recommendations, but experts agree that therapy and monitoring should be prescribed and supervised by experienced providers.

Counseling of patients and families with an aim to prevent spread of disease should include avoidance of behaviors that would increase the risk of transmission like donating blood and sharing razors, toothbrushes, or injection needles. Immunization against HAV and HBV should be performed or confirmed in all patients with chronic HCV infection.

Specific Treatment

Antiviral therapy has the potential to eradicate infection, thereby reducing the risk of transmitting infection and developing severe liver disease or hepatocellular carcinoma. These risks, weighed against the risks of therapy and the possibility of spontaneous viral clearance, inform decisions about whether and when to treat. Patients with genotypes 2 and 3, rather than genotype 1, and those with lower pretreatment HCV RNA levels respond better to therapy.

Interferon, injected subcutaneously, was once the main therapeutic agent and was effective at inducing sustained viral response (SVR; undetectable serum HCV RNA 24 weeks after the end of therapy) in about 10–15% of patients. Addition of ribavirin improved rates of SVR. Pegylated interferon (PEG-IFN) is superior to interferon at viral suppression and allows for once weekly dosing. PEG-IFN combined with ribavirin is currently recommended for adults, and the first large controlled trial of PEG-IFN showed that combination therapy with PEG-IFN and ribavirin was similarly effective in children as in adults, inducing SVR in 53% of all subjects.

The typical suggested duration of therapy for children is 48 weeks, but this may be extended to 72 weeks for patients who have persistently detectable HCV RNA at 48 weeks. Therapy can be stopped after 24 weeks in patients who do not show adequate response to therapy. Patients should be monitored for adverse effects of therapy, which include leukopenia, neutropenia, and autoimmune hypothyroidism. Patients with co-morbid diseases including thalassemia, HBV infection, and HIV infection deserve special attention. The iron overload associated with transfusion-dependent thalassemia worsens liver disease and requires active management in addition to antiviral therapy. Coinfection with HBV can worsen liver disease, and treatment with PEG-IFN and ribavirin is recommended. Coinfection with HIV can accelerate HCV liver disease, but this effect may be ameliorated with highly active antiretroviral therapy (HAART).

Future Development

New promising agents include new formulations of interferon, better-tolerated ribavirin-like drugs, and agents that inhibit enzymes involved in viral replication. Albeit challenged by the genetic heterogeneity and great propensity for mutation of the virus, efforts to develop effective vaccine products are underway.

Prevention

The most effective measure in reducing the incidence of HCV worldwide has been the widespread screening of donated blood for HCV, thereby reducing the risk of transfusion-related transmission. Because screening of donated blood products is not 100% effective, transfusion should be recommended judiciously. Avoidance of high-risk behaviors as well as screening and counseling those who engage in high-risk behaviors such as those with multiple heterosexual or same-sex partners and those who use injection drugs may help prevent the spread of disease.

Screening is not recommended for pregnant women owing to the lack of available measures to prevent mother-to-child vertical transmission, and though HCV RNA can be detected in breast milk, there is not sufficient evidence regarding any increased risk of transmission to discourage breastfeeding.

Hepatitis D

Hepatitis D virus (HDV) consists of its single-stranded, circular RNA molecule and its only protein product, the

delta antigen. Infection with HDV requires coinfection with Hepatitis B, as it requires the latter's outer coat for extracellular spread. Coinfection of HBV with HDV is associated with higher risk of acute liver failure as well as severe liver disease and cirrhosis. Infection may be acquired simultaneously with hepatitis B or via similar parenteral routes after infection with Hepatitis B. Prevalence is high in the Amazon and Mediterranean Basins, the Middle East, Central Asia, West Africa, and south Pacific islands, and higher in those who use intravenous drugs and themophiliacs. Epidemics have been observed, especially in the Amazon Basin.

Liver transplantation may be necessary for those with acute hepatic failure. In chronically infected patients, treatment with high-dose interferon can improve liver disease, but has a low likelihood of eradicating the virus. Control of this disease relies on improved prevention of hepatitis B infection through immunization.

Hepatitis E

Hepatitis E virus (HEV) is the other water-borne hepatitis virus, like Hepatitis A. Once classified in the Calicivirus family, the enveloped, single-stranded RNA virus is now unclassified. It is the primary cause of enterically transmitted non-A, non-B hepatitis, and is the most common cause of symptomatic hepatitis in children in endemic areas, including central and southeast Asia, India, China, Africa, and Mexico. Anti-HEV antibodies have been detected in sera of individuals in all areas of the world, but the only symptomatic cases reported in the United States or Europe have been in travelers to endemic areas. This incongruity is yet unexplained but may be related to subclinical disease, attenuated viral strains or cross-reactivity of anti-HEV antibodies to other antigens.

Symptoms are similar to acute hepatitis of other etiologies, include malaise, anorexia, abdominal pain, hepatomegaly, and jaundice, and are usually mild. Mortality is generally low, ranging from 0.4% to 4%. For reasons that are not yet clear, infection during pregnancy is much more dangerous with mortality around 20%, higher risk of acute liver failure, intrauterine fetal demise, preterm delivery, and stillbirth. Maternal-fetal and/or perinatal transmission is likely possible, and very poor outcomes in neonates born to mothers with acute HEV infection have been reported.

No specific treatment is available beyond supportive therapy. Most infected persons develop anti-HEV IgG, which is protective of future disease for up to 14 years, but development of a therapeutic anti-HEV immune globulin has not yet been successful. A recent large-scale randomized controlled trial of a recombinant bacteria-derived vaccine in adults in an endemic area of China showed significant protective effect and appears promising. Its use in outbreaks, endemic areas, and travelers will depend on the usual cost-benefit analysis and requires much further study. Prevention currently relies on safe systems of water sanitation and proper counseling of travelers to avoid unsafe drinking water, uncooked fruits, vegetables and shellfish, and to practice good handwashing.

Hepatitis F

A novel hepatitis F virus was proposed after a virus resembling those in the Togaviridae family was isolated from the livers of a few patients with fulminant hepatitis, but subsequent research has not confirmed it as a novel distinct hepatotropic virus.

Hepatitis G

A novel virus, initially named GB agent, referring to the young British surgeon from whose liver it was isolated, was inoculated into tamarins and caused hepatitis. Subsequent research has elucidated that at least four subtypes of GB virus exist: GBV-A; GBV-B (the likely agent originally isolated from the surgeon); GBV-C, which is identical to the simultaneously discovered virus called Hepatitis G virus (HGV); and GBV-D. GBV-C/HGV has been found in many patients with chronic Hepatitis B or C as well as the stool of normal children, and has been proven to be transmissible by transfusion. Infection is usually persistent, and studies suggest that anti-HGV antibodies are present in the blood of nearly one-quarter of the world's population. Despite its prevalence, the ability of the GB viruses to cause hepatitis in other animals and its attractiveness as a possible etiology of non-ABCDE hepatitis, HGV is not associated with human disease, and testing is not indicated in patients with hepatitis.

106 CMV Infections

Shannon A. Ross · Masako Shimamura · Suresh B. Boppana

The Virus

CMV (human herpesvirus 5) is the largest and most complex member of the family of herpesviruses. The virion consists of three regions: the capsid containing the double-stranded DNA viral genome, the tegument, and the envelope. The viral genome consists of more than 235 kbp, which contain more than 252 open reading frames. The complexity of CMV's genetic makeup confers extensive genetic variability among strains. Restriction fragment length polymorphism analysis as well as DNA sequence analysis has demonstrated that no two clinical isolates are alike. The viral tegument contains viral proteins that function to maintain the structural integrity of the virion, are important for assembly of an infectious particle, and are involved in regulatory activities in the replicative cycle of the virus. The viral envelope contains eight glycoproteins that have been described, as well as an unknown number of additional proteins. The most abundant envelope glycoproteins are the gM/gN, the gB, and the gH/gL/gO complexes, which are all important for virus infectivity. In addition, gB, gH, and gM/gN have been shown to induce an antibody response in the infected host and are major components of the protective response to the virus.

Epidemiology

Cytomegalovirus infections have been recognized in all human populations. CMV is acquired early in life in most populations, with the exception of people in the economically well-developed countries of northern Europe and North America. The patterns of CMV acquisition vary greatly based on geographic and socioeconomic backgrounds and seroprevalence generally increases with age. Studies have shown that most preschool children (>90%) in South America, sub-Saharan Africa, East Asia, and India are CMV antibody positive. In contrast, seroepidemiologic surveys in Great Britain and in the USA have found that less than 20% of children of similar age are seropositive. A recent study of CMV seroprevalence that utilized samples from the National Health and Examination Survey (NHANES), 1988–2004 showed that the overall age-adjusted CMV seroprevalence in the USA was 50.4%. That study also showed that CMV seroprevalence was higher among non-Hispanic black children and Mexican-American children compared with non-Hispanic white children.

Transmission of CMV

Although the exact mode of CMV acquisition is unknown, it is assumed to be through direct contact with body fluids from an infected person. Breastfeeding, group care of children, crowded living conditions, and sexual activity have all been associated with high rates of CMV infection. Sources of the virus include oropharyngeal secretions, urine, cervical and vaginal secretions, semen, breast milk, blood products, and allografts (*Table 106.1*). Presumably, exposure to saliva and other body fluids containing infectious virus is a primary mode of spread because infected infants typically excrete significant amounts of CMV for months to years following infection. Even older children and adults shed virus for prolonged periods (>6 months) following primary CMV infection. In addition, a significant proportion of seropositive individuals continue to shed virus intermittently. An important determinant of the frequency of congenital and perinatal CMV infection is the seroprevalence rate in women of childbearing age. Studies from the USA and Europe have shown that the seropositivity rates in young women range from less than 50–85%. In contrast, most women of childbearing age in less well-developed regions are CMV antibody positive.

Vertical transmission: CMV can be transmitted from mother to child transplacentally, during birth, and in the postpartum period via breast milk. Congenital CMV infection rates are directly related to maternal seroprevalence rates (*Table 106.2*). Rates of congenital CMV infection are higher in developing countries and for low-income groups in developed countries. Although the reasons for this increased rate of congenital CMV in populations with high seroprevalence rates are not clear, recent demonstration that infection with new or different virus strains occurs commonly in previously seropositive

individuals in a variety of settings suggests that frequent exposure to CMV could be an important determinant of maternal reinfections and subsequent intrauterine transmission. Studies of risk factors for congenital CMV infection showed that young maternal age, nonwhite race, single marital status, and history of sexually transmitted diseases have been associated with increased rates of congenital CMV infection.

Intrapartum transmission: Transmission of CMV during delivery occurs in approximately 50% of infants born to mothers shedding CMV from the cervix or vagina at the time of delivery. Genital tract shedding of CMV has been associated with younger age, other STDs, and greater number of sexual partners.

Postnatal transmission: Breastfeeding practices have a major influence on the epidemiology of postnatal CMV infections. CMV has been detected in breast milk in 13–50% of lactating women tested with conventional virus isolation techniques. Recent studies utilizing the more sensitive PCR technology demonstrated the presence of CMV DNA in breast milk from >90% of seropositive women. The early appearance of viral DNA in milk whey, the presence of infectious virus in milk whey, and higher viral load in breast milk have been shown to be risk factors for transmission of CMV infection. The consequences of CMV infection acquired via breast milk are negligible in full-term infants. In contrast, postnatal CMV infection can lead to symptomatic infection in about 10–50% of preterm infants leading to significant morbidity. Although an earlier study suggested an association between postnatal CMV infection and adverse neurodevelopmental outcome in preterm infants, a more recent prospective study demonstrated that none of the 22 preterm infants with early postnatally acquired CMV infection developed hearing loss or other neurologic sequelae.

Nosocomial transmission: Blood products and transplanted organs are the most important vehicles of transmission of CMV in the hospital setting; the latter is

unlikely to be of concern during pregnancy. Transmission of CMV through packed red blood cell, leukocyte and platelet transfusions poses a risk of severe disease for seronegative small premature infants and immunocompromised patients. Prevention of blood product transmission of CMV can be achieved by using seronegative donors or by special filters that remove white blood cells. Another potential source of nosocomial CMV infection that is of particular concern to those in reproductive medicine is semen donated for artificial insemination. Person-to-person transmission of CMV requires contact with infected body fluids and therefore should be prevented by routine hospital infection control precautions. Studies in health care settings found no evidence of increased risk of CMV infection in settings in which patients shedding CMV are encountered.

Child-to-child transmission: Young children are a known source of CMV infection. After early infancy, young children likely acquire CMV through horizontal transmission from other children or possibly indirectly through environmental contamination. Studies in day care centers throughout the world have demonstrated that young children shed virus in saliva and urine creating exposure opportunities for virus transmission to other children in the day care setting, to their parents, and to the day care or nursery workers. Besides child-to-child transmission, CMV is also found on toys and other environmental surfaces in day cares providing another viral source for CMV infection.

CMV transmission through sexual activity: An important source of CMV infection is through intimate contact with oral and genital secretions. Salivary glands are a site of persistent virus in humans, and it is likely that reactivations lead to the presence of infectious virus in oral secretions. Infectious virus can often be cultured from cervical secretions, and semen has been shown to be a rich source of virus in seropositive men. The association between sexual activity and CMV transmission can be summarized as follows: (a) the prevalence of CMV antibody more than doubles during the years of beginning sexual activity (15–30 years), (b) higher rates of seropositivity are found in male partners of seropositive women as compared to seronegative women, (c) CMV has been isolated from the cervix of 13–35% of women with suspected STDs, (d) seropositivity correlated with the presence of other STDs, (e) among seronegative women attending an STD clinic, the annual CMV seroconversion rate was noted to be 37% versus 1–2% per year in the general population, (f) seropositivity correlated with number of lifetime sexual partners and young age at onset of sexual activity, and (g) a negative correlation was made between the use of barrier contraception and seropositivity. Thus, there is strong epidemiological evidence that acquisition and transmission of CMV infection is associated with sexual activity and STDs.

Transmission of CMV to child care providers: Children in day care settings may also be a source of CMV infection for child care personnel. Numerous studies in the past decades have described the risk of CMV infection for women who provide care for children in an occupational setting. Risk factors for CMV seroconversion of child care providers have included workers <30 years of age, not wearing gloves when changing diapers, and caring for children ≤ 3 years of age for 20 h a week.

Pathogenesis

The pathogenesis of CMV infection in the naïve host has been characterized in humans as well as in animal models. After entry into a naïve host, cytomegalovirus infection induces a primary viremia with initial viral replication occurring in reticuloendothelial organs (liver and spleen). Secondary viremia subsequently ensues with viral dissemination to end organs. In healthy humans, both primary and secondary viremia may be asymptomatic, or the secondary viremia may be associated with mononucleosis-like symptoms including fever, transaminase elevation, and atypical lymphocytosis.

After immune-mediated clearance of acute viremia, the immunocompetent host may remain asymptomatic for life. Reservoirs of latent infection are not clearly defined but are thought to include monocytes and marrow progenitors of myeloid lineage, as well as possibly endothelium and secretory glandular epithelium such as the salivary, breast, prostate, and renal epithelium. The control of latency and reactivation is not well understood and has been intensively studied both in vitro and in animal models. It is believed that viral reactivation occurs intermittently in the immunocompetent host but fails to induce clinical disease secondary to intact immune control mechanisms. Up to 10% of the memory T-lymphocyte repertoire may be directed against CMV in the healthy host, and immune senescence ("T-cell exhaustion") may contribute to susceptibility to reactivation and reduced immunity to other infections in the elderly.

Immune Response to Infection

The innate immune system, particularly natural killer (NK) cells are responsible for initial control of viremia in

the normal host. Animal models demonstrate that activation of NK cells by virus-infected host cells contributes to viral clearance. Consistent with this, patients with NK cell deficiencies may develop life-threatening CMV disease as well as disease from other herpesviruses. Long-term control of CMV is maintained by adaptive immunity. Serum antibodies against CMV gB, gM/gN, and gH neutralize infection in vitro. IgM and IgG titers are used to determine clinical immunity and history of past infection. IgM is an indicator of recent infection, although IgM may persist for many months after primary infection. In addition, IgM antibodies can also appear during reactivations of CMV infection. However, hypogammaglobulinemia does not appear to be a risk factor for severe CMV disease except in conjunction with other forms of immunosuppression (e.g., transplant recipients). CMV-specific T-lymphocytes are critical for long-term control of chronic infection. The essential nature of CD4+ T-helper cells is demonstrated in HIV-infected patients who may develop CMV retinitis, colitis or esophagitis, hepatitis, or ventriculoencephalitis with loss of T-helper cell control of viral replication during late stages of HIV infection (http://www.cdc.gov/mmwr/preview/mmwrhtml/rr5804a1.htm). Immunorestoration of CD4+ and CD8+ T-lymphocytes in patients with AIDS after initiation of antiretroviral therapy correlates with control of CMV retinitis. The T-lymphocyte response has also been correlated with protection from CMV viremia in solid organ and stem cell transplant recipients.

CMV Immune Evasion Genes

CMV has evolved numerous immune evasion functions to permit coexistence in the normal host, which have been extensively reviewed elsewhere. For example, CMV downregulates MHC class I molecules on the infected cell surface, and encodes an MHC I homologue to inhibit immune recognition of the infected host cell. CMV encodes cytokine homologues such as UL111a mimicking human IL-10, chemokine receptors such as US28, and other immunomodulatory gene products which have been characterized in vitro.

As new pharmacologic immunomodulatory agents are developed to treat autoimmune diseases, the roles of specific cytokine pathways in the control of CMV infection are being elucidated. For example, patients with inflammatory bowel disease or rheumatologic diseases who are treated with monoclonal antibodies against TNF-α (etanercept or infliximab) have developed severe CMV disease, implicating this cytokine in the control of CMV.

Pathogenesis of Congenital Infection

The pathogenesis of central nervous system disease and sequelae including hearing loss in congenital CMV infection is not well understood. Few autopsy specimens are available for study and, because of the species specificity of the virus, human congenital CMV infection lacks a well-developed animal model that truly emulates human disease. Imaging studies of infants and children with congenital CMV infection reveal a variety of CNS abnormalities including periventricular calcifications, ventriculomegaly, and loss of white-gray matter demarcations. Histological examinations from CMV-infected fetuses has demonstrated evidence of virus by immunohistochemical staining for CMV proteins in a variety of brain tissue including cortex, white matter, germinal matrix, neurons of the basal ganglia and thalamus, ependyma, endothelium, and leptomeningeal epithelial cells. In most cases, virus was accompanied by an inflammatory response, sometimes severe and associated with necrosis. These findings together suggest that lytic infection as well as inflammation in response to infection contribute to the pathology in CNS infection. The neurological manifestations are unique in congenital CMV infection, leading to the hypothesis that the immature brain is more susceptible to infection. Animal models have supported this theory, wherein infection of the developing CNS leads to widespread lytic virus replication in neuronal progenitor cells of the subventricular gray area and endothelium.

Few temporal bones from congenitally infected children have been studied and described in the literature. Specimens displayed evidence of endolabyrinthitis and virus has been isolated from the endolymph and the perilymph. Cochlear and vestibular findings were variable, ranging from an occasional inclusion bearing cell within or adjacent to sensory epithelium of the cochlea or vestibular system to more extensive involvement of the non-sensory epithelium. Interestingly, inflammatory cell infiltrates were minimal and only reported in three cases. In contrast to the findings in infants, a study of the temporal bones from a 14-year-old with severe congenital CMV infection revealed extensive cellular degeneration, fibrosis, and calcifications in the cochlea and vestibular system. Studies in the guinea pig model of congenital CMV infection have shed some additional information on the possible mechanisms of CMV-related hearing loss and have demonstrated that not only was viral gene expression a prerequisite for damage to the inner ear and auditory abnormalities, but that an intact host immune response was also required.

From these studies in animal models and from the limited studies of human temporal bones, two mechanisms of hearing loss in congenital CMV infection are suggested. The presence of viral antigens or inclusions in the cochlea and/or vestibular apparatus of human temporal bones suggest that CMV can readily infect both the epithelium and neural cells in the inner ear and that hearing loss can occur as a result of direct virus-mediated damage to neural tissue. Alternatively, the host-derived inflammatory responses secondary to viral infection in the inner ear could also be responsible for damage leading to sensorineural hearing loss (SNHL).

Pathology

Cytomegalovirus was originally named for the cytomegalic changes and intracellular inclusions observed within infected cells during histologic analysis of infected tissues. The classic histologic finding in CMV pathology is the "owl's eye" nucleus, which is a large intranuclear basophilic viral inclusion spanning half the nuclear diameter, surrounded by a clear intranuclear halo beneath the nuclear membrane. Smaller cytoplasmic basophilic inclusions may also be seen in infected cells. Infected cell types include epithelial and endothelial cells, neurons, and macrophages, and can be found in biopsies of numerous tissues including brain, lung, liver, salivary glands, and kidneys. CMV-infected tissues may show minimal inflammation, or may demonstrate an interstitial mononuclear infiltrate with focal necrosis. In the intestine, CMV may induce ulceration and pseudomembrane formation. In congenital infection, chorioretinitis may be found in the eye, and pathologic findings in the central nervous system include microcephaly, focal calcifications, ventricular dilatation, cysts, and lenticulostriate vasculopathy.

Clinical Manifestations

Congenital Infection

Of the 20,000–40,000 children born with congenital CMV infection each year, the majority (approximately 85–90%) exhibit no clinical abnormalities at birth (asymptomatic congenital CMV infection). The remaining 10–15% are born with clinical abnormalities and are thus classified as having clinically apparent or symptomatic congenital infection. The infection involves multiple organ systems with particular predilection for the reticuloendothelial and central nervous system (*Table 106.3*). The most commonly observed physical signs are petechiae, jaundice, and hepatosplenomegaly with neurologic abnormalities such as microcephaly and lethargy affecting a significant proportion of symptomatic children. Ophthalmologic examination is abnormal in approximately 10%, with chorioretinitis and/or optic atrophy most commonly observed. Approximately half of symptomatic children are small for gestational age and one-third are born prior to 38 weeks gestational age.

Table 106.3
Clinical findings in 106 infants with symptomatic congenital CMV infection in the newborn period

Abnormality	Positive/total examined (%)
Prematurity[a]	36/106 (34)
Small for gestational age[b]	56/106 (50)
Petechiae	80/106 (76)
Jaundice	69/103 (67)
Hepatosplenomegaly	63/105 (60)
Purpura	14/105 (13)
Microcephaly[c]	54/102 (53)
Lethargy/hypotonia	25/104 (27)
Poor suck	20/103 (19)
Seizures	7/105 (7)

[b]Weight less than 10th percentile for gestational age
[c]Head circumference less than 10th percentile

Laboratory findings in children with symptomatic infection reflect the involvement of the hepatobiliary and reticuloendothelial systems and include conjugated hyperbilirubinemia, thrombocytopenia, and elevations of hepatic transaminases in over half of symptomatic newborns. Transaminases and bilirubin levels typically peak within the first 2 weeks of life and can remain elevated for several weeks thereafter while thrombocytopenia reaches its nadir by the second week of life and normalizes within 3–4 weeks of age. Radiographic imaging of the head is abnormal in approximately 50–70% of children with symptomatic infection at birth. The most common finding is intracranial calcifications, with ventricular dilatation, cysts, and lenticulostriate vasculopathy also observed.

Perinatal Infection

CMV infection acquired perinatally in a healthy, full-term infant is typically asymptomatic and without sequelae.

However, premature infants, particularly those with very low birth weight (VLBW) are at risk for life-threatening disease. Transfusion-acquired CMV infection in the VLBW infant can result in a sepsis-like syndrome with hepatosplenomegaly, thrombocytopenia, and respiratory deterioration. However, transfusion-associated CMV infections in neonates are now prevented through the use of blood from CMV-seronegative donors or blood that has undergone blood filtration to remove leukocytes.

Breast milk is currently the most common route of transmission in newborns, with preterm VLBW infants at highest risk for acquisition of the virus and symptomatic disease. Unlike congenital CMV infection, there has been no documentation of an association of perinatal CMV infection with sensorineural hearing loss or delay in neuromotor development.

Infection in the Healthy Host

CMV infection among infants, children, and adults with normally functioning immune systems is generally asymptomatic. However, CMV can cause a mononucleosis-type illness in healthy hosts. Patients most commonly present with fever and malaise, and elevated serum hepatic transaminase levels are commonly seen. Lymphocytosis is common and atypical lymphocytes may be seen. CMV infections in healthy individuals completely resolve; however, symptoms can persist for several weeks with a mean duration of symptoms of 7–8 weeks in one study of 124 adults with primary CMV infection. Severe infection due to CMV in the healthy host has rarely been described. Most commonly it involves overwhelming, multi-organ involvement but can involve only the central nervous system and present with encephalitis. Guillain–Barre syndrome, myocarditis and pneumonia requiring mechanical ventilation have also been reported to be associated with CMV infection in immunocompetent patients.

Infection in the Immunocompromised Host

CMV manifestations vary in the immunocompromised host depending upon the nature of the immunosuppression. In HIV-infected persons, CMV disease generally arises via reactivation from latency as the HIV infection induces progressive T-helper immunodeficiency. CMV retinitis and end organ disease (colitis, esophagitis, encephalitis, hepatitis) are opportunistic infections that may develop in patients with AIDS.

In transplant recipients, infection can be transmitted by the donor organ or by infected blood products, or may reactivate in the latently infected recipient. Acute CMV disease manifests as febrile syndromes, pneumonitis, hepatitis, splenomegaly, or bone marrow suppression. CMV infection (blood antigenemia or positive DNA PCR test) generally precedes onset of clinical disease. CMV disease in patients not receiving antiviral prophylaxis may develop around the first 30 days after transplant. Use of antiviral prophylaxis in high-risk patients (donor or recipient CMV seropositive transplants) delays the onset of CMV infection and disease, which may arise after discontinuation of antiviral prophylaxis. In solid organ transplant patients, CMV is also thought to exert immunomodulatory effects possibly related to dysregulation of CMV immune evasion functions in the immunocompromised host, rendering the patient more susceptible to coinfections with bacterial, fungal, and other viral pathogens.

CMV can induce colitis in patients with inflammatory bowel disease (IBD) and can mimic IBD exacerbations. Endoscopy and biopsy are often required to establish this diagnosis and to distinguish CMV colitis from that due to IBD. CMV disease and retinitis have also been associated with use of TNF-α inhibitors for IBD and for rheumatologic conditions.

Laboratory Diagnosis

Serology: Serological tests are useful for determining whether an individual has had CMV infection in the past, determined by the presence or absence of CMV IgG antibodies. The detection of IgM antibodies has been used as an indicator of acute or recent infection. However, assays for IgM antibody lack specificity for primary infection because IgM can persist for months after primary infection, and because IgM can be positive in reactivated CMV infections. Because of the limitations of the IgM assays, IgG avidity assays are utilized in some populations to help distinguish primary from non-primary CMV infection. These assays are based on the observation that IgG antibodies of low avidity are present during the first few months after the onset of infection and avidity increases over time, reflecting maturation of the immune response. Thus, the presence of high-avidity anti-CMV IgG is considered as evidence of long-standing infection in an individual.

Viral culture: The traditional method for detecting CMV is conventional cell culture. Clinical specimens are inoculated onto human fibroblast cells and incubated and observed for the appearance of characteristic cytopathic

effect (CPE) for a period of time ranging from 2 to 21 days. The shell vial assay is a viral culture modified by a centrifugation-amplification technique designed to decrease the length of time needed for virus detection. Centrifugation of the specimen onto the cell monolayer assists adsorption of virus, effectively increasing infectivity of the viral inoculum. Viral antigens then may be detected by monoclonal antibody directed at a CMV immediate-early (IE) antigen by indirect immunofluorescence after 16 h of incubation. This method was adapted to be performed in 96-well microtiter plates allowing for the screening of larger numbers of samples.

Antigen detection assays: The antigenemia assay has been commonly used for more than a decade for CMV virus quantification in blood specimens. Antigenemia is measured by the quantitation of positive leukocyte nuclei in an immunofluorescence assay for the CMV matrix phosphoprotein pp65 in a cytospin preparation of 2×10^5 peripheral blood leukocytes (PBL). This test not only gives a qualitative result but is also quantitative, correlating closely with viremia and clinical disease severity in immunosuppressed populations. The disadvantages of the antigenemia assay are that it is labor-intensive with low throughput and is not amenable to automation. It may also be affected by subjective bias. The samples have to be processed immediately (within 6 h) since delay greatly reduces the assay's sensitivity. Particularly in neutropenic patients, false-negative results may occur, since the antigenemia test depends on the presence of a sufficient number of polymorphonuclear leukocytes.

Polymerase chain reaction: PCR is a widely available rapid and sensitive method of CMV detection based on amplification of nucleic acids. The techniques usually target highly conserved regions of major IE and late antigen genes, but a number of other genes have also been used as targets for detection of CMV DNA. DNA can be extracted from whole blood, leukocytes, plasma, or any other tissue (biopsy samples) or fluid (urine, cerebrospinal fluid [CSF], bronchoalveolar lavage [BAL] fluid). PCR for CMV DNA can be either qualitative or quantitative, in which the amount of viral DNA in the sample is measured. Qualitative PCR has been largely replaced by quantitative assays due to increased sensitivity for detecting CMV and because quantitative PCR (Real-Time PCR) allows for continuous monitoring of immunocompromised individuals to identify patients at risk for CMV disease for preemptive therapy and to determine response to treatment. This method is generally more expensive compared to the antigenemia assay, but it is rapid and can be automated. Results are usually reported as number of copies/mL of blood or plasma.

Immunohistochemistry: Immunohistochemistry is performed primarily on tissue or body fluid samples. Slides are made from frozen or paraffin-embedded sections of biopsy tissue samples (e.g., liver, lung) or by centrifuging cells onto a slide. Monoclonal or polyclonal antibodies against early CMV antigens are applied to the slides and visualized by fluorescently labeled antibodies or enzyme-labeled secondary antibodies, which are detected by the change of color of the substrate. The stained slides are examined by fluorescent or light microscopy.

Antigen-specific cytokine release assay: The Quantiferon-Gold-CMV® is a recently commercialized enzyme-linked immunosorbent assay (ELISA) measuring gamma-interferon release by CMV-specific lymphocytes in response to peptide antigens containing sequences of CMV proteins and human MHC class I haplotypes. The patient's blood is incubated in a test tube containing these stimulating proteins, which induce any of the patient's CD8+ cytotoxic T-lymphocytes (CTLs) that have been primed against CMV proteins to release gamma-interferon. The cytokine is then measured by standard ELISA. Positive tests represent cytokine release by CMV-primed CTLs suggesting that the patient possesses an intact lymphocytic response to CMV antigens. The clinical indications for use of this test and interpretation of results in select patient populations have not yet been well established.

Congenital Infection

The diagnosis of congenital CMV infection is typically made by the demonstration of the virus, viral antigens, or viral genome in newborn urine or saliva (*Table 106.4*). The detection of virus in urine or saliva within the first 2 weeks of life is considered the gold standard for the diagnosis of congenital CMV infection. Since the detection of the virus or viral genome in samples obtained from infants after the first 2–3 weeks of life may represent natal or postnatal acquisition of CMV, it is not possible to confirm congenital CMV infection in infants older than 3 weeks. Serological methods are unreliable for the diagnosis of congenital infection. Detection of CMV IgG antibody is complicated by transplacental transfer of maternal antibodies, and the currently available CMV IgM antibody assays do not have the high level of sensitivity and specificity of virus culture or PCR.

Traditional tissue culture techniques or shell vial assay for the detection of CMV in saliva or urine are considered the standard methods for the diagnosis of congenital CMV infection (*Table 106.4*). Rapid culture methods have

Table 106.4
Laboratory diagnosis of cytomegalovirus infection by patient population

Congenital infection	Detection of virus or viral antigens in saliva or urine using standard or rapid culture methods; CMV PCR of blood is highly specific but insufficiently sensitive; PCR assays of saliva and urine are promising
Perinatal infection	Viral culture or PCR of urine; proof of absence of CMV shedding in the first 2 weeks of life
Healthy host	Detection of virus or viral antigens in saliva, urine, BAL washings
Immunocompromised host	Culture; antigenemia; PCR of blood or body fluids; immunohistochemistry; cytokine release assay

comparable sensitivity and specificity to the standard cell culture assays and the results are available within 24–36 h. A rapid method using a 96-well microtiter plate and a monoclonal antibody to the CMV IE antigen was shown to be 94.5% sensitive and 100% specific for detecting CMV in the urine of congenitally infected infants. This microtiter plate assay has been adapted for use with saliva specimens with comparable sensitivity and specificity. The utility of antigenemia assay in the diagnosis of congenital CMV infection has not been established.

Although PCR amplification of virus DNA is a very sensitive method for the detection of CMV in a variety of clinical specimens, the utility of PCR or other nucleic acid amplification assays for the diagnosis of congenital CMV infection has not been defined. Several studies have shown that PCR of saliva and urine specimens could be useful for the identification of infants with congenital CMV infection. Since dried blood spots (DBS) are collected for routine metabolic screening from all infants born in the USA, there has been increasing interest in utilizing PCR-based assays for the detection of CMV in newborn DBS samples. Most early reports have studied selected infant populations and did not include a direct comparison of PCR with a standard (i.e., tissue culture) method for identifying CMV infection. The sensitivity of DBS PCR in the diagnosis of congenital CMV infection may vary with the amount of blood collected on the filter card, the method used for DNA extraction, and the PCR protocol. Early studies have examined the utility of PCR on DBS obtained from infants in the nursery to diagnose congenital CMV infection retrospectively at the time of detection of SNHL. A number of studies from a group of investigators in Italy examined DBS from newborns and reported a sensitivity of the DBS PCR assay approaching 100% with a specificity of 99%. However, in a large multicenter study of more than 20,000 newborns, a DBS real-time PCR assay was compared with saliva rapid culture for identification of infants with congenital CMV infection and demonstrated that DBS PCR could only detect less than 40% of congenitally infected infants. The sensitivity and specificity of the DBS PCR assay when compared with the saliva rapid culture were 30.4% (95% confidence interval [CI], 21.5–41.0%) and 99.9% (95% CI, 99.9–100%), respectively. These results indicate that such methods as currently performed will not be suitable for the mass screening of newborns for congenital CMV infection. The high specificity of the DBS PCR assay suggests that a positive DBS PCR result will identify infants with congenital CMV infection. However, the negative DBS PCR assay result does not exclude congenital CMV infection. These findings underscore the need for further evaluation of high-throughput methods performed on saliva or other samples that can be adapted to large-scale newborn CMV screening.

Several previous studies that included smaller numbers of subjects examined the utility of testing saliva samples with PCR-based methods and demonstrated the feasibility and high sensitivity of these methods. However, none of these studies have included screening of unselected newborns or a direct comparison of a saliva PCR assay to the standard rapid culture method on saliva or urine. Although a more recent study from Brazil, in which more than 8,000 newborns were screened for congenital CMV infection, demonstrated the utility of a saliva PCR assay to screen newborns for CMV, the PCR assay was not directly compared to the standard culture-based assay. The utility of real-time PCR of saliva samples to identify infants with congenital CMV infections was evaluated in a multicenter newborn screening study of approximately 35,000 infants using rapid culture and PCR of saliva specimens. The findings of this study showed that PCR testing of both liquid and dried saliva specimens has excellent sensitivity (>97%) and specificity (99.9%).

There is growing interest in examining the feasibility of a newborn CMV screening program in conjunction with universal newborn hearing screening. Although DBS PCR assays have been shown to have insufficient sensitivity for the identification of most infants with congenital CMV infection, the development of saliva PCR assays could have the potential to adapt these methods in a high-throughput approach to screen large number of newborns for congenital CMV infection.

Perinatal Infection

For definitive diagnosis of perinatal CMV infection, it is important to demonstrate no viral shedding in the first 2 weeks of life, since CMV excretion does not begin until 3–12 weeks after exposure (Table 106.4). There is no agreed-upon standard method for diagnosis of perinatal CMV infections, however. Viral culture and CMV DNA detection by PCR using urine or saliva are the preferred diagnostic methods.

Healthy Host

Active CMV infection can be diagnosed through virus isolation from sites of viral shedding (e.g., urine, saliva, or bronchoalveolar washings) and the shell vial assay allows for this to be done within a 24 h period (Table 106.4). Serology is only useful for determining primary CMV infection by documenting seroconversion or by documenting IgM and low-avidity IgG. PCR for viral DNA in the blood or plasma may occasionally be used as supportive data to diagnose primary CMV in the healthy host but is rarely used in clinical evaluation of otherwise healthy patients.

Immunocompromised Host

Serologic detection of CMV infection in the immunocompromised host is limited by the abnormal host response to viral infection. Serology may be used in the transplant setting to determine the risk of transmission from a seropositive donor or reactivation from a seropositive recipient posttransplant, and has been used to guide the usage of prophylactic antiviral therapy or preemptive viral monitoring and therapy. Blood antigenemia and quantitative DNA PCR tests are commonly used for posttransplant surveillance to determine onset of CMV infection prior to clinical disease, and to monitor response to antiviral therapy (Table 106.4). It is anticipated that the Quantiferon-Gold CMV test may be utilized in the posttransplant setting to determine whether a patient has developed a CMV-specific (protective) T-lymphocyte response posttransplant. However, this test is not yet in common clinical usage. After clinical disease has developed, CMV may be isolated by culture, PCR, or histology of relevant tissues (BAL in pneumonitis; biopsy in hepatitis; endoscopy and biopsy in colitis) (Table 106.4).

In patients with HIV infection, serology may be used to determine whether the patient is at risk for primary disease (e.g., from blood transfusions) or reactivation when severely immunocompromised. However, because of impaired antibody responses in AIDS patients, serology may not be useful during severe immunocompromise to diagnose CMV disease. Diagnosis is generally directed toward the involved organ. Retinitis may be diagnosed by slit lamp/ophthalmologic evaluation. CMV colitis or esophagitis may be diagnosed by endoscopic evaluation and biopsy, and may be identified from biopsies by culture, immunohistochemistry, or rarely by PCR. CMV encephalitis may be evaluated by culture and PCR of CSF, or rarely by brain biopsy and immunohistochemistry. Neuroimaging may be used to support the diagnosis of CMV encephalitis.

CMV colitis in IBD patients is generally diagnosed by endoscopy and biopsy, with analysis as in colitis in AIDS patients. Diagnosis of CMV in other immunocompromised hosts should be directed toward the disease entity encountered, as for AIDS and transplant patients.

Differential Diagnosis

The differential diagnosis of CMV disease is broad. For mononucleosis-like illness and pharyngitis, the differential may include EBV infection, HHV-6, HSV-1, Group A strep, toxoplasmosis, acute HIV infection (acute retroviral syndrome), enterovirus, and adenovirus. Other infectious and noninfectious conditions may be considered based upon clinical features that may be found during acute CMV disease (fever, myelosuppression, etc.) and have been reviewed elsewhere.

Treatment

General Care

Treatment in the immunocompetent host generally consists of supportive care. Patients with acute mononucleosis-like syndrome may use analgesics, antipyretics, and supportive hydration. Acute CMV disease is self-limited in the immunocompetent host, and steroids and antiviral treatments are not indicated in these patients.

Antiviral therapy: Ganciclovir (GCV) is a nucleoside analogue of guanosine, which inhibits the CMV DNA polymerase. Ganciclovir requires phosphorylation by viral and cellular polymerases to acquire activity. Valganciclovir is an orally bioavailable analogue of ganciclovir. Cidofovir (CDV) is a nucleotide analogue of

cytosine which, unlike ganciclovir, is phosphorylated to the active form by cellular kinases without the requirement for viral kinase activity. CDV inhibits viral DNA polymerase similar to GCV. The primary complication of this treatment is nephrotoxicity. CDV does not cross the blood–brain barrier efficiently. Foscarnet is a pyrophosphate analogue that requires no intracellular metabolism to directly inhibit the viral DNA polymerase. Foscarnet is indicated for use in CMV retinitis and is also used in patients with suspected or proven CMV infection resistant to GCV and CDV. Metabolic derangements and nephrotoxicity are associated with foscarnet administration. Intravenous immunoglobulin (IVIG) and CMV hyperimmune immunoglobulin (CMVIg) may be used as adjunctive therapy to treat or prevent CMV disease.

Congenital Infection

Antiviral therapy for congenital CMV infection is limited. Only one randomized controlled trial has been performed to assess the effect of 6 weeks of intravenous ganciclovir therapy on hearing outcomes in infants with symptomatic congenital infection with involvement of the central nervous system. Although this study suffered from patient attrition, treatment suggested a possible benefit with hearing thresholds declining in 20% of ganciclovir recipients at 1 year of age or older compared with worsening of hearing in 70% of subjects that did not receive treatment. Time to resolution of clinical symptoms including splenomegaly, hepatomegaly, and retinitis were not different between the control and treatment group. Treatment was associated with significant neutropenia in 63% of ganciclovir recipients. The American Academy of Pediatrics Committee on Infectious Diseases thus states that "therapy is not recommended routinely in this population of infected infants because of possible toxicities and adverse events associated with prolonged intravenous therapy. . . ." Because congenital CMV infection is a chronic infection, little data is available to suggest the best time to begin therapy and the ideal length of therapy. Currently, the National Institute of Allergy and Infectious Diseases Collaborative Antiviral Study Group is conducting a randomized placebo controlled study to compare a 6-week versus 6-month course of oral valganciclovir in babies born with symptomatic CMV infection to assess the safety and efficacy in regards to hearing and development outcome (http://clinicaltrials.gov/ct2/show/NCT00466817?term=congenital+cmv+infection&rank=3). No studies have been conducted in children with asymptomatic infection at birth; therefore, antiviral therapy is generally not recommended in these patients as the risks of treatment far outweigh the potential benefit.

Immunocompromised Host

Ganciclovir is the primary antiviral drug used to treat active CMV infections in immunocompromised hosts. Ganciclovir and valganciclovir are also used in prophylactic and preemptive treatment to prevent CMV disease in high-risk transplant patients. Both prophylactic and preemptive strategies have been shown to be efficacious in prevention of CMV disease in high-risk transplant recipients. Ganciclovir may cause marrow suppression (neutropenia, thrombocytopenia) particularly during long-term usage, which may limit its utility in hematopoietic stem cell transplant recipients prior to engraftment. Marrow toxicity must be monitored while patients are receiving ganciclovir and is reversible with discontinuation of the drug. Drug-induced neutropenia has also been treated anecdotally with granulocyte-colony stimulating factor (G-CSF). In cases where GCV-resistant CMV is suspected or demonstrated, cidofovir or foscarnet may be utilized. However, depending upon the mechanism of resistance, GCV-resistant CMV may also be resistant to CDV.

Intravenous immunoglobulin (IVIG) and CMV hyperimmune immunoglobulin (CMVIg) have been used in high-risk immunocompromised patients who have or are at risk for hypogammaglobulinemia (e.g., solid organ and stem cell transplant recipients), to prevent acute CMV disease. Both IVIG and CMVIg are also thought to have broadly immunomodulatory functions that may have benefit to the patient. However, the efficacy of immunoglobulin prophylaxis to prevent CMV disease is not well documented and generally has not been recommended as a strategy to prevent CMV disease. CMVIg has also been used as adjunctive therapy in addition to antiviral treatment in hematopoietic stem cell transplant patients with CMV disease. Again, the efficacy of this therapy is not well established and if used should be accompanied by use of specific antiviral drugs to limit direct viral replication.

Prognosis

Congenital infection: Early studies of outcome in symptomatic congenital CMV infection demonstrated that approximately 10% of symptomatic infants will die in the newborn period. However, more recent data suggests

that the mortality rate is probably less than 5%. However, the majority of symptomatic children will suffer sequelae ranging from mild to severe psychomotor and perceptual handicaps. Multiple prospective studies have shown that approximately half of the children born with symptomatic infection will develop sensorineural hearing loss (SNHL), mental retardation with IQs less than 70, and microcephaly. Predictors of adverse neurological outcome in children with symptomatic congenital CMV infection include microcephaly, chorioretinitis, the presence of other neurologic abnormalities at birth or in early infancy, and cranial imaging abnormalities detected within the first month of life. In a recent study, Rivera et al. analyzed newborn findings and hearing outcome data on 190 children with symptomatic infection to identify clinical predictors of hearing loss. Univariate analysis revealed that intrauterine growth retardation, petechiae, hepatosplenomegaly, hepatitis, thrombocytopenia, and intracerebral calcifications were associated with the development of hearing loss. Logistic regression analysis showed that petechiae and intrauterine growth retardation were the only factors that were independently predictive of hearing loss.

In general, asymptomatic children have a better long-term prognosis than children with symptomatic congenital infection. However, approximately 10% of asymptomatic children will develop SNHL (*Table 106.5*). Many prospective studies of children with asymptomatic CMV infection have been performed to define the natural history of hearing loss in this group. These studies show that approximately one-half of children with asymptomatic infection who develop hearing loss will have bilateral deficits, which can vary from mild high-frequency loss to profound impairment. Additionally, hearing loss in these children is often progressive and/or of delayed onset requiring ongoing audiological evaluation. Other neurological complications can also occur in asymptomatic congenital CMV infection but at a much lower frequency than in symptomatic infection.

Perinatal infection: Unlike congenital CMV infection, no association of perinatal CMV infection and sensorineural hearing loss or delay in neuromotor development has been documented.

Healthy host: Immunocompetent hosts with acute CMV disease should experience complete recovery. Long-term sequelae are not associated with CMV infection. CMV does cause persistent lifelong infection, but after acute infection usually remains latent for the lifetime of the normal host.

Immunocompromised host: After acute disease, immunocompromised hosts may be able to develop protective immunity that would prevent additional episodes of clinical disease. However, depending on the source and duration of immunocompromise, patients may continue to be at risk for additional episodes of disease from reactivation or from reinfection.

Table 106.5
Audiologic results for children with congenital cytomegalovirus infection

	Symptomatic	Asymptomatic
No. (%) of children with SNHL	40.7%	7.4%
Bilateral loss	67.1%	47.9%
High-frequency loss only (4,000–8,000 Hz)	12.9%	37.5%
Delayed-onset loss	27.1%	37.5%
Median age (range) of delayed onset	33 month (6–197)	44 month (24–182)
Progressive loss	54.1%	54.2%
Fluctuating loss	29.4%	54.1%
Improvement of loss	21.1%	47.9%

Prevention

Hand washing is considered an effective means to limit spread of CMV in the community among immunocompetent hosts as well as nosocomial spread. Disinfectants such as chlorine, alcohol, and detergents (soap) destroy the viral envelope and render the virus noninfectious. It has been suggested that all women of childbearing age should know their CMV serostatus; however, this is controversial. There is evidence that hygiene counseling and change in behavior can decrease the rate of primary CMV infections in seronegative women during pregnancy.

For immunocompromised hosts, contact precautions including gown and gloves with hand washing/disinfection may prevent transmission in the hospital setting but are not feasible in the community. Use of disinfectants, soap, and avoidance of sharing food and beverages may limit exposure to CMV in the community for immunocompromised patients. Prophylactic antiviral therapy (ganciclovir or valganciclovir) may be used in high-risk transplant recipients to prevent CMV infection and disease. Research is ongoing to develop adoptive immunotherapy strategies in hematopoietic stem cell recipients at high risk for CMV

disease posttransplant, whereby lymphocytes are stimulated ex vivo with CMV antigens and subsequently infused into the at-risk transplant recipient, presumably providing virus-specific cytotoxic and/or memory T cells to the recipient. However, such treatments currently remain available only under research auspices.

Passive immunization with CMV hyperimmune globulin to prevent transmission and treat infected fetuses has been evaluated in one study of pregnant women with primary CMV infection. However, the study lacked randomization and a control group, thus the use of passive immunoprophylaxis in pregnancy awaits further studies.

Vaccine prevention of congenital CMV infection has been considered since the 1970s and directed toward prevention of primary CMV infection during pregnancy. Several vaccine candidates have been studied including an attenuated, replication-competent virus and an adjuvanted glycoprotein subunit vaccine. Both appear to induce an immune response and both produce at least some level of cellular immunity. In a phase 2 trial that included 464 CMV-seronegative women of childbearing age, an MF59-adjuvanted CMV glycoprotein B subunit vaccine had 50% efficacy (95% CI, 7–73) at preventing CMV infection. The overall benefits were modest and the study was not powered to assess efficacy in preventing maternal–fetal transmission. In addition, the strategy of preventing primary maternal infections does not address the CMV-associated hearing loss and other neurologic sequelae in congenitally infected children born to women with preexisting CMV immunity. Considerable interest exists regarding the potential use of a CMV vaccine in transplant candidates prior to transplantation, but no studies have been performed in this population.

107 Epstein-Barr Virus Infection

Sami Al-Hajjar

Epstein-Barr virus (EBV) is a ubiquitous virus that is widespread in the human population. Its distribution seems to be influenced by age, socioeconomic status, climate, and race, although all of these factors may simply reflect close contact and the ease of transmissibility. In developing countries, primary EBV infections occur in 80–100% of children by 3–6 years of age. In developed countries, only 30–60% of 6-year-olds have serologic evidence of EBV infection. Seroepidemiologic studies in Saudi Arabia have shown that 50% of children up to the age of 4 years have antibodies to EBV. In these settings, the vast majority of primary infections are usually asymptomatic. Among susceptible adolescents and young adults, primary EBV infection presents with symptomatic disease, the hallmark being infectious mononucleosis (IM).

Etiology

EBV or human herpesvirus 4 is a gamma-herpesvirus that establishes latency in memory B cells to persist in the host. A relatively unstable virus, EBV has not been recovered from environmental surfaces or formites. Two types of EBV (type A and B) have been recognized on the basis of divergence of several Epstein-Barr nuclear antigens. There is currently no evidence that type difference accounts for the wide range of conditions associated with EBV infection.

Epidemiology

Humans are the only known reservoir. Human-to-human transmission of EBV occurs mainly via saliva. Palatine tonsils act as an important site used by EBV for invasion of the host and as a reservoir. EBV is transmitted via salivary contact through kissing or exchange of saliva from child to child, such as that which occurs in day care centers. The incubation period is estimated at 4–7 weeks. Once transmitted, the virus infects the epithelial cells of the oropharynx and the salivary gland ducts. Periodic shedding from such tissue is linked to virus reactivation from latency. Shedding is sustained for months after infection and then falls gradually; in 15–20% of all attempts, the virus can be recovered from saliva. Immunocompromised hosts, including human immunodeficiency virus type 1–infected patients and allograft recipients, have higher rates of shedding (average 50–80%). Evidence of the virus presence in cervical epithelium and semen has emerged, but sexual transmission has not been proved. The virus can be transmitted to susceptible recipients by blood transfusion or bone marrow transplantation.

Pathogenesis

EBV infects epithelial cells of the oropharynx and the cervix and resting B lymphocytes. Infection of the epithelial cells results in replication of the virus, with the release of virions from the cells. In contrast, infection of B lymphocytes usually results in latent infection without replication or release of virus.

EBV enters B lymphocytes by means of the CD21 receptor, which is also the receptor of the C3d component of complement; 18–24 h later, EBV nuclear antigens are detectable within the nucleus of infected cells. Expression of the viral genome, which encodes at least two viral proteins, is associated with immortalization and proliferation of the cell. The EBV-infected B lymphocytes are polyclonally activated to produce immunoglobulin and express a lymphocyte-determined membrane antigen that is the target of host cellular responses to virus-infected B lymphocytes. The host mounts a cellular immune response to control B-cell proliferation (the characteristic atypical lymphocytes found in the peripheral blood). Cytotoxic lymphocytes (CD8) are activated for this function; later memory T cells maintain the capacity to limit proliferation of EBV-infected B cells to less than one per 10^6 circulating B cells.

Clinical Manifestation

Most early infections are asymptomatic in children. The full clinical picture of IM may take days or even weeks to

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_107,

evolve. The classic manifestation typically includes fever, tonsillopharyngitis usually accompanied by exudates, lymphadenopathy, malaise, and splenic or liver enlargement. In general, the spectrum of IM in children is similar to the classic form described in young adults (Table 107.1).

The fever is usually not higher than 39.5°C and lasts 1–2 weeks, but it may persist for 4–5 weeks. The enlarged lymph nodes are usually non-tender or minimally tender and have no overlying skin erythema. The affected lymph nodes are located principally along the cervical chains in a bilateral fashion, and generalized adenopathy also may occur. Children younger than 4 years frequently display hepatosplenomegaly, skin rashes, and abdominal pain than do older children and young adults. The skin rashes in young children appear to be spontaneous and do not correlate, as they do in young adults, with the administration of ampicillin. The reasons for these differences are not clear. The clinical manifestations of the illness last approximately 2–3 weeks, with peak involvement during the second week.

EBV has been linked with a number of malignancies, including Burkitt lymphoma, Hodgkin disease, and nasopharyngeal carcinoma. Transplant recipients, especially those who have received cyclosporine A, FK506 (tacrolimus), or anti-CD3 (OKT3) antibody, are at increased risk of developing a potentially fatal lymphoproliferative disorder resembling IM that often occurs within the first year after transplantation. They are also at risk of developing focal tumors, generally of the non-Burkitt lymphoma type; these usually occur more than 1 year after transplantation. Either specific antigens or the genome of EBV has been found in most of these tumors. Uncontrolled EBV-induced lymphoproliferation may occur in patients with the X-linked lymphoproliferative syndrome (Duncan syndrome). Within families with this syndrome, individual cases may end in overwhelming infection and death during the acute phase of the illness.

EBV is associated with the variety of other disorders in AIDS patients. At least four EBV-related disorders – non-Hodgkin lymphomas (Burkitt or non-Burkitt), leiomyosarcomas, lymphocytic interstitial pneumonitis, and oral hairy leukoplakia – may develop in patients with AIDS. In children with AIDS, EBV DNA has been demonstrated in non-Hodgkin lymphoma tissues, muscle cells of leiomyosarcomas, and lung biopsies in which there is histologic evidence of lymphocytic interstitial pneumonitis.

The initially suspected etiologic association between EBV or IM and the chronic fatigue syndrome now appears to be inaccurate. Chronic fatigue syndrome (chronic debilitating illness characterized by extreme fatigue syndrome, neuropsychological abnormalities, and myriad other problems) is now thought to be caused by an as-yet-unidentified retrovirus.

Table 107.1
Clinical findings in children with documented Epstein-Barr virus infectious mononucleosis by age group

Clinical findings (%)	Age of patient (yr)	
	<4	4–16
Fever	90	100
Lymphadenopathy	94	94
Sore throat/tonsillopharyngitis	68	76
Splenomegaly	80	51
Hepatomegaly	63	30
Cutaneous rashes[a]	34	27

[a]Cutaneous rashes can be erythematous, petechial, erythema multiforme-like, urticarial, or scarlatiniform

Diagnosis

Most acute EBV illnesses can be diagnosed by the presence of typical clinical, hematologic, and serologic findings. Patients with IM typically demonstrate an absolute lymphocytosis of 50% or more. Lymphocytosis is most severe during the second and third weeks of illness and lasts for 2–6 weeks. Usually, 20–40% of the lymphocytes are atypical, although not all patients have more than 10% atypical lymphocytes. The atypical lymphocyte is generally larger than the mature lymphocyte encountered in peripheral blood. The cytoplasm is often vacuolated and basophilic, and its edges have a rolled-up appearance. Nuclei are often lobulated and are eccentrically located. It should be remembered that atypical lymphocytes are not pathognomonic for IM and can also be noted in other illnesses (Table 107.2). Liver function tests (LFTs) are abnormal in more than 90% of patients with infectious mononucleosis.

Identification of heterophil antibodies, originally described by Paul and Bunnel, is the cornerstone of laboratory diagnosis. These antibodies are directed at antigens present on erythrocytes obtained from sheep, horses, or cattle. In the heterophil antibody test, the patient's serum is first absorbed with guinea pig kidney homogenate to remove cross-reacting antibodies such as Forssman antibodies and those naturally occurring in serum sickness. With IM, heterophil antibody is still present and is usually

detected by agglutination of sheep red blood cells. The heterophil antibody titer is the higher dilution of the absorbed serum required to agglutinate these erythrocytes. Horse red cell agglutination is more sensitive than are tests for sheep or beef red cell agglutination. Among school-age children and young adults, heterophil antibodies become detectable 80–90% of the time during the second week of clinical illness. This antibody will present in only 50% of children younger than 4 years of age. Heterophil antibodies may persist for 6–12 months after recovery from the illness. Most laboratories use one of many rapid agglutination tests, such as Monospot, to screen for EBV instead of the standard tube heterophil titer, which is labor intensive. The correlation between the results is obtained by the use of these rapid agglutination tests and those from the classic tube heterophil test.

Although EBV accounts for over 90% of mononucleosis syndrome cases, cytomegalovirus, rubella, adenovirus, Toxoplasma gondii, hepatitis A virus, human immunodeficiency virus, and human herpesvirus occasionally are responsible for a heterophil-negative mononucleosis-like syndrome. Virus-specific antibodies to EBV viral capsid antigen or nuclear antigen are usually demonstrable when patients develop EBV infection.

Table 107.2

Cytomegalovirus infections
Toxoplasmosis
Acute viral hepatitis
Adenovirus infection
Rubella
Drug reaction

If a typical clinical syndrome is accompanied by detectable heterophil antibodies, EBV-specific serologic studies are not indicated. However, in children less than 4 years old, in whom heterophil antibodies may never turn positive, EBV-specific serology should be performed (*Table 107.3*).

The acute phase of IM is characterized by serum immunoglobulin M (IgM) and immunoglobulin G (IgG) antibody responses to EBV capsid antigen and in most cases an IgG response to EBV early antigen complex. The IgM response to EBV capsid antigen is transient, lasting only one or two months and even less in very young children. The IgG response remains for life. Antibodies to EBV early antigen complex may last several months or even years after resolution of the IM episode. Antibodies to EBV nuclear antigen are typically late in onset, gradually emerging over several months following the acute IM episode, and may remain for life.

In some patients with lymphoproliferative disorders or atypical clinical disease, the serologic response to EBV antigens may be incomplete or even lacking. In such cases, it may be necessary to demonstrate the presence of EBV antigen using immunofluorescence or immunoblot techniques, or the presence of EBV nucleic acid in tissue sections or Quantitative polymerase chain reaction (PCR) can be used to measure Epstein-Barr virus DNA in plasma. Because of the narrow host range and long incubation period, culture of EBV for diagnostic purposes is not useful.

Complications

Most persons with IM will recover uneventfully. Approximately 20% of children will develop some type of complication (*Table 107.4*). Death from IM is rare. Of 20 deaths clearly associated with IM in one series, 9 were of neurologic origin, 3 each were caused by secondary

Hematologic	Hemolytic anemia, thrombocytopenia with hemorrhages
Infectious	Recurrent tonsillopharyngitis, bacteremia

infection or splenic rupture, 2 by hepatic failure, and 1 by probable myocarditis. EBV has been also implicated in hemophagocytic syndrome.

Treatment

Supportive therapy is usually all that is required in uncomplicated IM because more than 90% of patients recover uneventfully without specific therapy. Supportive therapy includes bed rest, drinking fluids, and administration of aspirin or acetaminophen. Because of the infrequent complication of splenic rupture, patients should be advised to avoid contact sports or strenuous physical exercise until the spleen is no longer palpable. Clinically, rupture is suggested by the presence of abdominal pain, hypotension, and/or shock-like syndrome. In some patients who are severely asymptomatic (e.g., impending airway obstruction) or patients with complicated illness (hematologic or neurologic complications), steroid therapy should be considered.

The use of antiviral drugs (acyclovir) in IM has been evaluated in double-blind placebo-controlled studies without any significant reduction of clinical symptoms in the early course of IM. In immunosuppressed patients with EBV-related lymphoproliferative disorders, acyclovir has shown some effects in some cases. Several other agents, such as ganciclovir, E-5 (2-bromovinyl)-2-deoxyuridine (VDU), and several other nucleoside analogues, exhibit greater effect in vitro than does acyclovir but have not been adequately evaluated by clinical trials.

Intravenous immunoglobulin is used to modulate immune function in the presence of autoantibodies. It has been used successfully in the treatment of immune thrombocytopenia associated with IM and for the treatment of EBV-driven posttransplant lymphoproliferative disease (PTLD) in combination with other treatment.

Some early case reports on the use of anti-B-cell antibodies for the treatment of lymphoproliferative disorders have suggested that this approach may have therapeutic value in the control of EBV-driven PTLD. Rituximab (a humanized murine monoclonal antibody that recognizes the CD20 antigen on B cells) is the next-generation immunoreagent that has recently been approved for the treatment of certain CD20-positive-B-cell non-Hodgkins lymphomas and anecdotal studies have reported favorable responses in PTLD patients.

108 Herpes Simplex Virus Infections

David W. Kimberlin

Introduction

Herpes simplex virus (HSV) infections are extremely common in people. Fortunately, most HSV infections are neither life threatening nor incapacitating. Generally speaking, HSV type 1 (HSV-1) infects above the belt, and HSV type 2 (HSV-2) infects below the belt. The most common disease manifestations of HSV are fever blisters (HSV-1) and genital herpes (HSV-2). Severe life-threatening disease can occur with either viral type in the neonate, with HSV-1 brain infection, or with either viral type in immunocompromised patients. Fortunately, safe and effective antiviral therapies exist for both mucocutaneous and life-threatening HSV infections.

Epidemiology

HSV Infections in Children and Nonpregnant Adults

General

Transmission of HSV occurs when the mucous membranes or abraded skin of a susceptible person come in contact with virus from the lesion of an infected host who is actively shedding infectious particles. This most often occurs during close, intimate contact. If a person who is susceptible to HSV infection (who lacks preexisting antibody) is exposed to HSV-1 or HSV-2, then a *first-episode primary infection* may result. Viral reactivation after the establishment of latency may result in a *recurrent infection*. If, however, a person with preexisting antibody to one type of HSV experiences a first infection with the opposite virus type, then a *first episode non-primary infection* will result. An example of a first episode non-primary infection is the person with preexisting HSV-1 antibodies from an episode of gingivostomatitis earlier in life who later acquires a genital HSV-2 infection.

Oropharyngeal HSV Infection

Herpes simplex virus-1 is found most commonly in the oropharynx. Primary infection with HSV-1 occurs most commonly in young children and is usually asymptomatic; when symptomatic, the child usually presents with gingivostomatitis. Primary infection in young adults has been associated with pharyngitis and, often, a mononucleosis-like syndrome. Primary gingivostomatitis results in viral shedding in oral secretions for an average of 7–10 days, but may occur for as long as 23 days. Neutralizing antibodies begin to appear between days 4 and 7 after clinical onset of disease, peaking at approximately 3 weeks. Virus can be isolated from the saliva of asymptomatic children and adults as well.

Factors which influence the frequency of primary HSV-1 infection include geographic location, socioeconomic status, and age. In the United States, one-quarter of white children and one-half of black children are infected with HSV-1 during their pre-adolescent years. Seroprevalence rates for both racial groups reach 85–90% by 60 years of age. HSV-1 antibody prevalence is higher in developing countries and in the lower socioeconomic classes of developed countries, illustrating the role that crowded living conditions plays in the epidemiology of infection. Recurrent herpes labialis accounts for the largest proportion of HSV infections. As with primary infections, recurrent disease may occur in the absence of clinical symptoms. At any given time, approximately 1% in normal children and between 1% and 5% in normal adults will be asymptomatically shedding HSV.

Genital HSV Infection

Genital HSV infections are usually caused by HSV-2, although in the United States at least 20% are attributable to HSV-1 and the frequency appears to be increasing. Conversely, in Japan and in Sheffield, England, these figures have been reported to be as high as 35% and 50%, respectively. Genital HSV-1 infections have been reported to be less severe and to recur less frequently than HSV-2 infections, a finding which could explain why recurrent genital herpes infections are caused by HSV-2 in 99% of cases.

The primary route of acquisition of HSV-2 infections is via sexual contact with an infected partner. As with oropharyngeal HSV-1 infection, HSV-2 can be recovered

from the genital tract of asymptomatic patients with primary, initial, or recurrent HSV-2 infection. As would be expected, antibodies to this virus are rarely found prior to the onset of sexual activity. As demonstrated in *Table 108.1*, gender, race, age, marital status, and lifetime number of sexual partners each correlates with likelihood of having antibody to HSV-2.

Recurrent genital HSV-2 infection can be either symptomatic (recognized by the patient) or asymptomatic (unrecognized throughout the time of recurrence). The duration of viral shedding is shorter during recurrent infection, and there are fewer lesions present.

Maternal Genital HSV Infection

It is apparent from the seroprevalence data that genital HSV infection in women is not uncommon. The clinical presentation of HSV infection during pregnancy is varied. The most common form of maternal HSV infection during pregnancy is localized genital infection. On the other extreme, pregnant women can develop life-threatening disseminate HSV disease due to the relative immunosuppression incumbent in pregnancy. More extensive disease is more likely to occur in women with first-episode genital herpes; the fact that approximately 10% of pregnant

women are at risk of contracting a primary HSV-2 infection from their HSV-2-seropositive sexual partners is noteworthy. Primary infections are associated with fever, malaise, myalgias, and other signs and symptoms of systemic illness. Eight percent of such patients develop aseptic meningitis, and 2% have sacral autonomic nervous system dysfunction with associated urinary retention. In contrast, systemic symptoms are distinctly uncommon in recurrent infections.

Between 60% and 80% of women who deliver an HSV infected infant have neither a past history of genital herpes nor a sexual partner reporting a history of genital HSV. In order for significant improvement in the prevention of neonatal HSV to occur, the means of identifying women who are seropositive but have no known history of genital herpes, as well as of identifying seronegative women at risk for acquiring infection from a seropositive sexual partner, must be greatly improved.

Neonatal Herpes Simplex Infection

Factors Influencing Transmission of Infection to the Fetus

Five factors increase the likelihood that a woman shedding HSV in her genital tract at the time of delivery will transmit the virus to her neonate. The most important of these is the category of maternal infection she is experiencing. The infants at highest risk for neonatal disease are those delivered to a mother with primary or initial HSV infection. If a woman is shedding HSV in her genital tract at the time of delivery, the risk of neonatal acquisition is almost 60% if she is experiencing a first-episode primary infection, 25% if she is experiencing a first-episode non-primary infection, but only 2% if she is experiencing a recurrent infection. The duration and quantity of viral excretion as well as the time to complete healing vary according to whether maternal genital infection is first-episode primary, first-episode non-primary, or recurrent. With primary infection, larger concentrations of virus are shed in the genital tract ($>10^6$ viral particles per 0.2 mL of inoculum) for a longer duration of time (up to 21 days). In contrast, virus is shed for an average of only 2–5 days and at lower concentrations (10^2–10^3 viral particles per 0.2 mL of inoculum) in women with recurrent genital infections.

The pregnant woman's antibody status at delivery also influences the severity of infection and the likelihood of viral transmission. Transplacentally acquired maternal neutralizing antibodies have a protective effect both on the acquisition of and the outcome from infection following neonatal exposure to HSV during delivery. Complete neutralization of virus by antibody may occur in some infants, and prolongation of the incubation period and modification of the infection may occur in others.

Additionally, the duration of membrane rupture and mode of delivery both impact the risk for acquisition of neonatal infection. Cesarean delivery in a woman with active genital lesions can reduce but not completely eliminate the infant's risk of acquiring HSV, especially if performed within 4 h of rupture of membrane. Based on this observation, it is recommended that women with active genital lesions at the time of onset of labor be delivered by cesarean section. Importantly, neonatal infection has occurred in spite of cesarean delivery performed prior to the rupture of membranes.

Lastly, the application of fetal scalp monitors around the time of delivery may increase the risk of neonatal HSV infection by providing a site of inoculation for the virus. The risks and benefits of such devices should be considered carefully for women with a history of recurrent genital HSV infections.

Incidence of Newborn Infection

While fluctuations in the incidence of neonatal HSV disease have been observed, the current estimated rate of occurrence is approximately one in 3,200 deliveries. Over the past 25 years, a progressive increase in the number of cases of neonatal HSV infection has been noted in some areas, paralleling the increased prevalence of genital HSV infection noted over the same time period. Still, neonatal HSV infections occur far less frequently than do genital HSV infections in the adult child-bearing population. Overall, the United States, with approximately 4.0 million deliveries per year, has an estimated 1,500 cases of neonatal HSV infection annually.

Times of Transmission of Infection

Herpes simplex virus infection of the newborn can be acquired at one of three times: in utero, intrapartum, and postnatal. Though the overwhelming majority of cases are acquired during the intrapartum passage through an infected birth canal, the other two modes of transmission must be recognized and identified in infants with HSV disease for both public health and prognostic purposes. Regardless of the route by which a neonate becomes infected with HSV, the potential for mortality and devastating morbidity is equally ominous.

Intrauterine acquisition of HSV accounts for about 5% of all neonatal HSV infections. Neonates typically present at delivery (and by definition within the first 24 h of life) with findings suggestive of in utero infection. Intrauterine infection occurs as a consequence of either transplacental or ascending infection. In the former case, the placenta may demonstrate necrosis and inclusions in the trophoblasts. Alternatively, histopathologic evidence of chorioamnionitis in other cases support ascending infection as an alternate mode of intrauterine acquisition of HSV infection. Risk factors associated with intrauterine transmission are unknown at this time. Both primary and recurrent maternal infection can result in infection of the fetus in utero.

Intrapartum contact of the fetus with an infected maternal genital tract is by far the most common source of neonatal HSV infection, accounting for about 85% of all cases. Risk factors associated with intrapartum transmission of virus are discussed above.

Postnatal acquisition of HSV accounts for roughly 10% of all cases of neonatal HSV infection. The possibility for postnatal acquisition of virus is especially concerning when HSV-1 is isolated from an infant. With at least 20% of genital herpes now caused by HSV-1, detection of this virus in the neonate does not prove that the timing of viral acquisition was postnatal; however, given the very large reservoir of HSV-1 in children and adults who have had orolabial infection, one should consider the possibility of postnatal acquisition when HSV-1 is determined to be the cause of neonatal infection. Relatives and hospital personnel with orolabial herpetic lesions may serve as a source of virus for infection of the newborn.

Clinical Presentation

Neonatal HSV Infection

The clinical presentations of neonatal HSV infections are a manifestation of both the site and extent of viral replication. Herpes simplex virus infection acquired either intrapartum or postnatally can be classified as: (1) disease localized to the skin, eye, and/or mouth; (2) encephalitis, with or without skin, eye, and/or mouth involvement; and (3) disseminated infection that involves multiple organs, including the central nervous system, lung, liver, adrenals, skin, eye, and/or mouth. The presentation and outcome of infection, particularly prognosis after therapy, vary significantly according to category. *Table 108.2* summarizes disease characteristics of 186 infants with neonatal HSV infections treated with intravenous acyclovir from 1981 through 1997 as part of studies conducted by the National Institute of Allergy and Infectious Diseases (NIAID)

Table 108.2

[a]Patients with CNS and disseminated HSV disease were disproportionately enrolled in the high-dose acyclovir study spanning 1989–1997. This fact accounts for the relatively lower percentage of patients with SEM disease in this report

Collaborative Antiviral Study Group. Table 108.3 summarizes the clinical characteristics that influence mortality on the basis of relative risk after multivariate adjustments.

Intrauterine Infection

Intrauterine infection accounts for about 5% of neonatal HSV infections. Thus, about one in 300,000 deliveries results in a child with intrauterine HSV infection. Manifestations of intrauterine HSV infection may be obvious or very subtle, closely resembling those findings encountered in other congenital infections. Since infection of the fetus can occur at any time during gestation, the earlier in gestation the infection occurs, the greater the likelihood of significant damage. Intrauterine infection is characterized by the triad of skin manifestations, chorioretinitis, and central nervous system involvement. A summary of 71 patients who have been reported in the literature is presented in Table 108.4.

Disseminated Disease

Infants with disseminated infection typically present to tertiary care centers around 10 or 11 days of life, although signs of infection usually begin an average of 5–6 days earlier (Table 108.2). Historically, this group of babies has accounted for approximately one-half to two-thirds of all children with neonatal HSV infection. However, this figure has been reduced to about 25% since the introduction of early antiviral therapy, likely the consequence of recognizing and treating SEM infection before its progression to more severe disease.

The principle organs involved during the course of disseminated infection are the liver and adrenal glands. Other organs which may be involved include the larynx, trachea, lungs, esophagus, stomach, lower gastrointestinal tract, spleen, kidneys, pancreas, central nervous system, and heart. Constitutional signs and symptoms include irritability, seizures, respiratory distress, jaundice, disseminated intravascular coagulopathy, shock, and, in 58% of patients with disseminated disease, the characteristic vesicular exanthem of HSV infections. Encephalitis is a common component of this category of infection, occurring in about 60–75% of infants with disseminated disease. While the presence of a vesicular rash can greatly facilitate the diagnosis of HSV infection, over 40% of neonates with disseminated HSV disease will not develop cutaneous vesicles during the course of their illness.

Prior to the advent of effective antiviral therapy for disseminated neonatal HSV disease, mortality exceeded 80%. With antiviral therapy, however, mortality from this category of disease has been decreased to approximately 30% (Fig. 108.1). The significant predictors of mortality in infants with disseminated disease are pneumonia, depressed levels of consciousness at presentation, and disseminated intravascular coagulopathy. Over 80% of survivors of disseminated neonatal HSV disease will have normal neurologic development at 12 months of age (Fig. 108.3).

Evidence of bone marrow dysfunction (leukopenia, thrombocytopenia), liver dysfunction (elevated AST, GGT; direct hyperbilirubinemia), coagulation problems (disseminated intravascular coagulopathy), and pneumonia (diffuse interstitial pattern on chest radiographs, progressing to hemorrhagic pneumonitis) are the best indicators of visceral involvement and thus disseminated infection. As such, the clinical laboratory and the radiology department are invaluable in monitoring extent of disease and disease progression.

CNS Disease

Infants with HSV infection can have involvement of the central nervous system as a manifestation of: (1) disseminated disease, or (2) encephalitis with or without skin, eye, and/or mouth involvement. Infants with disseminated infection probably seed the brain by a blood-borne route, resulting in multiple areas of cortical hemorrhagic necrosis. In contrast, neonates who present with only encephalitis likely develop brain disease as a consequence of retrograde axonal transmission of virus to the central nervous system, with a more focal pattern of CNS involvement. This contention is supported by the finding that neonates with encephalitis alone (those who do not have encephalitis as a manifestation of disseminated infection) usually present to tertiary care centers at approximately 19 days of life, whereas those with the more fulminate disseminated disease present at 10–11 days of life.

One-third of all neonates with HSV infection are categorized as having encephalitis with or without skin, eye, and/or mouth involvement. Clinical manifestations of encephalitis, either alone or in association with disseminated disease, include seizures (both focal and generalized), lethargy, irritability, tremors, poor feeding, temperature instability, and bulging fontanel. Of those infants with encephalitis without visceral dissemination, 63% have associated skin vesicles at any point in the disease course. Cultures of cerebrospinal fluid yield virus in 25–40% of all cases of neonatal HSV encephalitis. This is a significantly higher yield than the ~4% of positive CSF

Table 108.3

Prognostic factors identified by multivariate analyses for neonates with HSV

cultures from adult patients with HSV encephalitis. Anticipated cerebrospinal fluid indices include a mild pleocytosis (usually 50–150 cells) with a predominance of mononuclear cells (>70%), an elevated protein (>100 mg/dL), and a normal or slightly decreased glucose. The presence of red blood cells in CSF obtained from an atraumatic lumbar puncture is a reflection of cortical necrosis secondary to the viral infection. Serial examinations of cerebrospinal fluid in a neonate with encephalitis demonstrate progressive increases in the protein concentration. It is possible to have central nervous system involvement (as determined by a positive polymerase chain reaction test) but no abnormalities of CSF indices. The importance of cerebrospinal fluid examinations in all infants with suspected HSV infection is underscored by the finding that even subtle abnormalities have been associated with significant developmental delay.

Additional studies which are of benefit in the evaluation of the infant with suspected HSV encephalitis include electroencephalography (EEG) and computed tomography (CT) or magnetic resonance imaging (MRI). The EEG is diffusely abnormal in 80% of neonates with CNS involvement at the time of presentation; however, cranial CT scan at the time of presentation is usually normal.

Prior to the use of antiviral agents, mortality from neonatal HSV encephalitis with or without skin, eye, and/or mouth involvement was 50%. Since the advent of vidarabine and acyclovir therapy, though, this mortality rate has decreased to 6% (*Fig. 108.2*). As shown in *Table 108.3*, a semicomatose or comatose level of consciousness, as well as prematurity, significantly predict mortality in infants with encephalitis.

The impact of antiviral therapy on morbidity in neonatal HSV encephalitis is less impressive. More than two-thirds of survivors of neonatal CNS disease have neurologic impairment at 1 year of age and beyond (*Fig. 108.3*). The only factor which has been found to predict morbidity in patients with CNS disease is the presence of seizures. Neurologic sequelae of neonatal HSV encephalitis include microcephaly, spastic quadriplegia, persistent seizure disorder, blindness, and developmental delay.

Skin, Eye, and/or Mouth (SEM) Disease

Infection localized to the skin, eye, and/or mouth has historically accounted for approximately 18% of all cases of neonatal HSV disease. With the introduction of early antiviral therapy, this frequency has increased to approximately 45%. The association between this increase in SEM disease and the decrease in disseminated infection is likely the consequence of recognizing and treating SEM infection before its progression to more severe disease. By definition, SEM disease does not result in mortality. It is not known at this time whether the neurologic morbidity previously attributed to SEM disease actually related to subclinical CNS involvement which was not recognizable prior to the development of polymerase chain reaction technology. Regardless, neurologic morbidity following SEM disease, if it occurs at all, is an unusual event.

Neonates with HSV infection localized to the skin, eye, and/or mouth generally present for medical attention around 11 or 12 days of life, although evidence of the disease usually has been present for 5–6 days. The skin vesicles are typically 1–2 mm in diameter and erupt from an erythematous base. They may progress to larger, bullous lesions greater than 1 cm in diameter. Clusters of vesicles often appear initially on the presenting part of

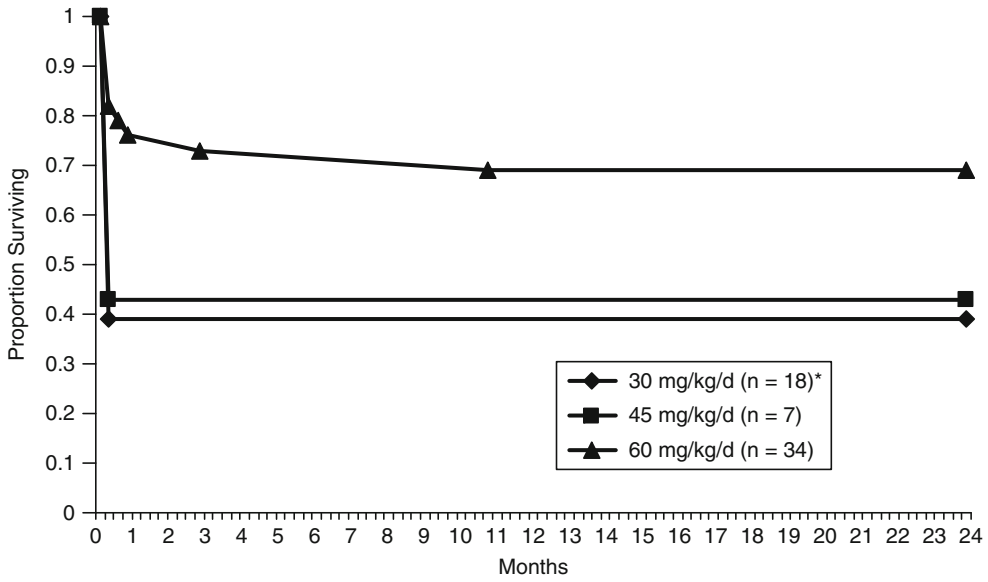

Figure 108.1
Mortality in neonatal HSV patients with disseminated disease

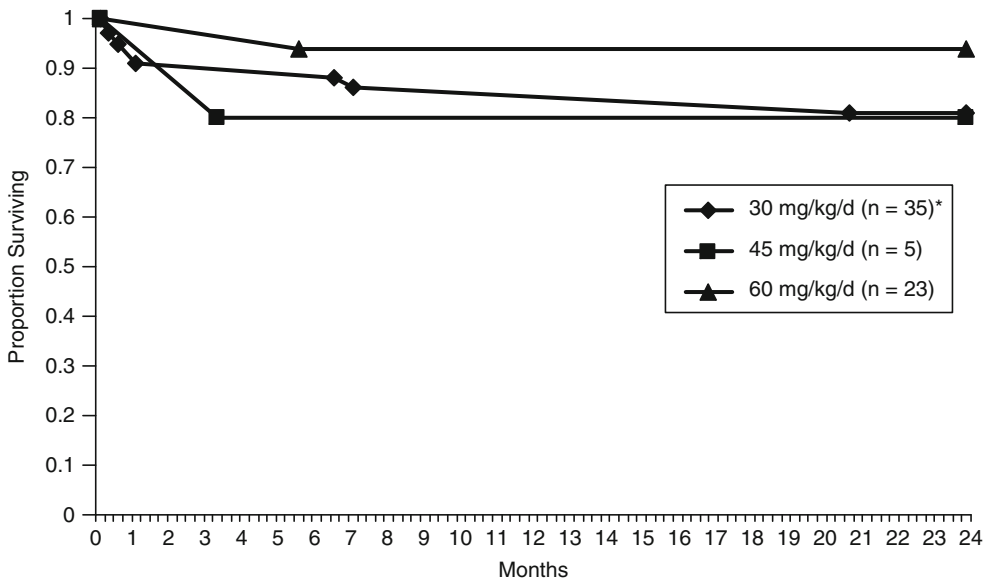

Figure 108.2
Mortality in neonatal HSV patients with CNS disease

the body that was in direct contact with the virus during birth. The rash may then progress to involve other areas of the body as well. While discrete vesicles on various parts of the body are usually encountered, crops and clusters of vesicles may also be seen. Such clusters of HSV vesicles have been described in a dermatomal, zosteriform pattern.

Oropharyngeal HSV lesions may occur with or without systemic involvement. Approximately 10% of all neonates with HSV infection have evidence of virus in the oropharynx. It is not clear, however, what proportion of these infants are excreting virus from this site in the absence of clinically apparent oropharyngeal lesions.

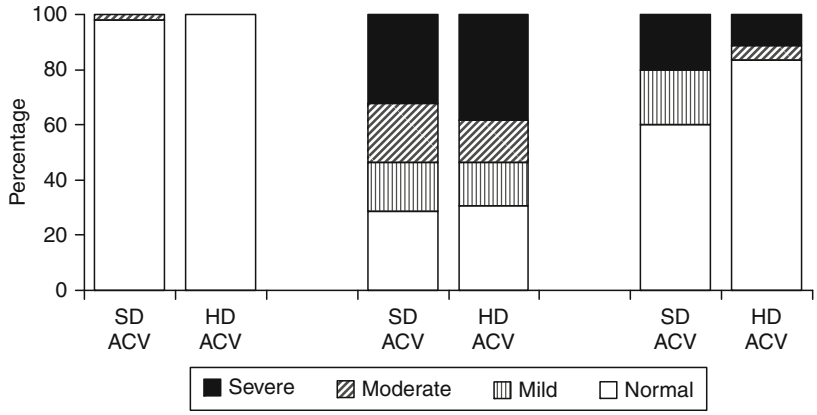

Figure 108.3
Morbidity among neonatal HSV patients with known outcomes after 12 months of age

Pediatric and Adolescent HSV Infections Beyond the Neonatal Period

Oropharyngeal HSV Disease

Most cases of primary HSV-1 infection in the pediatric age group are asymptomatic. When symptoms are present, they consist of variable combinations of fever, sore throat, ulcerative and vesicular oral lesions, gingivostomatitis, edema, localized lymphadenopathy, anorexia, and malaise. The incubation period for HSV-1 oropharyngeal infection ranges from 2 to 12 days, with a mean of approximately 4 days.

Symptomatic primary HSV-1 infection in children is characterized by buccal and gingival mucosal involvement. Clinical illness can last from 2 to 3 weeks, and fevers during that time can range from 101°F to 104°F. The degree of oropharyngeal involvement can predispose to dehydration due to the significant edema of the mucosal membranes and the associated pain. Oropharyngeal lesions evolve from vesicles to shallow ulcerations on erythematous bases, with subsequent slow healing. Intraoral vesicles are quite fragile and frequently rupture to leave the shallow ulcerations before being appreciated by the patient or his/her caregivers. Submandibular lymphadenopathy is a frequent component of primary HSV-1 illness, but is only rarely seen in recurrent disease. Other clinical signs and symptoms include sore throat, oral pain, malaise, tender cervical adenopathy, and an inability to eat or drink.

Symptomatic primary HSV-1 infection in adolescents and young adults is commonly associated with pharyngitis and a mononucleosis syndrome. Pharyngeal findings include tonsilar ulcerative lesions on erythematous bases and submandibular lymphadenopathy.

Within 24–48 h of clinical recurrence of HSV-1 vesicular lesions, a prodrome of pain, burning, tingling, or itching lasting fewer than 6 h commonly occurs. Vesicles most commonly appear at the vermillion border of the lip, persisting for only 48 h in most patients. Within 72–96 h, the lesions progress through ulceration to crusting, with a diminution of pain during this period. Healing is complete in 8–10 days. A typical recurrence consists of 3–5 vesicles localized to a small region of the vermillion border of the lip. The frequency of recurrences varies from person to person. Factors associated with recurrences of HSV-1 lesions include fever, stress, and exposure to UV light. HSV infection in patients with underlying eczema can result in severe cutaneous infection.

Genital HSV Disease

As is true with oropharyngeal HSV-1 infection, genital HSV-2 infection is more likely to produce symptoms when acquired for the first time, as opposed to recurrent infections. Primary HSV-2 infections can have associated fever, dysuria, localized inguinal adenopathy, and malaise. For reasons that are poorly understood, the severity of primary infection and complications thereof are higher in women than in men. Overall, systemic complaints occur in almost 70% of all cases of primary genital HSV infection.

Symptomatic primary genital HSV infections in women invariably involve the cervix, and vulvar lesions are usually bilateral. Additional sites of involvement can include the vagina, perineum, and buttocks. Lesions are usually exquisitely painful, with associated inguinal

adenopathy and dysuria. Eight percent of patients develop aseptic meningitis, and 2% have sacral autonomic nervous system dysfunction with associated urinary retention.

In men, symptomatic primary genital HSV infections manifest as clusters of vesicular lesions superimposed on erythematous bases, appearing usually on the glans penis or penile shaft. Numbers of vesicles are highly variable from patient to patient. Systemic complications in men with primary genital HSV infections are relatively uncommon, though aseptic meningitis can occur.

First-episode non-primary genital infection is associated with fewer and less severe systemic symptoms than primary disease. The number of lesions, severity of pain, and likelihood of complications are all notably decreased, likely due to the ameliorative effect of preexisting HSV-1 antibodies.

Herpes Simplex Encephalitis

Herpes simplex virus-1 causes encephalitis (HSE) in individuals of all ages and remains the most common cause of sporadic fatal encephalitis in the United States, accounting for approximately 1,250 cases yearly. The incidence of severe hemorrhagic focal encephalitis due to herpes simplex virus is approximately one in 200,000 persons per year. Mortality in untreated patients exceeds 70%, and only 2.5% of all patients return to completely normal neurologic function.

Clinical signs and symptoms which may be associated with HSE include focal neurologic findings, fever, altered consciousness, bizarre behavior, disordered mentation, and cerebrospinal fluid pleocytosis. Neuroimaging studies frequently demonstrate localized temporal lobe involvement. However, there are no characteristic series of findings which are pathognomonic for HSE. Thus, a high index of suspicion is crucial for the prompt diagnosis of this devastating disease. In pursuing this evaluation, however, other diagnostic possibilities should also be considered, as other treatable diseases can mimic HSE.

Herpes Simplex Keratoconjunctivitis

Primary herpetic keratoconjunctivitis initially manifests as either unilateral or bilateral conjunctivitis, followed by preauricular adenopathy. Associated symptoms include photophobia, tearing, eyelid edema, and chemosis. Herpetic ophthalmic infections beyond the neonatal period are usually caused by HSV-1, with approximately 300,000 cases diagnosed annually in the United States. Branching dendritic lesions are typically seen, and geographic ulcer of the cornea can occur in advanced ophthalmic disease. Recurrent HSV ophthalmic infections are common.

Diagnosis

Isolation of HSV by culture remains the definitive diagnostic method of determining HSV disease. If skin lesions are present, a scraping of the vesicles should be transferred in appropriate viral transport media on ice to a diagnostic virology laboratory. Such specimens are inoculated into cell culture systems, which are then monitored for cytopathic effects characteristic of HSV replication. Other sites from which virus may be isolated include the cerebrospinal fluid, urine, throat, nasopharynx, and conjunctivae. Duodenal aspirates for HSV isolation may be indicated in infants with hepatitis, necrotizing enterocolitis, or other gastrointestinal manifestations of disease. Typing of a HSV isolate may be done by one of several techniques and can be of value in determining the cause of the infection and prognosis for recurrence.

The diagnosis of HSV infections of the CNS and genital tract has been revolutionized by the development of polymerase chain reaction technology. PCR is now the gold standard for diagnosis of CNS involvement in neonatal HSV and in HSE. Increasingly, it also is used to detect viremia in neonatal HSV, and to document the presence of HSV in skin and mucosal surface lesions in HSV of all age groups. The test is now standardized to the point of being reliable in commercial laboratories, and has a much more rapid turnaround time compared with culture. With the exception of detection of viral DNA in CSF, if PCR is sent on non-CSF specimens, it generally is recommended that a specimen also be sent for HSV culture. The rationale for this apparent diagnostic duplication is that the sensitivity of HSV PCR is not as well defined in the non-CNS disease manifestations, and a positive viral culture will result in a viral isolate that can be studied further if needed.

In contrast to other congenital and neonatal infections, serologic diagnosis of HSV infection is not of great clinical value. The presence of transplacentally acquired maternal IgG confounds the assessment of the neonatal antibody status during acute infection. Serial antibody assessment may be useful in the very specific circumstance of a mother who has a primary infection late in gestation and transfers very little or no antibody to the fetus. Reliable, type-specific serologic assays are now commercially available and can be used to determine prior HSV-1 or HSV-2 infection in persons beyond the neonatal and infantile periods.

Treatment

Oropharyngeal HSV Disease

Orally administered acyclovir at a dose of 200 mg five times daily for 5 days reduces the length of time to the loss of crusts by approximately 1 day but does not alter the duration of pain or the length of time to complete healing. Increasing the dose to 400 mg five times daily for 5 days reduces duration of pain and length of time to the loss of crusts by about one-third, but only if treatment is started during the prodromal or erythematous stages of recurrent infection. Oral acyclovir begun within 96 h at a dose of 600 mg/m^2 four times daily for 10 days provides both virologic and clinical benefit when compared to placebo, though the duration of symptoms is decreased by only 2 days. Thus, oral acyclovir has a slight clinical benefit only if initiated very early after recurrence and cannot be recommended as routine treatment for herpes labialis in immunocompetent patients. Pediatric dosing of the valine ester prodrug of acyclovir, valacyclovir, has recently been defined.

Genital HSV Disease

Acyclovir administered topically, orally, and intravenously is effective in the treatment of primary genital herpes in the normal host, decreasing the duration of symptoms, viral shedding, and time to healing of lesions (*Table 108.5*). However, neither intravenous nor topical treatment of primary HSV lesions reduces the frequency or severity of recurrences. Episodic administration of oral or topical acyclovir for the treatment of recurrent genital HSV lesions provides only a modest benefit, with duration of lesions being shortened at most by 1–2 days. However, daily administration of oral acyclovir can effectively suppress recurrences of genital herpes in 60–90% of patients. There is no evidence that the frequency or severity of recurrent genital herpes is increased after cessation of long-term suppression therapy, and studies have evaluated suppressive therapy for as long as 3 years without evidence of substantial adverse effects. Treatment should be interrupted every 12 months to reassess the need for continued suppression. Valacyclovir and famciclovir are not more effective than acyclovir and cost more, but have

Table 108.5
Antiviral therapy in herpes simplex virus infections

Type of infection	Drug	Route and dosage[a]	Comments
Genital HSV			
Initial episode	Acyclovir	200 mg po 5 times/d × 10 day	Preferred route in normal host
		5 mg/kg IV q 8 h × 5 day	Reserved for severe cases
		5% ointment topically q 6 h × 7 day	Less effective than po
Recurrent episode	Acyclovir	200 mg po 5 times/day × 5 day	Limited clinical benefit
Suppression	Acyclovir	400 mg po BID	Titrate dose as required
Mucocutaneous HSV in immunocompromised patient	Acyclovir	200–400 mg po 5 times/day × 10 day	
		5 mg/kg IV q 8 h × 7–10 day[b]	
		5% ointment topically q 6 h × 7 day	For minor lesions only
HSV encephalitis	Acyclovir	10 mg/kg IV q 8 h × 10–14 day[c]	
Neonatal HSV	Acyclovir[d]	20 mg/kg IV q 8 h × 14–21 day	
Herpetic conjunctivitis	Trifluoridine	1 drop q 2 h while awake × 7–14 day	Alternate:
			Vidarabine
			Ointment

[a]The doses are for adults with normal renal function unless otherwise noted
[b]A dose of 250 mg/m^2 should be given to children <12 years of age
[c]A dose of 500 mg/m^2 should be given to children <12 years of age
[d]Acyclovir is not approved by the FDA for this indication

more favorable dosing intervals due to better oral bioavailability.

Mucocutaneous HSV Infections in Immunocompromised Patients

Topical acyclovir diminishes the duration of viral shedding and substantially improves time to cessation of pain and to total healing of HSV lesions in this patient population. Oral and intravenous acyclovirs are even more effective in improving outcome.

Prophylactic administration of oral or intravenous acyclovir to severely immunocompromised patients significantly reduces the incidence of symptomatic HSV infection (◉ *Table 108.5*). A sequential regimen of intravenous followed by oral acyclovir for 3–6 months can virtually eliminate symptomatic HSV infections in transplant recipients. Of note, however, acyclovir-resistant isolates have been identified in this group of highly immunocompromised patients.

Herpes Simplex Keratoconjunctivitis

Idoxuridine (Stoxil), trifluorothymidine (trifluridine, Viroptic), and vidarabine ophthalmic drops are effective and licensed for treatment of HSV keratitis. Of these compounds, trifluorothymidine is the most efficacious and the easiest to administer. In addition, trifluorothymidine is the compound most likely to penetrate the cornea, and thus may prove beneficial in the treatment of stromal keratitis and uveitis. As such, trifluorothymidine is the drug of choice for HSV ocular disease (◉ *Table 108.5*). Each of these ophthalmic preparations may cause local irritation, photophobia, edema of the eyelids and cornea, and superficial punctate keratopathy. Oral administration of acyclovir has been suggested as useful for both therapy and suppression of recurrent HSV ocular infections.

Herpes Simplex Encephalitis

Intravenous acyclovir is the drug of choice for the treatment of herpes simplex encephalitis (◉ *Table 108.5*). For the most favorable outcome, therapy must be instituted before semicoma or coma develops. While higher doses of parenteral acyclovir (45–60 mg/kg/day) are commonly used in the treatment of HSE, efficacy has not been studied and safety (particularly nephrotoxicity) should be assessed closely.

Neonatal HSV Infections

High-dose intravenous acyclovir (60 mg/kg/day in three divided daily doses) improves mortality following neonatal HSV disease. Treatment duration is 21 days for both CNS and disseminated disease, and is 14 days for SEM disease. Infants who have CNS involvement should have a repeat lumbar puncture obtained near the end of therapy to document clearance of viral DNA; in the unlikely event that the PCR remains positive, treatment should be extended for another week, with resampling of CSF for HSV DNA near the end of that extension as well. As such, treatment is extended until viral clearance is documented (◉ *Table 108.5*). Infants with ocular involvement caused by HSV should receive topical antiviral medication in addition to parenteral therapy. Trifluorothymidine (Viroptic) is the treatment of choice for HSV infection of the eyes of the neonate.

109 Human Herpes Viruses Type 6 and 7

David W. Kimberlin

Introduction

In 1986, a novel virus was isolated from six patients with lymphoproliferative syndromes, two of whom were also infected with the human immunodeficiency virus (HIV). Molecular and structural characterization of the new virus revealed an icosahedral core structure of 162 capsomeres, indicating that it was a herpesvirus. However, serological comparisons failed to demonstrate immunologic cross-reactivity with the five human herpesviruses known to exist at the time. Subsequent genomic analysis confirmed that the newly isolated virus was distinct from herpes simplex virus-1 (HSV-1), herpes simplex virus-2 (HSV-2), varicella-zoster virus (VZV), cytomegalovirus (CMV), and Epstein-Barr virus (EBV). Due to the initial belief that the new virus selectively infected freshly isolated human B cells, the virus was given the name human B-lymphotropic virus (HBLV). Subsequent investigation revealed a broader cell tropism, with notable T-cell lymphotropism. For this reason, current nomenclature refers to this virus as human herpesvirus-6 (HHV-6).

Four years following the discovery of HHV-6, Frenkel and colleagues isolated another novel virus from the $CD4^+$ lymphocytes of a healthy adult. Designated human herpesvirus-7 (HHV-7), this new virus is closely related to HHV-6, exhibiting partial antigenic cross-reactivity with HHV-6. This rapid pace of discovery continued during the early 1990s, with DNA from the eighth member of the human herpesvirus family being isolated from Kaposi's sarcoma lesions of HIV-infected individuals in 1994. Thus, in less than a decade, the number of known human herpesviruses increased from five to eight. New technologic advances [peripheral blood mononuclear cell (PBMC) culture, representational difference analysis (RDA)] and the emergence of the acquired immunodeficiency syndrome (AIDS) epidemic converged to create the circumstances necessary for this remarkable pace of discovery. This chapter will review the current knowledge of HHV-6 and HHV-7 biology, of the pathology resulting from infection with these viruses in normal hosts, and of the possible impact of these viruses in immunocompromised persons.

Etiology

HHV-6 and HHV-7 are lymphotropic members of the *Herpesviridae* family. Genomic analysis places both among the β-herpesviruses, along with human CMV. Similarities with respect to amino acid sequences, gene organization, and putative protein functions suggest that HHV-6 is closely related phylogenetically to CMV. On the basis of DNA restriction analysis, in vitro tropism studies, and antigenic relationships defined by reactivities of monoclonal antibodies, HHV-6 can be separated into two variants, designated variant A (HHV-6A) and variant B (HHV-6B). Essentially all postnatally acquired primary infections in children are caused by variant B strains, except infections in some parts of Africa. Among congenital HHV-6 infections, however, as many as one-third may be variant A.

Epidemiology

HHV-6 and HHV-7 infections are ubiquitous in children worldwide. Humans are the only known natural host for these viruses. Epidemiologic studies in normal children have shown that the vast majority of primary HHV-6 infections occur within the first year of life. Human herpesvirus-6 IgG can be detected in more than 90% of neonates, reflecting both the high seroprevalence of HHV-6 among adults and the active transport of HHV-6 IgG across the placenta. The prevalence of HHV-6 IgG drops significantly by 4–6 months of life as maternal antibodies decline, then increases through the third year of life and remains high into adulthood. The highest geometric mean titers of HHV-6 antibody occur in the first 3 years of life, indicating a predominant clustering of primary infections in infants and toddlers. More than 90% of normal children become infected with HHV-6 by 12 months of life, and virtually 100% acquire infection by 3 years of age.

Transmission of HHV-6 in these early childhood years probably results from asymptomatic shedding of infectious virus in secretions of a healthy family member or

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_109,

other close contact. Reports of isolation of HHV-6 from the saliva of healthy adults and patients infected with HIV document salivary shedding in more than 85% of persons. Thus, immunosuppression is not a prerequisite for recovery of HHV-6 from saliva. Viral shedding in saliva is intermittent, and serum antibody titer to HHV-6 does not correlate with the ability to isolate HHV-6 from saliva samples. Human herpesvirus-6 DNA can be detected by polymerase chain reaction (PCR) in saliva or PBMCs of 90% of healthy individuals, and viral DNA may be detected throughout life by PCR assay in multiple body sites, including the brain or cerebrospinal fluid (CSF). Breast milk is unlikely to be an important source of early HHV-6 infection. Infections occur throughout the year without a seasonal pattern. Secondary cases rarely are identified. Congenital infection of HHV-6 occurs in about 1% of newborns as determined by the presence of HHV-6 DNA in cord blood. Most congenital infections appear to result from the germline passage of maternal or paternal chromosomally integrated HHV-6, a unique mechanism of transmission of human viral congenital infection. Transplacental HHV-6 infection also may occur from reinfection or reactivation of maternal HHV-6 infection or from reactivated maternal chromosomally integrated HHV-6.

HHV-7 infection usually occurs later in childhood compared with HHV-6. By adulthood, the seroprevalence of HHV-7 is approximately 85%. Infectious HHV-7 is present in more than 75% of saliva specimens obtained from healthy adults. Contact with infected respiratory tract secretions of healthy contacts is the probable mode of transmission of HHV-7 to young children. HHV-7 has been detected in breast milk, peripheral blood mononuclear cells, cervical secretions, and other body sites. Congenital HHV-7 infection has not been demonstrated by the examination of large numbers of cord bloods for HHV-7 DNA.

The mean incubation period for HHV-6 may be 9–10 days. For HHV-7, the incubation period is not known.

Clinical Presentation

Primary HHV-6 infection can be symptomatic or asymptomatic. In approximately 20% of children, infection will manifest as exanthem subitum, or roseola. A common disease of childhood, exanthem subitum was first described in 1910 by Zahorsky, who termed the illness roseola infantum. In 1921, Veeder helped confirm this syndrome as a specific pathologic entity and suggested the name exanthem subitum. Illness is characterized by a constant or intermittent, high fever to 104–105°F for 3–5 days in a patient who appears relatively well. The patient may have mild catarrhal inflammation of the pharyngeal mucosa and otitis media. Coincident with or immediately following the return of the temperature to normal, a rose pink macular rash appears predominantly on the neck and trunk, although it may involve the proximal extremities, postaural regions, and face. The rash is not pruritic, does not desquamate, and fades after 24–48 h.

As early as 1950, a possible viral etiology of exanthem subitum was proposed. In that year, Kempe and colleagues demonstrated direct person-to-person transmission by inoculation of blood from a patient symptomatic with roseola and speculated that a herpes-like virus might be the cause of the illness. Hellstrom and Vahlquist also succeeded in transmitting the infection by intramuscular injection into children. It was not until 1988, however, that Yamanishi and colleagues definitively proved the viral pathogenesis of exanthem subitum by successfully isolating HHV-6 from the peripheral blood lymphocytes of four infants in the febrile phase of exanthem subitum and by documenting seroconversion to HHV-6 in these patients. Subsequent studies have confirmed exanthem subitum as a manifestation of primary HHV-6 infection.

Primary HHV-6 infection also can manifest as an undifferentiated febrile illness without rash or localizing signs, as well as other acute febrile illnesses, often accompanied by cervical and characteristic postoccipital lymphadenopathy, gastrointestinal tract or respiratory tract signs, and inflamed tympanic membranes. As with exanthem subitum, fever is usually high (temperature greater than 39.5°C [103.0°F]) and persists for 3–7 days. Approximately 20% of all emergency department visits for febrile children 6 through 12 months of age are attributable to HHV-6.

Febrile seizures are the most common complication and reason for hospitalization among children with primary HHV-6 infection. Approximately 10–15% of children with primary HHV-6 illnesses develop febrile seizures, predominantly between the ages of 6–18 months. Other neurologic manifestations which may accompany primary infection include a bulging fontanelle and encephalopathy or encephalitis. Hepatitis has been reported as a rare manifestation of initial illness. Congenital HHV-6 infection is generally asymptomatic at birth. Whether clinical manifestations subsequently develop is unknown.

Primary HHV-7 infection is not strongly associated with a specific clinical entity. Most primary infections with HHV-7 presumably are asymptomatic or mild and not distinctive. Second or recurrent cases of roseola can be

caused by HHV-7, and the virus also may produce mild upper respiratory tract symptoms. HHV-7 also has been isolated from a child with fever, hepatosplenomegaly, and pancytopenia who subsequently developed hemophagocytic syndrome. HHV-7 also may be associated with febrile seizures, although to a much lesser extent than HHV-6.

Following primary infection, both HHV-6 and HHV-7 remain in a persistent or latent state and may reactivate. The clinical circumstances and manifestations of reactivation in healthy people are unclear. Illness associated with HHV-6 reactivation has been described primarily among immunocompromised recipients of solid organ and hematopoietic stem cell transplants. Among the clinical findings associated with HHV-6 reactivation in these patients are fever, rash, hepatitis, bone marrow suppression, graft rejection, pneumonia, and encephalitis. A few cases of CNS symptoms have been reported in association with HHV-7 reactivation in immunocompromised hosts, but clinical findings generally have been less frequently reported with HHV-7 than with HHV-6 reactivation.

Some investigators suggest that the association of HHV-7 with these clinical manifestations results from the ability of HHV-7 to reactivate HHV-6 from latency.

Diagnosis

Multiple assays for the detection of HHV-6 and HHV-7 have been developed, but few are commercially available and many do not differentiate between new, past, and reactivated infection. Diagnostic assays include serology, isolation of the virus from tissue culture, detection of viral DNA by qualitative and quantitative PCR, and of RNA by reverse-transcriptase PCR in blood, secretions, and tissues. Most of these assays are available only in research laboratories. Some serologic and DNA detection assays are commercially available.

Serologic tests currently used include immunofluorescent antibody, neutralization, immunoblot, and enzyme-linked immunosorbent (ELISA) assays. A fourfold increase in serum antibody concentration alone does not necessarily indicate new infection, since an increase in titer also may occur with reactivation and in association with other infections. Seroconversion from negative to positive in paired sera is good evidence of recent primary infection. Detection of specific immunoglobulin (Ig) M antibody also is not reliable for diagnosing new infection, as IgM antibodies to HHV-6 and HHV-7 are not always detectable in children with primary infection and also may be present in some asymptomatic previously infected individuals. Antibody assays to HHV-6 do not differentiate between HHV-6A and HHV-6B.

Diagnosis of primary HHV-7 infection in a child with previous HHV-6 infection is confounded by antigenic cross-reactivity between the two viruses. HHV-6 antibody titers will rise during a new HHV-7 infection, as well as during periods of reactivation of HHV-6 from latency. Detection of low-avidity HHV-6 or HHV-7 antibody with subsequent maturation to high-avidity antibody has been used in such situations to identify recent primary infection. Isolation of HHV-6 or HHV-7 in conjunction with seroconversion or, in the infant with maternal antibody, a fourfold titer rise confirms primary infection.

Polymerase chain reaction detection of HHV-6 DNA from blood and CSF is available through several commercial laboratories. However, detection of HHV-6 DNA or HHV-7 DNA in peripheral blood mononuclear cells, other body fluids, and tissues does not differentiate between new infection and reactivation of latent virus from a prior infection. As such, their interpretation can be challenging. Chromosomal integration of HHV-6 is indicated by consistently positive PCR tests for HHV-6 DNA in blood with high viral loads ($\geq$ 1 copy of HHV-6 DNA per leukocyte), and is confirmed by the detection of HHV-6 DNA in hair follicles.

Treatment

Antiviral susceptibility patterns of HHV-6 in vitro closely resemble those of CMV. HHV-6 multiplication is readily inhibited by ganciclovir at concentrations of 2–10 μmol/L and by foscarnet at a concentration of 66 μmol/L, both of which are easily achievable in the plasma of humans. Cidofovir also has demonstrable in vitro activity against HHV-6. While acyclovir has an inhibitory effect in vitro against HHV-6, it is much less active than either ganciclovir or foscarnet. Despite these in vitro findings, controlled prospective clinical evaluations of antiviral therapy for HHV-6 infections have not been conducted. Individual case reports in bone marrow transplant patients with HHV-6 encephalitis, however, suggest that ganciclovir, foscarnet, or a combination of these drugs can be beneficial, but that antiviral resistance may occur.

110 Varicella-Zoster Virus Infections

Penelope H. Dennehy

Definition/Classification

Varicella-zoster virus (VZV) is a DNA virus and a member of the herpesvirus family. VZV is classified as an alphaherpesvirus and is related most closely to herpes simplex virus types 1 and 2. Like other herpesviruses, VZV has the capacity to persist in the body after primary infection as a latent infection.

Etiology

Varicella-zoster virus (VZV) is so named because it causes two distinct diseases, varicella and zoster. Primary infection with VZV causes varicella, commonly referred to as chickenpox. After the primary infection, VZV establishes latency in dorsal nerve root ganglion and can reactivate, usually many years later, to cause herpes zoster, also referred to as shingles.

Epidemiology

Varicella and herpes zoster are human diseases. Humans are the only reservoir of VZV. VZV infections occur worldwide. In temperate climates, it is estimated that 90–95% of individuals acquire VZV in childhood as a result of annual varicella epidemics. Varicella tends to be less of a childhood illness in the tropics, with higher rates of susceptibility in adults. Some data suggest that in tropical areas, varicella infection occurs more commonly among adults than children. The reasons for this difference in age distribution is not known, but may be related to lack of childhood varicella infection in rural populations. In temperate areas, varicella has a distinct seasonal fluctuation, with the highest incidence occurring in winter and early spring. Less seasonality is reported in tropical areas. Herpes zoster has no seasonal variation and occurs throughout the year.

Varicella is a highly contagious disease with an attack rate of 65–86% in susceptible individuals following household exposure. It is less contagious than measles, but more so than mumps and rubella. Patients who have zoster can transmit varicella to others because the vesicular lesions contain infectious VZV. Zoster however is less contagious than varicella.

In the United States, prior to the introduction of varicella vaccine in 1995, an estimated four million cases of varicella occurred annually. In the prevaccine era, approximately 85% of cases occurred among children younger than 15 years of age. The highest age-specific incidence of varicella just prior to the introduction of vaccine was among children 1–4 years of age, who accounted for 39% of all cases. This age distribution was probably a result of exposure to VZV in preschool and child care settings. Children 5–9 years of age accounted for 38% of cases. Adults 20 years of age and older accounted for only 7% of cases. The implementation of the varicella vaccination program in the United States has lead to a steady decline in the incidence of varicella in all age groups, with the greatest decline among children 1–4 years of age.

In the prevaccine era in the United States, there were approximately 11,000 hospitalizations for varicella or varicella-related complications each year. Hospitalization rates were approximately 2–3 per 1,000 cases among healthy children and 8 per 1,000 cases among adults. Death occurred in approximately 1 in 60,000 cases. From 1990 through 1996, an average of 103 deaths from varicella was reported each year. Most deaths occurred in immunocompetent children and adults. After introduction of varicella vaccine, the number of hospitalizations and deaths from varicella has declined more than 90%.

Despite high one-dose vaccination coverage and success of the vaccination program in the United States in reducing varicella morbidity and mortality, data from varicella surveillance from 2001 to 2005 indicated that the number of reported varicella cases reached a plateau, and increasing proportion of cases represented breakthrough infection (chickenpox occurring in a previously vaccinated person). Outbreaks were reported in schools with high varicella vaccination coverage (96–100%). These outbreaks had many similarities: all occurred in elementary schools; vaccine effectiveness was within the expected range (72–85%); the highest attack rates occurred among the younger students; each outbreak lasted about

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_110,

2 months; and persons with breakthrough infection transmitted the virus although the breakthrough disease was mild. Overall attack rates among vaccinated children were 11–17%, with attack rates in some classrooms as high as 40%. These data indicated that even in settings where almost everyone was vaccinated and vaccine performed as expected, varicella outbreaks could not be prevented with a one-dose vaccination policy. These observations led to the recommendation in 2006 for a second routine dose of varicella vaccine in the United States.

Patients who develop zoster usually have a history of previous varicella. Zoster remains an illness of individuals over the age of 50 years and immunocompromised persons, especially bone marrow transplant recipients and children with human immunodeficiency virus. Zoster also develops commonly in patients treated for cancer and after organ transplantation. An estimated 500,000 to 1 million episodes of zoster occur annually in the United States. The lifetime risk of zoster is estimated to be at least 32%. Increasing age and cellular immunosuppression are the most important risk factors; 50% of persons living until age 85 years will develop zoster.

Zoster can occur in childhood. The incidence of zoster is increased by a factor of as much as 20 in those who had varicella in utero or before age 2 years, possibly because the immune response to VZV in young infants is immature. Children who develop zoster should be screened for possible risk factors such as HIV infection and underlying immunodeficiency; however, predisposing factors rarely are identified. On occasion, zoster occurs in healthy children or young adults. Presumably, such infection is a result of a transient decrease in cell-mediated immunity caused perhaps by another inapparent viral infection.

Pathogenesis

VZV is transmitted from person to person by direct contact, inhalation of aerosols from vesicular fluid of skin lesions of acute varicella or zoster, or infected respiratory tract secretions that might also be aerosolized. The period of contagiousness is estimated to begin 1–2 days before the onset of rash and to end when all lesions are crusted, typically 4–7 days after onset of rash in immunocompetent persons, but this period may be longer in immunocompromised persons.

VZV enters the host through the upper respiratory tract. Early studies of pathogenesis suggested that the virus replicated at the site of entry in the nasopharynx and in regional lymph nodes. A primary viremia followed 4–6 days after infection and disseminated the virus to other organs, such as the liver, spleen, and sensory ganglia. Further replication occurred in the viscera, followed by a secondary viremia, with viral infection of the skin.

More recent studies show the virus infects the respiratory epithelial cells from which the virus gains access to highly permissive T lymphocytes in the tonsillar lymphoid tissue. The virus is transferred to skin sites of replication by infected T lymphocytes within 24 h of infection. The formation of skin lesions that penetrate the skin surfaces requires 10–21 days because cell-to-cell spread of the virus after T lymphocyte transfer is countered by the potent innate antiviral responses of epidermal cells. VZV may also replicate in reticuloendothelial organs, such as the liver and the spleen. Uninfected T lymphocytes that traffic through sites of VZV lesion formation may amplify VZV viremia. The virus can be cultured from mononuclear cells of an infected person from 5 days before to 1 or 2 days after the appearance of the rash. VZV reaches neurons in dorsal nerve root ganglia during primary infection either by the hematogenous route or by anteretrograde transport along neurons from skin lesions. VZV then establishes latency in dorsal nerve root ganglia.

VZV reactivation causes a localized vesicular rash that usually involves the dermatomal distribution of a single sensory nerve. Infectious VZV is present in herpes zoster lesions, but the virus does not appear to be released into respiratory secretions during reactivation. Although subclinical reactivation has been difficult to document, it is likely to occur.

Primary VZV infection elicits antibodies directed against viral proteins which have neutralizing activity and mediate destruction of infected cells by antibody mediated cellular cytotoxicity. However, intact cellular immunity appears to be critical for the host to terminate viremia and virus replication at localized cutaneous sites. Children with untreated agammaglobulinemia generally have uncomplicated varicella, whereas those with primary immunodeficiency diseases affecting cell mediated immunity often die. Persistent VZV immunity may be maintained by periodic reexposure to the virus during annual epidemics or by repeated antigenic stimulation from subclinical reactivation of latent VZV.

Pathology

The skin lesions of varicella and herpes zoster are identical to each other and also to the lesions of herpes simplex virus. Vesicles fill with neutrophils and soon erode to become shallow ulcers. In infected cells, VZV produces a characteristic cytopathic effect, consisting of intranuclear

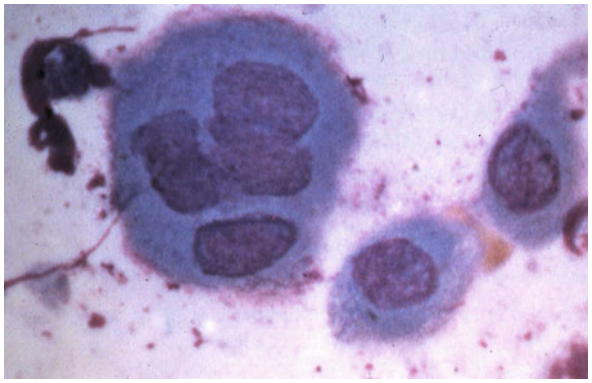

Figure 110.1
A Tzanck smear from a vesicular lesion showing multinucleated epithelial cells

Figure 110.2
Papules, vesicles, pustules and crusts may be present at the same time

inclusions (Cowdry type A). The inclusion is large and eosinophilic and is separated from the nuclear membrane by a clear zone (halo). Multinucleated cells are common (*Fig. 110.1*). Over several days, vesicles become pustules and then rupture and heal.

In herpes zoster, the dorsal nerve root ganglion typically exhibits intense inflammation accompanied by hemorrhagic necrosis of nerve cells. The ganglion undergoes eventual neuronal loss with subsequent fibrosis of afferent nerve fibers, particularly type-C nociceptors.

Clinical Manifestations

Varicella

The average incubation period for varicella is 14–16 days with a range of 10–21 days. The incubation period may be prolonged in immunocompromised patients and those who have received postexposure treatment with a varicella antibody–containing product.

Varicella usually lasts 4–7 days and is characterized a pruritic rash consisting of crops of macules, papules, and vesicles which appear in three or more successive waves and resolve by crusting. A mild prodrome may precede the onset of a rash. Adults may have 1–2 days of fever and malaise prior to rash onset, but in children the rash is often the first sign of disease. The rash is generalized and pruritic and progresses rapidly from macules to papules to vesicular lesions before crusting. The rash usually appears first on the head, then on the trunk, and then the extremities; the highest concentration of lesions is on the trunk (centripetal distribution). Lesions also can occur on mucous membranes of the oropharynx, respiratory tract, vagina, conjunctiva, and the cornea. Lesions are usually 1–4 mm in diameter. The vesicles are superficial and delicate and contain clear fluid on an erythematous base. Vesicles may rupture or become purulent before they dry and crust. Successive crops appear over several days, with lesions present in several stages of development (*Fig. 110.2*). For example, macular lesions may be observed in the same area of skin as mature vesicles. Healthy children usually have 200–500 lesions in two to four successive crops.

The clinical course in healthy children is generally mild, with malaise, pruritus (itching), and temperature up to 102°F (38.9°C) for 2–3 days. Adults may have more severe disease and have a higher incidence of complications. Respiratory and gastrointestinal symptoms are absent. Children with lymphoma and leukemia may develop a severe progressive form of varicella characterized by high fever, extensive vesicular eruption, and high complication rates. Children infected with human immunodeficiency virus also may have severe, prolonged illness. Recovery from primary varicella infection usually results in lifetime immunity.

Most VZV infections result in clinical illness, but about 5% of primary infections are subclinical. Second attacks of varicella are unusual in otherwise healthy individuals, although they are recognized to occur. One estimate is that 1 in 500 persons with a prior history of varicella will experience a second attack after a household exposure to varicella. As with other viral diseases, reexposure to varicella may lead to reinfection that boosts antibody titers without causing clinical illness or detectable viremia.

A modified varicella, known as breakthrough disease, can occur in some vaccinated persons because the vaccine is only 70–90% effective in preventing disease. Breakthrough varicella is mild in 70–80% of cases, with <50 skin lesions, less fever, and shorter duration of rash. The rash may be atypical in appearance with fewer vesicles and predominance of maculopapular lesions. Nevertheless, breakthrough varicella is infectious (although less than varicella in unvaccinated persons).

In utero infection can occur as a result of transplacental passage of virus during maternal varicella infection. Primary maternal varicella infection in the first 20 weeks of gestation is occasionally associated with a variety of abnormalities in the newborn, including low birth weight, hypoplasia of an extremity, skin scarring, localized muscular atrophy, encephalitis, cortical atrophy, chorioretinitis, and microcephaly. This constellation of abnormalities, known as congenital varicella syndrome, was first recognized in 1947. The risk of congenital abnormalities from primary maternal varicella infection appears to be less than 2%. Rare reports of congenital birth defects following maternal zoster exist, but virologic confirmation of maternal lesions is lacking.

Herpes Zoster

Herpes zoster, or shingles, occurs when latent VZV reactivates and causes recurrent disease. Zoster usually appears as a unilateral vesicular skin eruption involving one to three dermatomes (*Fig. 110.3*). Most often, this involves the trunk or the fifth cranial nerve. Two to four days prior to the eruption, there may be pain and paresthesia in the involved area. Skin vesicles may be pruritic or painful, especially in adults. Zoster generally is a milder disease in children than in adults. There are few systemic symptoms. In immunocompromised persons, zoster may disseminate, causing generalized skin lesions and central nervous system, pulmonary, and hepatic involvement.

From 25–50% of persons older than 50 years of age and the same proportion of immunocompromised patients who acquire zoster experience serious pain, termed postherpetic neuralgia, after the rash has healed. The cause of postherpetic neuralgia is unknown.

Figure 110.3
A zoster rash showing the distinctive unilateral dermatomal distribution

Diagnosis

Varicella generally is diagnosed clinically because of the characteristic vesicular rash and its distribution, as well as through epidemiologic information such as history of exposure and absence of prior varicella. Zoster also presents with a distinctive unilateral, dermatomal, vesicular rash that is diagnosed clinically. Laboratory diagnosis is not routinely required, but is useful if confirmation of the diagnosis or determination of susceptibility is necessary. The dramatic decline in varicella incidence as a result of routine varicella immunization in the United States has had the combined effect of increasing the number of atypical cases and of reducing physicians' experience in diagnosing varicella. As a result, the need for laboratory confirmation of varicella has increased.

Rapid varicella virus identification techniques are helpful for a case with severe or unusual disease to aid in the decision to initiate specific antiviral therapy. The diagnosis of varicella or zoster is made most definitively by demonstration of specific viral antigens in skin scrapings by immunofluorescence using a commercial monoclonal antibody to VZV conjugated to fluorescein (DFA) or by polymerase chain reaction (PCR). These diagnostic methods are highly sensitive and rapid. Real-time PCR methods are widely available and are the most sensitive and specific method of the available tests. Results are available within several hours. If real-time PCR is unavailable, DFA can be used, although it is less sensitive than PCR and requires more meticulous specimen collection and handling. Diagnosis also may be made by isolating virus from skin lesions, but this technique is more complicated and expensive, is less sensitive, and takes longer than DFA or PCR. The Tzanck test is not recommended because it lacks sensitivity and specificity. PCR can distinguish between vaccine and wild type VZV.

Skin lesions are the preferred specimen for laboratory confirmation of varicella disease. Specimens are best collected by unroofing a vesicle, preferably a fresh fluid-filled vesicle, and then rubbing the base of a skin lesion with a polyester swab. Crusts from lesions are also excellent specimens for PCR. Other specimen sources such as nasopharyngeal secretions, saliva, blood, urine, bronchial washings, and cerebrospinal fluid are considered less desirable sources than skin lesions because positive test results from such specimens are much less likely. Because viral proteins persist after cessation of viral replication, PCR and DFA may be positive when viral cultures are negative.

A reliable history of chickenpox has been found to be a valid measure of immunity to varicella because the rash is distinctive and subclinical cases are unusual. As a result, serologic testing of children is generally not necessary. However, serologic testing may be useful in adults where as many as 50% of those without a history of varicella will be found to be immune.

A variety of serologic tests for varicella antibody are available. Available tests include complement fixation (CF), indirect fluorescent antibody (IFA), fluorescent antibody to membrane antigen (FAMA), neutralization, indirect hemagglutination (IHA), immune adherence hemagglutination (IAHA), radioimmunoassay (RIA), latex agglutination (LA), and enzyme-linked immunosorbent assay (ELISA). ELISA is sensitive and specific, simple to perform, and widely available commercially. A commercially available LA assay is sensitive, simple, and rapid to perform. LA is generally more sensitive than commercial ELISAs, although it can result in false-positive results, leading to failure to identify persons without evidence of varicella immunity. This latter concern can be minimized by performing LA as a dilution series. Either of these tests would be useful for screening for varicella immunity.

Antibody resulting from vaccination is generally of lower titer than antibody resulting from varicella disease. Commercial antibody assays, particularly the LA test, may not be sensitive enough to detect vaccine-induced antibody in some recipients. Because of the potential for false-negative serologic tests, routine postvaccination serologic testing is not recommended.

For diagnosis of acute varicella infection, serologic confirmation would include a significant rise in varicella IgG by any standard serologic assay. Testing using commercial kits for IgM antibody is not recommended since available methods lack sensitivity and specificity; false-positive IgM results are common in the presence of high IgG levels.

Differential Diagnosis

In most cases, the characteristic features of the vesicular varicella rash establish the clinical diagnosis. The differential diagnosis consists mainly of allergic reactions, insect bites, Stevens–Johnson syndrome, generalized herpes zoster or herpes simplex infections, enterovirus infections, pityriasis lichenoides et varioliformis acuta (PLEVA) and guttate psoriasis. In the newborn, varicella must be differentiated from syphilis and incontinentia pigmenti. Before eradication of smallpox and in post-eradication surveillance, varicella was the disease most commonly confused with smallpox.

Treatment

General Care

Nonspecific treatment for varicella includes oral antihistamines, frequent bathing, calamine lotion, oatmeal baths, and the trimming of fingernails to discourage scratching. Fever should be controlled with acetaminophen. Use of aspirin for this purpose may predispose to Reye syndrome, and ibuprofen may predispose to Group A streptococcal infection.

Specific Treatment

Because most varicella infections are not serious and the illness usually is self-limited in otherwise healthy children less than 12 years of age, oral acyclovir is not administered routinely. Further, the drug is not well absorbed from the gastrointestinal tract. Specific therapy is reserved for those at higher risk for developing severe varicella and those who already have severe disease. Oral acyclovir should be considered for otherwise healthy people at increased risk for moderate to severe disease, e.g., persons aged >12 years; people with chronic cutaneous or pulmonary disorders; receiving long-term salicylate therapy; and receiving short, intermittent, or aerosolized courses of corticosteroids. Secondary contacts in household exposures may also be treated since these individuals also are at increased risk for more severe disease. Because controlled studies in children and adolescents given oral acyclovir for 5 days starting within 24 h of the rash of varicella have shown a modest benefit, prompt oral acyclovir therapy usually is recommended for healthy adolescents and young adults who are at moderately high risk for developing severe illness. The oral dose is 20 mg/kg PO four times daily for

5 days. Children who are relatively immunocompromised, such as those who have early seemingly mild varicella and those who have early HIV infection, may be given a closely monitored treatment trial of oral acyclovir and switched to intravenous acyclovir if clinically necessary.

Intravenous antiviral therapy, when administered within 24 h of onset of rash, is recommended for immunocompromised persons, including patients being treated with chronic corticosteroids. Patients at serious risk for or who have severe or potentially severe VZV infections should be treated with intravenous acyclovir (10 mg/kg every 8 h). There is a high correlation between early treatment and a successful outcome. Antiviral therapy for varicella does not prevent latent VZV infection. Acyclovir usually is very well tolerated. Adverse effects include phlebitis, rash, nausea, and neurologic symptoms such as headache. Patients whose creatinine clearance is less than 50 mL/min/1.73 m^2 are given one half to one third of the normal dosage with slow infusion, making sure that that hydration is adequate to avoid crystallization of acyclovir in the renal tubules.

Treatment of herpes zoster is associated with earlier healing of lesions and prevention of complications, particularly postherpetic neuralgia. Most available data regarding treatment of herpes zoster involves patients over 50 years of age. The three antivirals used for treatment of zoster are acyclovir, valacyclovir, and famciclovir. In general, these medications are well tolerated. Although oral acyclovir (800 mg five times daily) has been the mainstay of herpes zoster treatment, its poor bioavailability and need for frequent daily dosing prompted the development of later generation antiviral agents, valacyclovir and famciclovir, with improved pharmacokinetics and lower dosing frequency. Valacyclovir (1 g three times daily for 7 days) is now the drug of choice due to its increased bioavailability. The use of acyclovir may still be favored, however, if cost is an issue. Although famciclovir is now available in a generic formulation, its cost is still approximately threefold higher than acyclovir. If famciclovir is used, the standard dosing is 500 or 750 mg three times daily. Valacyclovir and famciclovir are not licensed in the United States for use in children or for the treatment of varicella.

Antiviral therapy is recommended for patients >50 years of age with uncomplicated herpes zoster who present within 72 h of clinical symptoms. The benefit of antiviral therapy in younger patients is not as clear, although the risk of adverse events is low. As a result, antiviral therapy is recommended for patients <50 years of age with herpes zoster who present within 72 h of clinical symptoms. All HIV-infected patients should be treated with antiviral therapy for episodes of uncomplicated herpes zoster, regardless of the age of onset. Intravenous acyclovir may be considered for more severe infections, such as disseminated disease or ophthalmic involvement.

Analgesic drugs are often needed in adult patients at presentation to address symptoms of acute neuritis. Most trials have demonstrated that early antiviral treatment for herpes zoster reduces the duration or incidence of postherpetic neuralgia. The routine use of corticosteroid therapy is not recommended since glucocorticoids do not decrease the risk of postherpetic neuralgia.

Prognosis

Acute varicella is generally mild and self-limited. Serious complications can occur, mainly in infants, adolescents, adults, and immunocompromised persons and include secondary bacterial infections of skin lesions, pneumonia, cerebellar ataxia, and encephalitis. Secondary bacterial infections of skin lesions with Staphylococcus or Streptococcus are the most common cause of hospitalization and outpatient medical visits. Secondary infection with invasive group A streptococci may cause serious illness and lead to hospitalization or death. Pneumonia following varicella is usually viral but may be bacterial. Secondary bacterial pneumonia is more common in children younger than 1 year of age. Central nervous system manifestations of varicella range from aseptic meningitis to encephalitis. Involvement of the cerebellum, with resulting cerebellar ataxia, is the most common and generally has a good outcome. Encephalitis is an infrequent complication of varicella (estimated 1.8 per 10,000 cases) and may lead to seizures and coma. Diffuse cerebral involvement is more common in adults than in children. Reye syndrome is an unusual complication of varicella and influenza and occurs almost exclusively in children who take aspirin during the acute illness. The etiology of Reye syndrome is unknown. There has been a dramatic decrease in the incidence of Reye syndrome during the past decade, presumably related to decreased use of aspirin by children. Rare complications of varicella include aseptic meningitis, transverse myelitis, Guillain–Barré syndrome, thrombocytopenia, hemorrhagic varicella, purpura fulminans, glomerulonephritis, myocarditis, arthritis, orchitis, uveitis, iritis, and hepatitis.

The risk of complications from varicella varies with age. Complications are infrequent among healthy children. They occur much more frequently in persons older than 15 years of age and infants younger than 1 year of age. For instance, among children 1–14 years of age, the fatality rate

of varicella is approximately 1 per 100,000 cases; among persons 15–19 years, it is 2.7 per 100,000 cases; and among adults 30–49 years of age, 25.2 per 100,000 cases. Adults account for only 5% of reported cases of varicella but approximately 35% of deaths from varicella.

Immunocompromised persons have a high risk of disseminated disease (up to 36% in one report). These persons may have multiple organ-system involvement, and the disease may become fulminant and hemorrhagic. The most frequent complications in immunocompromised persons are pneumonia and encephalitis. Children who have leukemia have a 30% rate of disseminated varicella, with a 7% mortality rate. Children with HIV infection are also at increased risk for morbidity from varicella and herpes zoster with the most severe infections and mortality occurring in those with AIDS.

The onset of maternal varicella from 5 days before to 2 days after delivery may result in overwhelming infection of the neonate and a fatality rate as high as 30%. This severe disease is believed to result from fetal exposure to varicella virus without the benefit of passive maternal antibody. Infants born to mothers with onset of maternal varicella 5 days or more prior to delivery usually have a benign course, presumably due to passive transfer of maternal antibody across the placenta.

Postherpetic neuralgia is a distressing complication of zoster. Postherpetic neuralgia is most likely to afflict the elderly and highly immunocompromised patients and is rare in healthy children with zoster. There is currently no adequate therapy available. The pain with postherpetic neuralgia may last a year or longer after the episode of zoster. Ocular nerve and other organ involvement with zoster can occur, often with severe sequelae.

Prevention

Varicella Vaccine

Varicella vaccine is routinely used for vaccination of healthy children in only some countries, including the United States, Uruguay, Qatar, Australia, Canada, Costa Rica, Germany, and South Korea. Varicella vaccine contains live, attenuated VZV. It is available as a monovalent formulation and in combination formulation, as measles–mumps–rubella–varicella (MMRV) vaccine, which is licensed in the United States for children 1–12 years only. In the United States, two doses of varicella-containing vaccine are now recommended for all susceptible persons older than 1 year without contraindications. The first dose should be administered at 12–15 months of age and the second dose at 4–6 years of age. A second catch-up dose of varicella vaccination is recommended for children, adolescents and adults who previously have received one dose. The minimum interval for children younger than 13 years is 3 months. The Centers for Disease Control's Advisory Committee on Immunization Practices (ACIP) now recommends that all others at least 13 years of age without evidence of immunity be vaccinated with two doses of varicella vaccine at an interval of 4–8 weeks. In cases with uncertain history, prior varicella disease is not a contraindication to varicella vaccination. Evidence of immunity to varicella includes any of the following:

1. Documentation of age-appropriate vaccination:
   - Preschool-age children aged $\geq$12 months: one dose
   - School-age children, adolescents, and adults: two doses
2. Laboratory evidence of immunity or laboratory confirmation of disease
3. Birth in the United States before 1980 (not a criterion for health-care personnel, pregnant women, and immunocompromised persons)
4. A health-care provider diagnosis of varicella or a health-care provider verification of a history of varicella disease
5. A health-care provider diagnosis of herpes zoster or a health-care provider verification of a history of herpes zoster disease

The most common adverse reactions following varicella vaccine are injection-site complaints (pain, soreness, redness, and swelling) that are self-limited. Fever was reported in uncontrolled trials in 15% of children and 10% of adolescents and adults. A macular or vesicular rash usually consisting of a few lesions at the injection site was reported in 3% and 1% of persons receiving the first and second dose, respectively. A generalized rash with a small number of lesions may rarely occur, within 3 weeks of vaccination.

Varicella vaccine induces latent infection similar to that caused by wild VZV. Consequently, zoster caused by vaccine virus has been reported. This appears to occur at a lower rate than following natural infection but longer-term follow-up is needed.

Contraindications to varicella immunization include: a severe allergic reaction to a vaccine component or following a prior dose, pregnancy or planned pregnancy within 4 weeks of vaccination, and immunosuppression. Single-antigen varicella vaccine does not contain egg protein or preservative. For the combination MMRV vaccine, live measles and live mumps vaccine are produced in chick

embryo culture. However, the risk for serious allergic reactions after administration of measles- or mumps-containing vaccines in persons who are allergic to eggs is low.

Persons with immunosuppression of cellular immune function resulting from leukemia, lymphomas of any type, generalized malignancy, immunodeficiency disease, or immunosuppressive therapy should not be vaccinated. Treatment with low-dose prednisone (e.g., <2 mg/kg of body weight/day or <20 mg/day) or aerosolized steroid preparations is not a contraindication to varicella vaccination. Persons whose immunosuppressive therapy with steroids has been stopped for 1 month (3 months for chemotherapy) may be vaccinated. Persons with impaired humoral immunity may be vaccinated. Because children infected with HIV are at greater risk for morbidity from varicella and herpes zoster than are healthy children, the ACIP recommends that varicella vaccine should be considered for HIV-infected children at least 12 months of age with CD4+ T-lymphocyte percentages ≥15% and without evidence of varicella immunity. Eligible children should receive two doses of single-antigen varicella vaccine, with a minimum 3-month interval between doses. Vaccination (two doses, administered 3 months apart) may be considered for HIV-infected older children, adolescents, and adults with CD4+T-lymphocyte count ≥200 cells/mL after weighing the risks and benefits.

Women known to be pregnant or attempting to become pregnant should not receive varicella vaccine. Pregnancy should be avoided for 1 month following varicella vaccination. The ACIP recommends prenatal assessment and postpartum vaccination for varicella. To date, no adverse outcomes of pregnancy or in a fetus have been reported among women who inadvertently received varicella vaccine shortly before or during pregnancy. The manufacturer, in collaboration with CDC, has established a Varicella Vaccination in Pregnancy registry to monitor the maternal–fetal outcomes of pregnant women inadvertently given varicella vaccine. The telephone number for the Registry is 800-986-8999. Breastfeeding is not a contraindication to the varicella vaccination.

The effect of the administration of immune globulin (IG) on the response to varicella virus vaccine is unknown. Because of the potential inhibition of the antibody response by passively transferred antibodies, varicella vaccines should not be administered for 3–11 months, depending on the dosage, after administration of blood (except washed red cells), plasma, or IG.

No adverse events following varicella vaccination related to the use of salicylates (e.g., aspirin) have been reported to date. However, the manufacturer recommends that vaccine recipients avoid the use of salicylates for 6 weeks after receiving varicella vaccine because of the association between aspirin use and Reye syndrome following varicella.

Available data suggest that transmission of varicella vaccine virus is a rare event. Instances of suspected secondary transmission of vaccine virus have been reported, but in few instances has the secondary clinical illness been shown to be caused by vaccine virus. It appears that transmission occurs mainly and perhaps only when the vaccinee develops a rash. If a vaccinated child develops a rash, it is recommended that close contact with persons who do not have evidence of varicella immunity and who are at high risk of complications of varicella, such as immunocompromised persons, be avoided until the rash has resolved.

A vaccine for zoster is available in the United States for use in adults 60 years of age and older. The primary clinical trial for this vaccine included more than 38,000 adults 60–80 years of age with no history of prior shingles. Efficacy was highest for persons 60–69 years of age (64%) and declined with increasing age. Vaccine recipients who developed zoster generally had less severe disease. Vaccine recipients also had about 66% less postherpetic neuralgia. The duration of reduction of risk of zoster is not known. As with all vaccines, a severe allergic reaction to a vaccine component or following a prior dose is a contraindication to zoster vaccination. As with other live virus vaccines, immunosuppression is a contraindication to zoster vaccination.

Postexposure Prophylaxis

Varicella vaccine is recommended for postexposure administration for healthy unvaccinated persons without other evidence of immunity. Administration of varicella vaccine to exposed susceptible persons ≥12 months of age, as soon as possible within 72 h and possibly up to 120 h after exposure, may prevent or modify disease and is recommended if there are no contraindications to its use. In several studies, protective efficacy was reported as ≥90% when children were vaccinated within 3 days of exposure.

In certain circumstances, postexposure prophylaxis with varicella zoster immune globulin is recommended. In 2004, the only US-licensed manufacturer of varicella zoster immune globulin (VZIG) (Massachusetts Public Health Biologic Laboratories, Boston, Massachusetts) discontinued production of VZIG. The supply of the licensed VZIG product was depleted in early 2006. In February 2006, an investigational (not licensed) VZIG product, VariZIG (Cangene Corporation, Winnipeg,

Canada) became available under an investigational new drug application (IND) submitted to the FDA. This product can be requested from the sole authorized US distributor, FFF Enterprises (Temecula, California). The investigational VariZIG, similar to licensed VZIG, is a purified human immune globulin preparation made from plasma containing high levels of anti-varicella antibodies. Unlike the previous product, the investigational product is lyophilized. When properly reconstituted, VariZIG is approximately a 5% solution of IgG that can be administered intramuscularly. As with any product used under IND, patients must be informed of potential risks and benefits and must give informed consent before receiving the product.

The decision to administer VariZIG to a person exposed to varicella should be based on (1) whether the person is susceptible, (2) whether the exposure is likely to result in infection, and (3) whether the person is at greater risk for complications than the general population. Persons at greater risk for severe complications who are not candidates for varicella vaccination who may benefit from postexposure prophylaxis with VariZIG include: susceptible immunocompromised persons (including people being treated with chronic corticosteroids $\geq$2 mg/kg of body weight or a total of 20 mg/day of prednisone or equivalent), susceptible pregnant women, newborns whose mothers had onset of varicella within 5 days before and 2 days after delivery, preterm infants at $\geq$28 weeks gestation whose mothers are susceptible to varicella, and preterm infants at $<$28 weeks gestation or $\leq$1,000 g birth weight, regardless of maternal history or serostatus. VariZIG provides maximum benefit when administered as soon as possible after exposure, but may be effective if administered as late as 96 h after exposure.

If administration of VariZIG does not appear possible within 96 h of exposure, administration of immune globulin intravenous (IGIV) should be considered as an alternative (IGIV should also be administered within 96 h of exposure).

111 Human Immunodeficiency Virus

Sami Al-Hajjar

General Considerations

It has been slightly more than one 25 years since the first cases of human immunodeficiency virus (HIV) were identified in children. HIV is the most common cause of acquired immunodeficiency syndrome (AIDS) in children. The virus is a member of the lentivirus subgroup of human retroviruses (RNA viruses). HIV selectively infects human helper T cells, the virus enters cell by attachment to the CD4 molecule and fusion with cell membrane, which results in the lytic degeneration of helper T cells. The destruction of helper T cells profoundly affects B-cell function, suppressor T cells, and cell-mediated immunity and results in a profound combined (B- and T-cell) immunodeficiency. HIV also infects macrophages, monocytes, neural cells, Kuppler cells in the liver, Langerhans cells in the dermis, and Hofbauer cells of the placenta.

The profound immunodeficiency places HIV-infected children at risk of a wide variety of infections (common and opportunistic). Among the common bacterial infections are otitis media, sinusitis, pneumonia, and meningitis. Serious invasive bacterial infections occur in 20% or more of immunocompromised HIV-infected children. The agents responsible for these invasive bacterial infections include common childhood agents such as *Pneumococcus*, *Staphylococcus aureus*, *Enterococcus*, *Haemophilus influenzae* type B (HIB), *Salmonella*, and *Pseudomonas*. *Pneumococcus* is responsible for the greatest number of infections, including 30% of all bacteremias. Somewhat later in the course of the disease, T-cell deficiency results in susceptibility to *Pneumocystis carinii* pneumonia (PCP) fungal, viral, and other opportunistic infections. Central nervous system (CNS) involvement is frequent in children and is usually a direct result of infections of the CNS with HIV-1, leading to loss of milestones and brain atrophy.

In 1994, a new classification system for HIV-infected children was established by the Centers for Diseases Control and Prevention (CDC). In the new system, infected children are classified into mutually exclusive categories according to three parameters: (a) infections, (b) clinical status (*Table 111.1*), and (c) immunologic status. Once classified, an HIV-infected child cannot be classified in a less severe category even if the child's clinical or immunologic status improves.

Epidemiology

Almost all HIV-infected children acquire the virus from their mothers before or during birth or through breastfeeding. Mother-to-child-transmission (MTCT), estimated to cause more than 90% of infections worldwide in infants and children, probably occurs late in pregnancy or during birth. Studies have suggested that breastfeeding introduces an additional risk of HIV transmission of approximately 10–14% among women with chronic HIV infection. In developing countries, an estimated one-third to one-half of all HIV infections are transmitted through breastfeeding; the rest are infected from contaminated blood and blood products, infected organs, and sexual abuse. As adolescents become sexually active and experiment with intravenous drugs, their modes of acquisition are similar to those in adults. Therefore, the epidemiology of childhood transmission is essentially the epidemiology of transmission in childbearing women. The majority of women (70%) are infected as a result of personal drug abuse or drug abuse by a sexual partner. The rest acquire HIV from sexual transmission or from blood transfusion. The estimated risk perinatal transmission from an infected mother is between 15% and 40%. (The risk varies significantly according to the maternal immunologic and virologic status as well as placental membrane inflammation).

HIV infection is concentrated in certain geographic areas and socioeconomic groups, particularly large cities of Southeast Asia, sub-Saharan Africa, India, the islands of the Caribbean, South America, and the inner-city areas of major cities of Europe and the United States. Statistics on the prevalence of HIV/AIDS in the Middle East are hard to come. According to the Joint United Nations Programme on HIV/AIDS (UNAIDS) about 460,000 people are living with HIV in the Middle East and North Africa and more than 22,000 children infected mainly by MTCT and other

Table 111.1
Summary of the 1994 revised clinical classification of human immunodeficiency virus in children under 13 years of age (Adapted from Centers for Disease Control and Prevention. 1994 Revised classification system for human immunodeficiency virus infection in children less than 13 years of age. MMWR Morbid Mortal Wkly Rep 1994;43 (No. RR-121): 1–10, with permission)

Category N: nonsymptomatic
Children who have no signs or symptoms considered to be the result of HIV infection or who have only one of the conditions listed in category A
Category A: mildly symptomatic
Children with two or more of the conditions listed below but none of the conditions listed in categories B and C – Lymphadenopathy (≥0.5 cm at more than two sites, bilateral = one site) – Hepatomegaly – Splenomegaly – Dermatitis – Parotitis – Recurrent or persistent upper respiratory tract infection, sinusitis, or otitis media
Category B: moderately symptomatic
Children who have symptomatic conditions other than those listed for category A or C that are attributed to HIV infection listed in CDC clinical categories surveillance
Category C: severely symptomatic
Children who have any condition listed in the 1987 surveillance case definition for AIDS, with the exception of lymphocytic interstitial pneumonitis

routes of transmission exist, however notably blood/blood product transfusion and from kidney's transplanted from paid high risk, live, and non-related donor.

Clinical Manifestations

There are two general patterns of congenital or perinatal infection. About 20% of infected child develop early disease. Common early manifestation includes failure to thrive or wasting, recurrent thrush, chronic or recurrent diarrhea unresponsive to treatment and without definable cause, parotitis, and a variety of recurrent bacterial infections, including otitis media, sepsis, pneumonia, and meningitis. PCP is the most common opportunistic infection in children who have AIDS; it is more likely to be acute. Fever, tachypnea, retractions, and reduced breath sounds are frequent findings. CNS involvement occurs in about 50–60% of HIV-infected children. Cardiomyopathy, hepatitis, and nephropathy occur in some children.

In the second pattern, seen in the remaining 80% of infected children, HIV infection tends to progress less rapidly, with many children not developing frank AIDS until they are in school or even in adolescence. Hepatosplenomegaly, lymphadenopathy, diarrhea, thrush, and a variety of recurrent infections are common. Lymphocyte interstitial pneumonitis is seen in this group, and cough, digital clubbing, and lymphadenopathy are frequent findings. Lung disease is characterized by micronodular infiltrates on chest x-ray. As the disease progresses, all HIV-infected children developed profound T4-cell deficiency, multiple organ system involvement, and array of opportunistic infections.

Diagnosis

A diagnosis of HIV infection or AIDS depends on establishing the presence of HIV infection, defining the immunologic status of the child, and diagnosing the pattern of clinical illnesses that occur secondary to infection and loss of immune function. In children older than 18 months, the diagnosis of infection can be made by using a standard anti-HIV immunoglobulin G (IgG) antibody test, which is usually confirmed by Western blot. In children born to HIV-infected mothers, diagnosis is complicated by the presence or maternal anti-HIV IgG. The majority of these children are HIV-antibody positive at birth, although only 15–30% are usually infected. Maternal antibody may persist up to 18 months in uninfected infants. Polymerase chain reaction (PCR) and virus culture are currently the most sensitive and specific assays for detection of HIV infection in children born to infected mothers. Use of these assays can identify approximately 30–50% of infected infants at birth and nearly 100% of infected infants by 3–6 months of age. The standard P24 antigen assay and anti-HIV IgG are less sensitive than either viral culture or PCR.

In HIV infection, abnormalities of humoral immunity precede those of cell-mediated immunity. Earlier in the illness, polyclonal hypergammaglobulinemia and decreased or absent response of lymphocytes to mitogens and antigens are common. A late manifestation may be hypogammaglobulinemia. A typical indicator of progression of disease is a decrease in the ratio of T4 (helper) to T8 (suppressor/inducer) lymphocytes. In infants and young children, CD4+ lymphocyte counts and

percentages are higher than in older children and adults. Therefore, the recommendation for initiation of prophylaxis for PCP must be based on age-related criteria.

Differential Diagnosis

In children with recurrent, severe, or unusual infections or unexplained failure to thrive, consideration should be given to both congenital and acquired immunologic deficiencies. Wiskott–Aldrich syndrome, severe combined immunodeficiency, complement deficiency, immunoglobulin deficiency, and DiGeorge syndrome are among the possibilities.

Management

There have been many improvements in the management of children with HIV infection. However, HIV is still a lifelong, usually fatal infection for which no cure is available or likely to be found in the near future. The most successful approach requires a multidisciplinary team approach. Objectives fall into three categories: supportive care and adequate nutrition, prevention of infectious complications, and specific antiretroviral therapy.

Supportive Care and Adequate Nutrition

Important aspects of this category include monitoring of growth and immunization against childhood diseases.

Monitoring of Growth and Development

Failure to thrive is common, so ensuring adequate nutrition is essential. Anorexia, impaired absorption, and increased utilization of calories require caloric intakes that exceed expected requirement. Supplementation of the diet with a number of commercially available products may be required.

Immunization

HIV-infected children should receive all routine non-live-viral immunizations, as recommended by national immunization programs. Routine immunization with combined diphtheria-tetanus-pertussis, hepatitis B, hepatitis A, conjugated HIB, conjugated pneumococcal and conjugated quadrivalent meningococcal (MCV4), and inactivated poliovirus vaccines should be given according to the usual immunization schedule.

Live virus (e.g., oral poliovirus) and live bacterial (e.g., bacillus Calmette–Guerin) vaccines should not be given to patients with AIDS or other clinical manifestations of HIV infection who are immunocompromised. Combined measles-mumps-rubella and varicella, rotavirus vaccines may be given to children with HIV infection with mildly impaired immunity. Children exposed to varicella or measles should receive varicella-zoster immune globulin. Annual influenza vaccination should be given to all children $\geq$6 months of age.

Prevention of Infectious Complications

Pneumocystis jiroveci pneumonia (PCP) remains a major cause of morbidity and mortality in HIV-infected children. New guidelines for PCP prophylaxis recommend beginning PCP prophylaxis (low-dose trimethoprim-sulfamethoxazole) at 4–6 weeks of age for all children who have been perinatally exposed to HIV until they determined to be HIV uninfected or presumptively uninfected with HIV. HIV can be presumptively excluded in nonbreasted infants with two or more negative virologics tests, with one obtained >14 days of age, and one obtained >1 month of age; or one negative virologic test obtained >2 months of age; or one negative HIV-antibody test result >6 months. For patients who cannot tolerate trimethoprim-sulfamethoxazole, intravenous pentamidine is an alternative. Aerosolized pentamidine for those 5 years or older has also been used.

Prophylaxis should continue throughout infancy for all children with definite HIV infection but should be discontinued for those found to be uninfected. For the remaining children with HIV infection, the age-adjusted CD4 lymphocyte counts at which PCP prophylaxis is recommended are as follows: 1–11 months, 1.500/mm^3 or less; 12–23 months, 750/mm^3 or less; 2–5 years, 500/mm^3 or less; and 6 years and older, 200/mm^3 or less. Intravenous immunoglobulin is indicated for children with hypogammaglobulinemia.

Specific Antiretroviral Therapy (ART)

The National Pediatric Resource Center Working Group on ART recommended that CD4 + cell count on percentage be used as a criterion for intuition of ART in children

with HIV infection. As of August 2010, 22 drugs have been approved for infected adults and adolescents, 17 of them have been approved for pediatric treatment indication in children, and 15 in pediatric formulation or capsule. Combination therapy with at least three drugs, including either a protease inhibitor or non-nucleoside reverse transcriptase inhibitor plus a dual nucleoside analogue reverse transcriptase inhibitor backbone, is recommended for initial treatment of HIV-infected children, because it provides the best opportunity to preserve immune function and delay disease progression. The goal of therapy in treatment naïve-children is to reduce HIV RNA levels to below the level of detection (if possible, determined using ultrasensitive assays) and preserve immune function for as long as possible. ART is recommended in all infants <12 months of age, regardless of clinical status, CD4%, or viral load. In children >1 year the decision to start ART depends upon HIV-related symptoms and CD4% +/− viral load.

Prevention

One of the most important successes is the intervention in transmission of HIV from mother to child. Recent clinical trials have provided strong evidence that the administration of a regimen consisting of AZT given antepartum and intrapartum to the HIV-infected pregnant woman and to the newborn for 6 weeks reduces the risk of mother-infant HIV transmission by approximately two thirds. Route of delivery depends on VL prior to delivery (at 36–38 weeks gestation) and general obstetrical considerations. If viral load is (VL) > 1,000, labor has not started, and rupture of membrane (ROM) has not occurred, schedule elective C-section (no evidence of benefit after onset of labor or ROM). Data support vaginal delivery when VL < 1,000 and on ART, unless other obstetrical indications. Breastfeeding is contraindicated where safe alternatives exist; replacement feeding is essential to reduce transmission risk in industrialized countries. However, formula feeding increases mortality in resource-limited settings; thus, breastfeeding with infant prophylaxis or maternal ART is recommended in those settings. Screening of blood and plasma for HIV antibody has markedly reduced the risk of infection through transfusion. Adolescent education is extremely important. Information regarding HIV infection should include mode of transmission, implications of infection, and strategies for prevention, including abstinence or safe sex and avoidance of intravenous drugs.

112 Influenza

Jonathan A. McCullers

Definition/Classification

Influenza is an acute, respiratory infection caused by members of the Orthomyxovirus family. Influenza viruses are enveloped, irregular, spherical particles containing a segmented, negative-sense RNA genome (*Fig. 112.1*). Three distinct types exist, termed influenza A, B, and C. Influenza A viruses are zoonoses derived from the wild bird population, while influenza B and C viruses are human pathogens. Influenza virus strains are named according to a standard nomenclature defining the type, the host species if not human, the geographic source, the isolate number from that geographic region, and the year, for example, B/Memphis/13/03. For influenza A viruses, the subtype is based on antigenic variation in the two major surface glycoproteins, the hemagglutinin (HA or H) and neuraminidase (NA or N), and this is indicated in parentheses during designation of strains (*Fig. 112.2*). There are 16 distinct HA subtypes and 9 NA subtypes in birds, although only 3 HA and 2 NA subtypes have to our knowledge established long-term lineages in human populations.

Etiology

Disease from influenza manifests from a complex mixture of direct viral damage, host responses, and the effects of co-pathogens. Primary influenza is considered a viral infection of the upper and lower respiratory tract. However, much of the disease that occurs during influenza epidemics and pandemics is mediated by secondary pathogens or host responses. The most common agents complicating influenza are the gram-positive bacteria *Streptococcus pneumoniae*, *Staphylococcus aureus*, and *Streptococcus pyogenes* (Group A streptococcus). Bacterial otitis media, sinusitis, pneumonia, and meningitis can all be mediated by co-pathogens in the setting of influenza. In addition, influenza interacts with host factors in vulnerable populations to cause disease through exacerbation of preexisting conditions. Acute worsening of cardiac disease, diabetes, asthma, and chronic obstructive pulmonary disease (COPD) are common accompanying morbidities during influenza. Deaths during influenza epidemics are often described as "excess" mortality since the underlying chronic diseases are classified in vital statistics as the official causes of death, even though influenza was the inciting factor.

Epidemiology

Seasonal influenza is primarily a disease of children, with clinical attack rates of 20–30% annually, concentrated in naive hosts. Children are also the primary vectors of disease due to this high clinical attack rate, their high social contact rate, and a relative lack of cross-reactive immunity allowing unrestricted replication and shedding of large quantities of the virus. However, most deaths are in persons with chronic comorbidities, so mortality is mostly in the elderly. Annual death rates are approximately 1 in 10,000 in developed countries and are presumed to be higher in the developing world, although data are lacking. The excess mortality rate for influenza A viruses varies significantly by strain and season, based on both the degree of preexisting immunity in the population, the potency of viral virulence factors, and how well the circulating viruses support secondary bacterial infections from regionally endemic bacterial strains. Since influenza B viruses do not have an animal reservoir and are well adapted to humans, their epidemiology resembles that of well-adapted seasonal strains with a high clinical attack rate in children, and little mortality outside of those with underlying chronic illnesses. The epidemiology of influenza C viruses is poorly understood, but it is not thought that significant disease results from typical infections.

Pandemics of influenza occur several times a century when a novel influenza A virus enters humans and achieves worldwide spread. A virus must meet three criteria to be considered pandemic: (1) a novel HA protein to which most of the population is immunologically naive, which allows a high clinical attack rate; (2) ease of transmission enabling worldwide spread; and (3) ability to cause severe disease. Four pandemics have taken place in the last 100 years. In 1918, an H1N1 subtype virus entered humans from the animal reservoir, causing severe disease and killing more than 40 million people worldwide.

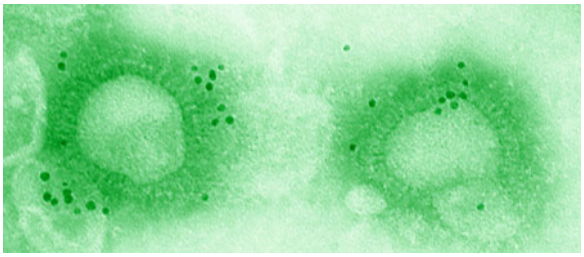

Figure 112.1
Influenza virions. Influenza virions as seen by electron microscopy. The dark beads are gold particles labeling neuraminidase spikes on the surface of the virions

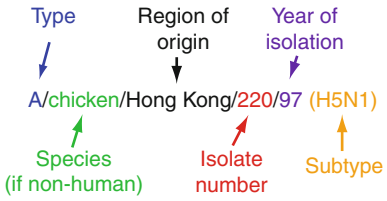

Figure 112.2
Nomenclature of influenza viruses

This virus adapted to humans and circulated until 1957, when it was replaced by an H2N2 subtype virus that took part of its gene constellation from the circulating H1N1 strain (since influenza viruses have a segmented genome, they can swap genes through a process called reassortment in intermediate hosts such as pigs), and the remainder from an avian source. The 1957 pandemic was severe, but not on the same scale as that of 1918, killing several million persons. In 1968, another novel strain emerged, again by reassortment. This H3N2 virus had a novel HA, but retained the NA and several other genes from the 1957 strain. Disease and mortality were milder than in previous pandemics, perhaps because of the retention of the NA antigen from the previously circulating strain. Adapted versions of this virus continue to circulate today. This virus was joined in circulation in humans in 1977 when a 1950 version of the previously circulating H1N1 strain was released from a frozen source. Although this virus achieved worldwide circulation and continues to be endemic in humans today, co-circulating with H3N2 strains, this event was not considered to be a pandemic since much of the population was immune and little disease ensued.

In 2009, the most recent pandemic strain emerged as a complex mixture of genes of avian, human, and swine derivation. It was again of the H1N1 subtype, but was most antigenically similar to the 1918 strain among viruses that circulated in the twentieth century. Because of this, only elderly persons who experienced influenza in the 1930s and 1940s had any cross-reactive immunity. Sero-archaeologic evidence suggests that as far back as the mid-1850s, H1, H2, and H3 subtype viruses have successively replaced each other as pandemic strains. It is not known whether this recycling phenomenon is limited to these subtypes due to factors presently not understood, or whether other subtypes are also capable of causing pandemics. The repeated incursions of highly pathogenic avian influenza viruses of the H5N1 subtype into humans since 1997 have created significant concern that a truly novel pandemic strain could arise, but as of yet these viruses seem incapable of sustaining chains of transmission in humans.

The 2009 H1N1 pandemic was marked by a high clinical attack rate in children, severe disease in older children and young adults, and relative sparing of the elderly due to cross-reactive immunity. Most cases of severe disease were found in persons with preexisting comorbidities, especially asthma, chronic cardiac or respiratory disease, and obesity. Bacterial pneumonia complicated the clinical course of about 30% of severe or fatal cases. The phenomenon whereby the elderly experience relatively less disease during pandemics than young persons appears to be related to the recycling phenomenon; the repeating reintroduction of the three most common subtypes leads to protection in the oldest sections of the populations as they will have antigenic experience with these unadapted viruses. Most disease is thus seen in younger persons. This is the inverse of the pattern of disease during seasonal epidemics with adapted viruses. Because most epidemics occur with drift variants that have been selected for their ability to cause disease in an immune population, the elderly are susceptible, and the relatively higher prevalence of comorbidities with increasing age drives higher rates of hospitalization and mortality. In pandemics, more than 90% of deaths are typically in younger age groups in whom the clinical attack rate is highest. During seasonal outbreaks, although young persons remain the primary vectors of transmission and are most likely to be infected, persons over 65 years account for about 95% of all mortality.

Transmission of influenza viruses can occur by contact, large droplet, and aerosol routes. Since most viruses are expelled during coughing and sneezing, direct contact with infected secretions or contaminated objects is thought to dominate in most settings. Transmission is affected by both temperature and humidity, and is favored in cold conditions and significantly diminished in the setting of high humidity. It has been suggested that aerosol transmission is more efficient in cool, dry environments,

facilitating explosive outbreaks when conditions are right. Most outbreaks in temperate climes are seasonal and occur in cooler, winter months when transmission is favored. However, a low level of infection can be detected year-round. In tropical parts of the world, circulation of viruses occurs all year, with inconsistent peaks related to poorly understood climactic changes. Herd immunity plays some role in the seasonality of influenza as well, since pandemic strains appear to transmit efficiently in the summer in temperate climes. The increased availability of susceptible hosts may overcome the temperature and humidity barriers to transmission of seasonal strains. The relative ability of influenza viruses to transmit is expressed by a term called the reproductive number R_0, which represents the average number of persons an infected individual will themselves infect. Any value over 1.0 suggests that sustained transmission is possible and therefore an outbreak can occur. Pandemic viruses may have an R_0 in the 2–3 range, higher than the average seasonal virus which may be $\sim$1.4, but much lower than comparable viruses such as measles which may have an R_0 of about 10–15.

Pathogenesis

Influenza viruses are segmented RNA viruses that encode 10–11 proteins. There are two surface glycoproteins, HA and NA, which are involved in attachment and budding, respectively, and are the main targets of antibodies. In addition to structural and polymerase proteins, the virus also encodes nonstructural proteins PB1-F2, which is a cytotoxin, and NS-1, which is an interferon antagonist. The lack of proofreading mechanisms for the polymerase complex during replication leads to a high mutation rate, which generates a multitude of variants within any population of viruses, termed a quasispecies. In the presence of selective pressure, such as adaptation to a new host or upon encountering antibody-mediated immunity, this breadth of options allows selection of fitter viruses. In the context of seasonal epidemics, the resulting drift of the surface antigens allows new variants to arise that can escape immune pressure in an experienced population, generating new epidemics. In addition, the segmented genome allows reassortment between two viruses infecting the same cell, which can lead to the genesis of a pandemic strain if the nascent virus encodes a novel HA from the animal reservoir.

The first encounter of the virus with the host is typically at a mucosal surface in the upper respiratory tract, where infection is initiated in epithelial cells. Clinically, influenza can be limited to this site or may spread down to the trachea and major bronchi. Penetration into the lower lung is limited by innate defenses such as collagenous lectins, which can bind glycoconjugates on the major surface glycoproteins HA and NA and neutralize infectivity. However, poorly glycosylated viruses, such as those recently emerging from avian sources, can evade this barrier and cause pneumonitis. The epithelial damage influenza viruses cause during replication can expose basement membrane, allowing adherence of bacteria and facilitating secondary infections. Severity of disease is thus a combination of the effective site of infection, which modulates both the viral syndrome and the type of secondary bacterial disease that might occur, together with the host response. The host response can be either helpful, by clearing the virus, or detrimental by furthering lung damage. Primary influenza is cleared by a combination of innate host defenses, IgM antibody, and a CD8+ T-cell response, which recognizes and kills infected cells. During this resolution stage, CD4+ T-cells facilitate class-switching of antibodies to IgG and induction of long-term memory. Thus, on later rechallenge with a related strain, infection is prevented or rapidly cleared through antibody-mediated neutralization of infecting particles. In the event that the new virus has drifted sufficiently that antibodies no longer recognize the surface proteins, infection is not prevented, but again the CD8+ T-cell response will clear the virus. This reliance of cellular immunity can be problematic in a compromised host, such as the elderly, who cannot clear virus as well and may suffer more severe disease. Paradoxically, robust immunity in older children can also contribute to disease if the T-cell response is strongly induced but cross-reactive antibodies are not present. Most of the clinical symptoms of influenza are due to either direct viral damage or the immune response.

Pathology

The hallmark of pandemic influenza is pneumonitis with diffuse alveolar damage, since these viruses typically penetrate well into the lower respiratory tract. Hemorrhage, fibrin deposition, edema, and formation of hyaline membranes are common. In severe cases, typical features of acute respiratory distress syndrome (ARDS) are seen. Findings suggestive of bacterial pneumonia, primarily manifest as a neutrophilic infiltrate with consolidation, may be superimposed on this pathologic picture. Antigen testing for bacteria in autopsy cases has been useful in recent studies to define the differences between primary viral and secondary bacterial pneumonia. Seasonal influenza rarely presents as severe, primary viral lower

respiratory tract disease; a mild to moderate tracheobronchitis is a more common presentation. Infiltration of lymphocytes in a peribronchial and perivascular distribution is typical. The epithelial lining of the major airways is predominantly affected, with cell death and sloughing of epithelial cells exposing basement membrane elements, upon which extracellular matrix material is deposited. Ciliated cells may also be killed during infection or may merely be functionally disrupted so that beat frequency and coordination of beat direction are altered, reducing clearance of mucus secretions. Pathologic alterations in other affected organs (e.g., heart, brain) are most commonly nonspecific, with edema and inflammatory changes present.

Clinical Manifestations: Symptoms, Signs

Influenza is a disease of rapid onset with both respiratory and systemic symptoms appearing together after a short, 2–3-day incubation period. After the first several days of illness when systemic symptoms dominate the clinical course, a transition takes place and systemic symptoms subside and cough and other respiratory tract–related symptoms become more prominent. Systemic symptoms include fever, chills, malaise, headache, dizziness, gastrointestinal disturbances, and myalgias. An erythematous maculopapular rash may be present briefly but it is not a common or prominent sign of infection. Common respiratory symptoms include cough, sore throat, rhinitis, nasal congestion, and eye irritation. Cough may be productive or nonproductive and may persist for weeks or longer. Typical features of bacterial pneumonia may be superimposed on this clinical presentation. Disease in adolescents and older children is similar to that of adults, and is dominated by the triad of fever, cough, and myalgias (*Table 112.1*). Cough is less prominent in younger children, and is sometimes absent entirely in infants. Myalgias are much less frequent in children than adults. Gastrointestinal symptoms are frequent in young children, and can manifest as vomiting, diarrhea, or abdominal pain. Infants may have fever and diarrhea as their sole presenting signs. Gastrointestinal symptomatology was more common during the 2009 H1N1 pandemic than is typically observed in seasonal influenza, and commonly affected older children and adults. Apnea and a sepsis-like syndrome can also occur in neonates and infants. Most children with influenza have a normal white blood cell count, but both leukopenia and leukocytosis can be seen. Leukocytosis with a predominance of neutrophils can be a sign of secondary bacterial infection, but can also occur with uncomplicated influenza. Blood chemistries are typically normal unless dehydration or complications are present. Influenza A and influenza B are indistinguishable clinically, although specific strains may have a predilection for certain clinical syndromes, and influenza B is more likely to cause clinical disease in younger children than in adults. Influenza C viruses typically cause more limited illness, with less-severe clinical presentations and a shorter duration of illness.

Table 112.1
Clinical manifestations of influenza

– Rare, + uncommon, ++ common, +++ very common
[a]Common (++) with 2009 pandemic influenza

Both viral and bacterial complications are common during childhood influenza. Otitis media, sinusitis, and pneumonia can all be due to either the primary viral infection or can be manifestations of coinfecting bacteria. Otitis media may present as a mild, serous exudate if it is solely due to the virus, but in young children mixed viral–bacterial infections are common and a painful, purulent exudate may result. Symptoms of sinusitis are common during acute influenza, and opacification of the sinuses can be seen on computed tomography in a significant proportion of affected persons. Bacterial sinusitis may result as a secondary complication, manifest as increased pain and a return of fever after an initial period of recovery. Laryngotracheobronchitis (croup) can be a manifestation of acute influenza in young children, and is often more severe than is typical for parainfluenzaviruses. An acute myositis manifest by severe pain and tenderness of both calves may occur during the early convalescence stage. This syndrome typically has an acute onset and is accompanied by elevations of serum creatine kinase and aspartate

aminotransferase and, occasionally, rhabdomyolysis in severe cases. Cardiac complications including myocarditis and pericarditis are associated rarely with influenza. The pathogenesis of these complications is unclear, as virus is rarely identified in affected tissues.

Neurological symptoms associated with influenza are confined almost exclusively to young children who are naive to the virus and have never received the influenza vaccine. Febrile seizures are relatively common and uncomplicated in this group, and up to 30% of all febrile seizures of childhood are due to influenza. Encephalopathy from influenza can present with a variety of symptoms and signs, but mental status changes ranging from delirium to behavioral disturbances to coma are most prominent. Cranial nerve pareses are unusual, as are meningitic presentations. Cerebrospinal fluid (CSF) examination is typically normal or reveals a mild pleocytosis, and virus can be detected in CSF by polymerase chain reaction (PCR) or in biopsy or autopsy material from affected brains in about 15% of cases. Electroencephalography (EEG) typically shows a general slowing without an acute focus, and computed tomography (CT) scans are either normal or demonstrate diffuse edema. A subset of patients present with a more fulminant course and have findings on CT suggestive of necrosis in the subthalamic regions, a syndrome termed "acute necrotizing encephalopathy." Influenza-associated encephalopathy is uncommon in much of the world, but was relatively common in Japan in the late 1990s and early 2000s for reasons that remain unclear. During the 2009 H1N1 pandemic, older children were affected more commonly than is typically seen with seasonal influenza, likely because of lack of preexisting cross-reactive immunity.

Diagnosis

Classically, influenza has been diagnosed on the basis of a compatible clinical presentation in the setting of supportive epidemiology. Local or regional data suggesting increased presentation to primary care centers coupled with an increased rate of laboratory diagnosis of influenza can usually be relied on to indicate the start of winter-time epidemics in temperate climes. Sentinel programs to track influenza are in place in many countries (e.g., through the Centers for Disease Control in the United States) and internationally through the World Health Organization. As an important epidemiologic clue, influenza will more frequently affect both adults and children together than other causes of similar clinical syndromes. In this context, an age-appropriate clinical presentation can usually be assumed to be influenza and appropriate measures taken without specific diagnostic testing. Chest radiographs may be employed to confirm lower respiratory tract involvement or define a complicating bacterial pneumonia. Recently, two factors have altered the utility of clinical diagnosis alone. First, co-circulation of viruses with disparate antiviral susceptibility patterns has created a need to not only to definitively diagnose, but also determine the subtype of an infecting influenza virus so that treatment can be targeted with specific antivirals, and unnecessary drug use can be avoided. Second, during circulation of the 2009 H1N1 pandemic strain, infection control measures in hospitals differed for this strain compared to seasonal influenza. Strain identity had to be established to provide appropriate health-care worker protections. These factors, coupled with increased use of antiviral medications with their associated expense, have led to an increased demand for accurate, point of care diagnostic methodologies.

Three methods of diagnosis of influenza are in widespread use at present. Point of care testing in outpatient settings is typically limited to antigen based testing. This is accomplished through the use of inexpensive kits that utilize colorimetric changes upon antibody recognition of virus in nasal swab material to rapidly demonstrate the presence of antigen. Some tests can distinguish type A from type B influenza, but none can currently subtype influenza A strains or distinguish specific strains within an influenza A subtype or between the two major influenza B lineages. These kits uniformly have a low sensitivity, so while a positive result is useful for directing care, a negative result does not rule out influenza. Rapid antigen testing is also commonly employed in hospitals as a point of care diagnostic in acute care settings such as emergency rooms, but typically with a more sensitive and specific test as a backup, performed in a central laboratory. Two methods are commonly employed. A fluorescent antibody test, where clinical material from a nasal swab or nasal wash is incubated in susceptible cell culture, and the presence of virus is determined by microscopy to detect fluorescence of dyes bound to antibodies which recognize the virus, has been in common use for decades. This method is more sensitive and specific than rapid antigen tests, but may take several days to achieve a result. This is being replaced in many centers by the use of PCR-based testing, particularly using rapid and sensitive real-time PCR assays. These assays have the advantages of quick turn-around times, improved sensitivity and specificity compared to all other methods, and can be designed to differentiate viruses by type, subtype, and even strain. In parallel, similar methods are now available to rapidly sequence portions of the viral genome to provide

indicators of the most common resistance mutations. Other potential methods to diagnose influenza, such as virus isolation or acute and convalescent serology, are now confined to research settings.

Differential Diagnosis

Because influenza can manifest as a variety of clinical syndromes, the differential diagnosis is broad. This is particularly true in infants, who may not have common signs of infection such as cough. Depending on the particular disease manifestations, many other pathogens can either be the primary cause or a co-pathogen. Other respiratory viruses such as parainfluenzaviruses, respiratory syncytial virus, human metapneumovirus, rhinoviruses, and coronaviruses should be considered in the differential diagnosis for upper respiratory tract infections, otitis media, and laryngotracheobronchitis (croup). Bacterial causes of epiglottitis, such as *Haemophilus influenzae*, *S. aureus*, and *S. pneumoniae*, must also be considered in the child with croup, particularly if acutely ill. *S. pneumoniae*, *S. aureus*, and *S. pyogenes* are common lower respiratory tract co-pathogens with influenza, but must also be considered in the differential diagnosis as primary agents of disease along with other common causes of community-acquired pneumonia such as *Mycoplasma pneumoniae* and *Chlamydia pneumoniae*. Numerous viral and bacterial pathogens can also present with fever and diarrhea, although gastrointestinal symptomatology with influenza is generally mild and the diarrhea non-bloody. The encephalopathy syndrome associated with influenza can mimic either bacterial meningitis or a viral encephalitis, so multiple causes must be considered. Finally, neonates with influenza can present with lethargy, poor circulation, and apnea, so other causes of sepsis must be considered.

Treatment

There are two classes of antiviral drugs approved for use against influenza viruses (*Table 112.2*). The adamantanes amantadine and rimantadine act by blocking the M2 ion channel, which prevents acidification of the virion during uncoating early in infection. Adamantanes have been in clinical use since the late 1960s for both prophylaxis and treatment of symptomatic influenza. Insomnia and difficulty concentrating are common side effects of amantadine that are less problematic with rimantadine due to its extensive metabolism in the liver. The NA inhibitors (NAIs) act by binding to and blocking the enzymatic activity of NA. This prevents budding of newly produced virions from infected cells, enhances aggregation at cell surfaces, and blocks escape from sialylated mucins. The NAIs oseltamivir and zanamivir were first licensed in the United States in 1999 and are now in widespread use throughout most of the world. Oseltamivir is available in a form that can be taken orally, while zanamivir is administered as a powder that must be inhaled with the use of a device. An intravenous form of zanamivir was made available in 2009 through an investigational new drug process to provide an alternative form of the drug for patients severely affected by pandemic H1N1 and unable to take oral or inhaled medications. A second NAI that can be administered intravenously, peramivir, was also made available during the recent pandemic through an emergency use authorization from the US Food and Drug Administration, and was licensed for clinical use in Japan. However, both of the US authorizations were withdrawn during the summer of 2010 at the conclusion of the pandemic, so licensed intravenous agents are not currently commercially available in any countries except Japan.

The primary clinical utility of existing antiviral agents is to halt progression of disease by preventing new host cells from being infected. If this intervention is administered early in the clinical course, it may alter the tempo of infection, allowing normal immune mechanisms to clear the virus. Earlier treatment works better in most cases because the infection is not yet widespread. Thus, the major effects of treatment are symptom reduction and a more rapid recovery, not immediate clinical cure. In clinical trials of NAIs, illness severity, ancillary medication use, and the frequency of prescriptions for lower respiratory complications were all reduced. The time to cessation of fever, alleviation of illness, and return to normal activity was decreased by about 24 h. Treatment of critically ill patients is complicated by lack of data regarding duration of therapy (all published data from prospective trials use short courses with a goal of symptom alleviation in acute, uncomplicated influenza) and by lack of a licensed intravenous formulation. Resistance has been a clinically significant issue for the adamantanes for years, limiting their utility. Widespread resistance to oseltamivir appeared in H3N2 viruses in 2007, and sporadic resistance in both seasonal and pandemic H1N1 viruses has been reported. Clinically significant resistance has not been seen with zanamivir, but viruses resistant to oseltamivir are typically also resistant to peramivir. Thus, while both zanamivir and peramivir could be considered for patients in need of intravenous therapy if they can be obtained, only zanamivir is currently an option for those with resistance

Table 112.2
Antiviral drugs available for treatment of influenza

Characteristics	Adamantanes[a]	Zanamivir	Oseltamivir	Peramivir
Licensure	1966, 1973	1999	1999	2009[b]
Target	M2 ion channel	Neuraminidase	Neuraminidase	Neuraminidase
Activity	Influenza A virus	Influenza A and B virus	Influenza A and B virus	Influenza A and B virus
Route	Oral	Inhaled, intravenous[c]	Oral	Intravenous
Effective against secondary bacterial infections	No	Yes	Yes	No data
Resistance[d]				
Seasonal H3N2	Resistant	Susceptible	Susceptible	Susceptible
Seasonal H1N1	Susceptible	Susceptible	Resistant	Resistant
Pandemic H1N1	Resistant	Susceptible	Susceptible	Susceptible

[a]Amantadine and rimantadine
[b]Emergency use authorization during 2009 pandemic only in United States; licensed in Japan
[c]Intravenous formulation available through investigational new drug (IND) application during 2009 pandemic only
[d]Based on 2008–2009 data

to both adamantanes and oseltamivir. The disparate resistance patterns of multiple viruses co-circulating over the last several years have made utilization of diagnostic PCR methodologies which can subtype viruses critical for appropriate management of severely ill patients. Combination therapy with multiple drugs within or across classes has been modeled in animals, and may improve effectiveness. However, these findings have not yet been proved in clinical trials.

Importantly, the effects on resolution of symptoms and the recommended duration of therapy (5 days) are based on studies in healthy persons with mild disease. It is not clear whether the dose, duration of therapy, and expectation of benefit should be the same in immunocompromised patients or in patients who have severe or complex disease manifestations. In regard to complications, oseltamivir both decreases the incidence of secondary bacterial pneumonia and reduces the severity of complications in animal models. Similar data are not available from a single, well-powered trial in humans, although a meta-analysis of data from multiple trials including unpublished data suggests these results can be extrapolated at least to healthy adults. In children, however, oseltamivir was shown to reduce the occurrence of otitis media by 44% compared to placebo. Retrospective reviews of insurance claims databases suggest that NA inhibitors reduce the risk of otitis media, pneumonia, respiratory illnesses other than pneumonia, and hospitalization in both adults and children, including in some at-risk groups such as diabetics. The best treatment for encephalopathy associated with influenza infection is uncertain. If viral replication in the brain is involved, effective antiviral treatment may not be possible, since neuraminidase inhibitors do not cross the blood–brain barrier (as do the adamantanes), and resistance to the adamantanes and lack of effect against influenza B viruses generally precludes their use. Reduction of virus titer in the lung with a neuraminidase inhibitor and supportive care may be the best available options.

The majority of clinically apparent cases of influenza can be managed as outpatients. The systemic symptoms that are prominent in the first several days of the acute infection often limit normal activity, causing missed school or work. General supportive care is often recommended, including antipyretics, rest, and hydration. Care must be taken in use of analgesics in children due to a past association of aspirin with an unusual manifestation of influenza known as Reye's syndrome and due to a concern that specific antipyretics or other herbal remedies in widespread use in Japan in the 1990s contributed to that country's high rate of influenza-associated encephalopathy. There is currently disagreement over the most appropriate use of antiviral medications. Most expert groups providing guidance have suggested that, at a minimum, persons at high risk for complications of influenza should receive early treatment with antivirals active against circulating strains of influenza. This guidance is tempered by a lack of study of these drugs in these specific groups. Clinical trials of these

compounds have typically been conducted in healthy persons, and clinical outcome measures have focused on reductions in symptoms and in duration of illness. Thus, whether these drugs are as active in persons with chronic medical conditions or are capable of preventing complications such as hospitalization and death are unclear. Duration of therapy and effective dose in critically ill patients and immunocompromised patients who may exhibit prolonged shedding are similarly unclear. There is currently little consensus on the issue of antiviral use in healthy persons including children, who have higher rates of hospitalization than adults. Some experts advocate withholding antivirals from healthy, well-appearing children on the basis of limited effectiveness data for significant outcomes such as hospitalization, coupled with the economic consideration of cost. However, the strategy of waiting to treat until complications develop may limit the effectiveness of therapy since early treatment has been proved to be superior to later treatment. In addition, many deaths in children are in otherwise healthy young persons of school age, and it has been argued that early intervention may prevent some of this mortality.

Numerous antiviral drugs directed against multiple targets of the influenza virus life cycle have progressed to preclinical or early clinical stages. As described above, intravenous formulations have seen some limited clinical use and at least one is now licensed in Japan. A long-acting drug in the NAI class has advanced through Phase III clinical trials, and may offer a single-dose option for uncomplicated influenza. Inhibitors of the HA, the polymerase complex, and combination chemotherapy approaches are also in various stages of clinical development and testing. Because of the prominent involvement of host immune responses in generation of symptoms and in the pathogenesis of severe influenza, immunomodulatory approaches have also been contemplated. Systemic steroids have been utilized to treat ARDS from H5N1 or pandemic H1N1 influenza, but the results have been generally disappointing, including some evidence that the disease may have been worsened by immunosuppression in some cases. Nonspecific anti-inflammatory therapies such as statins have also been utilized clinically, but no definitive, positive results have been reported. Use of antimicrobials is generally reserved for the treatment of complicated influenza when there is evidence of a secondary bacterial infection present. However, many pediatric deaths have been reported in recent years due to necrotizing *S. aureus* pneumonia, and this often presents as a fulminant disease. Early, directed anti-staphylococcal therapy should be considered in any critically ill child who presents with influenza-like illness or a confirmed diagnosis of influenza.

Prognosis

Viral disease from seasonal influenza is typically a self-limited illness in all but the most severe cases. Hospitalization and death are mainly due to complications, such as secondary bacterial infections, unusual non-pulmonary presentations (e.g., encephalopathy), or exacerbation of underlying illness. Bacterial disease when it accompanies influenza is often more severe than primary bacterial illness, and more difficult to treat. In particular, necrotizing staphylococcal pneumonia in association with influenza is considered an emerging disease in children. It presents as fulminant pneumonia progressing rapidly to respiratory failure, often with accompanying sepsis and multisystem organ failure, and may not respond to antibiotic therapy. Influenza-associated encephalopathy carries a high mortality rate. The severity of the initial presentation is considered a prognostic factor, with cases presenting in a comatose state carrying a high mortality rate and similarly high rate of severe neurologic deficit in survivors. Outcomes in immunocompromised children or in persons with chronic diseases are dependent on the severity of underlying illness and response to treatment. Need for hospitalization and the clinical course from influenza in the setting of preexisting cardiac or pulmonary disease is more often related to the underlying disease than to the inciting infection. Most children with cancer who contract influenza have a clinical course similar to that of immunocompetent children, but serious complications such as respiratory failure are more common. Disruptions of chemotherapy and hospitalization for fever in the setting of neutropenia are major problems in this group of patients. Prolonged viral shedding can occur, and in this setting prolonged antiviral therapy often leads to induction of resistance.

Prevention

Children experience the highest clinical attack rates, have the highest social contact rates to facilitate spread, and are the main vectors of transmission into vulnerable populations. Although mortality is unusual in children, more than 50% of rare complications and deaths are in healthy children without typical risk factors for hospitalization from influenza. For these reasons, universal influenza vaccination against children has been strongly advocated by most experts for many years. Current guidelines for vaccination of children vary widely between countries, but have been generally moving over time toward more inclusive recommendations. Vaccination of all children is now recommended in the

United States, as well as in many central European states, and is being considered in other countries. Prevention of influenza is clearly a cost-effective strategy compared to any currently available treatment options.

There are two basic types of influenza vaccines presently in use in children. Chemically inactivated, split-antigen vaccines grown in eggs (the "flu shot") are the standard vaccines that have been in use for more than 50 years and are licensed for children greater than 6 months of age. A cold-adapted, live, attenuated vaccine was introduced within the last decade and is licensed for use in children greater than 2 years of age. Both vaccines contain three antigens, one from the dominant, circulating type B strain, and the latest drift variants of each of the H1N1 and H3N2 subtypes of influenza A. The trivalent, inactivated vaccine (TIV) typically requires multiple exposures to achieve acceptable immunogenicity, efficacy, and durability in children under the age of 9 years, so current recommendations suggest two doses in anyone within this age group with fewer than two previous lifetime exposures. TIV is safe, with mild to moderate local soreness at the injection site the only common side effect. Guillaine–Barre syndrome does occur at a very low frequency after TIV, but at a lower rate than it does in association with influenza virus itself, the infection that the vaccine prevents.

The live, attenuated influenza vaccine (LAIV), which is administered as a nasal spray, appears to induce better initial immunity than TIV in young children who lack prior exposure, leading to better efficacy, longer durability, and improved cross-protection against drifted strains. It is unclear whether these advantages extend out of early childhood since available data suggest that LAIV has inferior efficacy in adults in some circumstances. This may be due to cross-protective antibody responses in more immunologically experienced hosts limiting replication of the vaccine virus. LAIV appears to be safe, with no evidence of reversion to wild type or transmission from vaccinated hosts. LAIV has been shown in one clinical trial to increase wheezing in children under 2 years of age, so administration to children with asthma or to those under 5 years of age with a history of wheezing is not currently recommended. Safety and efficacy have not been established in high-risk groups, so TIV is typically used for children with underlying chronic medical conditions.

Multiple alternative methods of producing influenza vaccines are either in clinical trials or already in use in adults. High-dose versions of standard TIV with four times the amount of each antigen show modestly increased immunogenicity in elderly adults, in whom vaccine effectiveness is generally poor, and are now licensed for this age group in many European countries and, more recently, in the United States. Adjuvanted vaccines, typically containing oil-in-water emulsions and lipids such as squalene or tocopherol, have also been extensively used in elderly adults in Europe to increase immunogenicity. Several of these vaccines that are in use in the elderly are in clinical trials in children, and may be available in the coming years as alternatives, where they might be particularly useful in at-risk groups where standard vaccine approaches are poorly immunogenic.

Introduction

With the emergence of the second wave of the 2009 influenza A (H1N1) virus, there have been concerns that this pandemic may rival those of 1957, 1968, and even 1918 in which not thousands, but millions of people around the world died from the disease (*Table 113.1*). WHO is advising the countries of the northern and southern hemisphere to prepare for a second wave of H1N1 pandemic in which large numbers of severely ill patients requiring more and more intensive care infrastructure are likely to be seen, creating pressures that could overwhelm in hospitals and intensive care units, and possibly disrupt the provision of care of other diseases. The newly developed H1N1 vaccine is expected to reduce the impact of the second wave of H1N1 influenza pandemic in the population, especially, on high risk groups, with diminished complications, hospitalization rates, and mortality. On the other hand, previous H1N1 strains have developed antiviral resistance, and this, as well as mutation to greater virulence, remain concerns for the future. Past pandemics were characterized by several features that have been seen since March 2009: the rapid spread of a virus with novel antigenic determinants, a change in pathogenicity with high death rates in younger age groups, successive pandemic waves, apparent higher transmissibility than that of the seasonal influenza,; and differences in impact in different geographic region. The overall mortality in the previous century's three pandemics ranged from 1 million to more than 45 million deaths. In the three previous influenza pandemics, vaccines were not produced in time to have any substantial impact. Even though the technology of vaccine manufacture, produced in embryonated eggs, has changed little since the 1930s, there is some hope that vaccines will be available to mitigate the force of later waves of the current epidemic. In addition, several clinically useful antiviral drugs are now available, although there are still concerns about development of resistance.

Influenza Virus: Back to Basics

The viruses that cause influenza are influenza A, B, and C belonging to the family Orthomyxoviridae, which is characterized by segmented minus-strand RNA genome. Influenza A and B viruses' genomes consist of eight separate segments. These include the following: three transcriptases (PB_1, PB_2, and PA); two surface glycoproteins, the hemagglutinin (H or HA) and neuramidase (N & NA); two matrix proteins (M_1 and M_2); and one nucleocapsid protein (NP). Epidemic disease is caused by influenza virus type A and B. Influenza C viruses cause sporadic mild influenza-like illness in children. The focus of this chapter will be on influenza A virus, which may infect humans and birds, and most importantly has the capability of developing into pandemic virus. Influenza A virus has been divided into multiple subtypes, and the natural host for most of these is various avian species. In addition, influenza A viruses of a few distinct subtypes have been isolated from pigs, horses, seals, whales, and human beings, and the genome of the virus codes for two important surface glycoproteins, the hemagglutinin (H or HA) and the neuraminidase (N or NA), have been identified. Based on both sequence and antigenic analysis, 16 distinct H (H1-H16) and 9 distinct N (N1-N9) subtypes are now recognized in animal and avian influenza viruses, but only 3 H subtypes (H1, H2, and H3) and 2 N subtypes (N1, N2) have caused extensive outbreaks in human beings. The influenza virus has a poor ability to proofread its genetic material while replicating, which results in frequent errors in progeny genes, and thus frequent mutations. When such minor changes occur in the H and N proteins, they result in "antigenic drift," the slow but significant change in antigenicity that occurs over time in both influenza A and influenza B, and that requires periodic changes in the yearly vaccine. An example of such drift occurred during the 2003/2004 influenza season when the H3N2 circulating virus developed over 80% drift from the virus that was used to make one of the three major vaccine components that year (*Table 113.2*). Further, marked changes in H, with or without similar changes in N, termed "antigenic shift" occur when new H or N gene segments are acquired by a process known as "reassortment." This may take place by the mixing of genetic segments during dual infection of cells by a human and an animal virus. When such viruses containing reassorted gene segments are introduced into

Table 113.1
Influenza pandemic of the twentieth century

Date	Strain	Estimate number of worldwide deaths	Comments
1918–1919 (Spanish Flu)	H1N1	Over 50 million	• Three waves: A first, mild wave in the spring of 1918 was replaced by a second wave in September to November, 1918 that resulted in a mortality rate over 2.5%. A third wave with equally high mortality rates swept around the world in 1919 • The virus probably originated from the United States and then spread to Europe
1957–1958 (Asian Flu)	H2N2	1–1.5 million	Two waves: The virus originated in Southern China in February 1957 and spread over 3 months to Singapore, Hong Kong, and Japan and in October 1957 reached United Kingdom and United States. A second wave was detected in January 1958
1968–1969 (Hong Kong Flu)	H3N2	3/4 million	Two waves in winters of 1968–1969 and 1969–1970. The virus originated from Hong Kong in July 1968

Table 113.2
Antigenic drift and shift

Drift	Shift
Minor change within subtype	Major change, new subtype
Point mutations	Exchange of gene segments
Occurs in A and B subtypes	Occurs in A subtypes only
May cause epidemics	May cause pandemic
Example: A/Fujian (H3N2) replaced A/Panama (H3N2) in 2003–2004	Example: H3N2 replaced H2N2 in 1968

a population that has no pre-existing immunity, they may lead to a pandemic. This happened in 1957 and 1968.

Devastating pandemics take place when populations are exposed to a new viral subtype in the absence of pre-existing immunity. The infectious capabilities of a new virus that emerges in this way through reassortment are likely to be acquired from one or more of the human influenza gene segments. Conditions favorable for the emergence of an antigenic shift (reassortment) involve humans living in close proximity to domestic poultry and pigs. Pigs play an important role in interspecies-transmission of influenza virus. Susceptible pig cells process receptors for both avian and human influenza strains, which allow the pigs to serve as mixing vessels for the exchange of genetic material between human and avian viruses, resulting in the appearance of novel subtypes. Analysis of the 1957 H2N2 pandemic strain found that the emergent virus resulted from the acquisition by previously circulating human H1N1 of three new gene segments of avian origin (the H2 gene, the N2 gene, and one other). Similarly, the 1968 pandemic H3N2 virus acquired two new genes from an avian virus closely related to viruses isolated from ducks in Asia in 1963. In contrast, the 1918 H1N1 virus appears to have been an avian-like influenza virus derived from an unknown source. The currently circulating novel influenza H1N1 viruses that have been isolated around the globe during 2009 appear to have originated from two unrelated swine viruses, one of them a derivative of the 1918 human virus (*Table 113.3*).

Evolution, Zoonotic Transmission, and Possible Origin of 2009 H1N1 (Swine Influenza)

The 1918 H1N1 pandemic is believed to have also affected swine at that time. Its descendents have been enzootic in pigs up ever since. The first influenza A isolated from diseased pigs in United States (USA) was in 1930. These H1N1 swine viruses are called the classical swine H1N1 viruses and have continued to circulate in pigs in the Americas, Asia, and, until 1980, also in Europe, and they remain relatively antigenically stable. This swine H1N1 subtype has crossed over to

Table 113.3
Evolution of swine Influenza A virus

1918–1919	H1N1 pandemic also affected swine
1930	The first isolation of H1N1 in pigs
1968	H3N2 infect swine in Asia after human pandemic
1976	Outbreak of new H1N1 swine strain of A/New Jersey/1976 occurred in military personnel at Fort Dix, New Jersey
1998	Triple reassortment viruses were isolated from pigs
1958–2005	37 human swine-origin influenza were reported
2005–2009	11 sporadic triple reassortment swine viruses were reported
2009	New strain of H1N1 influenza emerge is A /California/07/2009

humans periodically, including the Fort Dix outbreak in 1976, resulting in infections that have been occasionally fatal, particularly in pregnant or immunocompromised persons, but not producing human epidemics. Moreover, following the human pandemic of the H3N2 subtype in 1968, H3N2 influenza virus infected pigs, although such porcine strains have shown less antigenic drift in swine than in humans. In 1998, H3N2 viruses with genes derived from human, swine, and avian genes of North America ("Triple reassortant viruses") were first isolated from pigs in the USA. The triple reassortant H3N2 viruses also continue to acquire other virus genes via reassortment to generate triple reassortant H1N2 or H1N1 viruses. Swine viruses of subtypes H1N1, H1N2, and H3N2 have been reported to cause occasional human infection during this time. Between 1958 and 2005, 37 human swine-origin influenzas were reported. Twenty-two (51%) of these cases reported recent exposure to pigs. The overall fatality rate was 17%. Prior to the current pandemic, but after December 2005, 11 sporadic cases of triple reassortant H1 viruses were reported to the Centers for Disease Control and Prevention (CDC) in the USA, 10 carrying H1N1 genes and 1 carrying H1N2 genes. Some of the patients had close exposure to pigs. Possible limited human-to-human transmission was reported in several situations. Genetic analysis of 2009 H1N1 viruses isolated in North America, Europe, and Asia revealed quadruple reassortant swine influenza A viruses that have not been recognized previously in pigs or human. The virus resulted from the reassortment of North American H3N2 and H1N2 swine viruses (triple reassortment viruses: avian/swine/human with Eurasian swine viruses). Sequence analysis also suggests that PB2 and PA genes originated from American H3N2 avian virus; a PB1 originated from H3N2; HA, NP, and NS genes originated from classical swine virus; and NA and M genes originated from Eurasian swine virus (*Fig. 113.1*). One of the swine genes of this new virus has been derived from the 1918 human virus, so the strain causing the 2009 pandemic is a fourth generation descendant of the 1918 virus. The 2009 H1N1 viruses are more pathogenic in mammalian models than seasonal H1N1 viruses, showing the ability to replicate and cause appreciable pathology in the lungs of mice, ferrets, and non-human primates. The pathologic changes seen were similar to those found in the lungs of animals infected with the highly pathogenic H5N1 avian influenza virus.

Epidemiology and Impact

Epidemiological data now indicate that 2009 H1N1 influenza virus pandemic started as an outbreak of influenza like illness in the Mexican town of La Gloria, Veracruse in mid-February 2009. In mid-April, the Center of Disease Control (CDC) identified swine origin H1N1 influenza virus in two specimens, independently collected in southern California. By the end of April, international spread and human-to-human transmission prompted the WHO to increase the pandemic alert from Phase 3 to Phase 4 and shortly after to Phase 5. On June 11, 2009, the WHO raised its pandemic to the highest level, Phase 6, indicating widespread community transmission on at least two continents (*Table 113.4*). As of December 6, 2009, more than 208 countries and overseas territories/communities have each reported at least one laboratory-confirmed case of pandemic H1N1 influenza, with a total or more than 622,000 laboratory confirmed cases and at least 9,596 deaths. However, the number of cases reported vastly underestimates the real number of cases; the WHO ceased regular reporting of case counts on July 16, 2009, because many countries were having difficulty tracking their numbers, and the WHO judged that their time would be better spent on investigating severe cases and other exceptional events. Most patients in the world with 2009 H1N1 have been teenagers and young adults, with rates of hospitalization highest in very young children. Between 1% and 10% with clinical illness require hospitalization. Overall, 7% to 10% of all hospitalized patients are pregnant

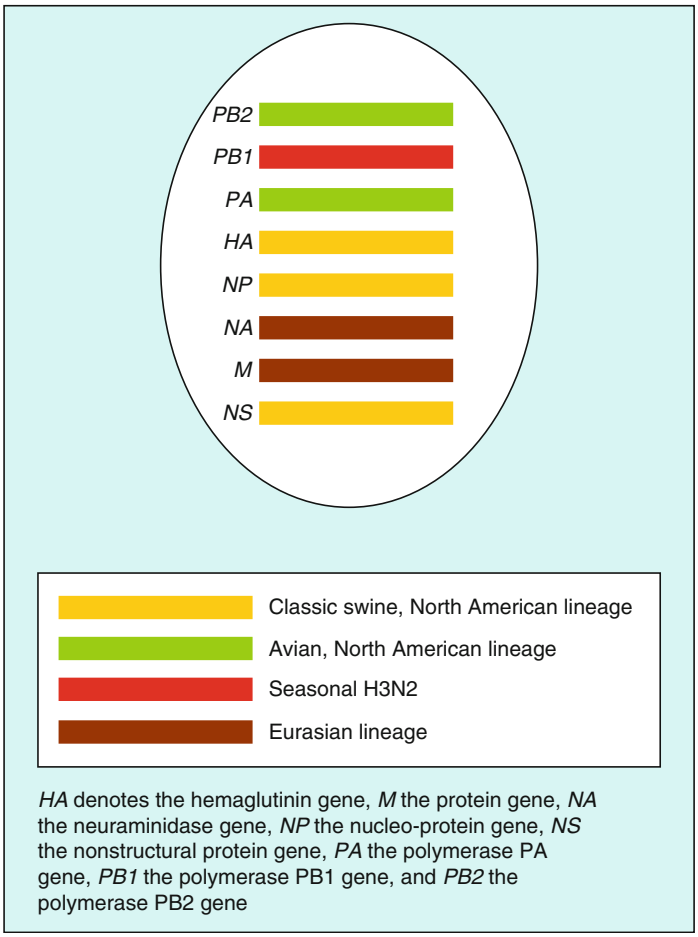

Figure 113.1
2009 Influenza A (H1N1) virus genotype

women in their second or third trimester. Of the hospitalized patients, 10% to 25% have required admission to intensive care, and 2–9% have died. Little is known about the level of pre-existing immunity to the 2009 H1N1 virus. Recent studies suggest that persons under the age of 30 years have little evidence of protective antibodies. However, a portion of older adults have pre-existing cross-reactive antibodies, presumably as a result of exposure to H1N1 strains circulating before 1957. Transmission of 2009 H1N1 virus from person to person is similar to that of other influenza viruses. The main route of transmission is respiratory through inhalation of large-particle respiratory droplets, and possibly via droplet nuclei. Transmission via large-particle droplets requires close contact because these droplets do not remain suspended in the air and generally travel only short distances (less than 2 m). Contact with contaminated surfaces is another possible source of transmission. All respiratory secretions and bodily fluids (e.g., fomites, diarrheal stool) of infected person should be considered potentially infectious. The secondary attack rates in households were estimated to be 27.3%, and in school settings, an infected school child was estimated to infect 2.4 other children within the school. The estimated incubation period could range from 1 to 7 days, but is most likely 1–4 days. Infected persons can be assumed to be shedding virus from 1 day prior to illness-onset until resolution of symptoms (up to 7 days following illness-onset). Children and immunocompromised or immunosuppressed persons may be contagious for longer periods. The amount of virus shed is greatest during the first 2–3 days of infection and appears to correlate directly with the height of fever. The 2009 pandemic H1N1 virus is expected to come in waves, and the middle of the second

wave is going on. This wave may continue during winter, or there may be a third wave. As of today no increase of severity has been seen, and genetic mutations have been minimal.

Clinical Features

The clinical manifestations can vary from asymptomatic infection to serious fatal illness that may include exacerbation of other underlying conditions or severe viral pneumonia with multi-organ failure. The Centers for Disease Control and Prevention (CDC) defines cases as influenza-like illness (ILI), if there is a fever of >37.8°C (>100°F) plus cough and/or sore throat in the absence of a known cause other than influenza. In the outbreak of 2009 H1N1 influenza pandemic in New York City, 95% of virologically proven cases satisfied the ILI definition. Fever has been absent in some outpatients and in, up to one in six surviving hospitalized patients. Vomiting and or diarrhea have occurred in up to 38% of outpatients in United States. Young children may have atypical influenza illness with the absence of fever and cough.

Table 113.4
World Health Organization pandemic levels

Phase 1 – No viruses circulating among animals have been reported to cause infections in humans
Phase 2 – An animal influenza virus circulating among domesticated or wild animals is known to have caused infection in humans, and is therefore considered a potential pandemic threat
Phase 3 – An animal or human-animal influenza reassortant virus has caused sporadic cases or small clusters of disease in people, but has not resulted in human-to-human transmission sufficient to sustain community-level outbreaks. Limited human-to-human transmission may occur when there is close contact between an infected person and an unprotected caregiver, but the virus is not widely transmitted among humans
Phase 4 – Verified human-to-human transmission of an animal or human-animal influenza reassortant virus able to cause "community-level outbreaks." The risk of pandemic is significantly raised
Phase 5 – Human-to-human spread of the virus into at least two countries in one WHO region. The declaration of Phase 5 is a strong signal that a pandemic is imminent
Phase 6 – The pandemic phase is characterized by community level outbreaks in at least one other country in a different WHO region in addition to the criteria defined in Phase 5. A global pandemic is under way

Among 89 children with confirmed H1N1 who required hospitalization in Birmingham, United Kingdom, the most common symptoms were fever (81%), cough (73%), and diarrhea (62%). Infant may present with fever and lethargy. The CDC case definitions for confirmed, probable, and suspected cases are in *Table 113.5*.

Three categories of clinical presentations have been seen during the current pandemic:

1. Mild illness is characterized by fever (some patients had no fever), cough, sore throat, diarrhea, myalgias, and headache. Other frequent findings have included chills and malaise. Vomiting and diarrhea have been reported in some patients, but no shortness of breath, dyspnea, or severe dehydration.
2. Progressive illness is characterized by mild illness in addition to signs or symptoms suggesting a progressive illness which include (*Table 113.6*):
   (a) Chest pain, tachypnea, or labored breathing in children
   (b) Hypotension
   (c) Confusion or altered mental status
   (d) Severe dehydration or exacerbations of chronic conditions (e.g. asthma, cardiovascular conditions)
3. Severe illness characterized by the following:
   (a) Profound hypoxemia, abnormal chest radiograph, and mechanical ventilation
   (b) Encephalitis or encephalopathy
   (c) Shock, multisystem organ failure
   (d) Myocarditis and rhabdomyolysis
   (e) Invasive secondary bacterial infection (e.g. pneumococcal disease)

Table 113.5
CDC: case definition for 2009 H1N1 Influenza virus

Confirmed case	An individual with an acute febrile respiratory illness with laboratory confirmed 2009 H1N1 infection by one or more of the following tests: • Real time reverse-transcription polymerase (rRT-PCR) or • Viral culture
Probable case	An individual with influenza like illness (i.e., an illness with a fever and cough or sore throat) who is positive for influenza A, but negative for H1 and H3 by rRT-PCR
Suspected case	An individual who does not meet the definitions of confirmed or probable pandemic H1N1 influenza A, but has ILI an epidemiologic link (e.g., likely exposure to a confirmed or probable case within the past 7 days)

Table 113.6
Clinical signs indicating rapid progression and need for urgent medical care

In adults	In children
• Difficult breathing or shortness of breath	• Tachypnea or labored breathing
• Pain or pressure in the chest or abdomen	• Skin color change, gray or blue
• Episodes of sudden dizziness	• Inadequate intake of oral fluids
• Severe or continuous vomiting	• Severe or continuous vomiting
• Influenza-like illness that improves but then returns with fever and cough	• Influenza-like illness that improves but then returns with fever and cough
• Confusion	• Irritable or not waking up

Complications

Most patients appear to have mild illness and recover spontaneously. Approximately 2–5% of laboratory-confirmed 2009 A (H1N1) influenza in Canada, and in the United States, as well as 8% in Mexico have required hospitalization. Nearly three quarters of cases in the USA requiring hospitalization, as well as 21 (46%) of 45 fatal cases in Mexico, involved one or more underlying conditions including asthma, diabetes, heart or lung disease, neurologic disease, pregnancy, morbid obesity, autoimmune disorders, and associated immunosuppressive therapies. Forty-five percent of patients admitted to intensive care units in the USA were children under the age of 18 years, and 5% were 65 years of age or older. Surveillance of pediatric deaths reported by CDC indicated that, of 36 children who died, 7 (19%) were aged <5 years, and 24 (67%) had one or more high-risk medical conditions. Twenty-two (92%) of the twenty-four children with high-risk medical condition had neuro-developmental disabilities which included cerebral palsy, developmental delay, autism, congenital neurological disorders, and other central nervous system disorders. Pneumonia is the most common and serious complication of the 2009 H1N1 pandemic influenza. The clinical course of 45 fatal cases in Mexico was characterized by severe pneumonia, hypoxemia with multifocal infiltrates including nodular alveolar, or basilar opacities on chest X-ray, and rapid progression to acute respiratory distress syndrome (ARDS) and renal or multi-organ failure. A similar experience was reported from Canada, Australia, and New Zealand. Some patients who required intensive care required advanced mechanical ventilation with high-frequency oscillatory bi-level ventilation and mean airway pressures of 32–55 cm/H_2O or veno-venous extracorporeal membrane oxygenation (ECMO) support. Bacterial co-infections likely played a role in almost one third of fatal cases of 2009 pandemic influenza A (H1N1) in the USA. The CDC investigators found evidence of concurrent bacterial infection in lung specimens from 22 of 77 patients (29%) with fatal pandemic H1N1 infection. A total of ten cases were co-infections with *Streptococcus pneumoniae*, six with *Streptococcus pyogenes*, seven with *Staphylococcus aureus*, two with *Streptococcus mitis*, and one with *Haemophilus influenza*. Four of the fatal cases involved multiple pathogens. The age of patients ranged from 2 months to 56 years, with a median of 31 years. Among other complications of pandemic H1N1 are acute neurologic syndromes reported in four patients aged 7–17 years who were admitted with signs of ILI, and findings that included seizures or altered mental status in two children, encephalitis in two, and ataxia in one. Three of the four patients had abnormal electroencephalogram (EEG). In all patients, pandemic H1N1 viral RNA was detected in nasopharyngeal specimen, but not in cerebrospinal fluids (CSF). All were recovered without sequelae. The overall case-fatality rate was 0.4% (compared with 2.4% for the 1918–1919 influenza pandemic) based on surveillance data from Mexico and mathematical modeling. There was a documented underlying medical condition in at least 49% of global documented fatal case.

Diagnosis

When influenza viruses are known to be circulating in the community, patients presenting with mild influenza can be diagnosed on clinical and epidemiological grounds alone. All patients should be instructed to return for follow-up should they develop any signs or symptoms of progressive disease (*Table 113.6*) or fail to improve within 72 h of the onset of symptoms. Under no

circumstances should influenza diagnostic tests delay initiation of infection control practices or antiviral treatment, if 2009 H1N1 pandemic disease is suspected. Laboratory testing should be prioritized to include hospitalized patients; patients where a diagnosis of influenza will inform decisions regarding clinical care, infection control or management of close contacts; and patients who have died of an acute illness in which influenza was suspected.

The gold standard for laboratory diagnosis of the 2009 H1N1 influenza is the real-timereverse transcriptase polymerase chain reaction (rRT-PCR) test, using primer and detector sequences tailored to the specific detection of this virus. A number of other diagnostic tests are available to detect the presence of 2009 H1N1 influenza in clinical specimens, but they differ in their sensitivity and specificity. Rapid influenza diagnostic tests (RIDTs) are based on various forms of antigen detection and have high specificity (>95%), but variable sensitivity (10–70%). Preferred respiratory specimens include a nasopharyngeal swab with a synthetic tip (e.g., polyester or dacron), nasal wash, bronchoalveolar lavage (BAL) or endotracheal aspirate. Lower respiratory tract specimens have a higher yield in patients with pneumonia due to viral replication in the lower respiratory tract. Many experts advise the use of a combination of nasopharyngeal swab with oropharyngeal swab. Isolation of H1N1 virus in cell culture or embryonated eggs is a diagnostic for infection but it may not yield timely result for clinical management; in addition, a negative viral culture does not exclude infection. All diagnostic laboratory work on clinical sample from patients, who are suspected cases of influenza H1N1 virus infection, should be done in a biosafety level (BSL) laboratory. Growth of H1N1 virus in cell culture or embryonated eggs should be performed in a BSL-2 laboratory using BSL-3 practices.

Management of 2009 H1N1 Influenza

The majority of individuals infected with the pandemic H1N1 influenza A virus can be treated with simple supportive care at home using antipyretics (e.g., acetaminophen or ibuprofen). Aspirin (acetylsalicylic acid) or aspirin-containing products (e.g., bismuth, subsalicylate-PeptoBismo) should not be used in children <18 years due to the risk of Reye's syndrome.

Empiric antiviral therapy should be started as soon as possible for persons with suspected, probable, or confirmed influenza and for:

Table 113.7
High risk groups for severe illness

1	Children younger than 2 years old
2	Pregnant woman up to 2 weeks post partum (regardless how the pregnancy ended)
3	Adult, 65 years of age or older
4	Persons younger than 19 years who are receiving long-term aspirin therapy
5	Persons with medical condition including asthma, neurological and neurodevelopmental conditions (including disorder of the brain, spinal cord, peripheral nerve and muscle such as cerebral palsy), chronic obstructive lung disease, cardiac disease, diabetes mellitus, and immunosuppressive conditions (including HIV/AIDS and cancer)

1. Illness requiring hospitalization
2. Progressive, severe, or complicated illness regardless of previous health status and/or
3. High risk for severe disease (*Table 113.7*)

Recent reports have shown that 21–25% of hospitalized patients with confirmed 2009 H1N1 infections have not received antivirals or have delay in receiving antivirals. Among 27 fatal cases in Mexico, the median time from the appearance of symptoms to treatment with antivirals was 8 days (range: 1–26 days).

Antiviral Drugs for Treatment of 2009 H1N1 Influenza

The neuraminidase inhibitors, oseltamivir (Tamiflu^{R}) and zanamivir (Relenza^{R}) are the drugs of choice for treatment and while the vast majority of pandemic H1N1 circulating strains are sensitive to these medications, all strains tested are resistant to amantadine and rimantadine (*Table 113.8*).

Oseltamivir and zanamivir are generally well-tolerated. Nausea and vomiting were reported with moderate frequency among adults receiving oseltamivir for treatment (nausea without vomiting, 10%; vomiting 9%). In children treated with oseltamivir, 14% reported vomiting. Oseltamivir suspension is formulated with sorbitol, which may be associated with diarrhea, and abdominal pain in patients who are fructose-intolerant. Zanamivir is formulated for oral inhalation and is contraindicated in patients with asthma or chronic obstructive disease. As of November 18, 2009, 39 isolates (among more than 1,000 tested) of pandemic H1N1 were resistant to oseltamivir. Among

Table 113.8
Antiviral treatment and chemoprophylaxis of 2009 H1N1 influenza

Medication/age groups		Treatment (5 days)	Chemoprophylaxis (10 days)
Oseltamivir			
Adults		75 mg twice daily	75 mg once per day
Children (age ≥12 months), weight	≤15 kg	30 mg twice daily	30 mg once per day
	15–23 kg	45 mg twice daily	30 mg once per day
	24–40 kg	60 mg twice daily	60 mg once per day
	>40 kg	75 mg twice daily	75 mg once per day
Children (age 3 months to <12 months)		3 mg/kg/dose twice daily	3 mg/kg/dose once per day
Children (0–<3 months)		3 mg/kg/dose twice daily	Not recommended, unless situation judged critical (limited data)
Zanamivir			
Adults		Two 5-mg inhalations (10 mg total) twice daily	Two 5-mg inhalations (10 mg total) daily
Children	≥7 years or older for treatment	Two 5-mg inhalations (10 mg total) twice daily	Two 5-mg inhalations (10 mg total) daily
	≥5 years for chemoprophylaxis		

the 32 cases for which detailed information were available, 16 were associated with antiviral prophylaxis, and 3 had no history of exposure to oseltamivir. Resistance was associated with the common H275Y mutation, with retention of zanamivir susceptibility. Antiviral therapy is most effective when started within 48 h after the onset of symptoms; however, evidence suggests that treatment may benefit patients with prolonged or severe illness, even when started more than 48 h after the onset of illness. The recommended duration of treatment is 5 days. Hospitalized patients with severe infection might require longer antiviral courses. Some experts have advocated use of double doses of oseltamivir in critically ill patient, despite lack of published dates about efficacy. Zanavimir-inhaled formulation is not designed to be used in any nebulizer or mechanical ventilator as there is a risk that lactose drug carrier can obstruct ventilator equipment. For patients who are unable to take oral medication or in whom oral medication appears to be ineffective, peramavir, which is an investigational neuraminidase inhibitor formulated for intravenous administration, can be requested from the CDC under Food and Drug Administration (FDA) and emergency use authorization, although studies on efficacy and safety are limited.

Symptomatic patients who have highly suspected or documented oseltamivir resistance should not be treated with peramivir, because strains with the H275Y mutation have demonstrated reduced in vitro susceptibility to peramivir. These patients should be treated with intravenous zanamivir, which is an investigational drug that can be requested from the FDA for compassionate use. The CDC suggests limiting the use of antiviral chemoprophylaxis to specific groups. Antiviral doses recommended for treatment and prophylaxis of 2009 H1N1 influenza in adult and children are listed in *Table 113.8*. Clinicians should consider empiric treatment with antibacterial drugs if bacterial co-infection is suspected during or after influenza. Antibiotics selection should take into consideration, local data regarding frequency of pathogen causing secondary infection and pattern of drug resistance. When pneumonia is present, treatment with antibiotics should follow evidence-based guidelines for community acquired pneumonia.

The use of corticosteroids for H1N1 influenza is controversial. High-dose systemic steroid are not recommended for use in viral penumonitis outside clinical trials. However, low-dose steroids may be considered in patient with septic shock who require vasopressors.

Isolation of the Hospitalized Patient with 2009 H1N1 Infection

CDC recommends standard, droplet, and contact precautions for care of patients with suspected or confirmed 2009 H1N1 influenza infection. Health care workers should use

ACIP priority target groups for H1N1 influenza vaccine

• Pregnant woman
• Household contact and caregivers for infant younger than 6 months of age
• All people from 6 months through 24 years of age
• Persons aged 25 through 64 years who have health conditions associated with high risk of medical complications from influenza (table)

surgical masks for routine non-aerosolizing patient care and N95-respirators for aerosol-generating procedures. Isolation precautions should continue for 7 days after illness-onset or until 24 h after the resolution of fever and respiratory symptoms. A longer period of isolation may be considered in the case of young children and severely immunocompromised patients.

2009 H1N1 Vaccine

An effective vaccine is the best tool to prevent the unpredictable spread of the current influenza pandemic. The 2009 H1N1 virus has the potential to cause severe disease, deaths, and potential socioeconomic dysfunction, and mathematical modeling suggests that the effect of the virus can be reduced by immunization. Two types of H1N1 vaccines have been prepared and have received approval from the FDA or the European Medicine Agency (EMEA) for use in the prevention of influenza caused by the 2009 pandemic influenza A (H1N1) virus. Both "adjuvanted" and "unadjuvanted" vaccine formulations are available. An adjuvant is a substance that boosts the immune response. It is made up of naturally occurring oil, water, and vitamin E. The "unadjuvanted" vaccine does not include this material. Vaccination campaigns are currently underway to protect populations from pandemic H1N1. Preliminary data indicate that both vaccines are safe and immunogenic. The Advisory Committee on Immunization Practice (ACIP) recommends that vaccination efforts should focus initially on persons in five target groups at high risk for influenza related complications (*Table 113.9*).

On November 19, 2009, the WHO estimated that around 80 million doses of pandemic vaccine had been distributed globally and around 65 million people had been vaccinated. The side-effect profile of the H1N1 vaccine ("adjuvanted" and "unadjuvanted"), particularly the frequency and severity of solicited adverse events, is consistent with previous experience from seasonal influenza vaccine. To date, less than ten suspected cases of Guillan-Barre syndrome have been reported in people who have received vaccines. These numbers are in line with normal background rates of this illness as recently reported. All such cases are being investigated to determine whether these are randomly occurring events or whether they might be associated with vaccination. WHO has received no reports of fatal outcome or confirmed cases of Guillain-Barre syndrome, since the H1N1 vaccination campaigns began. All cases have recovered. Intense active monitoring for rare adverse reactions of H1N1 vaccine is ongoing, but all data compiled to date indicate that pandemic H1N1 vaccines match the excellent safety profile of the seasonal influenza vaccines which has been used for more than 60 years.

114 Measles

Najwa Khuri-Bulos

Definition

Measles is a systemic viral infection which is characterized by fever, cough, coryza, and conjunctivitis followed by a characteristic enanthem and a maculopapular rash with distinct progression and dissemination. Measles virus is one of the most infectious agents known and its host range is limited to humans only. Before the introduction of measles vaccine in the 1960s, infection with measles virus was a universal occurrence by late childhood unless people lived in secluded island communities. In addition, measles was a major cause of mortality and morbidity causing more than one million deaths annually occurring mainly in underdeveloped countries and affecting primarily children less than 5 years of age. The most important complications of measles include pneumonia, diarrhea, otitis media, and encephalitis. All of these are more common in the very young, malnourished, and immune compromised individuals. Despite major advances at controlling measles by widespread use of measles vaccine, measles continues to be a major cause of concern since reemergence of measles easily occurs if the immune status in the population is allowed to wane by delays or incomplete vaccination in the population.

Etiology

Measles virus is an RNA virus that belongs to the genus morbilliviridae in the family paramyxoviridae. It is closely linked to two other animal viruses, rinderpest and canine distemper viruses. While there are theoretical considerations that measles virus emerged as a zoonotic agent in the distant past, measles virus has evolved to be restricted in its host range to humans only though nonhuman primates can be infected in the laboratory. The virus is a spherical, single-stranded enveloped RNA virus that is light and heat sensitive. The viral genome encodes for eight proteins two of which are surface proteins that play a major role in pathogenesis and in producing immunity. The H (hemagglutinin) protein helps in attachment of the virus to host cell surfaces while the F (fusion) protein facilitates entry of the virus into host cells. This later leads to fusion of the infected cells leading to large multinucleated cells in tissue culture as well as in humans pathologically. Morbillivirus is the only paramyxovirus that characteristically produces inclusion bodies in culture. Measles neutralizing antibodies that protect the host against measles and confer lifelong immunity against infection are mainly directed against the H protein. Even though RNA viruses are prone to mutations, there is no evidence that the surface proteins of measles virus have changed over the years and measles virus is monotypic. This is an important consideration for use of the measles vaccine which was formulated more than 40 years ago but continues to confer immunity till the present time. Based on the C terminal 450 nucleotide of the N gene or the entire coding region of the H protein, 8 clades, A-H have been described. New genotype designation is done when there is $>2\%$ variance in the nucleotide sequence in the H or 2.5% in the N protein. However, even though measles vaccine in use belongs to the A clade which has not been circulating widely in recent years, measles vaccine continues to be effective. While 23 genotypes have been described and gene sequencing has proved useful in epidemiological tracking of measles outbreaks, there is no evidence that genotype variation impacts on immunity to measles. Measles virus genome has also been sequenced and it is now possible to distinguish wild from vaccine strains which is also an important consideration as measles elimination activities intensify. Measles virus is light and temperature sensitive which is also applicable to measles vaccines making it necessary to keep the vaccine under strict environmental control in order to assure effectiveness in the host.

Epidemiology

Measles virus is one of the most contagious pathogens known in humans. Infection rate exceeds 90% among the exposed nonimmune individuals regardless of age and even brief exposure to measles can lead to infection in the nonimmune exposed individuals. Measles can be transmitted by different routes including contact, droplet, and airborne. It is noteworthy that the virus can remain

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_114,

viable and infectious up to 1 h in room air and outbreaks have been described in pediatric clinics even with no direct contact between patients. Respiratory secretions from sick patients are contagious 4 days before and 4 days after appearance of the rash. Since measles virus can remain infectious when suspended in air for up to 1 h, patients should be placed in single rooms and airborne isolation should be instituted upon hospitalization. Measles virus shedding may continue in immune compromised hosts for longer periods and isolation of these patients should continue for the duration of the illness which is an important consideration for their nonimmune contacts. The incubation period of measles is 8–14 days and the average number of secondary cases after exposure to an infectious case is 15–20 cases. Mathematical modeling has postulated that endemic spread of measles in a community can be maintained with a population of 250,000–500,000. The typical epidemiological pattern of measles infection before introduction of the vaccine was widespread infection with recurrent outbreaks every 1–2 years involving mainly very young children, less than 2 years of age in developing countries while in developed countries the age group tended to be older. During the same period, marked differences between these countries were noted in outcome and prognosis. In many of these developing countries, measles mortality was between 5% and 10% of cases while this was <0.1% in developed countries. In addition to the very young age of infection, malnutrition, which was also more prevalent in developing countries, was found to be a risk factor for poor outcome with measles. After introduction of measles vaccine the infected age group was older and the intervals between outbreaks became longer. This trend was associated with decrease in mortality and morbidity khuri-bulos. However despite a high level of immunization, outbreaks of measles continued to occur in both developed and developing countries. The last such outbreak in the USA occurred in 1991 when even though more than 90% of the population was immunized, a pool of susceptible individuals increased to the point and a widespread outbreak occurred. This was associated with 55,000 cases and more than 10,000 hospitalizations and 1,023 deaths. Since this failure to control the spread of measles was found to be due to vaccine failure in a small number of older children and low immunization coverage in younger ones, it was recommended that each child should receive two doses of measles vaccine after the age of 1 year. Following this two dose schedule in the USA, endemic transmission of measles ceased since 1993. Another initiative in Latin America to control measles was applied by PAHO. In this program of accelerated measles control, a combination of strategies including high routine immunization coverage coupled with supplemental immunization activities (SIAs) administered intermittently to all children led to interruption of measles transmission in the whole continent of South America since 2002. Following these successful strategies introduction of similar initiatives at measles mortality reduction and later elimination were started in many other regions of the world. The impact of these programs to control measles has been great and it was estimated that 23% of mortality reduction in children less than 5 years of age which occurred lately is due to the widespread use of measles vaccine with resultant reduction in measles cases (P. Strebel, personal information WHO). The success of these strategies coupled with the characteristics of the infectious agents and the disease itself makes measles eradication eminently feasible. At the present time measles is also considered one of the major indicators for achieving the MDG4 aimed at decreasing less than five mortalities by two thirds by 2015. The MDGs were undertaken by the United Nations in 2000 when measles was found to be the fifth major cause of death in children worldwide and the leading cause of vaccine preventable deaths in children globally.

Pathogenesis

Measles virus gains entry into the host through infection of the epithelial cells of the respiratory tract. The surface proteins H and F interact with the cell receptors CD46 and SLAM (signaling lymphocytic activation molecule or CD 150); CD 46 is a widely distributed human complement regulatory protein expressed on all cells. This normally acts as a cofactor for the inactivation of C3b. SLAM is expressed on all immune cells, immature lymphocytes, T, B cells and monocytes as well as mature dendritic cells. This explains the widespread dissemination of the virus. Both vaccine and wild strains bind on these receptors though to varying degrees. Once the virus gains entry into the cells there is local replication followed by spread to the regional lymph nodes where amplification of the virus occurs. This leads to entry of the virus into the reticuloendothelial cells in the spleen, liver, and lymph nodes where viral multiplication continues leading after a brief period to secondary viremia and spread of the virus to the skin, conjunctiva, lungs, and other organs. Pathologically, the most important distinguishing feature is the presence of giant cells, which are present in the lymph nodes and other tissues including the skin. The prodromal stage coincides with the onset of secondary viremia about 8–12 days after infection. During this period,

cell-associated viremia can be detected until appearance of the rash when virus-specific immune response appears and virus starts to disappear at the same time; however, while measles virus may not be detectable after appearance of antibodies by culture methods, viral RNA can be demonstrated for several weeks by PCR indicating slow clearance of the virus. The immune response to measles virus is a major determinant of the clinical manifestations of measles. In response to measles virus, CD4 cells are activated. Initially there is an increase in the IFN gamma levels, which is followed by a shift to IL4 and IL10 responses in the convalescent phase. While measles antibodies play a major role in prevention of infection from measles they are not as important in clearing the virus once infection has occurred and viral clearance is mainly attributed to the cellular immune response. Patients who have immunoglobulin deficiency develop typical measles rash and recover from measles, while patients with T cell immune deficiency frequently do not develop the typical measles rash and have difficulty in clearing the virus and develop a more protracted and severe illness often ending in death.

The initial antibody response following measles consists of production of IgM antibodies followed by a switch to IgG2 and IgG4 followed by IgG1 and IgG3 antibodies. In addition to immune activation, measles also leads to immune suppression. This includes lymphopenia and reduction in both CD4 and CD8 T lymphocytes and may lead to a falsely negative PPD and in some cases reactivation of tuberculosis.

Pathology

Similar to cells seen by tissue culture, the most characteristic lesion pathologically is giant cell formation that is seen in many tissues including lymph nodes, spleen, and the lungs in immunocompromised individuals who may develop giant cell pneumonia. In the central nervous system, demyelination is the major pathological finding in acute disseminated encephalomyelitis (ADEM) with no evidence of virus or inclusion bodies in the brain on microscopic examination. In these patients, there is no viral antigen or antibody detected in these brains or the cerebrospinal fluid. On the other hand in patients who suffer from T cell immune deficiency measles inclusion body encephalitis (MIBE) occurs. In this entity both inclusion bodies and measles antigen are detected in the brain. A third CNS complication of measles is subacute sclerosing panencephalitis (SSPE) which manifests many years after measles infection in what are apparently normal hosts. Pathologically, both inclusion bodies and measles virus antigen have been detected in the brain of these patients.

Clinical Manifestations

Classical Measles

Before the introduction of measles vaccine, measles infection was easy to diagnose with confidence depending on clinical manifestations alone. Following an incubation period of 8–14 days, there is onset of fever accompanied by what was termed the three "Cs" consisting of conjunctivitis, coryza, and cough. These increase along with the fever for a prodromal period of 3–4 days at the end of which the pathognomonic enanthem, the Koplic spots appear in the buccal mucosa. Koplic spots appear as pinpoint white blue lesions on the buccal mucosa best seen opposite the lower molars one day before and on the day of appearance of the rash. At the end of the prodromal phase, measles rash, which is a maculopapular rash, appears initially behind the ears and spread quickly to the face and over a period of 2–3 days in a centrifugal manner to the trunk and extremities involving on occasion the palms and soles. The rash may be so intense as to coalesce. Even though the characteristic measles is maculopapular on rare occasions the rash may be hemorrhagic. By the third day, the rash starts to fade in the same order it appeared. On occasion, fine peeling may occur. Fever, which continues during the appearance of the rash, disappears with disappearance of the rash. Fever extending beyond the fourth day of rash may indicate secondary bacterial infection. On occasion, patients with measles may also develop lymphadenopathy and splenomegaly.

Modified Measles

In situations where the host may have partial immunity to measles due to preformed antibodies, such as infants who still have persisting maternal antibodies or in recipients of intravenous gamma globulin or antibody containing blood products, clinical manifestations of measles may be modified leading to a longer incubation period, shorter prodromal illness with lower grade fever and a faint rash. Modified measles is also associated with fewer complications. In fact, the clinical manifestations maybe so mild as

to lead to misdiagnosis unless these cases are linked epidemiologically to a classical case of measles.

Atypical Measles

Contrary to modified measles, which is similar to classic measles but milder in severity, atypical measles is a distinct entity that occurs in patients who are infected with wild measles virus after having received killed measles vaccine, which was available between 1963 and 1968. Atypical measles is distinctly dissimilar to classical measles since it is characterized by sudden onset of high fever with abdominal and chest pain with cough and vomiting. The rash appears in the distal extremities initially and may progress from maculopapular to vesicular or even purpuric rash which does not occur with natural measles infection. Recovery may take 2–3 weeks. Atypical measles does not occur after live measles vaccine.

Complications

Even though otitis media is the most common complication of measles, pneumonia remains the most important cause of death following measles. It is important to note that measles virus itself infects the respiratory epithelium and while cough and bronchitis are common in the first 3 days of measles due to viral invasion of the respiratory epithelium, bacterial superinfection follows later in the course of the disease, usually 3–4 days after onset of the rash leading to bacterial bronchopneumonia. The most common pathogens leading to this complication include *H. influenzae*, *Streptococcus pneumoniae*, and staph aureus. Diarrhea is also an important complication especially in developing countries. This may be caused by the virus itself or maybe due to bacterial superinfection. Diarrhea exacerbates malnutrition in many of these children decreasing the immune response of the host further and increasing the risk of superinfection with resultant increase in mortality and morbidity.

Central Nervous System (CNS) Complications

An important major complication of measles is CNS involvement. Even in the absence of neurological manifestations clinically abnormal CSF and EEG findings have been reported. Measles virus can affect the CNS in several ways and clinically apparent neurologic complications of measles include three entities: measles encephalomyelitis or acute disseminated encephalomyelitis (ADEM), measles inclusion body encephalitis (MIBE), and subacute sclerosing pan encephalitis (SSPE). These three complications differ significantly in their pathogenesis, the time of onset, and clinical manifestations. The first to appear infection is measles encephalomyelitis or acute dissiminated encephalomyelitis (ADEM). This occurs in the recovery phase, about 2 weeks after the onset of rash, after acute measles infection with the onset of high fever, decreased level of consciousness, and seizures. The pathogenesis of this entity is an autoimmune demyelinating illness. No viral antigen or antibody has been detected in the CSF or the brain. Acute dissiminated encephalomyelitis occurs in about 1/1,000 patients following acute measles infection. It is a monophasic illness with guarded prognosis since a majority of these patients develop long-term sequelae. Another form of CNS involvement is measles inclusion body encephalitis (MIBE). This complication occurs primarily in patients who suffer from immune deficiency especially in decreased or abnormal T cells. It may follow both wild measles infection and administration of attenuated live measles vaccine. The onset is relatively rapid, 1–2 months following exposure, though some of these patients do not develop the characteristic measles rash and hence the acute measles infection may be missed. Disease manifestations include behavioral abnormalities, myoclonus, focal seizures, confusion, and coma. At biopsy, there is gliosis and inclusion bodies in neurons and glial cells. Measles virus can be detected though it might be defective. The third form of CNS involvement is subacute sclerosing pan encephalitis (SSPE). This is a very rare complication of measles with an incidence rate of ??2–40/1,000,000 population annually. The disease starts many years after measles with a latent period ranging from 2 to 22 years, usually 2–10, and is more common in patients who develop measles before the age of 1 year. SSPE follows wild measles infection mainly. The initial manifestation is deterioration in mental capacity with myoclonic jerks progressing to optic atrophy, followed by akinetic mutism and death over a period of several months to years. Patients have characteristic electroencephalographic changes and on CSF examination measles virus antibodies are detected. On pathology, inclusion bodies are present in neurons and glial cells and defective measles virus is identified. SSPE is very similar to MBIE but with immune deficiency the incubation period in MIBE is shorter than that seen in SSPE.

Measles in the Immunecompromised Host

A group of patients who have an exceptionally serious course with poor outcome following measles are the immune compromised, especially patients with T cell deficiency, since cell-mediated immunity is necessary for adequate response to measles virus. Following measles infection, these patients develop a widespread infection involving many organs with giant cell formation but no rash. Giant cell pneumonia and measles inclusion body encephalitis are major complications that frequently end fatally.

Diagnosis

During endemic conditions, the diagnosis of classic measles is possible using clinical criteria alone. In fact the clinical presentation is so characteristic that no further diagnostic test is needed in these situations. The introduction of measles vaccine on a wide scale, however, modified some of this classical clinical presentation and in these situations diagnosis is dependent on demonstration of antibody to infection. Antimeasles IgM antibodies are usually present by the time of appearance of the rash. Viral isolation is not necessary though demonstration of viral antigen by PCR is possible.

Differential Diagnosis

While measles has to be distinguished from several diseases leading to maculopapular rashes, the classical presentation with prodromal fever accompanied by coryza, conjunctivitis, and cough followed by the classical distribution of maculopapular rash with fever is almost diagnostic. Other diseases that can lead to a similar rash, however, include rubella, though the illness is less severe and there is a milder prodrome with no cough and the rash is milder; roseola infantum where there is little or no cough or conjunctivitis and fever subsides when the rash appears; parvovirus (fifth disease) with maculopapular rash but with no prodromal stage; scarlet fever is associated with sore throat and fever with no conjunctivitis or coryza. An important noninfectious disease to consider, however, is Kawasaki which gives rise to high fever and conjunctivitis and rash which maybe confused with measles. There is, however, no cough or koplik spots and the progression of the rash is dissimilar. Kawasaki may also lead to joint swelling which is absent with measles. However, since measles may be modified by partial immunity in some hosts, it is important to obtain laboratory confirmation of measles in some of these patients so as to make sure that control measures are started. This is becoming increasingly important as efforts at measles elimination and possible eradication are adopted.

Treatment

Even though antiviral agents such as ribavirin and isoprinosine have been tried there is no proved antiviral therapy for measles and treatment continues to be mainly supportive. Patients with acute measles should be well hydrated and offered antipyretics. These patients should also continue to be fed since many of them are living in poor conditions where their nutritional status is marginal. Patients who have suspected bacterial superinfection should be treated with appropriate therapy since pneumonia continues to be the major cause of death in measles. Another supportive measure that has proved beneficial is vitamin A. This vitamin has been found to improve the outcome with measles and vitamin A administration is recommended to patients with acute measles regardless of vitamin A status. A Cochrane review showed that two doses given on 2 consecutive days is recommended in order to decrease complications. The WHO recommends this for all children regardless of country of residence (*Table 114.1*).

Patients who have vitamin A deficiency should receive a third dose 2–4 weeks later.

Prognosis

Measles mortality and morbidity are increased at the extremes of age. Other factors that increase mortality include malnutrition, immune suppression especially

Table 114.1
Vitamin A treatment for measles

Age	Vitamin A dose	Two doses on 2 consecutive days
< 6 months	50,000 units	Two doses on 2 consecutive days
6–11 months	100,000 units	Two doses on 2 consecutive days
>12 months	200,000 units	Two doses on 2 consecutive days

T cell deficiency, chronic disease, and poor access to care. Mortality rates in children living in developing countries may be as high as 6% while this is less than 0.1% in developed countries.

Prevention

Natural measles infection leads to lifelong immunity. However, since measles infections lead to major complications and are associated with great mortality and morbidity, prevention of measles by immunization is mandatory. Immunization using the live attenuated measles is necessary to prevent measles and in patients who are immunocompromised, prevention of measles is possible by administration of immunoglobulin within 4 days of exposure to measles. Immunoglobulins, however, play no role in the treatment of measles once the infection has occurred.

Active immunization by the use of measles vaccine became possible with isolation and cultivation of measles virus by Enders. The first measles vaccine to be used was the killed measles vaccine which was introduced in 1963. This was later withdrawn from the market due to the occurrence of atypical measles in immunized individuals upon exposure to wild measles infection. This led to introduction of the first attenuated live measles vaccine in use. The first live measles vaccine in use was the Edmonston B strain which was associated with major side effects often necessitating the use of gamma globulin along with the vaccine. This strain was "further" attenuated leading to two strains the Moraten and Schwartz strains. These are the most widely used strains in Europe and the USA though other strains such as the Edmonston Zaghreb and other regionally attenuated strains are in use in other parts of the world.

Moraten and Schwartz strains are genetically identical and belong to the A genotype. While the original A genotype is not the commonly circulating genotype at the present time, individuals who have received measles vaccine in the past continue to be immune to measles and there is no need to change the formulation of the vaccine. Measles vaccine is also available as a combination vaccine with mumps and rubella vaccines. It contains no thimerosal but may contain sorbitol or gelatin as stabilizers. The vaccine is stable in the frozen state but the reconstituted vaccine is light and heat sensitive.

Measles vaccine induces antibody responses of the IgM class followed by IgG and IgA antibodies. Long-term immunological T cell memory is induced by CD4 and CD8 measles specific cells. The immune response to measles vaccine is dependent on absence of preformed measles antibodies which may inactivate the live vaccine. This may occur in infants who receive the vaccine at an early age during which maternal antibody may still be able to inactivate the vaccine. Measles vaccine may also be inactivated by blood or blood products. In these situations, measles vaccine should be delayed for several months depending on the product received. If a child received measles vaccine during that period this should be repeated at a later time. Another determinant of the immune response is the age at immunization and the viral dose and strain of the vaccine used. In most studies, the proportion of children who developed measles antibodies after receiving the vaccine was less than 75% in infants who received the vaccine before the age of 9 months and increased to 85% after the age of 9 months. This proportion increases gradually till 12 months of age when most studies show that 90–95% of recipients develop antibodies. Since measles is a very highly infectious disease and outbreaks can occur even in a highly immunized population a second dose of measles vaccine is recommended. This second dose is not a booster dose but is intended to lead to antibody response in the few who did not develop antibodies with the first vaccination effort. In studies of children who failed to respond to the first dose of measles vaccine, the seroconversion rate was in excess of 90% upon revaccination. After the age of 1 year, measles vaccine should be preferentially offered in combination with mumps and rubella vaccines which is not associated with increased risk of side effects and leads to immunity to all three antigens (MMR). A recently introduced formulation of MMR combined with varicella (MMRV), however, has been associated with a small increased incidence of seizures in recipients (1/2,000). This is mainly seen in patients who received the MMRV as a first dose between the ages of 12 and 48 months. A second dose can be administered using MMRV, however, with no increased risk of seizures.

The vaccine schedule for measles in many of the developing countries includes a dose to be administered at 9 months of age. This dose is necessary in order to prevent occurrence of measles infection in children who are less than 1 year of age in endemic countries. This group frequently has a higher mortality and morbidity than older children. In these situations, it is recommended that the MMR be administered again at 12–15 months of age and a second MMR be administered at 18 months or at 4 years of age. This strategy led to a major decrease in the number of cases of measles and measles elimination from many parts of the world. In the USA and Latin America, measles transmission has been interrupted since 1993 and 2002, respectively.

Side effects of measles vaccination in normal hosts are usually mild and self-limited. Fever occurs in 5–15% of vaccine recipients about 6–12 days following vaccination. Mild rash has also been reported in 5% of individuals. More serious side effects including thrombocytopenia occurs in less than 1/25,000 recipients while encephalitis has been reported in one in one million individuals.

Measles vaccine is contraindicated in patients who are immune compromised or are recipients of high dose steroids. This is defined as having received 2 mg/kg of >20 mg of prednisone for more than 14 days. Such patients can receive the measles vaccine 1 month after discontinuing steroids. Patients on inhaled steroids can receive measles vaccine, however. Measles vaccine is contraindicated in pregnancy, but children of pregnant women should be vaccinated and there is no evidence of transmission of the measles vaccine to contacts.

Care of exposed susceptible individuals includes administration of human immunoglobulin in a dose of 0.25 ml/kg in normal individuals and 0.5 ml/kg in immune compromised hosts within 6 days of exposure. Measles vaccine is not contraindicated in these situations, however, and may help protect the host if given in the first 3 days of exposure.

115 Mumps

Richard J. Whitley

Introduction

Mumps is an acute viral illness that has been recognized for millennia, first being identified by Hippocrates who described parotitis and orchitis. In the 1930s mumps was proven to be caused by a filterable agent from saliva that could be transmitted from infected patients to rhesus monkeys. Prior to the development of a vaccine, mumps was a frequent cause of outbreaks among military personnel. In spite of the availability of an excellent vaccine (measles, mumps, rubella with or without varicella), there have been outbreaks of mumps. In 2006, there was a multi-state outbreak of mumps that involved over 6,500 cases in the United States, occurring predominantly among Midwestern College students. A similar outbreak occurred in the summer of 2009, resulting in over 4,000 cases. On average, however, only 20 cases occur annually in the United States. Similar outbreaks have been reported globally by the World Health Organization.

Etiology

Mumps is a single-stranded RNA virus that is in the paramyxovirus family. Other members of this family include parainfluenza and Newcastle disease virus. Mumps virus grows readily in various human and subhuman primate cultures. It can be isolated from humans from multiple sites in those individuals who are infected.

Epidemiology

Mumps is transmitted by direct contact with infected oropharyngeal secretions. It occurs worldwide and humans are the only reservoir for disease. The highest incidence of mumps is late winter and early spring. Transmissibility of mumps is similar to that of influenza and rubella. Individuals with mumps are considered infectious 3 days before the onset of clinical illness to approximately 4 days after the onset of disease. Most cases occurred in young children between 5 and 9 years of age with 90% of cases occurring among children less than 15 years of age. Prior to vaccine licensure, it is estimated that there were over 200,000 cases of mumps annually in the United States. Males and females are equally affected. With widespread vaccination programs, current outbreaks, as noted above, tend to occur in older individuals, particularly those in college.

Clinical Manifestations

The case definition of mumps is acute onset of unilateral or bilateral tender, self-limited swelling of the parotid or salivary glands lasting greater than 2 days. The incubation period averages 14–18 days. Prodromal symptoms are usually nonspecific and include fever, malaise, anorexia, and myalgia. Approximately 20% of cases are asymptomatic.

Mild and self-limiting parotitis characterizes the clinical symptomatology and occurs in 30–40% of infected individuals. Symptoms tend to resolve over the first week of illness.

Importantly, mumps can be associated with significant medical complications, including orchitis, the most common of complications that occurs in post-pubertal males. Orchitis is associated with the acute onset of testicular swelling, pain, nausea, vomiting, and fever. It occurs in approximately 50% of individuals with clinical disease. Aseptic meningitis will also occur in approximately 15% of patients and tends to resolve without sequelae over a period of a week. Encephalitis is significantly less common.

Other complications include oophoritis (5% of post-pubertal females), pancreatitis, and myocarditis. Hearing loss attributed to mumps virus infection has been reported to occur in 1 in 20,000 cases.

Diagnosis

The diagnosis of mumps is usually made on the basis of clinical presentation. Specimens of saliva can be obtained either for isolation of virus in cell culture or for detection of viral DNA by polymerase chain reaction. The

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_115,

Figure 115.1

evaluation of acute and convalescent sera by enzyme immunoassay (EIA) is an easy way to determine evidence of acute infection. Reliable EIA assays to detect both evidence of IgM and IgG antibodies are available.

Prevention and Therapy

No therapy exists for the treatment of mumps infection. Similarly, the use of high-tittered immune globulin or routine IgG has not proven effective in post-exposure prophylaxis. Thus, current efforts focus on deployment of an efficacious vaccine.

The current vaccine strain Jeryl Lynn was a virus isolated from Dr. Maurice Hilleman's daughter and subsequently developed into a vaccine that was licensed in 1967. The mumps vaccine is available in combination with measles and rubella (MMR) or as a quadrivalent vaccine that includes varicella. The efficacy of the vaccine is considered to be in excess of 95% with immunity persisting greater than 25 years. Vaccine is routinely administered at greater than 12 months of age. A second dose of vaccine has been recommended for school age children by the Advisory Committee of Immunization Practices, Centers for Disease Control and Prevention.

The vaccine is considered contraindicated in individuals who are immunocompromised, pregnant women, or those who have had a severe allergic reaction to prior immunization. Since the MMR vaccine is a live attenuated vaccine, it requires a cold chain at all times.

116 Non-Polio Enterovirus: Infections

Sami Al-Hajjar

Enteroviruses (EVs) comprise nearly 72 serotypes within the family *Picomaviridae* (pico, small; ma, their characteristic nucleic acid component). Control of poliovirus in much of the world has focused attention on the nonpolio EVs which include Coxsackieviruses A and B, echoviruses, and the newer members of the EVs (*Table 116.1*). In recent years all newly identified enterovirus types have been designated simply as "enterovirus" followed by a number beginning with 68.

Morphologic and Biologic Features

The EVs are extremely small (22–30 nm in diameter), naked virions with icosahedral symmetry. They possess single-stranded positive RNA and four major polypeptides. EVs are distinguished from rhinoviruses (the other large genus of picomaviruses) by their resistance to acid (pH 3.0), the capability to replicate efficiently at 37°C, and a higher buoyant density.

Pathogenesis

The mechanism of pathogenicity of EV infection is the lytic infection of the host cell, resulting in severe cytopathic effects. EVs replicate in the lymphoid tissue of the oropharynx and gut. This phase occurs over 1–3 days and is symptom free. There follows a minor viremia with spread of virions to the reticuloendothelial system at 3–5 days. A subsequent major viremia results in viral dissemination to secondary organs such as the central nervous system, lungs, heart, and liver. This phase frequently is responsible for symptomatic illnesses.

Epidemiology

EVs are ubiquitous in humans, and humans are their only natural host. The EVs have a worldwide distribution, with a marked summer/fall seasonality in temperate climates and high year-round incidence in tropical and subtropical areas. The epidemiology of EV infections is not well studied in the Middle East and Arab Gulf Region. Early and recent reports have concentrated on the identification of wild polioviruses. In Saudi Arabia, there has been a significant increase in EVs during midwinter and early spring in addition to a year-round incidence of infection. Each enterovirus season in each part of the world is dominated by a few serotypes. Young children are most susceptible. As many as 13% of infants are born in the summer of life and one fifth of them are hospitalized with suspected bacterial sepsis and receive unnecessary antibiotics.

EVs can be isolated from the lower and/or upper alimentary tract and therefore can be spread both by fecal-oral and respiratory routes. In areas with poor sanitary conditions, fecal-oral transmission predominates. Transmission by respiratory routes can occur early in infection because the virus replicates in the upper respiratory tract.

After infection the viruses will persist in the oropharynx for 1–4 weeks, and they can be shed in the feces for 1–18 weeks. Sexual transmission of EVs has not been reported, and blood transfusions and insect bites seem not to be responsible for virus transmission. EVs can be isolated from sewage; therefore, a fecal-water-oral route of transmission is possible. Nosocomial transmission of EVs typically takes place in newborn nurseries and has been reported for several Coxsackieviruses of groups A and B and echoviruses. Incubation periods vary, but relatively short intervals (3–6 days) are frequent. Often illness will be seen concurrently in more than one family member, and the clinical features will vary within the household.

Clinical Manifestations

EVs are responsible for significant and frequent illnesses in infant and children and result in an array of clinical manifestations (*Table 116.2*). The most common presentations are nonspecific febrile illness or rashes. No disease is uniquely associated with specific EV serotype, and no serotype is uniquely associated with any one disease.

Of great clinical importance is enteroviral aseptic meningitis frequently caused by a group A or B Coxsackievirus or an echovirus. Onset of meningitis usually is sudden and

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_116,

Table 116.1

Echoviruses	31 types (types 1–9, 11–27, 29–33)
Enteroviruses	5 types (68–71)

fever of 38–40°C is the most consistent clinical finding. Headache and nuchal rigidity are more common in the school-age child. Cerebrospinal fluid (SF) analysis shows a moderate pleocytosis with a predominance of lymphocytes (early in the course the polymorphonuclear cell type is predominant), normal glucose, and slightly increased protein level. The duration of illness due to enteroviral meningitis is less than 1 week. Several studies indicate that as many as 10% of survivors of aseptic meningitis occurring before 3 months of age may suffer long-term neurologic sequelae, especially speech and language delay. Older children apparently recovered completely. Neurotropic strains, such as enterovirus 71, can cause aggressive central nervous system infection, and have overall fatality rate of 14%.

Coxsackieviruses B_1 through B_5 are among the most important pathogens of acute and chronic myocarditis and cardiomyopathy; also they are often implicated in pleurodynia (Bornholm disease), which is most common among children 5–15 years of age. It is characterized by the abrupt onset of pain over the lower rib cage or upper abdomen with moderate fever. Cough is notably absent.

Group A Coxsackieviruses usually cause herpangina, which is characterized by an eruption of tiny oral vesicles and ulcers (particularly concentrated on the posterior pharynx), high fever, anorexia, sore throat, and dysphagia. Complications are unusual and the child is generally asymptomatic by the seventh day.

Hand-foot-mouth syndrome, most commonly due to Coxsackievirus A_{16}, occurs particularly among children less than 5 years old. The course is similar to that of herpangina, but a vesicular exanthema is distrusted over the buccal mucosa and plate, with similar lesions appearing on the hands more commonly than the feet. Trunks, thighs, and buttocks may be involved. Recently strains of enterovirus 71 circulating in East Asia caused outbreaks of hand-foot-mouth disease that are associated with a severe rhombencephalitis (inflammation of brain stem),with significant mortality.

Acute hemorrhagic conjunctivitis, usually associated with Coxsackievirus A_{24} and Enterovirus 70, occurs in epidemics and pandemics, affecting as many as 50% of the entire population of a community. Typically patients have sudden onset of severe eye pain, tearing, photopia, swelling, and dramatic subconjunctival hemorrhage. Recovery occurs in a week to 10 days.

Approximately 2,500 babies each year develop perinatal disseminated EV infection. The risk of severe morbidity and mortality is highest in the first day of life. Meningoencephalitis, myocarditis, hepatic necrosis, and necrotizing enterocarditis may develop as well as disseminated intravascular coagulation, making this syndrome indistinguishable from overwhelming bacterial infection.

Unusual EV-associated illnesses include chronic meningitis or meningoencephalitis occurring in antibody-deficient individuals, inflammatory myositis, and rare cases of juvenile diabetes mellitus that have been related to Coxsackievirus B.

Diagnosis

Diagnosis of nonpolio EV infection is more readily established by virus isolation from throat swabs, stool or rectal swabs, body fluids, and occasionally tissues. Direct isolation of virus from affected tissues or body fluids in enclosed spaces (e.g., pleural, joint, pericardial, or cerebrospinal) usually confirms the diagnosis. Because EVs can persist in the lower gastrointestinal tract for as long as 8–12 weeks, fecal isolates may not be causally related to the patient's illness.

When there is central nervous system involvement, CSF cultures taken during the acute phase of the disease may be positive in 10–85% of cases, the mean time to grow EVs from the CSF ranges from 4 to 8 days. Recently a polymerase chain reaction assay was proven to be more sensitive (95–100%) and as specific (97%) as cell culture for detection of EVs in CSF of patients with aseptic meningitis and meningoencephalitis. Serologic screening without viral isolation is generally not indicated.

Treatment

Treatment is supportive only. Although there is no approved antiviral therapy for any enteroviral infection, pleconaril, a capsid-inhibiting compound, may play a role in the treatment plan for serious infections in the future. Intravenous immune globulin (IVIG) has been administered to B-cell-deficient patients (such as

agammaglobulinemia) with chronic meningoencephalitis, and in neonates with overwhelming EV infection with some benefit (uncontrolled trials).

Isolation and Control Measures

Enteric precautions must be observed for hospitalized patients during their hospital course. Particular attention should be given to hand washing and personal hygiene, especially after diaper changing.

117 Parvovirus B 19

Mahmoud M. Mustafa · Kenneth L. McClain

Parvovirus B 19 (B19) is the only known human pathogenic parvovirus. It was discovered accidentally in 1974 during a study screening healthy blood donors for hepatitis B using panels of serum samples. One sample (coded 19 in panel B) gave a positive result in counterimmunoelectrophoresis (CIE) but negative results in more sensitive assays. Electron microscopic examination of the excised precipitin line from the CIE showed the presence of 23-nm particles resembling parvovirus. Since that time, serologic surveys have demonstrated that B19 is a ubiquitous agent. Thirty percent to 60% of adults have antibody to the new virus. Systematic search of blood samples to identify infected patients and possible clinical correlates resulted in 1981 in the discovery of B19 in the serum of sickle cell anemia patients with aplastic crises. The next major association was made in 1983 when B19 infection was found to be the causative agent of erythema infectiosum. Since then, the spectrum of illness with which B19 is associated has grown to include intrauterine infection with hydrops, arthritis, idiopathic thrombocytopenic purpura, transient erythroblastopenia of childhood, neutropenia, hemophagocytic syndrome, encephalitis, pseudoappendicitis, and purpura. This chapter reviews the present knowledge on Parvovirus B 19 virology and epidemiology and its associated clinical manifestations.

Virologic Aspects of B19 Infection

Parvovirus B 19 is a small (*parvum* is Latin for small), nonenveloped, single-stranded DNA virus that belongs to the family Parvoviridae and is a member of the genus *Parvovirus*. As result of its lack of envelope and limited DNA content, B19 is extremely stable to physical inactivation by such mechanisms as heat (60 min at 56°C) and lipid solvents. Parvoviruses are species specific, and no animal model has been identified that permits the replication of B19. In addition, although the virus can be grown in fresh human bone marrow cells, erythroid cells derived from fetal liver, and erythroid leukemic cells, there is no practical in vitro system for isolation of B19 from clinical specimens.

Epidemiology

Infection with B19 is common. The reported prevalence of immunoglobulin G (IgG) antibodies ranges from 2% to 15% in children 1–5 years old, from 15% to 60% in children 5–19 years old, from 30% to 60% in adults, and up to 90% in the elderly. Women of child-bearing age show an annual seroconversion rate of 1.5%. Viremia in the general population, however, is rare. A study of the prevalence in blood donors showed that 1:20,000–1:40,000 units of blood contain high titers of B19 during the epidemic season. This is important to consider when many thousands of units of blood are pooled to make factor concentrates used for treatment of patients with hemophilia.

The distribution of B19 is worldwide. Seroprevalence studies from the United States, Western Europe, and Japan show similar patterns. The prevalence rates are slightly higher in developing countries. Infection in temperate climates is common in late winter, spring, and early summer. Infection with B19 follows a cyclic pattern, with increased rates of infection occurring every 4–5 years. The infection may be either epidemic or sporadic. The major route of transmission is through respiratory secretions of viremic patients. Transmission may occur among family members, from patient to patient, and from patient to health care or day care provider. The secondary attack rate among household contact is approximately 50%, and during school epidemics 10–60% of schoolchildren will develop erythema infectiosum. Outbreaks of erythema infectiosum in schools may be prolonged over months, suggesting close contact transmission rather than an aerosol transmission mode. Patients with erythema infectiosum are beyond their period of infectivity and present a low risk for further transmission; therefore, they need not be isolated. The principal risk in clinical settings appears to come from patients with high-titer viremia, such as patients with sickle cell anemia and aplastic crisis, or those with chronic pure red cell aplasia, such as human immunodeficiency virus–infected patients. These patients should be in contact and respiratory isolation, and pregnant health care workers should not take direct care of such patients.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_117,

Other routes of transmission include vertical and parenteral transmission and as an occupational hazard in medical laboratory workers. Vertical transmission may occur from mother to fetus in approximately one third of cases of serologically confirmed maternal infection. B19 has been shown to be transmissible in factor VIII and factor IX concentrates. B19 is heat resistant and can withstand the usual heat treatment (80°C for 72 h) used to destroy infectivity of factor concentrates. In addition, solvent detergent methods only inactivate lipid-enveloped viruses (B19 is a nonenveloped virus). B19 has been transmitted by steam- or dry-heated factor VIII and IX concentrates. The question of whether measures should be taken to reduce B19 infection by transfusion of blood components and clotting factor concentrates is eloquently discussed in a recent publication. Immunoglobulin products have not been associated with B19 transmission and may present a low risk because they contain high B19 antibody titer.

Pathogenesis

B19 has tropism for erythroid progenitor cells, including erythroid colony-forming and burst-forming units. The major receptor for B19 on erythroid target cells is the P antigen; B19 capsids bind to P antigen. B19 is critically dependent for its replication upon actively dividing cells. Virus replication occurs in the nuclei of the pronormoblasts. During its replication, B19 is cytotoxic to the infected cells.

The diverse clinical manifestations of B19 infection are the result of either erythroid progenitor (and/or possibly other hematopoietic progenitor cell) aplasia or host immune response. In the immunocompetent host, B19 infection typically results in a self-limited febrile illness characterized by asymptomatic red cell aplasia followed by a rash or arthropathy presumed to be immunologically mediated. Recovery is associated with the production of specific antibodies and probably lifelong immunity. Asymptomatic infection is common. In one study of a school outbreak, B19 caused asymptomatic infection in approximately 25% of adults. If the immunocompetent host has an underlying hematologic disorder (typically characterized by increased cell destruction) (*Table 117.1*), B19 may result in severe symptomatic anemia. However, in all such cases the aplastic anemia is transient. In contrast, B19 infection in immunocompromised patients may become persistent and results in chronic anemia. The fetus is particularly vulnerable because it might develop severe anemia and persistent infection due to its decreased red cell survival (about half that of a normal adult) and inability to mount an adequate immune response to clear the infection.

Table 117.1
Hematologic conditions predisposing patients to Parvovirus B 19–associated acute aplastic crisis

Hereditary disorders
Sickle cell anemia
Hereditary spherocytosis and stomatocytosis
Thalassemia
Glucose-6-phosphase dehydrogenase deficiency
Pyruvate kinase deficiency
Pyrimidine-5′-nucleotidase deficiency
Congenital dyserythropoietic anemia
Acquired disorders
Iron deficiency anemia
Chronic autoimmune hemolytic anemia
Cold antibody-mediated autoimmune hemolytic anemia
Malaria
Blood loss
Paroxysmal nocturnal hemoglobinuria
Normal host

The cause of transient neutropenia has not been well defined. Parvovirus has been detected in granulocytic- and erythroid-line cells in a patient with B19-induced pancytopenia. In addition, replicative forms of B19 DNA have been found in granulocyte-enriched fractions of human serum, suggesting a role for direct infection by B19. B19 has not been shown to replicate in megakaryocytes, but in vitro it inhibits megakaryocyte colony formation.

Diagnosis

For optimal diagnostic yield, the patient's clinical presentation, stage of disease at presentation, and the underlying hematologic and immunologic conditions must be considered when ordering a laboratory test. In a previously normal host who presents with erythema infectiosum or arthropathy, for example, a single immunoglobulin M (IgM) antibody assay is the only test required to confirm infection. IgM is detectable within 3 days after onset of disease, peaks in 2–3 weeks, and then begins to decline in 1–2 months. B19 IgM can be measured in patients' serum or saliva. Saliva can be a convenient alternative to

serum for the diagnosis of recent infection, particularly during outbreaks. Patients with chronic hematologic disorders, on the other hand, may present with aplastic crises before IgM or IgG antibodies are detectable. Furthermore, the fetus or patients with immune deficiency may have an unpredictable antibody response.

Serologic tests of viral infections can be confusing when more than one virus is sought as the cause of a particular set of symptoms. Some samples positive for *Parvovirus* IgM often give positive results for other viruses. In one study, of 25 initially B19 IgM-positive sera, 20% cross-reacted in an Epstein–Barr virus viral capsid antigen IgM test and 8% in a cytomegalovirus IgM test. Another report compared several enzyme immunoassays for the detection of parvovirus to a radioimmunoassay developed by the authors, which used baculovirus-expressed B19 protein. From 88 sera tested, approximately 50% agreement between tests was found. Test sensitivity ranged from 70% to 100% and specificity from 76% to 100%.

Tests of B19 DNA or viral antigens are most useful for patients with aplastic crises or immune deficiency states. The most sensitive assays for B19 DNA detection are polymerase chain reaction (PCR) and hybridization assays. Recent and rapid methods for detection of B19 DNA using a nested PCR reaction have been developed. PCR and hybridization assays have been applied successfully to a variety of clinical samples. B19 DNA may be detectable in serum of patients for several months even after an uncomplicated infection. Because of extreme sensitivity, meticulous care and adequate controls must be used to ensure reliable results. The PCR is often considered to be a specific and highly sensitive test for the viruses in clinical specimens. The nested PCR method for parvovirus was able to detect as low as 3–30 viral genome copies.

Assays for B19 antigens are available but are relatively insensitive. Electron microscopy can also be used to detect B19. In anemic patients, bone marrow aspirate examination shows giant cell proerythroblasts, which constitute strong evidence of B19 infection. In situ hybridization and immunohistochemical studies can be used to confirm the diagnosis. These studies can be used also on tissue obtained from other infected sites.

Clinical Overview of Nonhematologic Effects

In the normal host, B19 infection can be asymptomatic or causes disease such as erythema infectiosum, polyarthropathy syndrome, acute hepatitis, and Behçet's disease. Asymptomatic infection occurs in as high as 20–50% of children and adults. Most people with B19-specific antibody have no recollection of any specific symptoms.

Erythema Infectiosum (Fifth Disease)

Erythema infectiosum is the most common clinical manifestation of B19 infection. It is a moderately contagious disease affecting mainly children. It is called the fifth disease because it was the fifth of five illnesses described exhibiting somewhat similar skin rash. (The other four diseases were rubella, measles, scarlet fever, and Filatov–Dukes disease, the last of which is now considered a mild atypical form of scarlet fever.) Histopathologic changes of the skin include edema and lymphocytic infiltrate. The disease affects mainly children, is infrequently encountered in infants and adults, and is characterized by an initial nonspecific prodromal illness followed in 2–5 days with marked erythema of the cheeks sparing the circumoral and bridge of the nose regions (giving the child a slapped-cheek appearance) and a lacy rash on the trunk and extremities. The rash may involve the palms and soles. Infrequently the body rash may precede the facial one. It may be transient or recurrent over 1–3 weeks. Recrudescence may occur with exercise, warm baths, rubbing of the skin, or emotional upset. There may be great variation in the skin rash appearance. Pruritus may occur in as much as 70% of patients. The rash lasts from 2 to 39 days (mean, 11 days) and resolves without desquamation. Constitutional symptoms such as headache, pharyngeal pain, myalgia, arthralgia, and gastrointestinal disturbances are more frequent and more severe in adults. Less than 10% of children will have arthralgias or joint swelling.

Complications of erythema infectiosum are rare. Arthritis, hemolytic anemia, pneumonitis, and encephalopathy have been reported. No treatment is indicated and isolation is not required. Because the disease is mild and the duration of the rash is prolonged, affected children should be allowed to attend school.

Polyarthropathy Syndrome

The polyarthropathy syndrome in children is usually mild and of short duration. The role of viral infections in the etiology of acute and chronic arthritides of childhood is incompletely understood. There are several viruses that are known to cause acute arthritis, including rubella,

influenza, and B19. Among the many aspects of acute polyarthritis, B19 has been found associated with carpal tunnel syndrome, hepatic dysfunction, and possibly angioedema.

Myocarditis

Parvovirus has been identified as the cause of acute myocarditis and pericarditis in adults and children and may cause cardiac transplant rejection.

Hepatitis

Hepatic dysfunction has been noted in some children with erythema infectiosum. A retrospective investigation by PCR for *Parvovirus* in serum from 773 patients found four children with acute hepatitis of unknown origin who had B19 DNA. These four patients were between 7 months and 5 years old, and other common viral causes of hepatitis were excluded, including hepatitis A, B, or C viruses and Epstein–Barr virus.

Effects on Fetus

Seroprevalence studies have shown that 25–75% of pregnant women are seropositive and that the annual incidence of B19 infection in women of reproductive age is approximately 1.5%. Maternal infection during pregnancy, whether symptomatic or not, is usually followed by a successful outcome with delivery of a normal child. The risk of an adverse outcome in women with serologically confirmed B19 infection is less than 10%, and that in women with unknown immunity who are exposed in the household or in the school is 2.3% and 1.4%, respectively. Infection in the first 20 weeks of pregnancy is associated with the greatest risk of fetal loss, especially between weeks 10 and 20, which coincide with the development of erythroid precursors. The interval between maternal illness and fetal death is usually 3–5 weeks but may be as long as 11 weeks. All pregnancies complicated with nonimmune hydrops should be investigated by fetal blood sampling looking for the evidence of *Parvovirus* infection. Intrauterine transfusion should be reserved for hydropic fetuses with a low hematocrit.

A study of 618 pregnant women exposed to B19 found that 50% were immune to B19 and 259 remained susceptible after exposure, but only 52 (16.7% of all those susceptible) contracted B19 infection. None of the 52 fetuses of infected women developed nonimmune hydrops, and there were no fetal deaths attributable to B19 in this group. The relative risk of maternal B19 infection was 2.8 if the source was a related child living in the household, and the mother's occupation had no significant correlation. Symptoms reported by the women included polyarthralgia (46%), fever (19%), and nonspecific rash (38%) and were significantly more common ($p < 0.001$) in IgM-positive patients than in noninfected women. About one third of the IgM-positive women were entirely asymptomatic. The authors concluded that exclusion of pregnant women from the workplace during endemic periods with seasonal clusters of cases is not justified.

There is some controversy as to whether a child born to a mother with acute *Parvovirus* infection is at risk for developmental delay. A study of over 100 women who became seropositive for parvovirus during pregnancy revealed that there is no apparent increase in the frequency of developmental delays in children with exposure in utero to *Parvovirus*, but the authors stated that larger studies were needed.

The most common abnormality reported in the affected fetuses is hydrops fetalis. B19 infection accounts for up to one fourth of cases of nonimmune hydrops. The pathogenesis of B19-associated fetal damage is probably similar to that leading to aplastic crises in other conditions in which the red cells have a shortened life span. The resultant anemia is thought to cause cardiac failure and hydrops. However, anemia is not profound in all cases, and red blood cell lysis, myocarditis, and liver disease may contribute to the development of hydrops and fetal loss. Hydrops can resolve without treatment and result in the delivery of a normal infant. Intrauterine blood transfusion has been tried with successful outcome. However, this procedure is not without hazards, and the risk–benefit ratio must be calculated carefully before recommending such treatment.

B19 Infection in Patients with an Underlying Hematologic Disorder

The sudden onset of markedly lower red cell numbers in patients with sickle cell anemia and hereditary spherocytosis has been called "aplastic crisis" or transient aplastic crisis. An infectious etiology for aplastic crisis in sickle cell anemia patients had been hypothesized since the early 1980s because of clustering of cases and periodic epidemics. In 1981, two groups published evidence that linked acute parvovirus infection to the onset of aplastic

crisis in patients with sickle cell anemia. Since then, numerous additional chronic hemolytic anemias have been documented to have the same hematologic pathophysiologic findings (Table 117.1). B19 infection can occur, interestingly, without inducing an aplastic crisis even in patients with chronic hemolytic anemias. Recent transfusions could explain some of these cases.

The usual presentation includes a prodrome of fever and constitutional symptoms suggesting a viral illness from 1 to 17 days before the aplasia. Shortly afterward, the patient has extreme pallor and fatigue. More than half report abdominal pain, vomiting, or nausea. Nearly three quarters of the patients have aches and pains or distinct arthralgias. About one quarter of these patients also have faint maculopapular skin rashes. Patients with hepatic or splenic sequestration with the aplastic crisis have also been reported. Although life threatening and occasionally fatal, the aplastic episode is self-limited. Of considerable interest are the reports of aplastic crisis in individuals with previously undiagnosed and unsuspected compensated hereditary or acquired hemolytic anemia. Reticulocytopenia (reticulocyte counts 0–2.2%) and profound anemia with hematocrits as low as 7% are common. Bone marrow aspirates reveal marked erythroid hypoplasia with characteristic inclusions in the giant pronormoblasts. Reticulocytosis occurs from 2 to 14 days after presentation with the aplastic crisis. Most of these patients require red cell transfusions.

Any person with a chronic hemolytic anemia is at risk for aplastic crises because of the rapid turnover of their erythroid progenitors. It is important to note that occasional instances of aplastic crisis have been reported with pneumococcal, other streptococcal, and *Salmonella* infections. B19-associated aplastic crises have been reported in patients with hereditary spherocytosis, pyruvate kinase deficiency, autoimmune hemolytic anemia, thalassemia, and hereditary erythroblastic multinuclearity associated with a positive acidified serum test (Table 117.1).

Transient Erythroblastopenia of Childhood

Transient erythroblastopenia of childhood is a temporary failure of erythropoiesis in previously hematologically normal children. In the few cases that have been described with B19 infection, anemia was associated with thrombocytopenia, whereas in the classic transient erythroblastopenia of childhood the platelet count is high, suggesting that the two conditions are different. This entity does not appear to be caused by B19 infection.

B19 and Idiopathic Thrombocytopenic Purpura

Thrombocytopenia associated with B19 infection may occur before or after the rash appears in a patient with erythema infectiosum. In vitro studies have shown that B19 can suppress megakaryocyte formation and that B19 RNA may be found in the megakaryocytes. Typical immune thrombocytopenia (ITP) has been reported shortly after the onset of erythema infectiosum.

A longitudinal study to determine a possible role of B19 in ITP patients seen at one center over a 12-month period was reported. B19 DNA was detected by PCR in 17/35 ITP patients (49%). Of these, six had anti-B19 IgM titers and eight were seropositive for anti-B19 IgG. It was hypothesized that a chronic B19 infection would permit PCR detection of B19 DNA long after the acute viral infection, thus providing the association of IgG titers but no IgM anti-B19 antibodies. There has been some speculation that ITP patients have altered immune systems, but there are conflicting data on lymphocyte function and subsets. *Parvovirus* infection is known to induce anti-DNA and anti-lymphocyte antibodies in some individuals.

Neutropenia Secondary to Parvovirus Infection

Infection of normal individuals with B19 is accompanied by mild neutropenia 10–14 days after an intranasal injection; this is the time of fever, maximum viremia, and the IgM response to the viral infection. The neutropenia lasts for approximately a week. There have been several reports dealing with the effects of B19 infection and anemia, but also accompanied by lower numbers of myeloid precursors or mature neutrophils. Typically the neutropenia would only last a few days. One study found IgG antibodies to red cells, neutrophils, or platelets in four children with B19 infection. The neutropenia resolved within 10 days in all of these children, who were subsequently proven to have acute *Parvovirus* infection by elevated IgM titers. Interestingly, the anti-B19 IgM was detected after the neutropenia resolved in one patient.

Parvovirus has also been linked to autoimmune neutropenia in children. Typically the neutropenia lasts a median of 19 months (range: 6–64 months), with spontaneous recovery. IgM antibody to B19 has been found in a series of five patients with autoimmune neutropenia and accompanying anti-neutrophil NA-1 antibody. These authors failed to find the viral DNA by PCR analysis.

A larger study of children with chronic autoimmune neutropenia showed evidence of B19 DNA by PCR in the bone marrow of 15/19 children tested. Four of six sera specimens taken at the time of the bone marrow sample had IgG antibody to B19. None had IgM titers, although the immune response to B19 is often defective or delayed in chronic B19 infection. Since no control patients had evidence of B19 in their bone marrow, it is unlikely that contamination of the DNA specimens could be blamed for the 15/19 positives in the neutropenic patients.

B19 Infection in Patients with Congenital or Acquired Immunodeficiency States

In patients with either congenital or acquired immunodeficiency, B19 infection may become chronic, resulting in persistent viremia and chronic bone marrow failure. The clinical illness in such patients is usually characterized by acute anemia that is persistent, with or without neutropenia or thrombocytopenia; chronic viremia; and, on bone marrow examination, erythroid hypoplasia with giant vacuolated proerythroblasts similar to those described in acute B19 infection. Spontaneous recovery has been reported. Temporary cessation of immunosuppressive agents usually results in clearance of viremia and resolution of hematologic manifestations. Prompt decrease in viremia, increase in reticulocyte count, and increase in hemoglobin usually follow intravenous immunoglobulin (IVIG) administration. Long-term remissions have been documented, but repeated administrations are frequently necessary to sustain or reinduce remissions. Chronic B19 infection has been reported to occur in patients with a variety of underlying immunodeficiency states (*Table 117.2*).

Effective therapy of B19-induced pure red cell aplasia in immunocompromised patients consists of infusion of commercially available immunoglobulin preparations. These are good sources of neutralizing antibodies because most adult populations have been exposed to the virus. Patients with acquired immunodeficiency syndrome respond to a 5–10-day course of IVIG, but relapses are common. A second course or maintenance IVIG infusions may be required. In patients who are undergoing therapy with immunosuppressant drugs, temporary cessation of therapy may result in clearance of viremia and recovery of cytopenia. Measurement of serum virus can be helpful in determining optimal therapy and predicting relapse.

Table 117.2
Immunodeficiency disorders that have been associated with chronic Parvovirus B 19 infection

Congenital immunodeficiency

Renal transplantation
Liver transplantation
Cardiac transplantation
Bone marrow transplant recipients
Collagen-vascular diseases
Systemic lupus erythematosus
Rheumatoid arthritis

Vaccine Development

Effective vaccines have been developed for animals, and the prospects for a human Parvovirus B 19 vaccine are good. The availability of a genetically engineered expression system capable of producing unlimited quantities of B19 viral capsid antigens has made it possible to consider vaccine development. Viable candidates for B19 vaccines are now available, and vaccines should be in human trials soon.

118 Poliomyelitis

Mohammad Al-Shaalan

Poliomyelitis is a paralytic viral illness that is getting less in incidence with the implementation of the effective vaccine. Poliovirus belongs to enterovirus group and has three serotypes 1, 2, and 3. Most of the wild poliovirus infections are caused by serotype 1, whereas infections acquired from vaccine are caused by serotypes 2 and 3.

Epidemiology

After the introduction of the vaccine in 1950s, the incidence of poliomyelitis has decreased dramatically. America has been declared free of wild poliomyelitis in 1995. In addition, the disease is completely controlled in Western Europe and most of the countries in Asia and some countries of Africa. In 1995, 6,000 cases of poliomyelitis worldwide has been reported; 205 cases from Europe; 3,398 cases from southeast Asia, mostly from India; 738 cases from Eastern Mediterranean; and 344 cases from far east region. The main remaining endemic areas for poliomyelitis are the Indian subcontinent and some parts of USSR. This remaining endemicity is attributed to lack of proper vaccination and not to the failure of the vaccine.

Pathogenesis

The infection is acquired by oral route. The virus then multiplies in the pharyngeal and intestinal lymph nodes. From there the virus spreads via blood into the terminal nerves, where it travels along the axons into the neuronal cells mainly in the anterior horn; however, neurons in the intermediate gray matter and dorsal ganglion may be involved. Neurons in the brain stem and cranial nerves nuclei are also susceptible and may be involved. The cortex is spared with the exception of the immediate precentral area of the motor cortex.

The virus multiply in these areas and result in cellular destruction and degeneration with resultant neuropathy and musculopathy. Because of the edema involved with initial infection, an apparent more diffuse involvement of neurons occurs, but after the acute infection, the edema resolves and recovery of some involved neurons occurs. Most of the time only parts of neurons are involved and compensation by other surviving neurons occurs, and paralysis may resolve if the neuron destruction is not extensive.

Clinical Features

Asymptomatic Infections

Ninety percent to 93% of poliovirus infections are asymptomatic.

Abortive Poliomyelitis (Minor Illness)

In 2–5% of the cases, the infection is manifested by mild illness of low-grade fever, headache, myalgia, vomiting, and diarrhea. The disease is self-limiting and does not result in any sequelae.

Aseptic Meningitis

In 2–3% of the cases and after few days from subsiding symptoms of minor illness, symptoms of meningitis may develop with manifestation of headache, neck pain, and low-grade fever. CSF reveals elevated protein, normal sugar, and mild pleocytosis, usually of 10–200 cells/mL, which is initially neutrophilic and then shifts to be lymphocytic in 1 or 2 days. The disease lasts for 2–8 days and then resolves spontaneously.

Paralytic Poliomyelitis

One percent of symptomatic infections (i.e., 1/1,000 of poliomyelitis infections) results in flaccid (lower motor

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_118,

neuron) paralysis. The paralysis involves different muscle groups, and usually it is patchy in distribution. In addition to skeletal muscles, cranial nerves involvement may occur with resultant bulbar palsy.

Diagnosis

The mainstay of diagnosis is the isolation of poliovirus from throat, stool, urine or, rarely, CSF. The virus can be recovered shortly before symptoms and up to 2 weeks after the infection. In stool, the virus can be isolated up to 2 months after infection. Immunocompromised patients secrete the virus for a longer period of time. Serology tests, acute and convalescent are helpful. Recently, PCR is being developed, and it will help to differentiate between wild virus infection and infection acquired by vaccination.

Treatment

Treatment is supportive to decrease pain and fear by using analgesics. In those who develop respiratory failure, artificial ventilation may be needed. Swallowing may be impaired, and thus nutritional support by nasogastric tube feeds or total parenteral nutrition may be needed. Once the acute stage is passed and fever is resolved, the passive and active muscle movement should be initiated to prevent contracture and deformities.

Late Complications of Poliomyelitis

Late Post-Polio Syndrome

Some patients who had poliomyelitis may present 10–40 years later with new onset of weakness, decreased daily activities, and/or muscle atrophy. This is defined as progressive postpolio muscular atrophy. Other manifestations of post-polio syndrome include muscle pain, musculoskeletal deformities, fatigue, and cramps. This syndrome is usually associated with electrophysiological evidence of acute denervation superimposed on chronic denervation–inervation process. The progress of muscle deterioration in post-polio syndrome is usually slow and, in some cases, it may not be appreciated on year to year basis.

Orthopedic Deformities

Due to muscle weakness, bone deformities may arise due to malpositioning. This may result in scoliosis and cervical radiculopathy.

Neurological Abnormalities

Nerve entrapment may occur in polio patients and result in exacerbation of muscle atrophy and weakness.

Respiratory Complications

Scoliosis and muscle atrophy may result in restrictive lung disease which in turn results in respiratory insufficiency and core pulmonale.

Prevention

Enteric precaution is advised for all contacts of the patients with poliomyelitis. Immunocompromised patients and their contacts should not receive live attenuated vaccine. For vaccination recommendation, see section on immunization.

119 Respiratory Syncytial Virus

Suliman Al Jumaah

Respiratory syncytial virus (RSV) is the major respiratory pathogen in infants and young children. It is the most common cause of hospitalization for respiratory illness among children. Young age, chronic heart or lung disease, and immunosuppression are risk factors for sever RSV infection.

Etiology

RSV is an enveloped RNA virus that belongs to the Paramyxoviridae family. The RSV genome encodes for ten viral proteins. The F and G proteins are envelope-associated proteins, which were studied extensively as a vaccine candidate. F glycoprotein mediates fusion of the virus with the host cell. G protein is the attachment protein that mediates attachment of the virus to host cells. It is the most variable protein among RSV strains, while F glycoprotein is highly conserved among major RSV strains. RSV isolates fall into two groups, A and B. The major antigenic differences between group A and group B RSV are largely due to variability within G glycoproteins, with only 53% homology in amino acids between the two strains. In RSV season, both groups circulate concurrently. However, group A usually predominates, comprising 70–80% of isolates.

Epidemiology

RSV is the most important cause of lower respiratory tract infection (LRI) (bronchiolitis and pneumonia) in infants and young children, accounting for 60–90% of cases of bronchiolitis and 5–40% of cases pneumonia. In the United States, RSV isolation strongly correlates with LRI-associated deaths in children 1–11 months of age, with the strongest association among those less than 5 months. The virus infects one half of children by 1 year of age, and virtually all children are infected by 2 years of age. Reinfection with RSV is common, but the disease tends to be mild with repeated infection. One percent to 2% of RSV-infected children are admitted to the hospital. In the United States, RSV infection is responsible for 40–50% of the hospitalizations for bronchiolitis and 25% of pediatric hospitalization for pneumonia, of a total of 91,000 admissions annually at a cost of about $300 million. RSV infection occurs yearly as an outbreak between late fall and early spring. In addition to mortality and morbidity in the acute phase, RSV infection may be associated with abnormalities in pulmonary function testing in late childhood as well as development of asthma and chronic lung disease. However, causality has not been proven.

Certain factors are associated with an increased risk of repeated RSV illness. These include a family history of atopy, presence of older siblings, and exposure to passive smoking. Age is associated with increase severity and frequency of infection, with severe RSV disease occurring most commonly in early infancy. RSV LRI in patients with underlying cardiac and lung disease causes significant morbidity, with early estimates of mortality of up to 30%. More recent studies have shown that the mortality is one tenth of these earlier estimates. This may reflect the overall improvement in management of the underlying illness of such patients, resulting in a better clinical condition prior to RSV infection.

Morbidity due to RSV, in the form of prolonged of complicated hospitalization, remains high among patients with underlying cardiac or pulmonary disease. In retrospective and prospective studies examining the outcome of RSV infection in high-risk patients, the Pediatric Investigators Collaborative Network on Infections in Canada (PICNIC) group observed that patients with underlying illness had significantly prolonged hospitalization, ventilatory support, and oxygenation days as compared to other risk groups, including premature infants and infants less than 6 weeks old at the time of RSV infection.

Pathogenesis

The incubation period ranges from 2 to 8 days. The virus is usually inoculated through the upper airway passages, although the infection may extend to the lower respiratory tract. The pathology affects primarily the small airways, where the airways are infiltrated with lymphocyte and

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_119,

plasma cells, with syncytia formation. Subsequently, there will be sloughing and necrosis of the epithelium, resulting in airway obstruction evidenced by expiratory wheezing in bronchiolitis. There will be hyperinfiltration due to air trapping. These changes are due to direct viral invasion; however, an immune-mediated process may contribute to the pathogenesis of the disease.

Clinical Manifestations

RSV infection has a wide spectrum of clinical manifestations. These include bronchiolitis, pneumonia, tracheobronchitis, and upper respiratory tract infection. Young infants may present with a sepsis-like picture or apnea. The most important clinical presentation is bronchiolitis, which usually affects infants less than 1 year of age, with peak incidence at 6 months of age. Illness starts usually with upper respiratory tract infection with nasal discharge and pharyngitis that may be associated with fever. Cough may be present. After several days, infection may progress to involve the lower respiratory tract, with development of respiratory distress, wheezing, irritability, and feeding difficulty. Primary infection in young infants is more likely to involve the lower respiratory tract. In most cases the infection is mild and resolves in 1–3 days; however, on occasion, the infection can be quite severe.

The typical chest x-ray, showing hyperexpansion, is evident in 50% of cases. Peribronchial thickening and interstitial pneumonia are seen in 50–80% of cases. Consolidation is seen in 20–25% of cases. Among high-risk hospitalized infants, the mortality is about 1% from recent studies. Complicated RSV infection is most likely to occur in patients with underlying congenital heart disease, chronic lung disease of prematurity (CLD) or cystic fibrosis, and young and premature infants and post stem cell transplant patients. These patients are more likely to have prolonged hospitalization and require intensive care. Children with congenital immunodeficiency are at risk of severe RSV infection and prolonged viral shedding.

RSV infection may cause acute otitis media. Treatment failure and persistent middle ear effusion are high in the presence of coinfection of RSV and bacterial pathogens.

Diagnosis

Diagnosis of RSV LRI is usually made on the basis of clinical and epidemiologic findings. Confirmation of infection may be made by isolation of the virus on the proper cell culture line from secretions obtained by nasopharyngeal aspirate or nasal swab. The characteristic cytopathic effect is usually evident by 2–10 days. Rapid diagnostic tests such as direct fluorescent antibody staining and enzyme immunoassay are widely used because the results can be available within several hours. The sensitivity of these tests varies from 53% to 96%, mostly in the range of 80–90%, and the specificity approaches 100%.

Treatment and Prevention

Ribavirin is the only specific antiviral agent available for treatment of RSV infection. It is a synthetic guanosine analogue with broad-spectrum antiviral activity. The antiviral properties of rivabirin were first demonstrated in vitro and subsequently confirmed in the cotton rat model. Several controlled trials of aerosolized ribavirin in infants hospitalized with RSV LRI were carried out. Some of these studies were done in previously healthy infants and others included infants with underlying illnesses. Ribavirin improved respiratory score and oxygenation but was not shown to decrease hospital stay. Meta-analysis of all controlled trials showed that ribavirin therapy did not decrease mortality or respiratory deterioration. In ventilated infants, ribavirin therapy reduced days of ventilation; however, this reduction was sensitive to the exclusion of one study.

Ribavirin was approved by the US Food and Drug Administration in 1986. The aerosol route of administration and potential toxic side effects on health care provider in addition to modest clinical efficacy led to decrease in the use of ribavirin. The Committee on Infectious Diseases of the American Academy of Pediatrics stated that ribavirin is not recommended for routine use but may be considered for use in select patients with documented potentially life threatening RSV infection. Randomized clinical trials of bronchodilators have yielded conflicting results. Some studies comparing bronchodilators are beneficial, while others have shown no benefit. Corticosteroids failed to show a beneficial effect. Supportive treatment in the form of adequate oxygenation and hydration is the most important line of management of severe RSV infection.

Prophylaxis and treatment of RSV infection with pooled human immune globulin in laboratory animals was well tolerated and reduced viral shedding was not associated with duration of hospitalization. Monthly prophylaxis with standard intravenous immunoglobulin does not achieve an adequate titer of RSV-neutralizing antibodies (RSV-IGIV) for protection. More recently, randomized controlled trials have shown that monthly

prophylaxis with high-titer RSV immunoglobulin may prevent LRI in infants and young children with underlying cardiac or pulmonary disease and in premature infants. RSV-IGIV is no longer available.

The only available passive prophylaxis for RSV is Palivizumab, which is a humanized monoclonal immunoglobulin G-1 directed against an epitope on the F glycoprotein of RSV and is produced by recombinant DNA technology and approved for use since 2002. Palivizumab consists of 95% human and 5% murine amino acid sequences. Palivizumab is not derived from human immune globulin. It is highly active in vitro against type A and type B RSV isolates, where it was 50–100 times more potent than similar concentrations of RSV-IGIV. Two randomized controlled clinical trials have demonstrated that palivizumab results in significant reductions in the incidence of RSV hospitalizations in premature infants and infants with hemodynamically significant heart disease.

Palivizumab is administered monthly during RSV season. The period of exposure has been assumed to be 5 months during the winter season beginning in November or December, with the last dose given in March or April; however, this depends on local epidemiology of RSV.

RSV prophylaxis is recommended for children younger than 24 months of age with CLD of a prematurity who require on-going therapy within 6 months receiving the RSV season. It is recommended for children younger than 24 months with hemodynamically significant cyanotic and acyanotic heart disease and also for infants born at or before 32 weeks of gestation who are 6 months of age at the start of RSV season. Infants born between 32 and 35 weeks of gestation may be given prophylaxis if there are other risk factors.

Immunization

Currently, there is no effective vaccine against RSV. Children who received inactivated RSV vaccine in 1969 remained susceptible to infection and developed more severe disease after acquiring RSV infections than controls. The mechanism of this susceptibility remains unknown. Successful RSV vaccine has to be immunogenic in young infants, where the risk is maximal, and must not be hampered by passively transferred maternal antibodies. Live attenuated and subunit (utilizing F glycoprotein) vaccines are being developed to prevent RSV infection. Purified fusion protein vaccines (PFP1 and PFP2) are under investigation. These vaccines were shown to be safe and immunogenic in RSV-seropositive children. Enhanced pulmonary pathology was not noticed. Subunit vaccine induces systemic but not local immunity, and children who received the vaccine were not protected against RSV infection. Studies in cystic fibrosis patients showed that the vaccine was not protective against RSV infection; however, the number of LRIs was significantly reduced. Despite many attempts to generate RSV vaccine, using various technologies, no vaccine has been licensed for human use.

Rotavirus

Introduction

Rotavirus is the most common cause of severe diarrhea in infants and children of developed and developing countries worldwide. Globally, rotavirus gastroenteritis causes the death of more than half a million children younger than 5 years of age. This illness creates a disease burden to virtually all societies around the world.

Etiology

Rotaviruses are included in genus *Rotavirus*, part of the *Reoviridae* family. Negative contrast electron microscopy reveals the viral particles take on a wheel-like appearance in feces, leading to the prefix "rota."

Rotavirus particles are large in size (1,000 Å), nonenveloped, and have three concentric layers of proteins surrounding a viral genome. The genome is comprised of 11 segments of double-stranded RNA, a characteristic that allows reassortment during natural infection to yield new strains. These segments encode six structural viral proteins (VPs) that form virus particles and six nonstructural proteins (NSPs). The NSPs are synthesized in infected cells and interact with host proteins to influence pathogenesis and the immune response to infection.

The rotavirus outer capsid shell is made of the protein VP7. Spike-like projections protrude through the capsid shell and are formed by the glycoprotein VP4. The three-layered capsid renders it stable and resistant to the acidic pH in the stomach and to the digestive enzymes in the small intestine. This eases the fecal-oral transmission and delivery of the virus into the small intestine, where rotavirus causes pathological changes in structure and function.

Rotaviruses can be classified into Groups A-E, according to antigenic groups on the major capsid antigen, VP6. Only groups A, B, and C have been shown to infect humans, with group A causing the preponderance of human rotaviral gastrointestinal disease.

Rotaviruses are further classified into G and P types based on the identification of antigens on the outer capsid proteins VP7 and VP4. Most severe infections in young children are caused by serotypes G1-4. In general, the more densely populated countries show the most complex patterns of serotype prevalence. During the last two decades, G1 infections appear to have predominated globally.

Epidemiology

Worldwide, approximately 40% of hospitalizations for diarrhea in children younger than 5 years of age are attributable to rotavirus infection. The virus is identified in the stool in 10–40% of children admitted for acute diarrhea in developing countries and 35–50% in developed countries. Over 525,000 children younger than 5 years of age die annually from rotavirus, with more than 85% of these deaths occurring in African and Asian nations. In the United States, prior to the vaccine's introduction, rotavirus infection accounted for 400,000 doctor visits, 200,000 emergency room visits, 50,000 hospitalizations, and 20–60 deaths per year, with costs amounting to $1 billion yearly. See *Fig. 120.1*: Rotavirus disease burden.

Virtually all children have been infected with rotavirus by the age of 5, with various degrees of severity. It is common to have progressively less severe subsequent rotavirus infections as each causes a boost in mucosal immunity. Serious rotavirus infections occur most often in children 4–24 months of age. Neonatal infection is often asymptomatic in healthy, full-term infants, presumably due to passive immunity from transplacental and breast-milk antibodies. Adults are rarely severely affected, but roughly 20% of adult household contacts of an infected infant may develop symptomatic disease.

Rotavirus gastroenteritis has a seasonal variation pattern. In the United States and other countries with a temperate climate, infections predominate during the winter months, with annual epidemics occurring between December and June. Regional variations also exist within particular climates or countries. For example, the United States rotavirus season starts in the southwest in the fall and ends in the northeast

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_120,

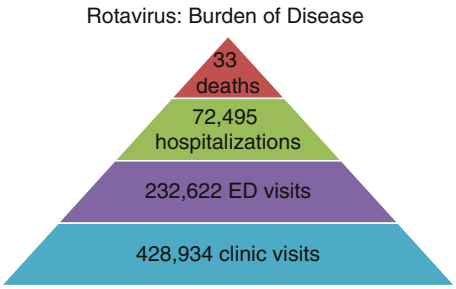

Figure 120.1
Annual rotavirus disease burden in the United States prior to vaccine introduction

in the spring. In Europe, the season begins in the southern region and spreads north over the fall to spring months. Rotavirus infections fluctuate less in the tropics, though a recent systematic review of 26 studies from tropical areas concluded that infections were more prominent in the coolest and driest months of the year.

Rotavirus is primarily transmitted person-to-person via the fecal-oral route. In developing regions, it may also be spread via fecally contaminated water. Infected individuals usually shed large quantities of virus, up to 10^10 particles per gram of stool. As few as ten viral particles may cause infection in rotavirus-naïve patients. Viral shedding may occur up to 2 days prior to the initiation of symptoms and continues for an average of 4 days, though shedding has been reported for up to 21 days in immunocompetent patients. Immunocompromised patients may excrete the virus for even longer periods.

The virus may survive at least 4 h on hands, days to weeks on environmental surfaces, and up to weeks in drinking water. Transmission is increased in settings such as child day-care centers and family homes, where diaper changing has been identified to be the highest-risk activity. Additionally, rotavirus has been found on toys, faucets, hand-washing areas, and even food preparation areas, indicating that fomites may play a role in viral transmission. The high infectivity, presymptomatic shedding, and prolonged environmental life span are all important factors in the transmission of rotavirus.

The transmission from animals to humans is rare. There is evidence, however, that animal rotaviruses can infect humans via direct transmission of the virus or by contributing one or more RNA segments to reassortants with human strains.

The respiratory spread of rotavirus via aerosolized particles has also been suggested. Rotavirus has been detected in respiratory secretions in a small number of patients, and cases of pneumonia have been described. Rotavirus RNA from air samples taken from rooms of hospitalized children with rotavirus gastroenteritis indicate that airborne spread may be a route of transmission of rotavirus, especially in hospital and day-care settings.

Rotavirus has its most profound effects in the gastrointestinal tract, yet systemic infection has been reported. RNA and proteins of rotavirus have frequently been detected in the blood of infected children, as well as the liver, heart, lung, and central nervous system.

Pathogenesis

Rotavirus particles are ingested orally. In the small intestine, the VP4 spikes on the capsid surface may be proteolyzed by the enzyme trypsin. This cleavage causes a conformational change in the spike structure, which then exposes other attachment sites on the surface glycoprotein. The virus is then attached to host receptors on enterocytes, and the entry process begins. The outer capsid shell is removed, and double-layered particles are inserted into the cytoplasm. These particles produce capped viral messenger RNAs (mRNAs) that are then displaced from the transcribing particles into the cell cytoplasm. There, they are then translated into proteins and replicated to new genomic RNA. This viral replication process is unique and occurs in viroplasms, electron-dense structures near the cell nucleus, and endoplasmic reticulum. Newly assembled particles with newly replicated dsRNA bud into the endoplasmic reticulum from the viroplasm and are equipped with outer capsid proteins. Fully developed virus particles are released from enterocytes via cell lysis or delivery of particles to the apical plasma membrane of cells.

Rotavirus primarily invades mature enterocyte villi, sparing the intestinal crypts. With enterocyte destruction, fluid moves into the intestinal lumen, resulting in a net loss of fluid and electrolytes in stool. Malabsorption occurs secondary to the loss of absorptive enterocytes, the decreased synthesis of lactase and other digestive enzymes, and the alteration of tight junctions between enterocytes that leads to paracellular leakage.

The rotavirus toxin, NSP4, is a nonstructural glycoprotein that may contribute to the pathophysiology by inducing a secretory component to the diarrhea. This viral enterotoxin is reported to increase intracellular calcium and activate cellular chloride channels, in turn increasing the secretion of chloride and consequently water into the lumen. NSP4 has also been found to activate the secretory reflexes of the enteric nervous system (ENS), further contributing to diarrhea.

Microischemia of villi, impaired polar transport of sucrase-isomaltase to the membrane surface, neuronally mediated intestinal hypersecretion, and altered intestinal motility are other possible mechanisms of rotavirus injury.

Pathology

Histologically, rotavirus is associated with a wide spectrum of changes, ranging from virtually normal mucosa or mild enterocyte vacuolization and loss to more significant villous blunting and crypt hyperplasia. The degree of inflammation is usually milder than that caused by other intestinal pathogens. There appears to be no direct correlation between histological findings and disease symptoms.

Clinical Manifestations

After a 2–7 day incubation period, symptoms often start abruptly with vomiting, followed by watery diarrhea. This is a noninflammatory process, with blood and white cells typically absent from the stool. In about one-third of patients, fever of over 38.9°C is reported. Other clinical features of acute rotaviral infection include anorexia and lethargy, with abdominal cramping being less common. The diarrhea can range from mild to severe, with resultant dehydration, shock, electrolyte imbalance, and even death. Severe, dehydrating rotavirus infection occurs mostly in children age 3–35 months. Rotavirus is generally a self-limited virus, with vomiting settling within 24–48 h and diarrhea in 2–7 days. Some studies have noted respiratory symptoms and otitis media in up to half of patients with rotavirus infection.

Intussusception in rotavirus infection may be caused by a disturbance in the motility of the gastrointestinal tract during an acute infection, as opposed to a typical lead point. Lipopolysaccharides may slow intestinal motility through the induction of various inflammatory agents, such as prostaglandins, cytokines, and nitric oxide.

Diagnosis

The Center for Disease Control and Prevention (CDC) defines a confirmed case of rotavirus gastroenteritis as diarrhea (3 or more loose stools within 24 h) or vomiting (1 or more episodes in a 24 h period) in a child with a positive stool detection of rotavirus by a standard assay, such as an enzyme immunoassay (EIA).

Confirmation of rotavirus infection is necessary for reliable surveillance and can be clinically useful to avoid inappropriate antimicrobial use. The most widely used method to detect rotavirus antigen in stool is EIA. These assays typically detect the rotavirus group antigen present on VP6. Many EIA kits are commercially available, providing rapid, inexpensive results with 90–100% sensitivity. Strains may be further characterized by additional enzyme immunoassay or reverse transcriptase polymerase chain reaction (RT-PCR).

Research centers use other techniques for detection and surveillance of rotavirus, including electron microscopy, RT-PCR, nucleic acid hybridization, sequence analysis, and culture. These techniques are more labor intensive and provide little additional clinical utility.

Differential Diagnosis

The non-bloody, watery diarrhea of rotavirus gastroenteritis is clinically indistinguishable from that caused by other enteric viruses, including norovirus and other caliciviruses, enteric adenovirus, and astrovirus. That said, rotavirus associated acute diarrhea may be more severe and more frequently associated with fever and vomiting. The presence of blood or leukocytes in the stool should suggest alternative diagnoses, including bacterial etiologies such as *Salmonella*, *Shigella*, *Yersinia*, *Campylobacter*, and *Escherichia coli*. Noninfectious etiologies, including intussusception, must also be considered in the infant with this presentation. Protozoal infection, particularly *Entamoeba histolytica*, *Giardia lamblia*, and *Cryptosporidium parvum*, should also be included in the differential diagnosis.

Prognosis

As mentioned, rotavirus infection is most frequently self-limited, with cessation of vomiting within 2 days and diarrhea within 7 days. Severe, dehydrating infection occurs more often in young children from age 3–35 months. Malnutrition is known to increase the severity of infection, with delayed small intestinal recovery and altered inflammatory responses.

Acute complications include dehydration, sodium imbalance, and possible seizures. Reye syndrome, encephalitis, rectal bleeding, and intussusception have all been associated with rotavirus, but evidence showing a causative effect is lacking.

Treatment

Rotavirus gastroenteritis is generally a self-limited illness, and treatment is largely supportive. Initial management should focus on the identification and correction of any underlying fluid and electrolyte imbalance. The assessment of dehydration and the use of oral rehydration therapy are critical and are reviewed elsewhere in this text (Chap. 187, "Acute Gastroenteritis in Infants and Children"). Undernourished children are particularly at risk of severe and/or persistent symptoms, and great care must be taken to encourage early resumption of normal feeding, typically including breastfeeding. There is no role for antibiotics in the treatment of rotavirus gastroenteritis. The use of antiemetics and antidiarrheals is generally avoided. Please see Chap. 187, "Acute Gastroenteritis in Infants and Children" for further details.

The oral administration of a probiotic, Lactobacillus GG, is effective in both reducing viral shedding and shortening symptom duration by roughly 1 day. This improvement is most notable when the probiotic is given early in the course of the illness and seems most prominent in young children. The mechanism may be due to an enhancement of the immune response against the virus.

Orally administered Human Immune Globulin, as an investigational therapy in immunocompromised patients, was found to shorten the course of diarrhea and decrease viral excretion. Further investigation is required, and the cost-benefit ratio may not justify usage of this therapy on a wide-scale basis.

Prevention

Rotavirus attack rates are similar between developed and developing regions, suggesting that improved sanitation is unlikely to play a significant part in disease prevention. The high infectivity of the virus makes control measures difficult.

Rotaviruses are relatively resistant to chemical disinfectants used widely in hospitals. Effective agents include chlorhexidine gluconate and quaternary ammonium compounds with high alcohol content (70%). Hand washing with plain soap is often ineffective against rotavirus and may even spread the virus over a larger area of the hands. The use of a waterless, alcohol-based hand-cleaning agent before and after patient contact is recommended.

Breastfeeding plays a protective role against acquiring rotavirus. This may be due to the presence of anti-rotaviral secretory IgA and trypsin inhibitors in breast milk. Breast-fed infants also excrete fewer viruses than formula-fed infants.

Based upon the significant morbidity and mortality of childhood rotaviral infection worldwide, great attention has been focused upon the development of a successful vaccine. Since 1983, multiple candidate vaccines have been tried. Initially, vaccines based upon the use of animal rotavirus strains that are not pathogenic in humans failed to provide sufficient clinical protection. Rotashield (Wyeth-Lederle Vaccines, Philadelphia, PA), a tetravalent simian/human reassortant rotavirus vaccine, was licensed by the FDA in 1998, based upon data showing an 80–100% protection against dehydrating rotavirus diarrhea. Within 9 months of its release, the CDC's Vaccine Adverse Event Reporting System (VAERS) reported 15 cases of intussusception in infants who had received the vaccine. Subsequent case control and retrospective cohort studies verified a temporal association. The relative risk for intussusception within 2 weeks following the first vaccine dose exceeded 20 in both studies, prompting the vaccine's withdrawal from the market.

Two subsequent oral rotavirus vaccines are now licensed in many nations around the world, including the United States. These vaccines have led to the decline of rotaviral infection and mortality worldwide. Rotarix™ (GlaxoSmithKline Biologicals, Rixensart, Belgium, 2006) is based on a live attenuated human rotavirus strain, G1P. RotaTeq™ (Merck & Co., Inc., Whitehouse Station, NJ, USA, 2008) is a pentavalent human–bovine reassortant, with a low rate of replication in the human gastrointestinal tract and a low rate of fecal shedding. Large phase III clinical trials have demonstrated that both Rotarix™ and RotaTeq™ are well tolerated. They have also been demonstrated to be immunogenic and highly efficacious, preventing 74–87% of all cases of rotavirus gastroenteritis and greater than 85% of those associated with severe diarrhea. In Africa and Asia, where more than 85% of rotavirus associated deaths occur, RotaTeq™ vaccination reduced cases of severe rotavirus diarrhea by greater than 50% during the first year of life when the disease burden and mortality is greatest. The World Health Organization's Strategic Advisory Group of Experts declared that rotavirus vaccines should be included in national immunization programs worldwide, particularly in nations with high diarrheal fatalities. Diarrhea-associated deaths in these developing countries could be reduced by 25%.

The RotaTeq™ vaccine is recommended to be given as a three-dose series to infants between the ages of 6–32 weeks. The Rotarix™ vaccine is recommended to be administered as a two-dose series at the ages of 2–4 months. Details of the vaccine schedules are provided in

Table 120.1

Rotavirus vaccine schedule per the Advisory Committee on Immunization Practices (ACIP) recommendations, 2009

	2 Months	4 Months	6 Months
Rotarix® (RV1)	Rotarix® #1	Rotarix® #2	NA
	*Minimum age 6 weeks, maximum age 14 weeks 6 days	*Minimum 4 weeks between doses;	
		Not to be given after 8 months of age	
RotaTeq® (RV5)	RotaTeq® #1	RotaTeq® #2	RotaTeq® #3
	*Minimum age 6 weeks, maximum age 14 weeks 6 days	*Minimum 4 weeks between doses #1 and #2	*Minimum 4 weeks between doses #2 and #3;
			Not to be given after 8 months of age

Table 120.1. Contraindications to the rotavirus vaccine include a previous severe life-threatening allergic reaction to any components of the vaccine and some immunocompromised states.

Data from the CDC's VAERS has shown that the observed rate of intussusception in RotaTeq™-vaccinated children is not higher than the age-adjusted background rate of intussusception. Similarly, studies show no increased risk of Kawasaki syndrome with the administration of RotaTeq™ vaccine.

Since the introduction of these vaccines in 2006, the incidence of rotavirus diarrhea in infants has dramatically decreased. One study noted that from 1986 to 2006, nearly 20% of hospitalized gastroenteritis patients younger than 5 years of age tested positive for rotavirus in the stool. In the three seasons after vaccine introduction (2007–2009), the percentage dropped to 12.4%, 9.6%, and 6.4%, resulting in a decline of 66% by the study's termination. Furthermore, the rotavirus season has been found to be shortened and delayed. See *Fig. 120.2*: Hospitalizations in children due to laboratory-confirmed rotavirus gastroenteritis.

Newer approaches, such as non-replicating virus-like particle (VLP) vaccines, are presently being evaluated. Meanwhile, the current rotavirus vaccines remain a success in decreasing the morbidity and mortality from this global health disease.

Noro-Caliciviruses

Etiology

Norwalk virus carries historical import as the first confirmed viral etiology for human gastroenteritis when it was identified by electron microscopy in stools from a severe outbreak of diarrhea in Norwalk, Ohio in 1972. Subsequently, similar appearing viruses were often called "Norwalk-like viruses." Recent reclassifications now define the family as *Caliciviridae*, which are 20–40 nm, non-enveloped, single-stranded RNA viruses. Within this family are four distinct genera. The *Norovirus* genus accounts for roughly 95% of Calicivirus-associated gastroenteritis and is discussed here in greater detail. The other three genera (Sapovirus, Lagovirus, and Vesivirus) are less clinically relevant.

Human norovirus strains are classified into several distinct genogroups and subgroups. Genogroup II has been identified as the most common strain infecting humans worldwide. A new pandemic strain emerges every 2 –4 years.

Epidemiology

Noroviruses are the most common cause of nonbacterial gastroenteritis outbreaks worldwide. Infections may occur year round, though more cases are reported during winter months. Both children and adults can be affected. The Center for Disease Control (CDC) estimates that noroviruses cause 21 million cases of gastrointestinal illness annually in the United States, accounting for half of all foodborne disease outbreaks. Norovirus infection leads to an estimated 70,000 hospitalizations and 500 deaths annually in the United States. There, only rotavirus leads to more hospitalizations for gastroenteritis in children. In developing countries, norovirus is also a common etiology for diarrhea. In India and Peru, 15% and 31%, respectively, of stool samples in hospitalized pediatric gastroenteritis patients tested positive for norovirus via PCR (*Table 120.2*).

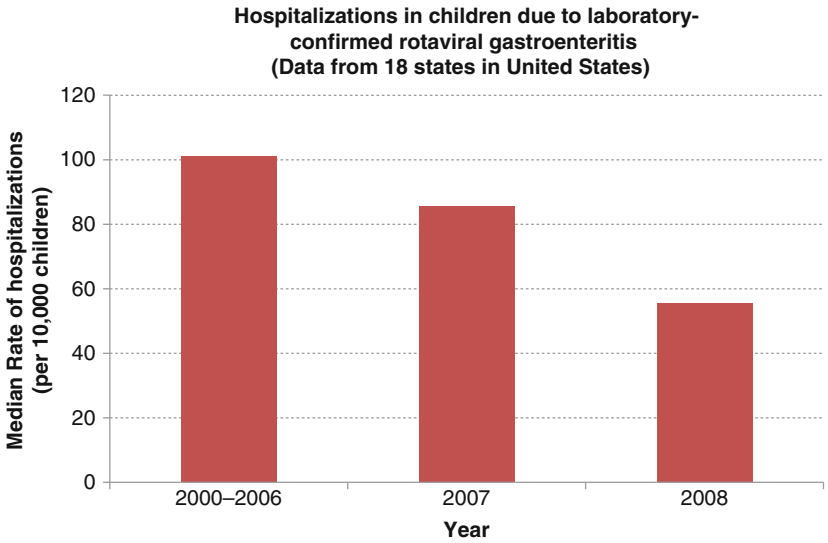

Figure 120.2

Hospitalizations in children due to rotavirus-confirmed gastroenteritis in 18 states of the United States, with data including pre-vaccination years 2000–2006 and 2 years following the introduction of a rotavirus vaccine

Table 120.2

Characteristics of rotavirus and norovirus infection

	Rotavirus	Norovirus
Genome	Non-enveloped; 11 segments of dsRNA	Non-enveloped; ssRNA
Population most affected	Children <5 years of age	Children and adults
Mode of transmission	Fecal-oral	Fecal-oral
Incubation period	2–7 days	12 h–2 days
Length of symptoms	2–7 days	< 3 days
Diagnostic testing	EIA most widely available	EIA for outbreaks
	Also RT-PCR, nucleic acid hybridization, sequence analysis, and culture	RT-PCR (limited availability)
Vaccine?	Yes; Rotateq® and Rotarix®	No

ds = double stranded
ss = single stranded
EIA = enzyme immunoassay
RT-PCR = Reverse transcriptase polymerase chain reaction

Norovirus outbreaks frequently occur in closed environments, such as cruise ships, camps, nursing homes, or schools. Typically, the outbreaks originate from direct contamination by an infected food handler. Food contaminated at its source, such as oysters from contaminated water, has also been described. As the viruses are highly contagious, outbreaks can be explosive, with potentially thousands of people being infected in a short period of time.

Norovirus is typically transmitted via the fecal-oral route or through the ingestion of contaminated food or water. Additionally, vomitus has been shown to contain infectious particles. As few as 10–100 virions are required for infection. Once exposed, roughly 30% of individuals may shed the virus prior to the onset of symptoms. Viral shedding then peaks 1–3 days after illness develops and may persist for up to 3 weeks. The virus is stable from freezing temperatures up to 60°C. All of these factors contribute to the ease of spread and the potential for large outbreaks.

Clinical Manifestations

The incubation period ranges from 12 – 48 h. Disease onset is then quite rapid, with vomiting and non-bloody, watery diarrhea. Fever occurs in roughly 40% of cases, and other constitutional symptoms such as headache, myalgias, and chills are common. In one-third of patients,

asymptomatic infection and viral shedding occur, playing a large part in viral transmission.

The illness is often mild and short-lived, with 85% of patients experiencing less than 3 days of vomiting and diarrhea. The risk for dehydration requiring hospitalization is greatest in children less than 5 years of age and in adults 65 years and older.

Pathogenesis and Pathology

In the infected host, the proximal duodenum demonstrates villous broadening and blunting, crypt-cell hyperplasia, cytoplasmic vacuolization, and inflammatory cell infiltration into the lamina propria. Histologically, the stomach and colon are spared. Intestinal brush border enzymes are diminished during acute infection, with resultant carbohydrate malabsorption. Mild steatorrhea is also noted. The prominent nausea and vomiting associated with norovirus gastroenteritis may relate to delayed gastric emptying, which has been documented in symptomatic adults.

Differential Diagnosis

The preponderance of vomiting and the high attack rate across all age groups are characteristic features of calicivirus gastroenteritis. Norovirus outbreaks can be distinguished from those caused by preformed toxins by the slightly longer incubation period (12–48 h vs. 2–6 h for toxins) and the emergence of secondary cases in household contacts. In general, calicivirus infection tends to have a milder, less dehydrating course than rotavirus. That said, the illness is not reliably clinically distinguishable from that caused by other enteric viruses, including rotavirus, enteric coronavirus, enteric adenovirus, and astrovirus.

Diagnosis

Human noroviruses cannot be cultured. Reverse transcriptase polymerase chain reaction (RT-PCR) can be used to detect viral RNA from stool or emesis samples, in addition to environmental swabs from food or water, in special circumstances. The technique is challenging as human caliciviruses are genetically diverse. Consequently, several sets of primers must be used to confirm infection. Real-time quantitative RT-PCR assays have increased both the sensitivity and specificity of this diagnostic modality. RT-PCR detection is available in some public health and research laboratories but is not readily commercially available in most areas.

Enzyme immune assays (EIAs) for norovirus detection have been approved for commercial use in some countries, though the poor sensitivity of current assays (<50%) limits their use in sporadic cases. In outbreak situations, however, they can be used to rapidly identify norovirus as the causative agent.

In many situations, microbiologic confirmation of a suspected norovirus outbreak is not possible. The "Kaplan criteria" were developed in 1982 to distinguish outbreaks caused by norovirus from those caused by bacterial etiologies. The criteria (vomiting in greater than 50% of affected persons, a mean illness duration of 12–60 h, a mean incubation period of 24–48 h, and no bacterial pathogen identified in stool culture) are highly specific (99%) and moderately sensitive (68%) in this regard. As roughly 30% of norovirus-induced outbreaks will not satisfy all four criteria, it is still important to consider this virus in the appropriate clinical setting. Until norovirus diagnostic tests become widely available, the application of these criteria may be the most useful diagnostic aid in identifying food-borne gastroenteritis outbreaks due to norovirus.

Prognosis

As noted above, Calicivirus gastroenteritis is, in general, fairly mild and self-limited. Immunocompromised hosts, infants, and the elderly are at the highest risk for protracted illness and more severe dehydration. Reports have arisen suggesting an association of norovirus with necrotizing enterocolitis in newborns, benign seizures in infants, and inflammatory bowel disease exacerbations in pediatric patient. Further studies are required to investigate these possible links.

Treatment and Prevention

There is no specific treatment available. As with other causes of viral gastroenteritis, supportive care and attention to fluid and electrolyte balance is crucial. Please see Chap. 187, "Acute Gastroenteritis in Infants and Children" for additional details.

During an outbreak, preventing secondary spread is important in halting further progression. Enforcing personal hygiene, using contact precautions, decontaminating environmental surfaces, and using an

alcohol-based hand sanitizer have all been found to decrease the spread of infection. People with diarrhea due to norovirus refrain should refrain from the use of recreational water venues, such as pools and lakes, for at least 2 week following the resolution of symptoms.

The development of effective preventative measures is of great interest, given the significant socioeconomic burden of large, prolonged outbreaks. In contrast to rotavirus, humans do not acquire long-term immunity with norovirus infection, making vaccine development challenging. A virus-like particle vaccine is currently being evaluated.

121 Rubella

Richard J. Whitley

Introduction

Initially, rubella was considered to be a variant of measles or scarlet fever; however, in 1814, rubella was recognized as a distinct clinical entity. In 1866, Veale introduced the name rubella for the clinical syndrome associated with a maculopapular rash of children and young adults. Rubella is frequently called "German measles" and is the third of six viral exanthems of childhood, with measles and scarlet fever being the first and second. In 1914, Hess suggested a viral etiology predicated on work performed in animal models; however, the etiology was never firmly established until 1938 when Hiro and Tosaka confirmed the viral origin by passing disease to children using filtered nasal washings (16 nonimmune children).

Rubella was considered a benign disease until the early 1940s when, following a widespread outbreak in Australia, an Australian ophthalmologist, Norman Gregg, first described congenital defects, as described below, of infants born to mothers who developed rubella early in pregnancy. With an increasing recognition of the congenital rubella syndrome and after pandemics between 1962 and 1965, a definitive need for the development of a vaccine became apparent. Parkman and Weller first isolated rubella in cell culture in 1962, which ultimately led to the development and licensure of a vaccine in 1969.

Etiology

Rubella is a single negative stranded RNA virus that is enveloped. It is classified as a togavirus, genus rubivirus of the togaviridae family. The other genus in the family of togaviridae is alphavirus. In contrast to the alphaviruses, which replicate in arthropods and invertebrates, rubella virus has no invertebrate host. The only known host of rubella is humans. This virus is relatively unstable and is inactivated by lipid solvents, formalin, ultraviolet light, low pH, and heat. There is only one immunologically distinct serotype of rubella virus. The spherical particles of rubella virus measure 50–70 nm in diameter.

Pathogenesis

Rubella virus is transmitted by the respiratory route. After exposure, replication of the virus is thought to occur in the upper respiratory tract including the nasopharnyx and regional lymph nodes. Viremia ensues approximately 5–7 days after exposure. During periods of viremia, transplacental infection can take place, resulting in fetal damage, particularly during the first trimester of gestation. In studies conducted with volunteers, virus can be detected 7 days prior to and approximately 14 days after the onset of rash. Rubella has a worldwide distribution, although clinically recognized disease occurs less frequently in tropical regions than in temperate zones. Humans are the only known host. As noted above, rubella is spread from person to person via airborne transmission. Rubella is highly contagious and the incidence of infection during an epidemic cycle approaches 100% for susceptible individuals.

In temperate climates such as North America and Europe, rubella is most prevalent from March through May. Persons with subclinical infection are contagious and can transmit infection to others.

Fetal infection can occur at any time during pregnancy; however, the risk is greatest during the first trimester and decreases thereafter. The risk of congenital anomalies in live-born children following fetal infection varies according to the month of pregnancy in which maternal infection occurred, being the highest during the first 8 weeks at 85%.

Clinical Manifestations

The incubation period for rubella is approximately two weeks with a range of 12–23 days. Symptoms are generally mild and many infections are totally asymptomatic. A maculopapular rash is characteristic of infection, as illustrated in *Fig. 121.1*. The rash begins on the face and progresses distally, persisting approximately 3 days. Arthralgia and arthritis are frequent complications in adults (occurring in as many as 70% of adult women).

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_121,

Figure 121.1

When arthritis occurs, it frequently involves the fingers, wrists, and knees. Encephalitis is a rare complication, occurring in approximately 1 in 6,000 cases. Additional complications include orchitis, neuritis, and a late-onset syndrome of progressive pan encephalitis. In addition, hemorrhagic manifestations may be present during the acute illness.

The most significant complication of rubella is the congenital rubella syndrome. Prevention of this syndrome has been the main objective of rubella vaccination programs worldwide. Fetal infection may lead to death, or premature delivery. The congenital rubella syndrome involves virtually all organ systems. Deafness is the most common finding of congenital infection. Other manifestations include ocular abnormalities of cataracts, glaucoma, retinopathy, and microphthalmia. Cardiac defects include peripheral pulmonic stenosis and coarctation of the aorta. Neurologic abnormalities include microcephaly and, ultimately mental retardation. A late-onset congenital rubella syndrome has been described that results in diabetes mellitus and a progressive encephalopathy.

Diagnosis

While clinical findings can suggest a diagnosis of rubella, maculopapular rashes can be attributed to a variety of other etiologies. Thus, laboratory confirmation is required. Definitive diagnosis is achieved by isolation of virus either in cell culture or by polymerase chain reaction. Rubella virus can be detected in blood, urine, cerebrospinal fluid, and nasal and throat swabs. It is present generally 1 week prior to the onset of illness and 2 weeks after rash onset.

Serology is a common method for confirmation of diagnosis. Acute and convalescent serospecimens can be tested by enzyme-linked immunosorbent assays for evidence of antibodies directed against rubella virus. The application of IgM antibodies for confirmation of diagnosis has been used; however, infection attributed to parvoviruses will cause false-positive IgM tests.

Treatment and Prevention

There is no definitive antiviral therapy for rubella infection. Administration of immunoglobulin to susceptible persons experimentally exposed to rubella can prevent clinical disease; however, there have been many reports of failure. As a consequence, it is not routinely recommended.

Since 1979, the RA27/3 rubella vaccine, a live attenuated virus, has been used for the prevention of rubella. The vaccine virus is not communicable except in the setting of breast feeding. It is combined with measles and mumps as an MMR vaccine, or, in addition, with varicella as MMRV. Over 90% of vaccinated individuals will derive significant protection from both clinical disease as well as blood-borne infection for a minimum of 15 years. The first dose of vaccine is recommended for administration between 12 and 15 months of age, with a subsequent dose at school entry (4–6 years of age).

The vaccine can be administered to individuals exposed to rubella within 3 days of exposure.

The vaccine is contraindicated for pregnant women and those who are immunodeficient or receiving immunosuppressive therapies, including individuals with leukemia, human immunodeficiency virus infection, lymphoma, or other malignancies.

Adverse reactions to the vaccine have included arthralgia and arthritis, attributed to the rubella component of MMR. The development of a rash is most likely attributed to the measles component of the vaccine. Additional common complaints include fever, lymphadenopathy, and arthralgia.

Primary Immunodeficiency Disorders

Harb A. Harfi

122 The Immune System: Development and the Immune Response

Michael Loubser

Development of the Immune System

The immune system develops from gut-associated tissues. Multipotential hemopoietic stem cells first appear in the yolk sac at approximately two and a half weeks of gestation and migrate to fetal liver by the fifth week. They later migrate to the bone marrow where they remain throughout life. The cells of the lymphoid system develop from these multipotential stem cells and differentiate to T- and B-lymphocytes or NK cells depending upon the organs or tissues to which the stem cells traffic. Primary lymphoid organs (thymus and bone marrow) develop during the middle of the first trimester. Secondary lymphoid organs (spleen, lymph nodes, tonsils, Payers patches) develop a little later. These organs serve as sites of differentiation and maturation of T-lymphocytes, B-lymphocytes and natural killer cells throughout life. Both initial organogenesis and continued cell differentiation occur as a consequence of the interaction of lymphocytes with a great number of micro-environmental cells, surface molecules, and proteins.

Lymphoid Organ Development

Lymphoid tissue is proportionately smaller but rather well developed at birth and matures rapidly in the postnatal period. The thymus is largest relative to body size during the fetal life and at birth is ordinarily two thirds of its mature weight. It attains its mature weight during the first year of life. The peak mass is however attained just prior to puberty and it gradually involutes thereafter. By a year of age all lymphoid structures are mature histologically. Absolute histiocyte counts in the peripheral blood reach a peak during the first year of life. Peripheral lymphoid tissue increases rapidly in mass during infancy and childhood, reaches adult size by approximately 6 years of age and reaches those dimensions during the prepubertal years, and then undergoes involution coincident with puberty. Spleen gradually increases its mass during maturation and does not reach full weight until adulthood. The mean number of Payers patches in the gut is approximately one half of the adult number at birth and gradually increases until the adult mean number is reached during the adolescent years.

T- and B-lymphocytes are the components of the immune system which are responsible for adaptive immunity. The adaptive immune response is characterized by antigen specificity and the development of immunologic memory. Natural killer (NK) cells are lymphocytes that are also derived from hemopoietic stem cells; there is evidence that they share some of the development pathways of T-cells. NK cells have a role in host defense against viral infection and tumor surveillance. The proteins synthesized and secreted by T, B, and natural killer cells and by the cells with which they interact, for example, macrophages and endothelial cells, are referred to as cytokines. Cytokines have the ability to act in an autocrine, paracrine, and/or endocrine manner to promote and facilitate differentiation and proliferation of the cells in the immune system.

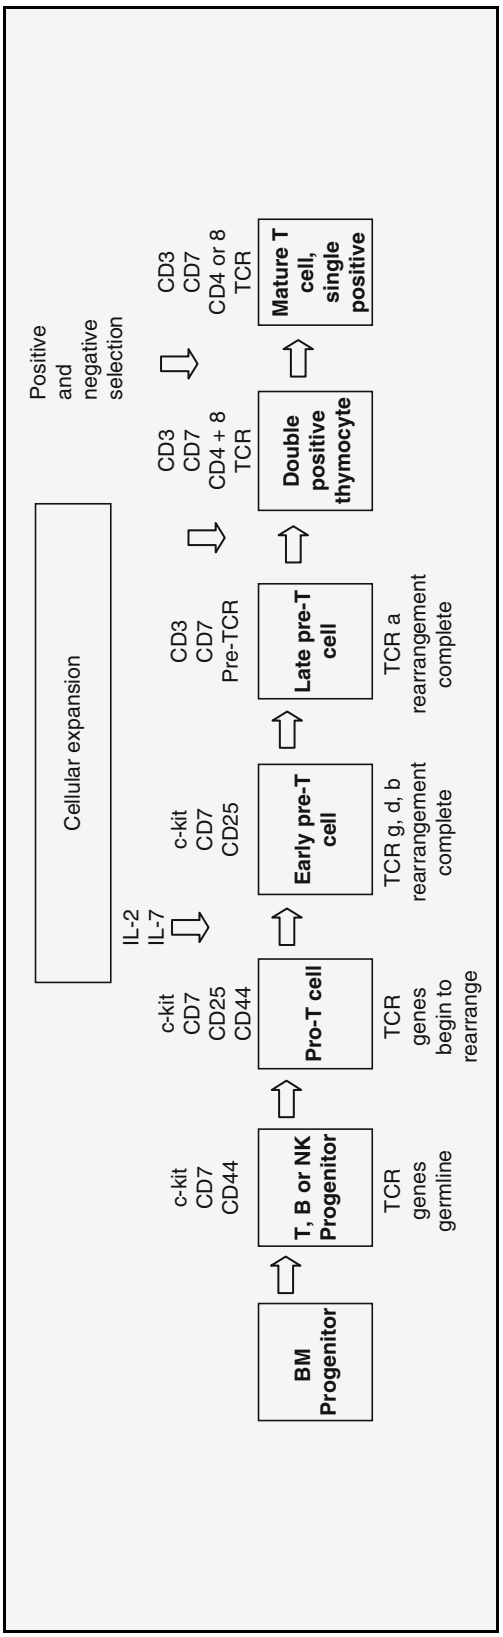
T-Cell Development and Differentiation

The thymic rudiment develops from ectoderm of the third brachial cleft and endoderm of the third branchial pouch during the fourth week of gestation. Beginning in the seventh to eighth week, the right and left rudiments move caudally and fuse in the midline. Blood-borne T-cell precursors, initially from the yolk sac and fetal liver and later from the bone marrow, colonize the perithymic mesenchyme in a number of waves at approximately 8 weeks of gestation. Clear delineation of the thymic cortical and medullary regions becomes discernable by the 12th week of gestation.

The pro-T-cells are identified by the presence of surface proteins CD7 and CD34 and the absence of CD3, the T-cell receptor (TCR), and CD4 and 8 – so-called triple negative thymocytes (*Table 122.1*). The role of CD 7

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_122,

Table 122.1
Thymic development of T-lymphocytes



in T-cell differentiation is not known. It may be a ligand for a complex family of glycoproteins called galectins, whose physiology remains unclear. Toward the end of the eighth week CD7 positive cells are found in the thymus, some of them co-express CD4 and CD8 – so-called double positive thymocytes. Also at this time a number of cells are found bearing incomplete T-cell receptor (TCR) molecules. The mature TCR is a heterodimer comprising either α and β or γ and δ chains; 95% of circulating mature T-cells express a TCR composed of α and β chains. Much of the biology of γδ T-cells remains to be elucidated. TCR αβ or γδ chains are co-expressed on the cell's surface with the CD3 complex which is composed of five polypeptide chains, CD3 γ, δ, ε, ζ, η. TCR diversity is achieved by a process of TCR gene rearrangement. TCR gene rearrangement begins shortly after colonization of the thymic cortex with stem cells between the eighth and tenth weeks of gestation. By 9½ to 10 weeks of gestation, 95% of thymocytes are CD7, CD2, CD4, CD8 positive and have cytoplasmic CD3. By 10 weeks, 25% of thymocytes have functional αβ TCRs. This process is crucial for normal T-cell maturation and involves a mechanism in which large non-contiguous blocks of DNA are spliced together. These segments known as variable (V), diversity (D), and joining (J) each have a number of variants. The VDJ segments are joined at a constant region on the alpha gene and the VJ segments are joined to the beta gene to complete the receptor polypeptide gene. Random combinations of these segments account for much of the enormous diversity of TCR, giving human fetal lymphocytes the ability to recognize millions of different antigens at birth. The development of this vast antigenic repertoire occurs in the absence of exposure to antigen. TCR gene rearrangement is facilitated by recombinase activity genes. Some of these recombinases are specific to the lymphoid cells and others are more generally distributed. The generally expressed recombinase enzymes are KU 80, DNA-PK, and XRCC-4. They are responsible for repair of double-stranded breaks within the genetic replication machinery. More specific to the immune system, however, are two recombinase activating genes referred to as Rag-1 and Rag-2. Lack of recombinase activity resulting from mutations in Rag-1 and/or Rag-2 genes has clinical significance in that there are both animal and human forms of severe combined immunodeficiency resulting from these defects. Affected individuals have low or undetectable levels of circulating T- and B-lymphocytes, the so-called $T^{-}B^{-}$ phenotype.

Rearrangement of TCR genes signifies a developmental step in which pro-T-cells become committed to the T-cell lineage as so-called pre-T-cells. As the immature cortical thymocytes begin to express T-cell receptors, the process of positive and negative selection takes place. This process occurs at the thymic corticomedullary junction. In order for the immune system to be effective, T-lymphocytes must be able to recognize the multitude of foreign antigens that they will encounter over the lifetime of the individual while at the same time they must avoid self-antigens – this differentiation is achieved by positive and negative selection.

Positive selection occurs through the interaction of the TCR of thymocytes with major histocompatibility complex (MHC) antigens present on cortical thymic epithelial cells. There is emerging evidence that normal self-peptides associated with self-MHC capable of having low-affinity interactions with TCRs mediate positive selection. Positive selection is critical for determining the T-cell repertoire and early clonal proliferation. Positive selection is, in fact, the rescue from certain programmed cell death, the eventual fate of the vast majority of thymocytes. Those thymocytes that recognize antigen in the context of MHC class II are selected to become single positive $CD4^{+}$ lymphocytes and conversely those that recognize antigen in the context of MHC class I are selected to become single positive $CD8^{+}$ lymphocytes.

Negative selection is mediated by interaction of the surviving thymocytes with host peptides presented by MHC class I or II antigens on bone marrow–derived macrophages, Langerhans cells, and possibly B-cells. Lymphocytes bearing TCRs with high affinity for self-antigens undergo genetically programmed cell death (apoptosis). In this way autoreactive lymphocyte clones are deleted. Fetal cortical thymocytes are among the most rapidly dividing cells in the body, but as a consequence of positive and negative selection, approximately 97% die. The surviving cells are no longer CD4 and 8 double positive but remain singly positive for one or the other. The single positive, mature cells migrate to the thymic medulla. The medullary thymocytes emigrate from the thymus to the periarteriolar areas of spleen, paracortical areas of the lymph nodes, and appendix at approximately 12 weeks of embryonic life and into the tonsils by 14–15 weeks. They are found in great numbers in the thoracic duct lymph. By the 12th week of gestation T-cells are able to proliferate in response to plant lectins (phytohaemagglutinin and concanavalon A) and allogeneic cells. Lymphocytes capable of responding to exogenous antigen are found by 20 weeks of gestation. Hassell's corpuscles (swirls of terminally differentiated medullary epithelial cells) are first seen in the thymic medulla at 16–18 weeks of embryonic life.

B-Cell Development and Differentiation

B-cell development begins in the fetal liver prior to the 11th week of gestation. Fetal liver CD34 positive stem cells are seeded to the bone marrow of the clavicles by 8 weeks of embryonic life and to the long bones by 10 weeks. There are two broad developmental steps in the maturation of B-cells. These stages of development are defined by cell surface markers (Table 122.2). The first step is antigen independent while the second step leading to the production of high-affinity immunoglobulins is antigen dependent.

Antigen-independent development: Stages of development from pre-pro-B-cell to mature, resting, or virgin B-cell are defined by expression of specific surface proteins and immunoglobulin gene rearrangement patterns (Table 122.2). The precise combination of signals resulting in the differentiation of hemopoietic stem cells into B-cell progenitors is not fully understood. Various cytokines such as interleukins (IL)-3 and IL-7, insulin-like growth factor 1, and stem cell factor (SCF) are known to promote development of B-cell precursors. The earliest detectable cellular markers of B-cell development are D-JH gene rearrangement and the surface expression of CD7, CD10, and CD19.

During the process of B-cell development, B-cell receptor (immunoglobulin) genes undergo rearrangement in much the same way as TCR genes rearrange during T-cell development. The immunoglobulin (Ig) heavy chain genes usually rearrange first, and early B-cell stages express a complex of an Ig heavy chain together with molecules called surrogate light chains. The first heavy chain to be expressed is the μ heavy chain. The surrogate light chains are the products of genes close to the lambda light chain locus. They have some homology with Ig light chain V and C regions, but are not true lambda light chains.

Several of these genes have been identified in humans. V pre-B is a non-rearranging gene encoding most of an Ig V domain. The other genes are a family called lambda 5. The surrogate light chain genes are expressed only in pre-B-cells, and the complex containing the Ig heavy chain with surrogate light chain is called the pre-B-cell receptor.

Genetic defects that prevent expression or interfere with the pre-B-cell receptor function lead to an absence of B-cells and agammaglobulinemia. This has been described in humans with mutations involving.

IgM C region genes, lambda 5 surrogate light chain gene, signal transducing molecules Ig-alpha genes, Bruton's tyrosine kinase (btk) genes, and B-cell linker

Table 122.2
Surface markers defining stages of B-cell development

	Antigen-independent phase					Antigen-dependent phase			
	Pre-pro- B-cell	Pro-B-cell	Pre- B-cell	Immature B-cell	Mature B-cell	Activated B-cell	Blast B-cell	Memory B-cell	Plasma B-cell
MHC Class II	+	+	+	+	+	+	+	+	
CD10*	+	+					+		
CD19*	+	+	+	+	+	+	+	+	
CD20*		+	+	+	+	+	+	+	
CD21*			+	+	+	+

protein (BLNK) genes. In addition, a V pre-B gene mutation has been described in mice.

Protein tyrosine kinases (PTK) predominantly expressed in T-lymphocytes and natural killer cells, ZAP-70, and a Syk-family PTK also appear to play a role in the transition of pro-B to pre-B-cells.

Following successful production of a true Ig light chain and its combination with the heavy chain, a complete IgM antibody molecule appears on the cell surface. This is the hallmark of the immature B-cell stage – by this stage CD10 and CD34 surface expression has been lost.

In a process closely mirroring negative selection during T-cell development, an immature B-cell expressing surface IgM that has a strong interaction with membrane-bound self-antigen (such as MHC) on other cells, results in that B-cell either undergoing apoptosis, or further Ig gene rearrangement to create a new Ig with a different specificity – a process known as receptor editing.

After exiting the bone marrow, B-cells complete their development in the spleen. The mature, resting, or virgin B-cell expresses surface IgM and IgD.

Antigen-dependent development of B-cells occurs after the mature or virgin B-cell is stimulated by antigen through its antigen receptor. As previously noted, the antigen receptor in the case of the B-cell is surface immunoglobulin. The outcome of the antigen-dependent maturational stage is the production of plasma cells which synthesize and secrete antigen-specific immunoglobulin and the production of surface immunoglobulin positive memory B-cells. There are five immunoglobulin isotypes, IgM, IgG, IgA, IgE, and IgD, each determined by the immunoglobulin heavy chain that it bears, μ, γ, α, ε, and δ, respectively. IgG and IgM are the only complement fixing isotypes and are the most important immunoglobulins in the blood and other internal body fluids. IgM is confined primarily to the intravascular compartment because of its large size. IgG is present in all body fluids. IgA is the predominant immunoglobulin in external secretions and plays a major role in mucosal immunity. IgE is present in both internal and external body fluids and plays a major role in host defense against parasites. Because of the high-affinity IgE receptors on basophils and mast cells, IgE is the principal mediator of immediate-type hypersensitivity. The significance of IgD is not clear. There are also subclasses of immunoglobulins, again defined by unique heavy chains. IgA and IgG have two and four subclasses, respectively. These subclasses have different biologic roles, antibodies directed primarily against protein antigens are found in the IgG_1 and IgG_3 subclasses whereas those directed predominantly against polysaccharide antigens are found in the IgG_2 and IgG_4 subclasses.

Although fetal B-lymphocytes are able to differentiate into immunoglobulin-synthesizing plasma cells, they are not found in fetal tissues until about 20 weeks of gestation. This is primarily because the uterine environment is sterile and the antigen-dependent steps of B-cell development do not occur. Prior to birth, lymph nodes have primary but not secondary follicles. The human fetus receives significant quantities of maternal IgG transplacentally from the 12th week of gestation. This quantity steadily increases until cord blood serum concentrations of IgG are comparable to or greater than maternal serum. IgG is the only class of immunoglobulin to cross the placenta. All four subclasses of IgG cross the placenta but IgG_2 does so to a lesser degree. Small quantities of IgM, IgA, IgD, and IgE are present in cord blood. None of these proteins cross the placenta so they are therefore presumed to be of fetal origin.

Natural Killer Cell Development

Natural killer cell (NK cell) activity is found in the fetal liver by about 8–11 weeks of gestation. NK cells are derived from bone marrow precursors and share some of the developmental features of T-lymphocytes. Thymic processing appears not to be necessary for NK cell development. NK cells are defined by their capacity to mediate non-MHC-restricted cytotoxicity. NK cells do not rearrange antigen receptor genes during their development. Virtually all NK cells express CD56 and greater than 90% express CD16. Other CD antigens found on the NK cells include CD57, CD7, CD2, and CD8. NK cells, therefore, share surface antigens common to T-lymphocytes and myeloid cells, leading to some ambiguity as to their ontogeny. Humans who have deficiencies in T- and B-cells often have a relative increase of NK cells. Deficiencies of NK cells have been described and these individuals have normal T- and B-cell development. After release from bone marrow NK cells enter the circulation and migrate to the spleen. There are very few natural killer cells in the lymph node. NK cells recognize virally infected or tumor cells by the absence or decreased expression of MHC class 1 on their surfaces. This MHC-unrestricted killing is mediated by perforin/granzyme apoptotic pathways. A second mechanism of cytolysis is antibody mediated and is termed antibody-dependent cell-mediated cytotoxicity (ADCC). Here, target cells that have bound IgG_1 or IgG_3 trigger the FcRIIIa on NK cells and induce cytolysis. In normal individuals, NK cells compromise approximately 10% of lymphocytes. This percentage is often slightly lower in cord blood.

The Immune Response and Effector Mechanisms

The T-Cell Response: Cell-Mediated Immunity and Cell-Mediated Cytotoxicity

T-lymphocytes may be conceptualized as the conductors of the immune orchestra. They provide help for antibody production by B-cells while participating actively in antigen-specific cell-mediated immunity (CMI). CMI plays a central role in elimination of cells infected by intracellular organisms (viruses and certain bacteria) as well as cells that exhibit abnormal growth and development (neoplastic cells). CMI plays an important role in allograft rejection and in some autoimmune disorders.

The T-cell receptor is made up of a complex of molecules and is exclusively membrane bound – unlike the B-cell receptor – immunoglobulins – that secrete into plasma. T-cell receptors recognize foreign peptides bound to the MHC molecules expressed on the surface of antigen-presenting cells or on the surface of cells that become the target of cytotoxicity.

Antigen-presenting cells are key to the initiation of the T-cell effector mechanism. Common to all antigen-presenting cells is the constitutive or inducible expression of MHC class II; examples of these cells are dendritic cells, monocytes, and macrophages. Antigens presented in the groove of MHC class II have the capacity to interact with the TCR on lymphocytes co-expressing CD4 – this interaction initiates a complex process of cytokine production and co-stimulatory molecule interaction that results in activation and clonal proliferation of the specific T-cell as well as B-cell help. In general, antigens presented on the context of MHC II have arisen from extracellular sources. Almost all somatic cells express MHC I. In general, antigens presented in the context of MHC I have resulted from intracellular processes (viral or intracellular bacterial infection, tumor, etc.). Cells expressing MHC I are capable of binding to TCRs that exist on lymphocytes co-expressing CD8 – the so-called cytotoxic T-cells. This interaction results in lysis of the affected cell. B-cells express MHC II and are able to activate memory T-cells but cannot activate resting naïve T-cells.

The details of antigen processing and presentation are beyond the scope of this chapter, briefly though; professional antigen-presenting cells such as dendritic cells utilize surface receptors, e.g., Toll-like proteins that bind to a variety of microbiological products, e.g., lipopolysaccharide. When the receptor is bound by its ligand, the dendritic cell undergoes maturation and, under the influence of cytokines, migrates to the secondary lymphoid organs where it interacts with the T- and B-cells. The dendritic cell takes up the antigen and in the cytoplasm degrades it into smaller peptides that are loaded onto MHC I or II molecules for later presentation to the relevant lymphocyte.

T-Cell Activation: Essential for T-cell activation is an intact TCR complex, interaction with antigen in the context of MHC, the interaction of a number of co-stimulatory molecules, and an intact transmembrane and intracellular signaling network. The outcome of the activation process is the production of various cytokines that ultimately dictate the outcome of the activation process.

The T-cell receptor complex is comprised of the CD3 complex and a heterodimer comprising either α and β or γ and δ subunits. The so-called $\alpha\beta$ T-cells account for the majority of circulating lymphocytes (90%) and their biology is best understood while the $\gamma\delta$ T-cells are found predominantly in the gut-associated lymphoid tissues and their function is incompletely elucidated.

Each mature T-lymphocyte co-expresses either a CD4 or a CD8 molecule. As mentioned previously, the interaction between the TCR and MHC II bearing a foreign antigen, in the presence of the CD4 molecule is largely responsible for activation of T-cells that produce an array of cytokines that ultimately facilitate the cell-mediated immune response. Conversely, the interaction of a lymphocyte bearing TCR and CD8 with a cell-presenting antigen in the context or MHC I will ultimately lead to the production of a variety of cytokines that ultimately facilitate cell-mediated cytotoxicity and cell lysis.

The above-mentioned interaction is, however, insufficient to activate the naïve T-cell. In fact, binding of TCD–CD3 complex without engaging any co-stimulatory molecules leads to a state of unresponsiveness (anergy) and even death by apoptosis. This may be an important mechanism in T-cell tolerance. One important interaction is that between CD28 on the T-cell with CD80 on the antigen-presenting cell. In the primed T-cell, this interaction triggers the production of interleukin-2 (IL-2) and cellular proliferation. This is at least partially mediated by a positive feedback mechanism between IL-2 and its receptor, CD25.

The process whereby TCR–CD3 complex binds to MHC antigen complex and co-stimulatory molecules triggers a cascade of intracellular events. The details of these biochemical events are beyond the scope of a general pediatric text. Briefly, the intracellular components of the receptor molecules interact with protein tyrosine kinases, triggering three major pathways, mitogen-activated tyrosine kinases (MAPK), Rho family GTPases, and the phosphoinositol regulated pathways. The ultimate result

of these interactions is to send signals to the nucleus via nuclear transcription factors that ultimately result in the production of cytokines.

Based upon the patterns of cytokine production observed for different T-cells, attempts have been made to classify T-cells as either Th0, Th1, Th2, or Th3. This classification is useful from a descriptive point of view, but it is not clear whether truly distinct functional subgroups of T-cells actually exist in the human. The Th0 subgroup is thought to represent undifferentiated T-cells. Cells exhibiting the Th1 cytokine profile (interferon gamma and IL-2) are predominantly involved in macrophage activation and the induction of cellular cytotoxicity, whereas Th2 cells produce cytokines (IL-4 and IL-10) that stimulate IgE, IgG_2, and eosinophil production – all involved in the immunological response to parasites. In clinical practice, the Th2 response seems to be the predominant profile of the atopic reaction. Th3 cells produce transforming growth factor beta (TGF-beta) and are thought to play a role in suppression or negative regulation of the immune response.

Regulation of the immune response is critical to the maintenance of health. Unchecked activity of the effector mechanisms leads to tissue damage as evidenced by the autoimmune connective tissue diseases. T-cells play a central role in the regulation of both T- and B-cell-mediated immunologic processes. The regulatory process is complex and involves both cell-to-cell contact and the production of circulating factors. Two specific receptors play an important role in negatively regulating T-cells – CD 95 and Tumor necrosis factor-2 (TNF-2). When bound to their extracellular ligands, these molecules promote cell death and hence a down regulation of the inflammatory response. The role of Th3 cells in negative regulation has also been alluded to previously.

The B-Cell Response: Humoral Immune Response

Circulating antibodies are acquired either *passively* (during human gestation by the transplacental transfer of maternal IgG, and postnatally via colostrum and breast milk through transepithelial Ig transport by the neonatal Fc receptor, FcRn) or *actively* by natural infection or immunization with vaccines. During the second trimester of pregnancy, IgG crosses the placenta and enters the fetal circulation; IgA and IgM are not transported across the placenta and occur in only very small concentrations in the fetus. Maternally acquired IgG is gradually lost and essentially disappears by 6 months of postnatal age.

Active (or adaptive) immunity is the response generated during the encounter of the immune system with antigen, either naturally occurring or in the form of vaccination. These interactions are responsible for the antigen-dependent stage of B-cell development. This process involves B-cell activation, proliferation, and eventually differentiation into memory B-cells or antibody-secreting plasma cells. Broadly speaking, there are two types of antibody response, one that is independent of T-cell help and the other that is regarded as being T-cell dependent.

T-independent B-cell responses – occur in response to a number of different antigens; some plant and microbial antigens are capable of stimulating polyclonal (i.e., nonspecific) responses and are called mitogens.

Certain strains of Epstein Barr virus can transform B-cells to proliferate in the absence of T-cell regulation. Finally and perhaps most importantly the majority of carbohydrate antigens are handled in this way, one of the most significant organisms being *Streptococcus Pneumonia*. Surface Ig cross-linking is insufficient to induce B-cell proliferation and differentiation, but renders B-cells receptive to T-cell signals (cytokines) which further stimulate their progression toward antibody-secreting cells. In this setting, T-helper-cells do not need to make physical contact with B-cells. This is referred to as non-cognate T-cell help.

T-cell-dependent B-cell responses – account for the majority of responses to protein and glycoprotein antigens. In this instance, antibody production requires close collaboration between T- and B-cells. Initially, T-cells are activated by recognizing antigen associated with MHC molecules presented to them by an antigen-presenting cell. The activated T-cell produces cytokines and becomes capable of providing help to a B-cell for antibody production. A second interaction involves direct contact between a B-cell and the T-helper-cell. B-cells internalize antigen that binds specifically to the B-cell receptor (Ig molecule); the antigen is processed and associated with MHC class II molecules, as occurs with the professional antigen-presenting cells. This action is necessary for a T-helper-cell to be able to recognize appropriate B-cells to which they deliver stimulating signals. Analgous to T-cell activation, B-cells additionally require interaction with other molecules to complete and mature the humoral immune response – examples include interactions with complement proteins, activation molecules such as CD21 and molecules that mediate class-switching from IgM to other classes, specifically CD40L (CD154). Once a sufficient set of activating signals are received, the B-cell enters a differentiation pathway leading either toward a plasma cell, or a memory cell. By influencing the process of Ig class-switching,

cytokines also influence the relative proportions of various Ig isotypes produced in antibody responses.

Intracellular signaling in B-cells is regulated by tyrosine, serine, or threonine phosphorylation of one or more components of the pathway. Protein kinases (PTKs) and phosphatases, respectively, phosphorylate and dephosphorylate their various substrates ultimately leading to nuclear activation and protein synthesis.

123 Innate Immune Defects

Jordan S. Orange · Nina Poliak

The innate immune system serves as an initial immunologic defense against microorganisms. Once a microorganism penetrates the body's physical barriers, the innate immune system responds almost immediately. Steps in function of the innate immune system include *recognition* of danger, *amplification* of a signal, and a functional *response* to foreign material. As a whole, the innate immune system utilizes numerous individual components to affect these objectives. Almost any of these have the potential to be defective in children, leading to susceptibility to infection and environmental exposures. There are many individual different known defects of the innate immune system, some of which define specific syndromes or disorders. The individual diagnoses are best suspected after characteristic patterns of infection that suggest a particular defective element of innate immune defense. The recognition of these infectious paradigms can facilitate the consideration of a particular disorder and help target an appropriate diagnostic approach. In this chapter, individual defective elements of innate immunity as well as specific disorders are reviewed. Emphasis is placed upon the infectious susceptibility demonstrated by the "typical" patient affected by the given disorder.

Phagocyte Defects

Neutrophils are the chief phagocyte of the immune system and function to isolate, engulf, and kill pathogens. Neutrophils express adhesion receptors, such as integrins, and immunoglobulin (Ig) receptors, and complement receptors to facilitate uptake of opsonized dangerous elements. Defects in neutrophils are the cause of several diseases of innate immunity and comprise approximately 18% of all primary immunodeficiencies. These are presented in ❯ *Table 123.1* along with the respective genes impaired in each and include chronic granulomatous disease, Chediak–Higashi syndrome (CHS), Griscelli syndrome (GS), Hermansky–Pudlak syndrome (HPS) type 2, leukocyte adhesion deficiency (LAD) (Type I, Type II, and Type III), neutrophil-specific granule deficiency, myeloperoxidase deficiency, cyclic neutropenia, severe congenital neutropenia (Kostmann syndrome), X-linked neutropenia, and hyper-IgE syndrome (HIES).

Chronic granulomatous disease (*CGD*) occurs in approximately 1 in 200,000 live births and is caused by a defect in the NADPH oxidase complex and resulting inability of phagocytes to produce a respiratory burst. There are several individual components of the NADPH oxidase complex and deficiencies of any one can cause CGD. Since one, $GP91^{phox}$ is encoded by a gene on the X chromosome, CGD can be either X-linked or autosomal recessive. In general, the X-linked form is both more common and more severe. Patients usually present in early childhood with abscesses of skin and deep-seated infections of lungs, lymph nodes, liver, and bones. The most common pathogens are catalase-positive bacteria such as *Staphylacoccus, Klebsiella, Serratia, and Burkholderia*. Fungal infections also represent a major susceptibility of CGD patients and most commonly are caused by *Aspergillus species*. Aspergillus pneumonia is historically the leading cause of fatal infection in CGD. Approximately 17% of patients with CGD develop a difficult–to-treat form of inflammatory bowel disease. Patients also develop inflammatory granulomas in sites such as the stomach, esophagus, ureter, and bladder, which can lead to obstructive symptoms. CGD can be diagnosed by determining phagocyte oxidase activity by measuring the reduction of a fluorescent dye such as dihydrorhodamine (DHR). DHR reduction after cell activation will produce a quantitative change in fluorescence that can be easily measured by flow cytometry.

Treatment of CGD focuses on the prevention of life-threatening infections through the use of indefinite antibiotic prophylaxis. The currently recommended prophylactic regimen includes both trimethoprim-sulfamethoxazole and itraconazole and has been validated to substantially reduce infection in placebo-controlled studies of CGD patients. Studies have also demonstrated a benefit for prophylaxis with Interferon–γ in reducing infections. Hematopoietic stem cell transplantation (HSCT) has more recently been demonstrated to correct immune defects in CGD patients and thus has the

Table 123.1
Phagocytic cell disorders and its characteristics

Phagocytic cell disorders	Inheritance	Gene	Defective immune mechanism	Clinical presentation susceptibility	Diagnosis	Treatment
Chronic granulomatous disease (CGD)	75% XR	CYBB	Mutations in phagocyte NADPH oxidase complex. XR: defect in the gene for gp91phox	Recurrent, pyogenic, deep-seated, granulomatous infections of skin and internal organs with catalase-positive bacteria (S. aureus, Serratia, Klebsiella, Aerobacter, Salmonella, Burkholderia cepacia,), and fungi (Aspergillus, Nocardia, Candida). ~17% of patients develop IBD Granulomas can cause obstruction of stomach, ureter, or esophagus.	Measurement of phagocyte oxidase activity via dihydrorhodamine reduction assay (or similar) Specific gene sequence	1. Prophylactic antimicrobial and antifungal therapy or 2. IFN-γ injections 3. Granulocyte transfusions 4. HSCT 5. Gene therapy
	25% AR	CYBA NCF1 NCF2 RAC2	AR: defects in genes p47phox or p67phox or p22phox, or RAC2			
Chediak–Higashi syndrome (CHS)	AR	LYST	Mutations of LYST causing abnormal lysosomal trafficking leading to aberrant formation and function of phagolysosomes and melanosomes.	Pyogenic infections of skin, respiratory tract Partial oculocutaneous albinism, photophobia Nystagmus, ataxia, peripheral neuropathy. Accelerated phase: lymphoproliferative disease with hemophagocytosis that is often fatal.	Microscopic evaluation of neutrophils to demonstrate the presence of giant azurophilic granules Reduced or absent NK cell cytotoxicity Specific gene sequence	1. Prophylactic antibiotics 2. HLA-identical HSCT Allogeneic HSCT 3. High-dose cocorticosteroids and chemotherapy for accelerated phase
Griscelli Syndrome (GS)-II	AR	RAB27A	RAB27A mutation leading to defective transit of phagolysosomes, lytic granules, and melanosomes	Pyogenic infections Pigmentary changes in hair (large melanin clumps in the shaft) and skin Accelerated phase like Chediak–Higashi	Reduced or absent NK cell cytotoxicity Specific gene sequence	1. Prophylactic antimicrobial therapy 2. Chemotherapy for accelerated phase 3. HSCT

Table 123.1 (Continued)

Phagocytic cell disorders	Inheritance	Gene	Defective immune mechanism	Clinical presentation susceptibility	Diagnosis	Treatment
Hermansky–Pudlak syndrome (HPS) type 2	AR	AP3B1	Abnormal formation of neutrophil granules Mutation of the adaptor protein complex 3 subunit	Same as for Chediak–Higashi with the addition of: Severe thrombasthenia-Congenital neutropenia	Neutropenia Reduced or absent NK cell cytotoxicity Prolonged bleeding time Specific gene sequence	1. Prophylactic antimicrobial therapy 2. Control of bleeding 3. Chemotherapy for HLH 4. HSCT
Leukocyte adhesion deficiency (LAD), Type I	AR	ITGB2	Absence or partial deficiency of adhesive integrins on neutrophils and lymphocytes (CD11/CD18 deficiency)	Recurrent non-purulent soft tissue and mucous membrane infections such as gingivitis, stomatitis, otitis, perirectal abscesses; Destructive periodontitis Impaired wound healing Delayed umbilical cord separation	Decreased or absent expression of CD18 on neutrophils by flow cytometry Elevated white blood cell counts Specific gene sequence	1. Prophylactic antimicrobial therapy 2. Surgical debridement of wounds 3. HSCT
LAD, Type II	AR	FUCT1	GDP-fucose transporter gene defect Decreased level of Sialyl Lewis X protein (CD15)	Recurrent infections especially of lungs Coarse facial features Developmental delay and mental retardation Bombay blood type and leukocytosis	Decreased or absent Sialyl Lewis X by flow cytometry (CD15) Specific gene sequence	1. Prophylactic antimicrobials 2. Fucose supplementation 3. HSCT
LAD, Type III	AR	CALDAG-GEF1	CALDAG GEF1 mutation Integrin activation defect on leukocytes also affecting platelets	Recurrent severe non-purulent infections Petechiae or severe bleeding from birth, Leukocytosis	Specific gene sequence	1. Prophylactic antimicrobials 2. Blood transfusions 3. HSCT
Specific granule deficiency	AR	CEBPE	Absence of neutrophil-specific granules resulting from absent function of the transcription factor C-EBPε.	Recurrent skin and respiratory tract infections with S. aureus, Pseudomonas, Candida.	Microscopic examination of stained eutrophils Specific gene sequence	1. Supportive treatment of infections

Table 123.1 (Continued)

Phagocytic cell disorders	Inheritance	Gene	Defective immune mechanism	Clinical presentation susceptibility	Diagnosis	Treatment
Severe congenital neutropenia (including Kostmann syndrome)	AR	HAX1 ELA2 G6PR P14 GCSFR	Various depending upon the specific gene mutation all resulting in the near absence of neutrophils in peripheral blood	Bacterial respiratory tract infections Otitis, gingivostomatitis, perineal and vaginal ulcerations, fever and malaise	Serial measurements of neutrophil counts Specific gene sequence	1. Therapy with granulocyte colony stimulating factor (G-CSF) 2. Supportive treatment of infections
Cyclic neutropenia	AD	ELA2	Deficiency of elastase 2 (ELA2)	Low neutrophil counts approximately every 21 days (range 14–36 days) Neutrophil counts nadirs usually present for 3–6 days Fever, stomatitis, periodontitis, and skin infections when neutrophil counts are low.	CBC check $\geq$ weekly for 6–8 weeks Specific gene sequence	1. G-CSF 2. Supportive treatment for infections
X-linked neutropenia	XR	WASP	Constitutively activating mutation in Wiskott–Aldreich syndrome protein	Bacterial infections	Serial CBC Specific gene sequence	G-CSF
Myeloperoxidase deficiency	AR	MPO	Diminished capacity to enhance hydrogen peroxide-mediated microbicidal activity	Healthy individuals who can develop fungal infections when deficiency is associated with systemic diseases (e.g., diabetes, lupus)	Diminished or absent myeloperoxidase	Therapy for fungal infections
Hyper-IgE syndrome (HIES)	AD AR	STAT3 DOCK8 TYK2	Defective function of STAT3 transcription factor and absence of Th17 cells	Recurrent lung infections with Staphylococcus and Aspergillus Bronchiectasis Pneumatoceles Recurrent skin infections Chronic eczematous dermatitis with frequent superinfections S. aureus. Coarse facial features	Elevated IgE levels Eosinophilia Specific gene sequence	1. Aggressive and prophylactic antibiotics 2. antifungal 3. dental evaluation for retained primary teeth 4. HSCT is not curative as disease recurs.

AR autosomal-recessive, *AD* autosomal dominant, *XR* X-linked recessive

potential to "cure" the immunodeficiency. Preliminary evidence with gene therapy in the X-linked form has identified some potential benefits.

CHS is characterized by abnormal neutrophil granules and subsequent defective antimicrobial killing. Partial oculocutaneous albinism, neurological symptoms, and increased susceptibility to pyogenic infections affecting skin, respiratory tract, and other organs are typical. Microscopic examination of neutrophils can reveal giant azurophilic granules that result from the defective formation of these and related cell organelles in CHS and lead to impaired function. Patients with CHS can develop an "accelerated phase" after certain types of viral infections, which is characterized by unchecked systemic inflammation and can be fatal without aggressive immunosuppressive therapy. HSCT can cure the immunologic abnormalities in CHS.

GS is a heterogeneous disorder and has several distinct phenotypes, with the feature common to all being a global pigmentary dilution with silvery gray hair. While there are features characteristic of each form of GS, GS2 includes a phagocytic immunodeficiency that is similar to CHS and results from abnormal management of intracellular granules. This results in a susceptibility to pyogenic infections and similar to CHS can also develop an accelerated phase. HSCT can also cure immunologic abnormalities in GS.

HPS is similar to CHS and GS as it results from abnormal generation of phagocytic granules. It also presents with oculocutaneous hypopigmentation, susceptibility to bacterial infections, and developmental delay, and can be associated with an accelerated phase. There are several forms of HPS, and it is HPS2 that is associated with immunologic abnormalities. Unlike CHS and GS, HPS is associated with bleeding as certain platelet granules are also affected. Treatment of HPS includes antibiotics prophylaxis, control of bleeding, and the use of HSCT, which can cure immunologic abnormalities.

LAD is extremely rare and represents an inability of leukocytes to localize to sites of inflammation due to defective adherence mechanisms. As a result, there are extraordinarily high numbers of white blood cells in the circulation. LAD is autosomal recessive and has three distinctive subtypes. *LAD Type I* patients present with recurrent non-purulent infections of the skin such as cellulitis, omphalitis, poor wound healing, severe periodontitis, and respiratory tract and intestinal infections. Diagnosis can be established by detection of absent or severely decreased CD11a/b and CD18 integrin components on leukocytes using flow cytometry. This disorder has been classically associated with delayed separation of the umbilical cord stump in the perinatal period. This, however, is quite common, while LAD is very rare. In addition, the delayed separation of the cord in LAD is almost always associated with omphalitis and elevated white blood cell counts. Prophylactic and therapeutic antimicrobial regimens and early HSCT are the current management strategies for LAD Type I. *LAD Type II* is similar to LAD Type I clinically, but also presents with severe mental retardation, growth delay, and dysmorphic facial features. In contrast to LAD type I, decreased or absent CD15 by flow cytometry is diagnostic for LAD Type II, and this deficiency results in the inability of leukocytes to marginate to sites of inflammation. *LAD Type III* is also clinically similar to the others, but here integrins are present on leukocytes, but cannot be activated. This also affects platelets and thus patients develop petechiae and hemorrhage in early infancy.

Severe congenital, cyclic, or X-linked neutropenias are characterized by susceptibility to septicemia, bacterial respiratory tract infections, soft tissue infections, gingivostomatitis, periodontitis, and oral vaginal and rectal mucosal ulcerations. The severity of the infectious complications parallels the severity of neutropenia. Serial measurements of neutrophil counts are necessary to distinguish persistent from cyclic neutropenia and to establish the diagnosis.

Neutropenia in severe congenital neutropenia and X-linked neutropenia is persistent, while in cyclic neutropenia, decreased cell counts typically occur every 21 days but may range from 14 to 36 days.

HIES is a rare primary immunodeficiency that involves the immune and musculoskeletal systems. Patients with HIES present with eczema, recurrent staphylococcal furunculosis and abscesses, mucocutaneous candidiasis, and respiratory infections. The clinical hallmark of HIES is recurrent pneumonia with pneumatoceles and bronchiectasis. Patients with HIES develop characteristic facial features including prominent forehead, wide-set eyes, and thickening of the ears and nose. Skeletal abnormalities lead to recurrent pathological bone fractures and prolonged retention of primary teeth. Laboratory findings include elevated polyclonal IgE (IgE levels of more than 2,000 IU/ml), eosinophilia, and absence of TH17 cells. Treatment of HIES consists of aggressive skin care, prophylactic and therapeutic antibiotics. Immunoglobulin replacement therapy is held to be useful in some patients as deficiencies in polysaccharide-specific antibodies can be documented. HSCT is not curative in HIES as the symptoms are not ameliorated and IgE levels return after transplant to pre-transplant levels.

Natural Killer Cell Defects

Natural killer (NK) cells are lymphocytes of the innate immune system that function to help control of infection through cytotoxicity, cytokine production, or costimulation of other immune cells. There are isolated NK cell deficiencies in addition to immunologic syndromes associated with NK cells defects. A wide variety of combined primary immunodeficiencies affect NK cells as part of the overall immunological defect in that disease. These include severe combined immunodeficiency, CHS, GS type II, the X-linked lymphoproliferative syndrome (XLP), Wiskott–Aldrich syndrome, and *NF-κB essential modulator* (NEMO) deficiency.

Isolated NK cell deficiencies (not affecting other components of the immune system) are rare and are characterized by the absence of NK cells or their functions. Presently, only one genetic aberration has been associated with this diagnostic category, and thus they are categorized phenotypically (◉ *Table 123.2*). Patients with NK cell deficiencies typically have increased susceptibility to herpesviral infections and treatment includes therapeutic and prophylactic administration of antiviral medications.

Familial Hemophagocytic Lymphohistiocytosis (*FHL*) has five different forms (FHL1-5) and represents a serious life-threatening disease that manifests early in life as hematophagocytic lymphohistiocytosis (HLH). The symptoms and laboratory findings of HLH include high, prolonged fever without evidence of bacterial infection, hepatosplenomegaly, pancytopenia, and elevated inflammatory markers/acute phase reactants. This symptomatic phase of FHL is lethal if not treated and is often triggered by herpesvirus infection. Absent cytotoxic activity of NK cells is a characteristic feature of FHL and relates to the underlying defective mechanism. FHL type 1, does not have an identifiable genetic cause but types 2–5 are caused by mutations in specific genes (◉ *Table 123.3*). Specific

Table 123.2
Isolated natural killer cells deficiencies

NK defects	Inheritance	Gene	Peripheral blood NK cells	Clinical susceptibility	Diagnosis	Treatment
Absolute NK deficiency	Unknown	Unknown	Absent NK cells and NKT cells	Severe VZV, CMV, HSV, bacterial and mycobacterial infections	No CD56+ cells_	1. Treatment and prophylaxis of infections 2. HSCT
Classical NK deficiency	unknown	unknown	Absent NK cells with present T cells	HPV, trichophyton	Absent classic NK cells (CD56+/CD3−) and absent NK cytotoxicity	1. Prophylaxis against herpes viruses 2. aggressive therapy of HPV 3. HPV vaccination 4. HSCT
Functional NK deficiency	Unknown	Unknown	NK cells present, but unable to mediate cytotoxicity	EBV, HSV	Presence of NK cells but absence of their activity	1. Prophylaxis against herpes viruses 2. Possibly cytokine therapy (IL-2)
NK cell deficiency due to CD16 impairment	AR	FCGR3A	NK cells present, have impaired spontaneous cytotoxicity	Severe HSV, VZV, EBV	Flow cytometry showing absent CD16 as recognized by mAb B73.1 (CD16 is present when assessed using mAb 3G8)	1. Prophylaxis against herpes virus

Table 123.3
Primary immunodeficiencies associated with defect in natural killer cells

Defects involving NK cells	Inheritance	Gene	Defect	Susceptibility	Diagnosis	Treatment
Familial erythrophagocytic lymphohistiocytosis	AR	PFP1 MUNC13–4 STX11 MUNC18–2	Defect in perforin (PFP1) or the ability to appropriately release the contents of lytic granules	EBV, CMV, VZV, HSV	Reduced NK cell cytotoxicity, Flow cytometry for absence of perforin (PFP1) or degranulation via CD107a upregulation in NK cells Fulfillment of FHL diagnostic criteria (5/8) Specific gene sequence	1. Treatment of infection. 2. Immunosuppression 3. Chemotherapy 4. HSCT
XLP	XR	SH2D1A XIAP (BIRC4)	Ligation of 2B4 fails to induce lysis of EBV-infected cells	EBV	Specific gene sequence Reduced NK cell cytotoxicity Elevated CD8+ cells Absence of SAP protein by flow cytometry	1. Treatment and prophylaxis of EBV 2. IVIG 3. Immunosuppression 4. HSCT

guidelines for the diagnosis of FHL have been published and require the presence of 5/8 criteria, or the definition of a known associated gene mutation. Management of FHL immunosuppression during the acute phase of the illness and ultimately HSCT, as it is the only curative treatment.

XLP presents clinically in previously healthy individuals after infection with Epstein-Barr virus (EBV). These patients develop extreme symptoms of their EBV infection and demonstrate a profound proliferation of infected B cells, leading to multiorgan system abnormalities. Once triggered, clinical disease in XLP patients is difficult to manage and frequently, lethal. Thirty percent of XLP patients have B cell lymphoma as an initial presentation and normal immunologic functions become impaired in most. Treatment includes immunoglobulin replacement, antiviral therapy, rituximab, immunosuppressants, and HSCT. Prognosis of patients with XLP is poor with mortality of 10% within the first 10 years of life and early transplantation after diagnosis (even if not yet symptomatic) is recommended.

Cytokine Deficiencies

Cytokines are a heterogeneous group of soluble glycoproteins that serve important roles in inducing innate immunity are produced by the innate immune system to facilitate adaptive immunity. While many cytokines function in innate immunity, a family of defects referred to as the Type I cytokine pathway defects are especially relevant. These include IFN gamma receptor (R1 or R2) deficiency, IL-12 receptor deficiency, IL-12 p40 deficiency, and STAT1 deficiency. All these deficiencies are inherited as autosomal recessive disorders and result in susceptibility to atypical mycobacterial disease. Specifically, the actions of these cytokines and the STAT1 transcription factor used by these cytokines allow for the appropriate activation of monocytic cells so that they can destroy mycobacteria in the phagosome. Patients with IL-12 defects also are susceptible to Salmonellosis. Diagnosis can be suspected on account of an aberrant production of IFN-γ (in IL-12 deficiencies), or response to IFN-γ. In the IFN-γ receptor deficiencies, there are also elevated

levels of serum IFN-γ. Treatment includes antimycobacterial regimens, antimycobacterial prophylaxis, IFN-γ for the IL-12 and partial IFN-γ receptor deficiencies, and potentially HSCT.

Toll-like Receptor Function Defects

Ten toll-like receptors (TLRs) have been described in humans and serve as pattern recognition receptors for dozens of molecules (both foreign and self) that contain motifs signifying danger. As a result, they represent key initiators of the innate immune response. Patients with defective function of the TLR system have specific infectious susceptibilities (*Table 123.4*). Some defects affect a number of TLRs by impairing common signaling pathways downstream of the receptors. Examples include IRAK-4 and MyD88 deficiency in which patients are susceptible to pyogenic infections. Laboratory evaluation of patients with suspected defect in TLR includes a TLR

Table 123.4
Primary immunodeficiencies involving TLR

Immunodeficiency	Inheritance	Gene	Defect	Susceptibility	Diagnosis	Treatment
Interleukin-1 receptor associated kinase 4 (IRAK-4) deficiency	AR	IRAK4	TLR-IRAK signaling pathway	Pyogenic infection	TLR assay abnormality Direct gene sequence	1. prophylactic antibiotic treatment 2. IVIG
MyD88 deficiency	AR	MYD88	Deficiency of downstream adaptor of TLR	Pyogenic infection	TLR assay abnormality Direct gene sequence	1. prophylactic antibiotic treatment 2. IVIG
Herpes simplex encephalitis (HSE)	AR	UNC93B1	Defect in UNC-93B dependent IFN induction	HSV encephalitis	TLR assay – measurement of IFN-λ Direct gene sequence	Prophylaxis and treatment of HSV
	AD	TLR3	Defect in TLR3 dependent IFN induction	HSV encephalitis Influenza cerebritis	TLR assay - measurement of IFN-λ Direct gene sequence	Prophylaxis and treatment of HSV
NEMO Deficiency (some with Ectodermal dysplasia with immunodeficiency)	XR	NEMO (IKBKG) mutation	Defective NF-κB activation downstream of TLR and other immunoreceptors	Pyogenic bacteria, mycobacteria, pneumocystis, DNA viruses	NEMO gene sequencing TLR assay NK cell abnormality Low immunoglobulins Impaired specific antibody production	1. Myocbacterial and Viral prophylaxis 2. IVIG 3. HSCT
Ectodermal dysplasia with immunodeficiency (AD)	AD	IKBA	Defective NF-κB activation downstream of TLR and other immunoreceptors due to gain of function alteration in IκBα	Pyogenic bacterial infection, mycobacteria, and Anhidrotic ectodermal dysplasia	Same as for NEMO, except sequencing of IKBA	1. Bacterial prophylaxis 2. IVIG 3. HSCT

assay to measure the production of proinflammatory cytokines after exposure of PBMC to TLR ligands. Therapy includes prompt antimicrobial treatment of infections as well as antibiotic prophylaxis and IVIG therapy. Other deficiencies of TLR are less intuitive biologically, but important nonetheless. These include TLR3 and UNC93B deficiencies, which result in a susceptibility to herpes simplex virus encephalitis.

NF-κB essential modulator (*NEMO*) *and the inhibitor of NF-κB-α* (*IκBα*) *deficiency* can result in *anhidrotic ectodermal dysplasia with immunodeficiency* (EDA-ID), interfering with the signaling downstream of most TLRs. Thus, patients share much of the infectious susceptibility associated with IRAK-4 and MyD88 deficiency. These patients, however, also have signals interrupted downstream of other important immunological receptors and thus have a broader immunodeficiency syndrome; they are frequently infected with atypical mycobacteria, pneumocystis, and DNA viruses. A majority of patients will have the EDA-ID phenotype, but many will not, and the diagnosis should not be excluded on that basis alone. Diagnosis can be suspected by identifying a combined immunodeficiency, which in most cases will include a demonstrable impairment of TLR function and can be confirmed by direct gene sequencing. NEMO deficiency is X-linked recessive and IκBα is autosomal dominant. Treatment includes immunoglobulin replacement therapy, prophylactic antibiotics and HSCT has been curative for some, but not all patients.

Complement Deficiency

Complement deficiencies comprise approximately 2% of all primary immunodeficiencies. Deficiencies of almost all soluble complement components have been described and the most common are of C2 and C9. *Deficiency of the early classical complement pathway components* usually present with susceptibility to bacterial infection and autoimmunity (including systemic lupus erythematosus, polymyositis, and vasculitis). *Terminal complement component deficiencies* present with increased susceptibility to Niesserial infections and recurrent disease is characteristic. Thus, meningococcal vaccination and antibiotic prophylaxis is essential. Diagnostic assessments can include a total hemolytic complement of the classical (CH50) and alternative (AH50) pathways for screening for defects in the complement system. Both will be abnormal in deficiencies of terminal complement components. The levels of individual complement components can also be measured directly or functionally.

Hereditary angioedema (*HAE*) is an unusual deficiency of the C1 esterase inhibitor, which presents with angioedema, but not with increased risk of infections. HAE is diagnosed by the presence of significant angioedema, depressed C4 levels, and absent C1 esterase inhibitor. It is treated by replacement of C1 esterase inhibitor for prevention and treatment of attacks. Therapeutic androgens can increase the level of functioning C1 esterase inhibitor and can be used for the prevention of exacerbations.

124 Humoral Immune Defect

Mark Ballow · Brian Safier

Early B-Cell Differentiation Defects

Definition/Classification

These defects disturb the maturation of the B-cell lineage, and result in agammaglobulinemia. B-cell development is arrested at the level of the pro-B-cell or early pre-B-cell stage (*Table 124.1*).

Etiology

This category of B-cell defects results from gene mutations associated with X-linked or autosomal recessive inheritance, or sporadic genetic mutation: X-linked agammaglobulinema (XLA) and various autosomal recessive forms of agammaglobulinemia, including mutations affecting the Ig μ heavy chain, the Igα (CD79A) component, the adaptor protein BLNK (B-cell linker protein), and the λ5/14.1 surrogate light chain (*IGLL1*). One third to one half of XLA cases are sporadic.

Epidemiology

The estimated minimal birth rate of XLA in the USA is 1:379,000 total births per year, or 1:190,000 male births per year. The mean age at diagnosis of patients with sporadic XLA is 35 months old. Most patients with familial XLA are diagnosed before the age of 2 months. XLA represents approximately 85% of early B-cell differentiation defects. Defects in μ heavy chain are the most common of the autosomal recessive agammaglobulinemias. The mean age at diagnosis for patients with μ heavy chain defects is 11 months old.

Pathogenesis

Mutation in Bruton's tyrosine kinase (Btk) is X-linked; the *BTK* gene maps to the mid-portion of the long arm of the X-chromosome at Xq21.2-22.2. Btk is expressed at all stages of B-cell development but is down-regulated in plasma cells. Btk is required for B-cell receptor signaling. The pre-B-cell receptor consists of the μ heavy chain, surrogate light chain (Vpre-B and λ5/14.1), and transmembrane signal transduction components Igα and Igβ. Mutation of these structures follows an autosomal recessive inheritance pattern, and manifests with a phenotype similar to XLA (Vpre-B mutations have not been identified in patients with agammaglobulinemia). Pre-B-cell receptor expression and signaling is necessary for positive selection of B-cells, prevention of apoptosis, and progression of B-cell development. Gene mutations in BLNK, necessary for receptor signaling, also block B-cell differentiation (*Fig. 124.1*).

Pathology

The lymphoid tissues (e.g., adenoids, lymph nodes, tonsils, and spleen) are absent or markedly hypoplastic.

Clinical Manifestations: Symptoms and Signs

The onset of recurrent bacterial infection is typically during the latter part of the first year of life, when maternal antibodies are reduced below protective levels. However, a significant number of patients may present at 3–5 years of age (10–20%), and may present even later in life as misdiagnosed common variable immunodeficiency (CVID). The sinopulmonary tract is a frequent site of infection (60% of patients). Other types of infection include gastroenteritis (35%), pyoderma (25%), meningoencephalitis (16%), septicemia (10%), chronic conjunctivitis (8%), and osteomyelitis (3%). *S. pneumonia* and *H. influenzae* are commonly associated with these infections. Poorly treated pulmonary infections eventually lead to bronchiectasis. Chronic lung disease is one of the most common complications of XLA, and may be seen without an overt case of acute pneumonia. Patients with XLA are not at increased risk of viral infection, fungal infection, or

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_124,

Table 124.1
Early B-cell differentiation defects

Disease	Laboratory features	Clinical features	Gene defects
X-linked agammaglobulinemia	• B-cells <2% of lymphocytes • Agammaglobulinemia or severe hypogamaglobulinemia • Poor specific antibody responses • Absent isohemagglutinins	• Absent/hypoplastic lymphoid tissue • Recurrent and severe bacterial infection • Enteroviral infection • Chronic lung disease • Increased malignancy risk	• *BTK*
Autosomal recessive agammaglobulinemias	• Same as XLA	• Same as XLA, with earlier onset and more severe complications	• μ heavy chain, Igα, Igβ, BLNK, λ5 (*IGLL1*)

tuberculosis, because cellular immunity is intact. Exceptions to this include viral hepatitis; enteroviral infections such as polio (vaccine-associated poliomyelitis may occur), echovirus, or coxsackievirus; and chronic enteroviral meningoencephalitis.

Repeated bacterial infections of susceptible target organs, such as the middle ear, sinuses, and lungs, lead to positive physical findings of active inflammation, with eventual scarring or damage to the site. Infections caused by enteroviruses or *Ureaplasma urealyticum* may cause arthritis. Enteroviruses may also cause a dermatomyositis-like syndrome. Gastroenteritis is not uncommon, and may be caused by *Giardia lamblia*, *Campylobacter* species, or rotavirus.

Patients with autosomal recessive agammaglobulinemia have an earlier onset of disease compared with patients with XLA, and they are more likely to have severe complications.

Diagnosis

Definitive diagnosis of XLA requires that a male patient have less than 2% mature B-cells (CD19+ B-cells), and at least one of the following: mutation in Btk; absent Btk mRNA on Northern blot analysis of neutrophils or monocytes; absent Btk protein in monocytes or platelets (Western blot or flow cytometry); maternal cousins, uncles, or nephews with less than 2% CD19+ B-cells.

Diagnosis is likely in a male patient with less than 2% CD19+ B-cells in whom all of the following are positive: onset of recurrent bacterial infections in the first 5 years of life; serum IgG, IgM, and IgA more than 2 SD below normal for age; absent isohemagglutinins and/or poor response to vaccines; other causes of hypogammaglobulinemia have been excluded.

If a mutation in Btk is not identified and findings are consistent with a diagnosis of XLA, it may be worthwhile to screen for defects in the components of the pre-B-cell receptor complex, or B-cell signaling pathway, e.g., Igα and Igβ, and BLNK.

Differential Diagnosis

Other causes for severe hypogammaglobulinemia. Myelodysplasia, including those with monosomy 7, trisomy 8, or dyskeratosis congenita.

Treatment

Aggressive treatment of acute or chronic infections is essential. Patients should be treated with replacement doses of IgG immunoglobulin, intravenous (IVIG) or subcutaneous (SCIG), to obtain serum IgG levels of >750 mg/dL. Infections are usually well controlled on IVIG. However, the use of prophylactic antibiotics may be needed. Live viral vaccines are contraindicated. Disseminated enteroviral infections have been treated with high doses of IVIG.

Prognosis

Prognosis is variable depending on the disease. Some patients have life-threatening or fatal infections in the first year of life. With early diagnosis and appropriate treatment with IVIG most patients live into adulthood. Nevertheless, mortality rates can be as high as 30% over 10

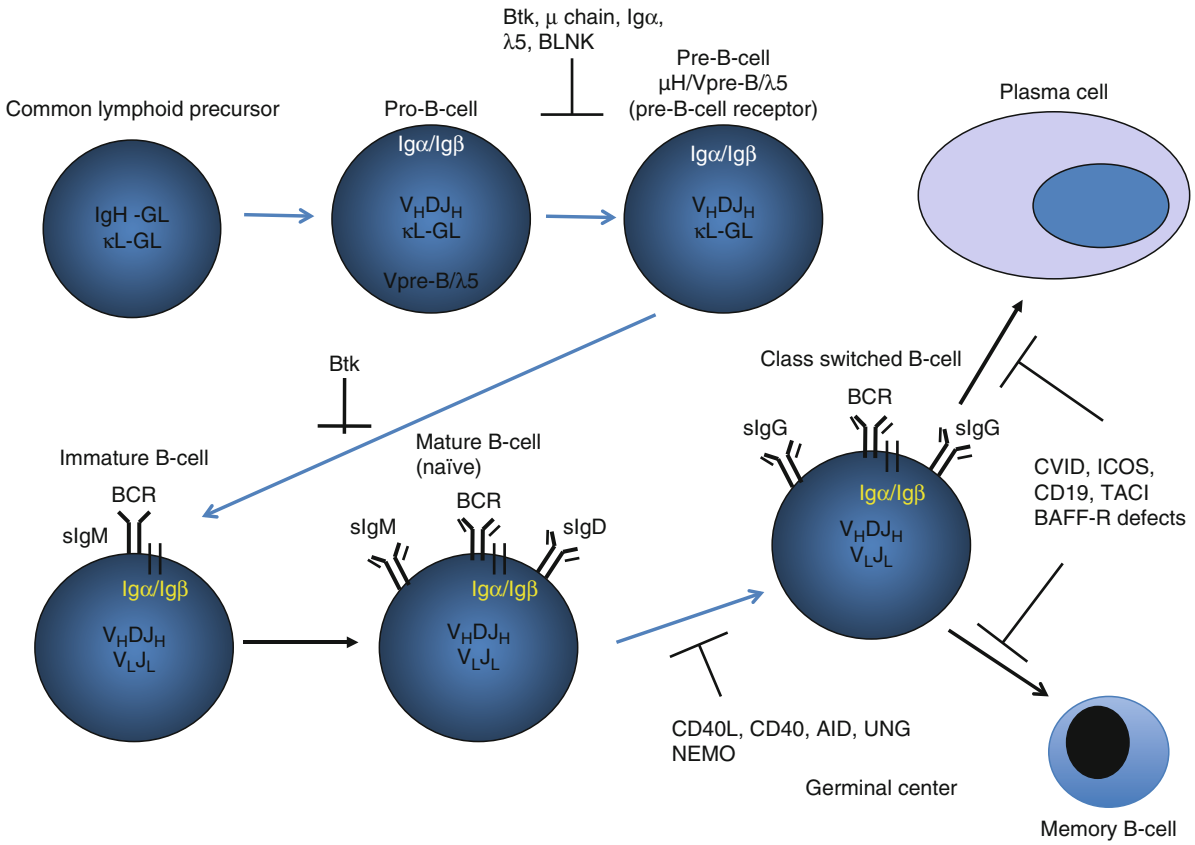

Figure 124.1

Common lymphoid precursor cells give rise to pro-B-cells, in which the germline heavy chain genes (IgH-GL) undergo rearrangement of their immunoglobulin heavy-chain gene segments ($V(D)J_H$). Subsequently, the immunoglobulin heavy-chain gene segments join with the surrogate light chain gene products (Vpre-B/λ5) to form the pre-B-cell receptor (μH/Vpre-B) with Igα and Igβ, cytoplasmic signaling molecules. The immunoglobulin light-chain genes in the germ line configuration (kL-GL) undergo rearrangement to complete the formation of a functional IgM B-cell receptor on immature B-cells. Engagement of the B-cell receptor on immature B-cells results in the proliferation and differentiation of these immature B-cells with class switch recombination and somatic hypermutation leading to antibody secreting plasma cells and long-lived memory B-cells. Genetic mutations have been identified to cause disruption at distinct junctures of this developmental process, as indicated in the figure above. Defects in the genes encoding Btk, μ heavy chain, Igα, λ5 surrogate light chain, and BLNK lead to a block in the generation of pre-B-cells. Gene mutations in CD40L, CD40 receptor, AID, UNG, and NEMO lead to abnormalities in class switch recombination and somatic hypermutation. Gene defects associated with ICOS, CD19, TACI, and BAFF-R are associated with abnormalities in terminal B-cell differentiation. *AID* activation-induced cytidine deaminase, *BAFF-R* B-cell activating factor receptor, *BCR* B-cell receptor, *BLNK* B-cell linker, *Btk* Bruton's tyrosine kinase, *CD40L* CD40 ligand, *CVID* common variable immunodeficiency, *ICOS* inducible T-cell co-stimulator, *NEMO* nuclear factor κB essential modulator, *TACI* transmembrane activator and calcium-modulating cyclophilin-ligand interactor, *UNG* uracil *N*-glycosylase

years even with comprehensive care. Lung complications are the most common issue especially with undertreatment with replacement IVIG. XLA patients have an increased incidence of lymphoreticular malignancies of 0.5–6%.

Prevention

Early diagnosis and proper treatment may prevent some infectious complications. Maternal and family testing with genetic counseling is important.

Late B-Cell Differentiation Defects

Definition/Classification

These defects involve processes of late B-cell differentiation and interfere with the development of properly functioning memory B-cells and plasma cells. This category of B-cell defects includes common variable immunodeficiency (CVID) and selective IgA deficiency (IgAD) (Table 124.2).

Etiology

Approximately 10–20% of CVID and IgAD are inherited, and the pattern of inheritance is variable. Familial studies suggest an allelic relationship between IgAD and CVID. In some patients, IgAD may be the early manifestation of CVID.

Epidemiology

CVID is the most common symptomatic primary immunodeficiency, with an estimated incidence in Europe and North America between 1:10,000 and 1:50,000. CVID is rare among Asians and blacks. With CVID, the mean age of onset of symptoms lies in the third decade of life and the age at diagnosis in the fourth decade of life. The variable in CVID denotes variability in the age at presentation (e.g., early childhood, adolescence, or as young adults) and variability in the degree and type of hypogammaglobulinemia. There is no gender predisposition.

The prevalence of selective IgA deficiency is estimated to be 1:400 to 1:3,000. The frequency is significantly lower in Japanese and Chinese populations. It is the most common form of primary immunodeficiency.

Pathogenesis

CVID is a heterogeneous group of disorders involving both B-cell and T-cell immune function, the predominant manifestation of which is hypogammaglobulinemia. Serum Ig levels are markedly diminished but are usually higher than those found in XLA. There can be tremendous variability in the degree of hypogammaglobulinemia; any or all isotypes of Ig can be affected. Specific antibodies are absent or reduced, and isohemagglutinin titers are usually diminished. The proportions of circulating B-cells in the peripheral blood are usually normal, but a subset of CVID patients may have very low circulating B-cells. T-cell function can be variable. Approximately half of the patients have absent delayed skin hypersensitivity to recall antigens, low numbers of circulating T-cells, and depressed in vitro responses to mitogens and specific antigens.

Several mechanisms have been proposed to explain the immune abnormalities in patients with CVID, including an intrinsic B-cell defect, excessive T-suppresser cell activity, deficient T-cell helper function, cytokine deficiencies, suboptimal T-cell–B-cell interactions through deficient expression of the CD40 ligand, and defects of antigen-

Table 124.2
Late B-cell differentiation defects

Disease	Laboratory features	Clinical features	Gene defects
CVID	• IgG, and IgA or IgM >2 SD below mean for age • Poor specific antibody responses • Absent isohemagglutinins • B-cell numbers usually normal; reduction in memory B-cells • T-cell function variable	• Sinopulmonary infection with encapsulated pathogens • Bronchiectasis • Autoimmune disease • Malignancy –lymphoma and gastric • Liver disease • Gastrointestinal disease-infection, NLH, granulomas, IBD • Granulomatous inflammation	• ICOS, TACI (TNFRSF13B), CD19, BAFF-R (TNFRSF13C), MSH5 • Mostly unknown
IgA deficiency	• IgA <7mg/dL • Normal IgM and IgG • Normal specific antibody responses • Normal B-cell numbers	• Mostly asymptomatic • Sinopulmonary and gastrointestinal disease • Autoimmunity • Atopy	• TACI, MSH5 • Mostly unknown

NLH nodular lymphoid hyperplasia, *IBD* inflammatory bowel disease

presenting cells. Studies have demonstrated each of these immune dysregulations independently.

Approximately 10–20% of CVID is familial, with the majority of these cases being transmitted in an autosomal dominant manner with variable penetrance; approximately 10–20% is inherited in an autosomal recessive fashion. Most of these families have members affected by CVID, selective IgA deficiency, or intermediate states of humoral immunodeficiency. Family members of patients with CVID also have an unusually high incidence of autoimmunity and malignancy. Genetic linkage studies have identified genetic susceptibility loci near the HLA region on chromosomes 6, 4q, and 16q, though responsible genes within these regions have yet to be identified.

Mutations in several genes have been implicated in contributing to the CVID phenotype, including *ICOS*, *TNFRSF13B* (encoding TACI), *CD19*, and *TNFRSF13C* (encoding BAFF-R). Polymorphism in the encoding gene for a repair protein involved in class switch recombination (*MSH5*) has been associated with IgA deficiency and CVID.

With IgA deficiency peripheral blood B-cells co-express IgA, IgM, and IgD, similar to IgA-bearing B-cells found in cord blood. However, these cells fail to mature into IgA-secreting plasma cells. The pathogenesis of IgA deficiency is unknown, although abnormalities in Ig class switching and the cytokines involved in isotype switching have been implicated. IgA deficiency shares with CVID the inheritance of a restricted MHC extended haplotype, and may share a common cause with CVID since these two disorders share many immune aspects. Mutations in TACI and polymorphisms in the gene encoding Msh5 have been identified in patients with IgAD, further supporting the link between IgAD and CVID. However, T- and B-lymphocyte subpopulations and activation/differentiation markers differ significantly between the two entities (*Fig. 124.1*).

Pathology

Hypertrophy of lymphoid tissues, including peripheral lymph nodes, the spleen, and occasionally the liver, are frequently seen. Secondary neutropenia or thrombocytopenia may result from the hepatosplenomegaly.

Clinical Manifestations

CVID patients most frequently have sinopulmonary tract infection. The most common pathogens are encapsulated bacteria such as *H. influenza*, *S. penumoniae*, and *M. catharralis*. Recurrent pneumonia often results in bronchiectasis, as well as lung fibrosis and emphysema, though pneumonia occurs frequently before the diagnosis of CVID and subsequent initiation of replacement IVIG. Despite appropriate treatment, chronic lung disease, e.g., bronchiectasis is among the most common causes of morbidity and mortality in these patients. Infrequently, patients may have recurrent *Herpes zoster* and infections with *Mycoplasma* spp. which is often associated with arthritis. Chronic CNS infections with enteroviruses are found in patients with CVID, though less commonly than with XLA. Opportunistic infections are rare.

Gastrointestinal disease is present in approximately 21% of CVID patients, presenting with malabsorption, weight loss, and chronic diarrhea. Lactose intolerance, celiac disease, protein-losing enteropathy, or superimposed infection of the small bowel with *Campylobacter*, *Salmonella*, or *Yersinia* species or the parasite *Giardia lamblia* contribute to the gastrointestinal symptoms. Atrophic gastritis with achlorhydria may lead to pernicious anemia. Nodular lymphoid hyperplasia (e.g., hypertrophy of the Peyer's patches in the small bowel), diffuse lymphoid infiltration, and loss of villi are characteristic in patients with CVID.

Autoimmune disorders occur in approximately 22% of patients with CVID and include rheumatoid arthritis and seronegative arthritis; autoimmune hematologic disorders, such as hemolytic anemia, idiopathic thrombocytopenic purpura, and pernicious anemia; autoimmune neurologic diseases, such as Guillain-Barré syndrome; chronic active hepatitis often related to hepatitis C virus; autoimmune endocrinopathies, particularly involving the thyroid; and vasculitides. More commonly seen in CVID patients with autoimmune disorders, though not exclusively, are noncaseating granulomatous lesions infiltrating organs such as the liver, lymph nodes, lungs, and skin. These lesions are often confused with sarcoidosis.

The incidence of malignancy is increased (11–13%) in CVID during the fifth and sixth decades of life. The majority of these malignancies involve the gastrointestinal tract and the lymphoid tissues. As many as one third of CVID patients will develop a nonmalignant lymphoproliferative disease.

Up to 90% of individuals with IgA deficiency are clinically asymptomatic. IgAD patients with compensatory increase in secretory monomeric IgM in their upper respiratory tract secretions and gastrointestinal fluids tend to be less symptomatic. IgAD patients with more severe and recurrent sinopulmonary infection tend to have an associated IgG2/IgG4 or IgG4 subclass deficiency.

Patients with symptoms have sinopulmonary infections and involvement of the gastrointestinal tract with giardiasis and nodular lymphoid hyperplasia. An increased frequency of autoimmune disorders has also been associated with IgA deficiency, including arthritis, a lupus-like illness, autoimmune endocrinopathies, chronic active hepatitis, ulcerative colitis, Crohn's disease, a sprue-like disease, and autoimmune hematologic disorders. IgAD is also strongly associated with atopy.

IgAD may be found in association with other immune abnormalities, including ataxia-telangiectasia. It may also occur in association with the administration of drugs, such as phenytoin, sulfasalazine, hydroxychloroquine, and D-penicillamine. IgAD has been described in association with a number of chromosomal abnormalities, especially on chromosome 18.

Diagnosis

CVID requires a reduction, at least two standard deviations below normal, in two immunoglobulin isotypes: IgG and IgA or IgM, an onset of immunodeficiency after the age of 2 years, and absent isohemagglutinins and/or defective vaccination responses. IgA deficiency is defined as a patient greater than 4 years of age who has a serum IgA of less than 7mg/dL with normal serum IgM and IgG levels. Both IgA subclasses, IgA1 and IgA2, are usually markedly reduced or absent, although isolated deficiencies have been described. Other causes of hypogammaglobulinemia must be excluded. Patients with IgA deficiency have a normal IgG antibody response to vaccination.

Differential Diagnosis

Excessive loss of immunoglobulins (e.g., nephrosis, protein-losing enteropathy, severe burns)
Hypercatabolism of immunoglobulin (e.g., proximal myotonic myopathy)
Malignancy (e.g., chronic lymphocytic leukemia, Good's syndrome, non-Hodgkin's B-cell lymphoma, myeloma)
Drug-induced (anticonvulsants, gold salts, glucocorticoids, δ-penicillamine, antimalarial agents, methotrexate)
Infectious disease (e.g., Epstein-Barr virus, HIV, and congenital rubella, CMV, Chlamydia, mycoplasma, HSV, cytomegalovirus, or *Toxoplasma gondii*)
X-linked agammaglobulinemia
Hyper-IgM syndromes
Ataxia-telangiectasia
Late-onset adenosine deaminase deficiency
Atypical forms of severe combined immunodeficiency
X-linked lymphoproliferative disorder (Epstein-Barr virus-associated)
Warts, hypogammaglobulinemia, infections, and myelokathexis syndrome
Immunodeficiency, centromeric instability, and facial anomalies
Chromosomal anomalies (e.g., chromosome 18q syndrome, monosomy 22, trisomy 8, trisomy 21)
Vitamin B12 deficiency

Treatment

Replacement immunoglobulin (IgG) therapy with IVIG is key in the prevention of recurrent and chronic lung infections. Close monitoring and aggressive treatment of acute or chronic infections are essential with antibiotic therapy for breakthrough infections, and treatment of associated disease complications and sequelae. Additionally, prophylactic antibiotics may be considered in select patients.

Replacement immunoglobulin therapy is generally not indicated in IgA deficiency. Prophylactic antibiotics are indicated for patients with recurrent infection. In symptomatic patients with IgAD and IgG subclass deficiency immunoglobulin replacement must be used with caution. IgAD patients with IgA levels less than 7 mg/dL are at risk for developing anti-IgA antibodies on receipt of blood products, including immunoglobulin replacement. Medic-Alert bracelets may be useful with these patients.

Complete blood count with differential, a comprehensive metabolic panel, serum immunoglobulins, and pulmonary function tests should be obtained every 6–12 months. Chest computed tomography should be done at diagnosis, and periodically thereafter to monitor for bronchiectasis.

Prognosis

In CVID, lower levels of IgG at the time of diagnosis and poor T-cell function are associated with an earlier age of death. The 20-year survival rate after diagnosis is approximately 65–67%, which when compared to the general population is about 30% lower.

The prognosis for IgAD patients is usually not associated with a shortened life expectancy. Rare instances of disease resolution have been observed, particularly in young patients. A small percentage of patients evolve into CVID.

Prevention

Early diagnosis and proper treatment may prevent complications of infection and associated conditions.

Class Switch Defects and Defects of Somatic Hypermutation

Definition/Classification

These defects involve defects in the ability of the B-cell to undergo isotype switching, e.g., from IgM to IgG, IgA or IgE, and/or increase antigen specificity through somatic hypermutation. This category of B-cell defects includes the hyper-IgM syndromes (HIGM1-4) and gene mutations associated with impaired nuclear factor (NF) κB activation (Table 124.3).

Etiology

HIGM1 (or X-linked HIGM) is caused by defects in CD40 ligand (CD40L/*TNFSF5*). Autosomal recessive forms include HIGM2 which is the result of defects in activation-induced cytidine deaminase (*AID*) gene (HIGM2), or uracil N-glycosylase (*UNG*) gene (HIGM4); and absence of CD40 receptor on B-cells (HIGM3; *TNFRSF5*). HIGM4 (UNG deficiency) is downstream of AID activity, and is characterized by defective class switch recombination with preserved somatic hypermutation. Other similar entities in clinical phenotype, e.g., normal or elevated IgM with low serum IgG and IgA, include defects in nuclear factor-κB essential modulator (NEMO, also known as IKK-γ gene (*IKBKG*)) that is present on the X-chromosome, or gene mutations in IκBα (*NFKBIA*). Many of these patients also have ectodermal dysplasia and dyshidrosis.

Epidemiology

These groups of patients are very rare, and are usually associated with consanguineous families. The prevalence of HIGM is estimated to be approximately 1:500,000 in the Caucasian population, and represents between 0.3% and 2.9% of all patients with primary immunodeficiency in registries from Europe, Asia, and South America. The estimated minimal incidence of HIGM1 in the USA is 1:1,030,000, which represents two thirds of all HIGM

Table 124.3
Class switch defects and defects of somatic hypermutation

Disease	Laboratory features	Clinical features	Gene defects
HIGM1	• Normal or elevated IgM with IgA and IgG >2 SD below mean for age • Normal T-cell number, abnormal function • Normal or elevated B-cell number • Poor specific antibody responses • Neutropenia in 50%	• Recurrent bacterial infection of sinopulmonary and gastrointestinal tracts • Opportunistic infection, particularly *P. jiroveci* • Sclerosing cholangitis • Parvovirus-induced aplastic anemia • Autoimmunity and malignancy	• CD40L (*TNFSF5)*
HIGM2	• Normal or elevated IgM with IgA and IgG >2 SD below mean for age • Normal B-cell number • Poor specific antibody responses	• Recurrent bacterial infection of sinopulmonary and gastrointestinal tracts • Lymphoid hyperplasia (large germinal centers)	• *AID*
HIGM3	• Normal or elevated IgM with IgA and IgG >2 SD below mean for age • Normal T-cell number, abnormal function • Poor specific antibody responses	• Recurrent bacterial infection of sinopulmonary and gastrointestinal tracts • Opportunistic infection, particularly *P. jiroveci* • Lymphoid hypoplasia	• CD40 (*TNFRSF5)*
HIGM4	• Normal or elevated IgM with IgA and IgG >2 SD below mean for age • Poor specific antibody responses	• Recurrent bacterial infection of sinopulmonary and gastrointestinal tracts • Lymphoid hyperplasia	• *UNG*
NEMO defect	• Normal or elevated IgM with IgA and IgG >2 SD below mean for age • Impaired NK cell function and Toll-like receptor signaling	• Hypohydrotic ectodermal dysplasia • Pyogenic bacterial infection • Herpes, CMV, and HPV infection • Atypical mycobacterial infection	• IKBKG (NEMO) • NFKBIA (IκBα)

patients; more than half of these patients are diagnosed by 1 year of age, and almost all by 4 years of age. HIGM2 is typically diagnosed in the second or third decade of life. The mean age at diagnosis for HIGM4 is 8.8 years old. 55–65% of HIGM patients are male.

Pathogenesis

Appropriate interaction between CD40L on the activated T-cell and CD40 constitutively expressed on the B-cell is essential for switching of IgM to another Ig isotype. AID is only present on activated B-cells, and is one of the enzymes triggered by CD40 engagement and activation. The role of AID is to deaminate DNA cysteine to uracil with subsequent initiation of a base excision repair process. UNG removes uracil to form abasic sites allowing for cleavage at these DNA sites and eventual class switching. These components are also all essential for somatic hypermutation which is the process of genetic alteration that allows for the development and selection of antibodies with increased affinity for antigen. The result is patients with normal or elevated levels of IgM, with decreased IgG, IgA, and IgE, and generally low antibody affinity for antigen.

IKBKG (NEMO) and *NFKBIA* (IκBα) mutations cause abnormal activation of NFκB. NFκB affects AID and UNG transcription; therefore some of these patients have decreased class switching and somatic hypermutation, leading to the observed increase in IgM levels. With *IKKG* mutation, there is abnormal toll-like receptor signaling (including lipopolysaccharides responses), deficient production of antibody specific for carbohydrate antigens, variable degrees of total antibody deficiency, and defective NK cell function. *NFKBIA* mutation is associated with T-cell deficiency (Fig. 124.1).

Pathology

The patients with autosomal recessive inheritance of hyper-IgM syndrome have enlarged secondary lymphoid tissues, and show marked follicular hyperplasia with abnormally large germinal centers. In contrast, patients with the x-linked form of hyper-IgM syndrome have no germinal centers in their lymph nodes.

Clinical Manifestations

HIGM patients are characterized by severe recurrent bacterial infections, particularly of the sinopulmonary and gastrointestinal tracts. HIGM1 and HIGM3 patients are susceptible to opportunistic infections, especially for pneumonia caused by *Pneumocystis jiroveci*. This is due to defective T-cell CD40L interaction with CD40 on monocytes/dendritic cells, resulting in abnormal cellular immune responses. HIGM2 and HIGM4 patients are not susceptible to opportunistic infections and typically present later in childhood. Liver disease is common in HIGM1, and is often associated with *Cryptosporidium* or CMV infection. HIGM1 is also associated with autoimmune disease and malignancy (particularly gastrointestinal, hepatic and biliary). Neutropenia is common (50%) in HIGM1.

NEMO mutations cause a variable clinical phenotype of hypohydrotic ectodermal dysplasia and immunodeficiency including susceptibility to pyogenic bacterial infection in early childhood, atypical mycobacterial infections in early or late childhood, and viral infection, particularly herpesviruses, CMV, and human papilloma virus.

Diagnosis

Diagnosis of HIGM1 is definitive in a male patient with serum IgG concentration at least 2 SD below normal for age and one of the following: mutation in the CD40L gene; maternal cousins, uncles, or nephews with confirmed diagnosis of HIGM1. Diagnosis is likely in a male patient with a serum IgG concentration at least 2 SD below normal for age and all of the following: normal number of T-cells and normal T-cell proliferation to mitogens; normal or elevated numbers of B-cells but no antigen-specific IgG antibody; absent CD40 ligand cell surface staining on activated CD4+ T-cells as assessed by binding to soluble CD40 or by binding of monoclonal antibody to CD40 ligand; one or more of the following infections or complications: recurrent bacterial infections in the first 5 years of life, *P. jiroveci* infection in the first year of life, neutropenia, cryptosporidium-related diarrhea, sclerosing cholangitis, parvovirus-induced aplastic anemia.

Other forms are diagnosed based on normal or elevated IgM with IgA and IgG levels at least two SD below normal, and normal numbers of B-cells (some HIGM4 patients have decreased memory B-cells). Diagnosis is confirmed using flow cytometry and/or mutational analysis.

Patients with NEMO have impaired NK cell function, and Toll-like receptor signaling is impaired in the majority of patients.

Differential Diagnosis

X-Linked agammaglobulinemia
Common variable immunodeficiency
Transient hypogammaglobulinemia of infancy
Severe combined immunodeficiency
Secondary causes of agammaglobulinemia, e.g., congenital rubella

Treatment

These patients require replacement immunoglobulin therapy, but this does not decrease susceptibility to opportunistic infections. Therefore, the use of prophylactic antibiotics for *P. jiroveci* is indicated for HIGM1 and HIGM3 patients. G-CSF may be necessary to treat neutropenia in HIGM1 and HIGM3 patients. Bone marrow transplant may be considered in HIGM1 patients $\leq$8 years old without serious infection if an optimal donor is available. Prevention of *Cryptosporidium* infection using boiled or filtered water is recommended. Baseline and follow-up pulmonary function tests, chest and sinus X-Rays or CT scans, CBC, and CMP are important.

For patients with NEMO, antibacterial, antimycobacterial, and antiviral prophylaxis should be considered.

Prognosis

The most common cause of death in HIGM1 patients is opportunistic infection, followed by liver disease and malignancy. A European study suggests that only 20% survive past 25 years of age.

Prevention

Early diagnosis and proper treatment may prevent complications of infection and associated conditions.

B-Cell Defects of Unknown Etiology

Definition/Classification

B-cell immunodeficiency of unknown etiology. This group of B-cell abnormalities includes transient hypogammaglobulinemia of infancy (THI), IgG subclass deficiencies, and selective antibody deficiency (*Table 124.4*).

Epidemiology

An exact incidence of these disorders is not known. These conditions are rarely familial and are more common in males.

Clinical Manifestations

THI is an exaggeration and prolongation of the normal physiologic hypogammaglobulinemia that occurs between 2 and 4 months of age, which may persist to age 3–5 years.

Table 124.4
B-cell defects of unknown etiology

Disease	Laboratory features	Clinical features	Gene defects
Transient hypogammaglobulinemia of infancy	• Low IgG levels +/−low IgA and/or IgM • Normal antibody responses to protein antigens • Viral respiratory antigen antibody response may be reduced	• Recurrent upper respiratory tract infection • Hematologic abnormalities (e.g., neutropenia) • Atopy	• Unknown
IgG subclass deficiency	• Reduced >2 SD below mean for age • Normal total IgG • May have poor specific antibody responses, especially to polysaccharide antigens	• Recurrent respiratory tract infection • Atopy • Autoimmunity • Associated with IgA deficiency and ataxia-telangiectasia	• Unknown
Selective antibody deficiency	• Normal serum Ig and IgG subclass levels • Abnormal response to immunization with unconjugated polysaccharide vaccine	• Recurrent sinopulmonary infection	• Unknown

Patients may have recurrent upper respiratory infections, including otitis media, sinusitis, and less commonly, pneumonia. Often, hematologic abnormalities are present, most notably neutropenia. Less frequently, gastroenteritis and failure to thrive occur in this patient population. There is an increased incidence of atopy in this patient population.

IgG subclass deficiency is defined as low serum levels of one or more IgG subclasses (more than 2 SD below normal serum levels for age). However, even healthy individuals without recurrent infection can have low IgG subclass levels. Some immunologists question whether the entity represents a true immunodeficiency disease. However, IgG subclass deficiency has been associated with recurrent respiratory tract infection, bacterial and viral. Symptomatic IgG2 subclass-deficient patients typically have infections with *H. influenza* or *S. pneumoniae*, and most are unable to produce specific antibodies after immunization with unconjugated polysaccharide antigens (e.g., Pneumovax). The authors believe that this entity is a developmental immune delay since most of these children eventually stop having recurrent infections and are able to produce specific antibodies to polysaccharide antigens. IgG2 subclass deficiency is the most common subclass deficiency in children, whereas in adults IgG3 subclass deficiency is the most common. IgG subclass deficiency may be seen in conjunction with other primary immune deficiency disorders, such as ataxia-telangiectasia and IgA deficiency. Atopy and autoimmunity are frequent in patients with IgG subclass deficiency.

Selective antibody deficiency is defined by normal serum immunoglobulins but poor ability to make specific antibodies to polysaccharide encapsulated bacterial antigens. Patients have recurrent sinopulmonary infections. Most of these patients are between 3 and 6 years of age, possibly reflecting a maturational delay of the humoral immune system.

Diagnosis

THI is best defined as low levels of IgG, with or without depression of IgA and/or IgM, in a child older than 6 months of age in which other primary immune deficiencies have been excluded. Antibody responses to protein antigens are normal, but may be reduced to viral respiratory antigens.

IgG subclass deficiency is defined as the presence of one or more IgG subclasses more than 2 SD below the mean with normal total IgG levels, in a patient with recurrent infections and a significant defect in antibody responsiveness.

Selective antibody deficiency is defined as normal serum Ig and IgG subclass levels with abnormal response to immunization with unconjugated polysaccharides, such as Hib capsular antigen, or to pneumococcal polysaccharide antigens.

Differential Diagnosis

Primary and secondary causes of hypogammaglobulinemia
CVID
Protein losing enteropathy or nephropathy

Treatment

For each of these entities, Ig levels, including IgG subclasses, and antibody responses should be evaluated every 6–12 months to monitor for disease resolution or progression to other immunodeficiencies, such as CVID. Chest and sinus radiographs or CT scan may also be indicated.

Patients with recurrent infections may be treated with prophylactic antibiotics. Immunoglobulin replacement therapy is typically not indicated but may be considered if recurrent infection is poorly controlled with antibiotics. For patients with selective antibody deficiency and recurrent acute sinusitis, immunization with conjugate vaccines to Hib or pneumococcal polysaccharide can be helpful in decreasing the frequency of infection including booster vaccination after the primary conjugate series has been administered. This is because antibody responses to conjugate polysaccharide vaccine tend to fall within the IgG1 subclass instead of the IgG2 subclass.

Prognosis

THI is a self-limited disorder with no long-term sequelae.

Most IgG subclass deficiency patients do well with appropriate supportive therapy and prophylactic antibiotics. Children under 10 years of age may recover spontaneously, whereas adults may progress to CVID. Children with selective antibody deficiency usually recover over time. Those who do not recover may develop CVID. Adults are more likely to have this condition indefinitely.

Prevention

Early diagnosis and proper treatment may prevent complications of infection and associated conditions.

125 T-Cell Immune Defects

Evelina Mazzolari · Luigi D. Notarangelo

T-cell immunodeficiency comprises a heterogeneous group of disorders with impaired development and/or function of T lymphocytes (◉ *Fig. 125.1*). The thymus is the primary lymphoid organs where development of T lymphocytes takes place, starting from a common lymphoid progenitor that originates from a bone-marow-derived hematopoietic stem cell. Within the thymus, several differentiation steps mark progressive maturation of thymocytes, and ultimately lead to generation of mature naïve T lymphocytes. The earliest stages of T-cell development are characterized by lack of CD4 and CD8 expression (double negative T cells). This is followed by co-expression of CD4 and CD8 molecules, along with expression of the T-cell receptor (TCR), at the double-positive (DP) stage of T-cell differentiation. Expression of the TCR enables positive selection of thymocytes in the thymic cortex, followed by further differentiation into single positive (SP) CD4 or CD8 thymocytes that migrate to the thymic medulla, where negative selection of self-reactive T cells takes place. Eventually, mature naïve T lymphocytes leave the thymus and reach the periphery, where they colonize the lymph nodes, the spleen, and patrol the skin, the mucosa, and peripheral tissues.

Development of T lymphocytes is under strict genetic control. Sigle-gene disorders that affect the early stages in T-cell development (up to DP stage of differentiation) are associated with Severe Combined Immune Deficiency (SCID), with lack of circulating T lymphocytes. Some of these genetic disorders may also compromise development of B and/or NK lymphocytes. Defects that affect later stages in T-cell development and/or function are also known as Combined Immune Deficiencies (CID), and are characterized by the presence of a variable number of circulating T lymphocytes. Finally, defects in the ontogeny of the thymus also compromise development of T lymphocytes. DiGeorge syndrome represents the prototype of such conditions. In this chapter, we will review the clinical features, pathophysiology, diagnostic approach, and treatment to human T-cell immunodeficiencies.

Severe Combined Immunodeficiencies (SCID)

Clinical Presentation

SCID include a heterogeneous group of genetic disorders characterized by inability to generate mature T lymphocytes. While some of these defects also affect development of B and/or NK lymphocytes, all forms of SCID are characterized by impaired humoral immunity, due to the lack of helper T-cell activity. Hence, the clinical presentation of SCID is marked by early onset and severe infections of bacterial, viral, or fungal origin. Opportunistic infections are very common. Interstitial pneumonia is very frequent and may be due to *P. jiroveci*, cytomegalovirus (CMV), adenovirus, parainfluenza 3, and respiratory syncitial virus (RSV). Chronic diarrhea typically leads to failure to thrive. Persistent candidiasis is also common. Typically, infections develop already in the first months of life, reflecting the essential role of T lymphocytes in mediating and orchestrating pathogen-specific immune responses. The early onset and the severity of infections in infants with SCID mark a clear difference vs. pure antibody deficiencies, whose clinical manifestations most often consist of recurrent bacterial infections, that tend to become more prominent when maternally derived immunoglobulins have disappeared. Skin manifestations (maculopapular rash, erythroderma, alopecia) may also be observed in patients with SCID, and often represent manifestations of immune dysregulation due to infiltration by maternal T lymphocytes that have engrafted into the fetus, or the presence of a residual number of autologous and activated T lymphocytes. Infants with SCID typically have hypoplastic lymphoid tissue (tonsils, lymph nodes), and absence of a thymic shadow can be demonstrated on chest X-ray. Additional features are characteristically associated with specific forms of SCID. For instance, microcephaly is present in most infants with SCID due to defects in DNA repair. Sensorineural deafness is observed in infants with reticular dysgenesis, but may also be present in patients with adenosine deaminase

(ADA) deficiency. Progressive neurological deterioration is often seen in patients with purine nucleoside phosphorylase (PNP) deficiency, and neurobehavioral problems are common also in ADA deficiency. ADA-deficient patients also often have flaring of the ribs at chest X-ray.

Pathogenesis and Genetics

SCID comprise a heterogeneous group of mendelian disorders, and their overall prevalence is estimated to be 1:50,000 to 1:100,000 births, with significant geographic variability. In Western countries, the most common form of SCID is inherited as an X-linked trait; however, a variety of autosomal recessive (AR) forms are also known. AR-SCID are more common in countries with higher consanguinity rate or among restricted ethnic groups.

The pathophysiology of the various forms of SCID reflects distinct defects in critical steps along T-cell development. In some cases, these defects may also involve additional blood lineages, including B and/or NK lymphocytes or myeloid cells, or may affect non-hematopoietic cells as well.

Increased apoptosis of lymphoid precursors is observed in reticular dysgenesis (RD), ADA deficiency, and PNP deficiency, three autosomal recessive forms of SCID. RD is due to mutations of the *AK2* gene, encoding for adenylate kinase 2. This defect is associated with perturbed homeostasis of ADP and ATP levels in mitochondria, resulting in increased cell death. The defect is not restricted to T lymphocytes, but also involves myeloid neutrophil progenitors and the inner ear, accounting for severe neutropenia and sensorineural deafness.

ADA and PNP are two enzymes of the purine salvage pathway. ADA converts adenosine (Ado) and deoxy-adenosine (dAdo) into inosine and deoxy-inosine, respectively. In the absence of ADA, high intracellular levels of Ado, dAdo, and their toxic phosphorylated metabolites cause apoptosis of lymphoid precursors, and hence result in the virtual absence of T lymphocytes that is usually associated with marked reduction of B and NK lymphocytes ($T^-B^-NK^-$ SCID). PNP catalyzes the phosphorylation of inosine, guanosine, and deoxyguanosine. In the absence of PNP, high intracellular levels of dGTP cause lymphoid and neuronal toxicity. Immature thymocytes are particularly susceptible to PNP deficiency. Accordingly, the immunological phenotype of PNP deficiency is characterized by decreased T-cell counts, whereas B and NK lymphocytes are often unaffected. Both ADA and PNP deficiency have extraimmune manifestations, reflecting the ubiquitous expression of these genes.

Interleukin-7 (IL-7)-mediated signaling plays a critical role in the expansion of early thymocyte progenitors, which express IL-7 receptor (IL-7R), composed of an IL-7R α chain and a common γ chain (γc), also shared by

receptors for IL-2, IL-4, IL-9, IL-15, and IL-21. In all of these receptors, the γc is coupled to the intracellular tyrosine kinase JAK3. In humans, defects of IL-7-mediated signaling abrogate T-cell development, whereas impaired signaling through IL-15R affects development of NK cells. X-linked SCID, due to *IL2RG* mutations, represents approximately 40% of all cases of SCID, and is characterized by lack of T and NK lymphocytes but normal development of B cells ($T^-B^+NK^-$ SCID). B lymphocyte function, however, is severely compromised by both the lack of T-cell help and γc. JAK3 deficiency is inherited as an autosomal recessive trait, and its phenotype is identical to that of X-linked SCID ($T^-B^+NK^-$ SCID). In contrast, autosomal recessive IL7R deficiency due to mutation of the α chain is characterized by the selective lack of T cells ($T^-B^+NK^+$ SCID).

Expression of the pre-T-cell receptor (pre-TCR), which is composed of a pre-Tα chain, a TCR β chain, and the CD3 γ,δ,ε, and ζ chains, marks the next step in T-cell development. Signaling through the pre-TCR permits rearrangement of the TCRα chain and expression of a mature TCRαβ. Alternatively, thymocytes may express the γδ chains of the TCR. Signaling through the TCR is essential for positive selection of cortical thymocytes. Defects in the mechanisms of assembly and signaling of the pre-TCR and TCR complexes result in SCID in humans. Rearrangement of the TCR loci is accomplished by means of the V(D)J recombination, whereby the lymphoid specific RAG1 and RAG2 proteins mediate DNA cleavage at the Variable (V), Diversity (D), and Joining (J) elements of the TCR loci. DNA Double Strand Breaks (DSB) at the coding ends are initially sealed as a hairpin, which are then resolved by Artemis (encoded by the *DCLRE1C* gene). Eventually, sealing of coding and signal joins is mediated by the Ku70/80 heterodimer, XRCC4, DNA ligase IV (LIG4), DNA-Protein Kinase catalystic subunit (DNA-PKcs), and Cernunnos/XLF. The V(D)J recombination process is essential not only in T cell development, but also for B cell development, where it mediates rearrangement at the immunoglobulin heavy and light chain loci. Hence, defects in any of the steps of the V(D)J recombination process cause $T^-B^-NK^+$ SCID. RAG1 or RAG2 deficiencies are the most common V(D)J recombination defect and account for about 10% of all forms of SCID. Defects in Artemis, DNA-PKcs, LIG4, and Cernunnos/XLF are less frequent. Importantly, while expression of the *RAG1* and *RAG2* genes is restricted to lymphocytes, Artemis, DNA-PJcs, LIG4, and Cernunnos/XLF are ubiquitously expressed and mediate nonhomologous end joining (NHEJ) DNA repair. Accordingly, deficiency in any of these proteins is associated with increased cellular radiosensitivity and extraimmune clinical manifestations (microcephaly, growth and developmental defects, increased risk of malignancies).

The CD3 δ,ε, or ζ chains represent the signaling elements of the pre-TCR and of the TCR. Defects in these molecules cause autosomal recessive $T^-B^+NK^+$ SCID. In contrast, CD3γ deficiency is associated with mild T-cell lymphopenia and a variable clinical phenotype.

CD45 is a tyrosine phosphatase that is also involved in signaling through the TCR and the B-cell receptor (BCR). CD45 deficiency has been reported in few patients with $T^-B^+NK^+$ SCID.

Diagnostic Approach

Diagnosis of SCID is based on clinical and family history and on typical laboratory features. Presentation early in life with severe infections, especially if sustained by opportunistic pathogens, should always prompt to consider SCID as a possible diagnosis. Family history should be addressed to document other male subjects on the maternal side who presented and/or died with severe infections early in life (suggestive of a possible X-linked form of the disease) or the presence of parental consanguinity (indicative of possible autosomal recessive inheritance). Laboratory investigation should be primarily based on careful evaluation of the absolute lymphocyte count (ALC), and values should be compared with age-matched controls. The vast majority of infants with SCID present with severe lymphopenia. If the ALC is $<2{,}000/mm^3$, analysis of lymphocyte subsets should be immediately performed. Typically, infants with SCID have markedly reduced or absent circulating T cells. Depending on whether the development of B and/or NK lymphocytes is also affected, SCID can be classified into distinct immunological phenotypes: (a) $T^-B^+NK^-$ SCID (the most common variant), (b) $T^-B^+NK^+$ SCID, (c) $T^-B^-NK^+$ SCID, or (d) $T^-B^-NK^-$ SCID. These different immunological phenotypes reflect distinct genetic defects (*Table 125.1*) and thus may guide in the molecular diagnosis. However, a normal ALC does not rule out SCID, if suggestive clinical features are present. In particular, subnormal or even normal ALC in SCID may reflect maternal T-cell engraftment, a phenomenon observed in more than 50% of infants with SCID. Most often asymptomatic, it may cause skin rash or, less frequently, typical graft-versus-host disease (GvHD) with generalized rash, liver disease, profuse diarrhea, jaundice, and cytopenias (thrombocytopenia, anemia, leukopenia) due to bone

Table 125.1
Molecular basis of SCID, divided by immunological phenotype

Immunological phenotype	Underlying molecular defect	Inheritance

	AK2	AR

XL: X-linked; AR: autosomal recessive

marrow damage. The presence of detectable T lymphocytes in peripheral blood in infants with SCID may also reflect hypomorphic mutations or somatic reversions in SCID-causing genes, which allow for residual development of autologous T cells, resulting in a "leaky" SCID phenotype. Characteristically, maternally engrafted T lymphocytes in patients with SCID, and autologous T cells in patients with leaky SCID, express the CD45R0 memory/activation antigen on their membrane, whereas most T cells in normal infants have a naive $CD45RA^+$ phenotype. Furthermore, autologous activated T cells in infants with leaky SCID have a restricted TCR repertoire, as indicated by expression of a limited set of TCR Vβ families with a restricted diversity of CDR3 length. Lymphocytes from SCID infants fail to proliferate in vitro to mitogens and specific antigens. Patients with PNP deficiency often show progressive decline of T lymphocyte number and function, and are at increased risk for autoimmune hemolytic anemia. Ineffective thymopoiesis in patients with SCID is also marked by very low or undetectable levels of T-cell receptor excision circles (TRECs) in circulating lymphocytes. TRECs are a by-product of V(D)J recombination that consist of circularized signal joins and are maintained in newly generated mature T lymphocytes that leave the thymus. Because TRECs cannot be detected in infants with SCID, assessment of TREC levels by polymerase chain reaction has been proposed for newborn screening for SCID.

Regardless of the presence or absence of circulating B lymphocytes, patients with SCID show hypogammaglobulinemia. However, normal IgG levels may be observed early in life, reflecting transplacental passage of maternal immunoglobulins. Specific antibody responses to immunization antigens are abolished. However, humoral immunity may be spared in patients with PNP deficiency.

Eosinophilia and elevated IgE levels are common, especially in patients with leaky SCID, whereas infections may associate with anemia, thrombocytopenia, and/or neutropenia. Bone marrow dysplastic changes may be observed, especially in patients with Cernunnos/XLF or with LIG4 deficiencies.

Differential diagnosis of SCID includes secondary forms of immunodeficiencies, especially HIV infection. Congenital rubella or CMV infections, severe malnutrition, and defects of vitamin B12 and folate metabolism may also mimic the SCID phenotype.

Treatment

SCID are inevitably and rapidly fatal unless immune reconstitution is attained by means of treatment. Treatment of active infections and initiation of appropriate laboratory testing should be immediately performed in infants with possible SCID. *P. jiroveci* pneumonia is usually treated with high-dose intravenous sulfamethoxazol/trimethoprim (20 mg/kg). CMV or adenoviral infections must be treated with gancyclovir or cidofovir, respectively. Administration of antitubercular Bacillus Calmette-Guerin (BCG) immunization at birth carries risk of BCGosis, and should prompt treatment with isoniazid and rifampicin, regardless of the presence of clinical signs of infection. Regular use of intravenous immunoglobulins and antimicrobial prophylaxis are part of the mainstay of therapy. Enteral or parenteral nutrition may be required in infants with chronic diarrhea and malnourishment.

Live-attenuated vaccines should not be administered to infants with SCID because of the risk of disseminated infection due to vaccine strain (59–61). All blood products should be irradiated to avoid fatal transfusional graft-versus-host disease (GvHD):

Ultimately, survival of SCID infants depends on attainment of robust immune reconstitution. Hematopoietic cell transplantation is the treatment of choice, and was successfully used for the first time in humans in a patient

with X-linked SCID. Excellent results, with >90% long-term survival, have been obtained with HCT from HLA-identical family donors, with no need of pre-transplant chemotherapy. However, this option is available only to 15–20% of patients. Excellent results without chemotherapy have been reported also after haploidentical transplantation, if performed in the neonatal period or in the first 3.5 months of life; however, survival is only 50–65% if haploidentical HCT is performed at a later age. Promising results have been reported with HCT from matched unrelated donors (MUD) and unrelated cord blood (UCB). Although graft rejection should not be possible in infants with SCID (making the use of pre-transplant chemotherapy not necessary), engraftment and immune reconstitution are problematic in recipients of haploidentical HCT, especially for $T^-B^-NK^+$ SCID, ADA deficiency, and reticular dysgenesis. Furthermore, B-cell reconstitution may not be achieved, unless pre-transplant conditioning that favors engraftment of donor stem cells is used.

Most patients with SCID enjoy good quality of life after transplant, however infections, autoimmune/inflammatory complications, and GvHD are observed in a significant fraction of patients. ADA or PNP deficiency and SCID with increased cellular radiosensitivity are at particularly higher risk for these complications, and for neurological and developmental problems, even if successful T-cell reconstitution is achieved.

For patients with ADA deficiency, an alternative form of treatment is represented by enzyme replacement therapy with weekly intramuscular injections of pegylated bovine ADA, although T-cell counts often remain low, in spite of successful detoxication.

Gene therapy has led to immune reconstitution in infants with X-linked SCID or with ADA deficiency; however, 5 out of 20 patients with X-linked SCID treated by gene therapy have developed leukemic proliferation due to insertional mutagenesis.

Other Combined Immunodeficiencies

Combined immune deficiencies (CID) include disorders with residual ability to support T-cell development and/or function. They may be due to either: (a) hypomorphic mutations in SCID-causing genes that allow for some T-cell development or (b) genetic defects that affect late stages in T-cell development or peripheral T-cell function. The clinical features of CID overlap with SCID, but also include autoimmunity and/or inflammatory manifestations reflecting unbalanced immune homeostasis.

Omenn Syndrome

Omenn syndrome (OS) is characterized by severe infections associated with early-onset generalized skin rash/erythroderma, alopecia, lymphadenopathy, hepatosplenomegaly, eosinophilia, and oligoclonal expansion of anergic, activated autologous T lymphocytes that infiltrate and damage target tissues. Serum immunoglobulins are usually very low, but IgE levels are increased. Hypoproteinemia is common, leading to edema. OS is associated with hypomorphic mutations in SCID-causing genes that allow for residual T-cell development. The few T cells that are generated in the thymus undergo extensive homeostatic proliferation in the periphery. Poor thymopoiesis in OS causes abnormalities of thymic stroma, with impairment in the mechanisms of negative selection of autoreactive T cells and of generation of regulatory T cells. These abnormalities contribute to the immunopathology of OS. Mutations in *RAG1* and *RAG2* are the most common genetic defect in OS; however, mutations in *DCLRE1C* (Artemis), *IL7R*, *LIG4*, *RMRP*, *IL-2RG*, *ADA*, and *ZAP70* have been also reported.

Patients with OS have a variable number of circulating T lymphocytes that carry a characteristic activated/memory ($CD45R0^+$) phenotype and have a restricted repertoire. The distribution of CD4 and CD8 subsets is generally skewed. The in vitro lymphocyte response to antigens is abolished; responses to mitogens are variable, but are often reduced. Depending on the nature of the underlying genetic defect, B and NK lymphocytes may be absent or present.

Differential diagnosis includes maternal T-cell engraftment and complete atypical DiGeorge syndrome. HCT represents the mainstay of treatment. In preparation for HCT, aggressive treatment of infection, nutritional support, correction of hypoproteinemia, and immune suppression with steroids and/or cyclosporine A to control extensive T-cell-mediated tissue damage are necessary.

ZAP-70 Deficiency

The Zeta-associated protein of 70 kDa (ZAP-70) is an intracellular kinase that is involved in TCR-mediated signaling. In humans, mutations of the *ZAP70* gene result in autosomal recessive CID with selective deficiency of CD8+ T cells. $CD4^+$ lymphocytes are present, but are functionally impaired. Variable defects have been reported in immunoglobulin levels and antibody responses. Clinical features do not differ from what observed in

SCID, however lymph nodes are palpable, and the thymus can be visualized by chest X-ray.

Differential diagnosis includes MHC class I deficiency and CD8α deficiency, two conditions also characterized by a severe reduction of $CD8^+$ lymphocytes (110, 111). The only curative treatment of ZAP-70 deficiency is HCT.

MHC Class I Deficiency

MHC class I deficiency is an autosomal recessive disorder, characterized by reduced expression of MHC class I molecules at the cell surface. It is caused by defects in the *TAP1* (112), *TAP2* (113), or Tapasin (114) genes, which encode for molecules involved in intracellular loading of peptide antigens MHC class I molecules, and cell surface expression of the complex.

Patients with MHC class I deficiency suffer from recurrent respiratory infections, chronic inflammatory lung disease, and skin lesions that resemble Wegener's granulomatosis. The number of circulating $CD8^+$ T cells is reduced because positive selection of $CD8^+$ lymphocytes in the thymus depends on the recognition of MHC class I molecules. In vitro lymphocyte proliferation is normal, facilitating differential diagnosis with ZAP-70 deficiency, and accounting for a less severe clinical phenotype. Levels of serum immunoglobulin may be variable.

Antibiotic prophylaxis to prevent recurrent respiratory infections, and topical treatment of the cutaneous granulomatous lesions, are the mainstay of treatment.

MHC Class II Deficiency

MHC class II molecules are constitutively expressed by B lymphocytes, monocytes, and dendritic cells, but may also be expressed by other cells (T lymphocytes, endothelial and certain epithelial cells) upon activation. Recognition of MHC class II molecules in the thymus promotes positive selection of $CD4^+$ thymocytes. In the periphery, recognition of antigens in the context of MHC class II molecules is essential to elicit $CD4^+$ T-cell-mediated responses.

MHC class II deficiency is inherited as an autosomal recessive trait and is caused by mutations in any of four different genes (*CIITA*, *RFXANK*, *RFX5*, and *RFXAP*) that encode for transcription factors that control MHC class II genes expression.

The clinical phenotype is marked by increased susceptibility to bacterial, viral, and opportunistic respiratory tract infections; chronic diarrhea; and sclerosing cholangitis, often secondary to *Cryptosporidium* or CMV infection. However, less severe presentations and survival into adulthood have been also reported.

The number of circulating $CD4^+$ T cells is markedly reduced, reflecting an impairment of positive selection in the thymus. Delayed-type hypersensitivity responses are absent, but in vitro proliferative responses to mitogens are preserved. Hypogammaglobulinemia and poor antibody response to immunization are also present. Differential diagnoses include HIV infection and idiopathic CD4 lymphopenia. Both these conditions are characterized by a reduced number of circulating $CD4^+$ lymphocytes; however, expression of MHC class II molecules is preserved.

Most patients with MHC class II deficiency die in their first years of life of severe infections. Antibiotic prophylaxis, immunoglobulin replacement therapy, and adequate nutritional support are an important part of treatment, but definitive cure can be only achieved with HCT. However, the results of HCT for this disease are far less satisfactory than in other forms of severe T-cell immunodeficiency.

Defects of Thymocyte Egress and of Lymphocyte Activation

Once they have completed their intrathymic maturation, T lymphocytes are exported to the periphery. This process requires active cytoskeleton reorganization. Coronin 1A is an actin regulator that plays a key role in regulating thymocytes egress and trafficking of naïve T lymphocytes to secondary lymphoid organs. Coronin 1A mutations have been shown to cause peripheral T-cell lymphopenia and severe and recurrent infections. The disease can be cured by HCT.

In the periphery, activation of T lymphocytes requires mobilization of intracellular calcium stores and influx of extracellular calcium across calcium-release activation channels (CRACs). Mutations of Orai1 (a component of CRAC channels) and of Stim1 (a sensor of Ca^{2+} concentration in the endoplasmic reticulum) have been identified in patients whose clinical features resembled SCID, associated with non progressive myopathy autoimmune cytopenias. In these patients, the number of circulating T lymphocytes is normal, but in vitro proliferation to mitogens is drastically decreased. The disease is fatal, unless immune reconstitution is achieved following HCT. However, myopathy persists.

Defects of Thymic Development

DiGeorge Syndrome

The DiGeorge Syndrome (DGS) is a disorder caused by impaired migration of neural crest cells of the third and fourth pharyngeal arches during early embryonic development. This abnormality causes impaired formation of the thymus and of the parathyroid glands, defects of the aortic arch, and facial dysmorphisms. However, significant variability of the clinical phenotype, and especially of the immunological phenotype, can be observed. Neonatal hypocalcemia is characteristic and reflects hypoparathyroidism. Approximately 80% of infants with DGS require calcium supplementation and/or treatment with calcitriol; however, hypoparathyroidism often resolves during the first year of life due to hypertrophy of residual parathyroid tissue. Cardiac malformations affect the outflow tract in particular. Interrupted aortic arch, Fallot's tetralogy, and truncus arteriosus are particularly common. Facial dysmorphisms include low-set ears with abnormal folding of the pinna, short nasal philtrum, and micrognathia. Velopharyngeal insufficiency is also very common. Feeding difficulties, mostly due to esophageal dysmotility and gastroesophageal reflux, may represent a significant concern. Laryngomalacia and aspiration pneumonia are common. During adult life, psychiatric and behavioral problems have been frequently diagnosed.

The immunodeficiency is an important component of DGS, but its severity is variable. Most patients present with *partial DiGeorge syndrome*, characterized by mild to moderate immune deficiency, with a low but detectable number of circulating T lymphocytes. The *complete DiGeorge syndrome* phenotype consists of congenital cardiac defects, hypocalcemia due to parathyroid insufficiency, and profound T-cell immune deficiency as a consequence of thymic aplasia. Finally, a few patients with DGS may present with an atypical phenotype characterized by a pronounced erythematous rash and lymphadenopathy, associated with oligoclonal, activated, and anergic T cells. This phenotype, which mimics Omenn syndrome, is also known as *complete atypical DiGeorge syndrome*. The different degrees of immunological impairment in patients with DGS dictate the spectrum of clinical manifestations related to immune dysfunction. Oral thrush and recurrent infections are common; however, patients with complete and atypical complete DGS suffer from early onset and severe infections (*P. jiroveci* pneumonia, interstitial pneumonia, or disseminated infections of viral origin) and warrant immediate attention. Autoimmune manifestations are also relatively common in patients with DGS.

DGS may be sustained by different mechanisms. Hemizygous deletion of chromosome 22q11.2 accounts for DGS in 55–65% of the patients. CHARGE association is responsible for about 25% of the cases of DGS, whereas diabetic embryopathy and monosomy of chromosome 10p have been documented in 15% and 2% of the patients, respectively. The 22q11.2 region contains the TBX1 gene that encodes for a transcription factor; isolated mutations of this gene have been identified in a few patients with DGS.

Diagnosis of DGS is based on typical clinical features, and should not be restricted to patients with 22q11 deletion, that can be demonstrated by FISH. ALC and enumeration of CD3 count is important to define the degree of immunological impairment. In most cases, variable CD3 lymphopenia is documented; however, a severe deficiency of circulating T cells is typical of complete DGS. The total CD3 count can be normal in patients with atypical complete DGS, but in these cases the circulating CD3+ T cells co-express activation (CD45R0, DR, CD25) antigens, there are very few if any recent thymic emigrants ($CD4^+$ $CD45RA^+$ $CD31^+$) in the peripheray, and the TCR repertoire of circulating T cells is severely restricted. In vitro proliferative responses are most often normal in patients with partial DGS, but are significantly reduced in the most severe cases. Most patients with DGS have normal immunoglobulin levels and antibody responses; however, impairment of humoral immunity can be also observed. Treatment of DGS consists of correction of congenital heart defects, when present, and of hypocalcemia. Depending on the severity of the immune deficiency, patients may require antibiotic prophylaxis; IVIG replacement therapy may be needed in selected cases. However, complete DGS (including atypical presentation) is associated with a very high mortality rate early in life. In such cases, survival strictly depends on immune reconstitution. Thymic transplantation is the treatment of choice. The thymus, usually obtained from infants undergoing partial thymectomy at the time of heart surgery, is sliced, cultured, and then implanted in the quadriceps muscle. T cells develop approximately 4–5 months after thymic transplantation in patients with complete DGS, and 1-year survival is close to 75%. Patients with complete atypical DGS often require immune suppression prior to thymic transplantation, to control the effects of activated and oligoclonal T cells. Unmanipulated bone marrow transpplantation from HLA-identical related donors has been also used with success in infants with complete DGS; in these cases, long-term immune reconstitution has been

provided by mature T cells contained in the graft, which have expanded and persisted for up to 20 years.

FOXN1 Deficiency

The transcription factor FOXN1 is essential to promote differentiation of thymic epithelial cells. In mice, Foxn1 mutations are associated with the nude/scid phenotype, with lack of circulating T cells and of hair. Mutations of the FOXN1 gene have been identified in Italian siblings who presented with severe infections, alopecia, and nail dystrophy. One of the affected siblings also showed features of Omenn syndrome. The immunological phenotype consisted of T-cell lymphopenia that involved predominantly the $CD4^+$ subset. Immune reconstitution was obtained in one of the siblings following unmanipulated bone marrow transplantation from her healthy HLA-matched brother.

Conclusions

Irrespective of the specific diagnosis, all forms of T-cell immunodeficiencies are characterized by significant morbidity and some of them also by high early-onset mortality rates, thus emphasizing the critical role played by T lymphocytes in ensuring effective immune defense mechanisms and in maintaining homeostasis. Therefore, accurate clinical and laboratory evaluation are critically important in patients with a putative T-cell immunodeficiency. Whereas the clinical and family history and physical examination may disclose the diagnosis in some forms of T-cell immunodeficiency, laboratory evaluation is most often required to provide a definitive diagnosis. Simple laboratory assays (total lymphocyte count and subsets distribution, in vitro proliferative responses) are usually sufficient to confirm the suspicion. Some forms of T-cell immunodeficiencies, and SCID in particular, represent true medical emergencies that warrant prompt and accurate evaluation and early treatment by HCT.

126 Immune Dysregulation Disorders

Thomas A. Fleisher

Appropriate activation of the immune system in response to a microorganism is an absolute requirement for normal host defense. However, down regulation following an appropriate immune response is also an essential process to insure that the host does not suffer unnecessary and/or protracted inflammation and its consequences. In addition, normal homeostasis also requires the immune system develops in such a manner that it is not directly reactive against self. These processes fall under the general concept of immune homeostasis and include control mechanisms that prevent immunologic responses to self as well as control the extent of immune activation. Central to the prevention of auto-reactivity is a complex set of processes referred to as immunologic tolerance. These involve central tolerance that occurs in primary lymphoid organs (thymus, bone marrow) resulting in the eliminatation of self-reactive cells and peripheral mechanisms that maintain immunologic tolerance at the site of immunologic reactions. It is now clear that this homeostatic or regulatory side of the immune system is also subject to congenital defects that result in immune dysregulation disorders and these are typically accompanied by autoimmunity with or without increased susceptibility to infection. These "experiments of nature" represent prototypic disorders that provide important insights into mechanisms required for tolerance and the control of immune responses. In this chapter, congenital disorders that impact central deletion of autoreactive T cells in the thymus as well as those that impact other mechanisms involved in the maintenance of tolerance in the periphery will be discussed. In all of these disorders the clinical phenotype includes autoimmunity together with other manifestations of immune dysfunction.

Autoimmune Polyendocrinopathy, Candidiasis, Ectodermal Dystrophy (APECED)

APECED (OMIM #240300) is a rare, autosomal recessive disorder of defective central immune tolerance that is found disproportionately in individuals with Finish, Sardinian, and Iranian Jewish backgrounds. It is characterized by systemic autoimmunity that primarily affects endocrine organs, particularly the parathyroid and adrenal glands. Hypoparathyroidism, adrenal insufficiency, and chronic mucocutaneous candidiasis typically characterize the syndrome but patients may also develop type 1 diabetes, gonadal failure, pernicious anemia (secondary to atrophy of gastric parietal cells), autoimmune hepatitis, and other cutaneous manifestations.

Genetics and Immunopathogenesis

APECED is caused by mutations in the gene encoding the autoimmune regulator (AIRE) protein, a transcription factor that plays a role in ectopic expression of tissue-specific antigens expressed by thymic medullary epithelial cells (mTEC). Based on experimental models, this gene appears to play a significant role in facilitating the elimination of autoreactive T cells within the thymus before exit into the peripheral circulation where they could cause autoimmunity. Recent data suggest that AIRE also may play a role in the generation of functional regulatory T (T_{REG}) cells that act as immunologic suppressor cells suggesting that APECED may not only have a defect in central tolerance but also deficient peripheral mechanisms for maintaining tolerance.

Diagnosis and Treatment

APECED should be suspected in patients who have two of the following three primary symptoms: hypoparathyroidism (typically presenting as hypocalcemia), adrenal insufficiency, and mucocutaneous candidiasis. Suspicion is raised further by the presence of other autoimmune manifestations including diabetes, gonadal insufficiency, hepatitis, and pernicious anemia. There are no specific standard diagnostic lab tests and the definitive diagnosis can only be made by sequencing the *AIRE* gene.

Therapy for APECED is generally focused on symptomatic treatment including calcium supplementation, steroid replacement, as well as management of diabetes and other endocrinopathies. Mucocutaneous candidiasis

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_126,

can be a problem in that it often persists and can cause significant morbidity as well as increase the risk of oral malignancies. Over time, the Candidal species may become resistant to azole antifungals, further complicating long-term management. Immunosuppressants are not routinely used in APECED unless patients develop autoimmune hepatitis or renal disease in which case, azathioprine and cyclosporine A have shown benefit. Bone marrow transplantation generally has not been considered for APECED, even in severe cases.

Box 1: Key Concepts

Autoimmune Polyendocrinopathy, Candidiasis, Ectodermal Dystrophy (APECED)

- Hypoparathyroidism, adrenal insufficiency, and chronic mucocutaneous candidiasis typically characterize the syndrome
- Patients may also develop type 1 diabetes, gonadal failure, pernicious anemia, autoimmune hepatitis, and other cutaneous manifestations
- Autoimmunity due to a failure of central tolerance as a result of a defect in the gene encoding the autoimmune regulator (AIRE) protein

Immune Dysregulation, Polyendocrinopathy, Enteropathy, X-Linked (IPEX)

IPEX syndrome (OMIM #304930) is a rare X-linked recessive disorder that presents with a clinical triad including autoimmune enteropathy, early onset endocrinopathy, and dermatitis. The enteropathy typically presents very early in life as watery diarrhea, frequently resulting in malnutrition and failure to thrive. Type I diabetes is the most common endocrinopathy but clinical and/or laboratory evidence of thyroiditis is common as well. Eczema is the most common dermatitis in IPEX but erythroderma, psoriasiform dermatitis, and pemphigoid nodularis have also been observed.

In addition to the "IPEX-triad," most patients with IPEX also have other associated autoimmune disorders including autoimmune hemolytic anemia, thrombocytopenia, neutropenia, nephropathy, or hepatic disease (Torgerson & Ochs, unpublished data). These conditions contribute substantially to the morbidity of patients with IPEX and increase the risk of death from disease. Patients with the classical form of the disease typically die secondary to malnutrition, electrolyte imbalances, or infection before the age of 2 years unless treated with aggressive immunosuppression.

Genetics and Immunopathogenesis

IPEX is caused by mutations in FOXP3, a protein expressed by T_{REG} cells that act to suppress the immune response and in this capacity provide a critical means of maintaining immunologic tolerance in the periphery. Recent studies have demonstrated that FOXP3 is required for T_{REG} cells to develop suppressor function. A great deal of work remains to identify the key FOXP3-regulated gene (or genes) that confers suppressor function on T_{REG} cells.

Diagnosis and Treatment

IPEX is generally suspected in any patient who demonstrates at least two of the three basic clinical features of IPEX including enteropathy, endocrinopathy (type I diabetes or thyroiditis), and dermatitis. Evaluation for the expression of the FOXP3 protein in T_{REG} cells using flow cytometry is a valuable tool to rapidly screen for the absence of T_{REG} cells. Currently, identification of a mutation in *FOXP3* represents the definitive means for establishing the diagnosis of IPEX. This is complicated by the fact that in centers with substantial experience with IPEX, mutations are identified in less than 50% of patients in whom there is a clinical suspicion of disease. Patients with normal *FOXP3* analysis are often categorized as "IPEX-like" and generally have a somewhat less severe clinical phenotype. From a clinical laboratory standpoint, the most consistent abnormality among patients with IPEX is markedly elevated IgE, which is present in the majority of cases while "IPEX-like" patients tend to have normal or minimally elevated IgE levels.

Treatment of IPEX focuses primarily on suppression of the unregulated immune system using cyclosporine A, tacrolimus (FK506), or sirolimus (Rapamycin). These are often combined with steroids and/or other immunomodulatory agents and in cases where there is evidence for pathogenic autoantibodies; Rituximab (anti-CD20) has also proven to be effective in dampening the dysregulated inflammatory response. These therapies are often effective initially but long-term cure is currently only achievable with hematopoietic stem cell transplantation. Rapid diagnosis and transplantation early in the course of disease, before the pancreatic islet cells are destroyed, should be the therapeutic goal in IPEX.

Box 2: Key Concepts

Immune Dysregulation, Polyendocrinopathy, Enteropathy, X-Linked (IPEX)

- Clinical triad of autoimmune enteropathy, early onset endocrinopathy (diabetes and/or thyroid disease), and dermatitis (typically eczema)
- Often also associated with autoimmune hemolytic anemia, thrombocytopenia, neutropenia, nephropathy, or hepatic disease
- Results from a defect in the gene encoding FOXP3 resulting in an absence of T regulatory (T_{REG}) cells
- Highly lethal and hematopoietic stem cell transplantation is currently the only curative therapy

Defects in IL-2 Signaling

Recognition that experimental animals lacking CD25 (the α-chain of the three protein chain high-affinity receptor for IL-2) have a phenotype similar to IPEX raised the possibility that defects in IL-2 signaling in humans might lead to an IPEX-like presentation. This hypothesis is now supported by findings in a small number of patients with defective IL-2 signaling.

CD25 Deficiency

Two unrelated patients with CD25 deficiency (OMIM #606367) have been described. Similar to the clinical manifestations of IPEX, both patients developed severe, chronic diarrhea and villous atrophy in infancy (one at 6 weeks and the other at 8 months of age). One also developed early-onset insulin-dependent diabetes and later developed eczema. Subsequently, both patients developed autoantibodies, hepatosplenomegaly, lymphadenopathy, and lymphocytic infiltrates in various organs (e.g., gut, liver) indicative of ongoing immune dysregulation. In addition to autoimmune features, both CD25-deficient patients had infectious complications including recurrent CMV pneumonitis suggestive of a more extensive defect in cellular immunity that rendered the patients susceptible to opportunistic organisms.

Genetics and Immunopathogenesis

In each case, inheritance was found to be autosomal recessive leading to a complete lack of CD25 protein expression on activated T cells. Animal studies suggest that the failure to express CD25 is associated with a defect in the survival, maintenance, and competitive fitness of mature T_{REG} cells associated with immune dysregulation as well as defects in T cell responsiveness that underlie the immune deficiency that is seen in these very rare patients.

Diagnosis and Treatment

Both patients lacked CD25 expression on T cells suggesting that flow cytometry to evaluate expression of this protein should be an effective screening tool to identify CD25-deficient patients. Sequencing of the *CD25* gene, however, is recommended to confirm the diagnosis. Because of the "severe combined immunodeficiency (SCID)-like" features of this syndrome, one patient underwent a successful hematopoietic stem cell transplant from a matched sibling donor and has done well. It is possible, however, that patients may respond to IL-2 therapy at an appropriately modified dose based on the deficiency of the high-affinity IL-2 receptor although this has not been proven to date.

STAT5b Deficiency

Deficiency of STAT5b (OMIM #245590) causes a rare autosomal recessive disorder reported in only a small number of patients. STAT5b is an intracellular protein that mediates signaling by various growth factors (including cytokines). In this disorder, the most recognizable clinical features are dwarfism, a prominent forehead, a saddle nose, and a high-pitched voice. STAT5b is also critical in mediating the response of T cells to IL-2 so most of these patients also have a marked immunodeficiency similar to SCID, with recurrent Varicella virus, Herpes virus, and *Pneumocystis jiroveci* infections.

In addition to frank immunodeficiency, most patients who lack functional STAT5b also have symptoms suggestive of immune dysregulation including chronic, early onset diarrhea, eczema, and lymphocytic interstitial pneumonitis.

Genetics and Immunopathogenesis

This is an autosomal recessive disorder and patients studied to date have markedly reduced or absent STAT5b expression. In addition, these patients had significantly fewer T_{REG} cells than normal individuals and these cells

failed to demonstrate in vitro suppressive activity suggesting that maintenance of peripheral tolerance is likely abnormal in these patients.

Diagnosis and Treatment

Diagnosis of STAT5b deficiency is suspected in patients with the overt physical features of dwarfism combined with evidence of a significant immunodeficiency. Patients typically have normal serum growth hormone levels but very low insulin-like growth factor-1 (IGF-1) levels. Sequencing of the *STAT5b* gene should be done to confirm the diagnosis.

Treatment of patients with STAT5b deficiency is generally focused on symptomatic therapy and prophylaxis against infections. Hematopoietic stem cell transplantation has not been reported in this disorder although one would predict that the immune deficiency and immune dysregulation would be corrected by this therapy but that the non-immunologic problems would not.

Autoimmune Lymphoproliferative Syndrome (ALPS)

In 1967, Canale and Smith described a group of patients who presented in early childhood with generalized lymphadenopathy and hepatosplenomegaly associated with autoimmune anemia, thrombocytopenia, and increased gammaglobulins. In 1992, patients with similar features were noted to have a marked increase in a unique T cell referred to as an α/β–double-negative T (DNT) cell that normally constitutes a very small proportion of the peripheral lymphocytes. These patients had autoimmunity and lymphadenopathy as noted in the original description together with the expansion of α/β-DNT cells leading to the hypothesis that they had a disorder equivalent to the phenotype of certain murine models of autoimmunity. This led to an extensive evaluation based on the findings in the animal models that revealed an underlying defect in programmed cell death (apoptosis), one mechanism that plays a role in regulating the immune response.

The typical clinical course in ALPS (OMIM #601859) begins within the first 5 years of life with nonmalignant peripheral lymphadenopathy that is often associated with splenomegaly and hypersplenism that may necessitate splenectomy. Clinically apparent autoimmunity most commonly presents as autoimmune hemolytic anemia either alone or together with idiopathic thrombocytopenic purpura (ITP). Some ALPS patients may also develop neutropenia that can be immunologically mediated or secondary to hypersplenism. Dermatologic findings may be seen in ALPS, with urticarial rashes being the most common. Although less common, other autoimmune disorders may be present in ALPS including glomerulonephritis, polyneuropathy, autoimmune hepatitis, and Guillain–Barre syndrome. Perhaps the most life-threatening manifestation of ALPS is the dramatically increased incidence of lymphoma in individuals with *FAS* mutations, with an increased relative risk of 51-fold for Hodgkin disease and 14-fold for non-Hodgkin lymphoma.

Genetic and Immunopathogenesis

The majority (~65%) of ALPS patients have germline heterozygous (single allele) mutations in *FAS* with the site of the mutation having a direct impact on the development of disease manifestation. Recently, somatic mutations in *FAS*, affecting primarily DNT cells with variable presence in other leukocytes have been described in some patients with sporadic ALPS. The current classification scheme for ALPS is:

- ALPS-FAS: germline mutation in the gene encoding Fas *(TNFRSF6)*
- ALPS-sFAS: somatic mutation in the gene encoding Fas
- ALPS-FASLG: mutation in the gene encoding FasL *(TNFSF6)*
- ALPS-CASP10: mutation in the gene encoding caspase 10 *(CASP10)*
- ALPS-U: no known mutation
- RALD (RAS associated autoimmune leukoproliferative disorder): somatic mutation in the genes encoding NRAS (*NRAS*) or KRAS (*KRAS*)

Diagnosis and Treatment

The constellation of clinical and laboratory findings in ALPS patients is rather unique. However, the initial presentation of lymphadenopathy often raises the issue of malignancy that generally requires a biopsy to differentiate between these two diagnoses. The initial findings can also be suggestive of a chronic viral infection such as Epstein–Barr virus (EBV), although there are no serologic studies or in situ hybridization data that support a role for EBV in ALPS. The autoimmunity seen in ALPS patients is most commonly directed against red blood cells and platelets.

The laboratory findings include immunophenotyping that typically reveals peripheral lymphocytosis with expansion of αβ-DNT cells together with other changes in lymphocytes. A polyclonal increase in serum immunoglobulins is seen in virtually all patients. Typically, in the setting of autoimmune hemolytic anemia the direct Coombs' test is positive while autoantibodies directed to platelets and neutrophils are also found but may not directly correlate with the clinical manifestations of thrombocytopenia or neutropenia. Many of the laboratory findings associated with the autoimmunity do not distinguish patients with ALPS from those who do not have this disorder in that there is a broad range of autoantibody specificities observed. Interestingly, serum vitamin B12 levels are elevated in most ALPS patients, for unknown reasons. There also are markedly elevated serum levels of IL-10 and soluble Fas ligand (sFasL) in ALPS patients and these findings appear to correlate best with mutations affecting *FAS*. Finally, the histological findings of the enlarged lymph nodes are unique and typical for ALPS.

The initial diagnostic triad for ALPS was nonmalignant lymphoaccumulation, defective in vitro lymphocyte apoptosis, and increased levels of αβ-DNT cells. Flow cytometric evaluation of peripheral blood lymphocytes is necessary to evaluate increased levels of αβ-DNT cells. The assessment of lymphocyte apoptosis is only available in specialized centers and hence the identification of a disease associated genetic defect is now an alternative disease criteria (see Box 3).

The lymphoid expansion typically diminishes with age; thus, therapy directed at this feature of ALPS is generally not necessary. The finding of splenomegaly is often associated with hypersplenism, and splenectomy has commonly been performed among the ALPS patients referred to our institution. Because overwhelming infection with *Strep. pneumoniae* has been observed in ALPS patients postsplenectomy (perhaps at a higher rate than in other postsplenectomy patients), it is important to provide prophylactic antibiotic and vaccination protection in this setting. The autoimmune cytopenias typically respond to corticosteroids; this therapy is also associated with a decrease in lymphadenopathy but this rapidly reappears after discontinuation of therapy. Exacerbations of ALPS-related thrombocytopenia are not uncommon and these may become resistant to conventional therapy. The response to intravenous immunoglobulin therapy is less satisfactory than in childhood ITP cases. Preliminary data suggest that mycophenolate mofetil may be useful in the treatment of ALPS patients with ITP who are unresponsive to standard therapy. Importantly, the increased risk for the development of lymphoma appears to be lifelong and careful vigilance is required to monitor for this complication in all family members known to have *FAS* mutations.

Box 3: Key Concepts

Autoimmune Lymphoproliferative Syndrome (ALPS)
Required Criteria for Diagnosis

- Nonmalignant lymphadenopathy
- Increased percentage and/or numbers of α/β T cell receptor double-negative T cells

Plus one of the two following criteria:

- Defective in vitro lymphocyte apoptosis
- Identified deleterious mutation in *FAS*, *FASLG* or *CASP10*

Supportive Criteria for Diagnosis

- Elevated serum vitamin B12, IL-10, and/or soluble Fas ligand
- Autoimmune disease (typically autoimmune cytopenias)
- Family history
- Typical histologic findings on lymph node biopsy

Wiskott–Aldrich Syndrome

The Wiskott–Aldrich syndrome (WAS, OMIM 301000) was first described in the 1930s based on a family with multiple males who developed bleeding problems. It is now known to be an X-linked recessive immunodeficiency disease that has a characteristic clinical triad of bleeding associated with microthrombocytopenia, eczema, and increased susceptibility to infection. Microthrombocytopenia refers to the low numbers of platelets that are characteristically small and the immune dysfunction associated with WAS is not only accompanied by recurrent infections but also by a high incidence of autoimmunity and malignancy.

The typical presentation of a patient with WAS begins postpartum with the appearance of petechiae, easy bruising, and bloody diarrhea. In addition, there is typically excessive bleeding in WAS patients who undergo circumcision. Eczema often appears during infancy, is usually persistent and can be very severe. The recurrent infections often start with otitis media and pneumonia involving bacterial agents but over time, opportunistic infections evolve as a clinical problem. Bleeding remains a management issue throughout

a patient's life due to the persistence of microthrombocytopenia. This clinical story together with the laboratory finding of low numbers of small platelets are strongly suggestive for the diagnosis of either WAS or a related disease, X-linked thrombocytopenia (XLT).

Genetic and Immunopathogenesis

The WAS is caused by a mutation in the WAS protein gene (*WASP*) and interestingly defects in this gene have now been associated with four different related diseases: WAS, XLT, intermittent XLT, and X-linked neutropenia (XLN). The WAS protein (WASP) is directly involved in regulating actin polymerization in hematopoietic cells and mutations in *WASP* cause defects in cell signaling, cell locomotion, and immune synapse formation. A general genotype–phenotype relationship has emerged in which mutations that result in WASP absence typically present with WAS, mutations that impair WASP production usually result in XLT, and mutations that occur in one specific site within the gene produce a gain of function mutation that results in XLN. However, the genotype–phenotype relationship is not absolute and clinical findings in the patient dictate the clinical course regardless of the mutation identified.

The immunologic defects involve both the adaptive and innate immune systems. Humoral immunity is abnormal with decreased response to protein and polysaccharide antigens as well as low isohemagglutinin titers together with elevated serum IgE and IgA levels. T cell function is diminished based on ex vivo function testing, reduced T cell numbers, and opportunistic infections. Finally, NK cell function is also decreased when tested ex vivo. In addition to the increased susceptibility to infection, WAS patients have a very high incidence of autoimmunity (40–70% among European and US patients) that include autoimmune hemolytic anemia, vasculitis, arthritis, nephropathy, immune thrombocytopenia, neutropenia, and inflammatory bowel disease. The cytopenias were previously treated with splenectomy but follow-up has determined that this results in a poorer prognosis related to postsplenectomy infectious complications and thus, splenectomy is generally no longer recommended in WAS.

The frequency of malignancies in WAS was 13% in a North American cohort study with an average age at onset of 9.5 years. In this study, the most common malignancy was a B cell lymphoma that often was EBV positive. The outcome in these patients was poor with the majority not surviving beyond 2 years following the tumor diagnosis. Currently, there is no information regarding the risk of malignancy in patients with a *WASP* mutation associated with diagnoses other than WAS (i.e., XLT, XLN).

Diagnosis and Treatment

The diagnosis of WAS should be considered in any male child with bleeding problems that start early in life. The finding of thrombocytopenia with small platelets on the blood smear would be further evidence supporting this diagnosis. A significantly elevated IgE level is typical in WAS but is not a specific finding. A number of other immunologic tests are usually abnormal including lymphocyte proliferation, specific antibody production, and NK cell cytotoxicity. Definitive testing focuses on evaluating for WASP expression and performing mutation analysis for a defect in *WASP* gene.

Conventional management approaches include providing replacement immunoglobulins when there is evidence of abnormalities in specific antibody production. Prophylaxis for *Pneumocystis jirovecci* is also often utilized based on the defective T cell response. It is important to avoid live vaccines in patients with WAS as they are susceptible to infection with the modified vaccine strain virus. Therapy of eczema and autoimmunity should follow the standard approaches used in other patients. It is noteworthy that in the face of a cytopenia, splenectomy should be reserved as a last resort since WAS patients are particularly susceptible to postsplenectomy sepsis. In a situation where a patient is splenectomized, he must be placed on lifelong, appropriate prophylactic antibiotics. Currently, the only curative therapy for WAS is a hematopoietic stem cell transplant. The outcome has been good in settings where there is an HLA matched family, an unrelated matched, or a partially matched cord blood donor but far less satisfactory with a mismatched family donor. There are currently preclinical studies directed at determining the feasibility of gene therapy directed at the patient's hematopoietic stem cell.

Conclusions

In recent years, identification of the gene defects in a handful of clinical syndromes with congenital systemic autoimmunity has led to the definition of a new class of primary immune deficiency in which the defect involves specific features of the regulatory compartment of the immune system. Lessons learned from these disorders

have clarified aspects of thymic selection, T_{REG} function, and Fas-mediated apoptosis. There are a number of unresolved issues that include defining other contributing genetic and/or environmental factors and clarifying the basis for the specific patterns of autoimmunity seen in these disorders and the underlying basis for the marked increase in autoimmunity seen in WAS. In addition, defining the molecular basis that contribute to other findings in these various disorders will further our understanding of the immune system. Certainly, studying these experiments of nature will continue to be a fertile field of investigation over the coming years as we strive to uncover the basic mechanisms of immune homeostasis and immunologic tolerance.

127 Miscellaneous Immunodeficiencies

Harb A. Harfi

Ataxia-Telangiectasia

This syndrome is characterized by telangiectasia, a progressive ataxia, sinopulmonary infections, hypersentivity to ionizing radiation, and combined immunodeficiency.

Clinical features: Clinical presentation is variable and may be of early or late onset. The ataxia is cerebellar but may become generalized. Apraxia is almost always present. Patients are normal until they start walking with an ataxic, unsteady gait with frequent falls. The face may appear expressionless and may give the impression of stupidity. The speech becomes slurred and handwriting is characteristic as the child becomes severely ataxic. Strabismus, drooling, and weakness are common features in older children. Mental retardation occurs in some patients.

Extrapyramidal and posterior column signs are common. Telangiectasia begins in the palpebral conjunctiva between 1 and 6 years. It may become generalized and visible on the earlobes, nose, and antecubital areas. Some patients have little or no telangiectasia. Other cutaneous manifestations may include premature graying, hypertrichosis, hyperpigmentation, hypopigmentation, atopic dermatitis, and pyoderma.

Infections are usually in the form of sinusitis and pneumonia. Bronchiectasis and chronic lung damage will eventually lead to right-sided heart failure. These patients are usually small and retarded in growth. Many may not develop secondary sex characteristics. Mitral valve prolapse may develop in some patients.

Malignancy is a real threat that interrupts the lives of many patients. It has been estimated that, in about 38% of those who die, the direct cause of death is malignancy. Such malignancies include lymphosarcoma, Hodgkin disease, leukemia, adenocarcinoma, gonadoblastoma, reticulum cell carcinoma, medulloblastoma, dysgerminoma, and T- and B-cell lymphomas. Family members are at an eightfold higher risk of developing breast cancer, compared to the general population.

Those who survive long enough into adulthood become wheelchair bound and, later on, bedridden.

Pathology: There is cerebellar atrophy with loss of Purkinje cells. Peripheral nerve cells have malformed nuclei of Schwann cells. The thymus is hypoplastic with absent Hassall corpuscles.

Genetics and immunopathogenesis: The syndrome of ataxia-telangiectasia (A-T) is inherited as an autosomal recessive disorder. The ATM gene is located on the 11q22–23 chromosome. There is lack of nuclear DNA repair that leads to extensive and wide-ranging cellular damage in different organs. Some of the organs affected include the central nervous system, endothelium of blood vessels, T- and B-lymphocytes, and thymus. There is increased production of alpha-fetoprotein (A-FP). There are both cellular and humoral immune defects.

Epidemiology: Carriers of defective AT gene are more common in Caucasians and is in the range of 1.4–2%. The incidence of the disease is around 1 in 20,000–100,000 live births.

Diagnosis: The clinical and phenotypic features are characteristic. Signs and symptoms of immunodeficiency with recurrent infections may not develop early. Laboratory diagnosis may reveal lymphopenia and eosinophilia. Immunologic abnormalities include one or more of the following: IgA deficiency (in about 70%); high IgA and low IgG; decreased IgG; decreased IgA and IgM; decreased IgG, IgA, and IgG2; decreased IgG and IgG4; depressed specific antibody response; increased autoantibodies; depressed T-cell number and function; and very high A-FP. There is excessive chromosomal breakage. Endocrine abnormalities include decreased 17-ketosteroids and high urinary follicle-stimulating hormone; also, these patients have abnormal response to insulin-induced hypoglycemia. Magnetic resonance imaging of the brain shows atrophy and dilated ventricles.

Treatment: There is no curative therapy. Propranolol can be used to decrease tremors. IVIG is not beneficial, and the prognosis is very gloomy.

Caution: Radiologic examinations should be avoided as much as possible. Exposure to ionizing radiation increases the chromosomal breakage and, hence, development of malignancy.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_127,

Cartilage-Hair Syndrome

The syndrome is characterized by short stature, with short limbs, fine sparse hair, and immune deficiency mostly cellular. It is inherited in an autosomal recessive mode.

The immune deficiency is characterized by lymphopenia, defective delayed immune response, and markedly decreased T-cell response to mitogens. These patients are susceptible to fungal, bacterial, and viral infections. Antibody response is also poor in more than one third of the patients. Fatal varicella infections have been reported. Some of the patients may have severe anemia, Hirschsprung disease, and increased incidence of cancer. The phenotypic features, however, are variable with some patients having immunodeficiency with normal hair, and normal skeletal system. Others may have normal hair and intact immune system. Mutations in RNA processing (RMRP) gene have been reported in patients with immunodeficiency. The treatment is supportive with antibiotics in patients with immunodeficiency. Bone marrow transplant may cure some patients with immunodeficiency.

Partial Albinism, Immunodeficiency, and Progressive Neurologic Disease (PAID Syndrome/Griscelli Syndrome)

Some features of the syndrome were partially reported (Griscelli) in 1978 in two Tunisian girls.

Since then sporadic cases have been reported from different countries. The largest number of cases is reported from Saudi Arabia with new features of the syndrome being described. The syndrome is characterized by partial albinism, recurrent fever, and accelerated phase with pancytopenia and hemophagocytic lymphohistiocytosis. In the majority of cases the final course is characterized by organomegaly, with neurological involvement which progresses into coma and death.

Clinical features: The syndrome is so characteristic it can be recognized at birth especially in dark-skinned patients. The salient features of the syndrome are silvery tint to golden gray hair with a "dead ash" appearance especially on the eye brows (see ❯ *Fig. 127.1*); hypopigmented skin, recurrent fever, hepatosplenomegaly; CNS involvement with demyelination of the white matter, and early death, in the majority.

The syndrome is inherited in an autosomal recessive mode. Recently three mutations have been described with three different clinical presentations:

Figure 127.1
Close-up to show the typical hair and skin color in Griscelli syndrome

Type 1 Griscelli (GS1) is characterized by the presence of CNS disease with no hemophagocytic abnormalities and immunodeficiency.

Type 2 patients have hemophagocytic abnormalities, immunodeficiency, and variable neurological involvement.

Type 3 has abnormal melanin pigment distribution with partial albinism but no immunological, hematological, or neurological abnormalities. This type is more compatible with longer longevity.

Cutaneous manifestations: The skin is light in color, with areas of normal pigmentation and others without pigmentation giving freckled appearances. In some patients the skin is bronzy in color. The hair is grayish to silvery, or even golden gray, especially on the eyebrows. This is more apparent in brown or dark-colored skin and black hair. The parents usually make the diagnosis of the abnormality very early.

Recurrent fever: The clinical course in the majority of patients is characterized by frequent episodes of fever. Most febrile episodes yield negative cultures, but some may be indications of sepsis, pneumonia, or otitis media.

Neurological abnormalities: Neurological involvement is variable; some patients have hypotonia, or hyper reflexia in the lower extremities, others have seizures, coma, and death. Some patients may be mistakenly diagnosed as aseptic meningitis. The main lesion of the CNS is demyelination process that starts initially in the posterior fossa and spreads to the rest of the white matter (❯ *Fig. 127.2a, b*). CNS findings in 18 of our patients are summarized in the ❯ *Table 127.1*. Among the 18 patients (index cases) and their 16 affected siblings, 95% had CNS involvement. Four of the 18 patients had optic neuritis and visual loss. The

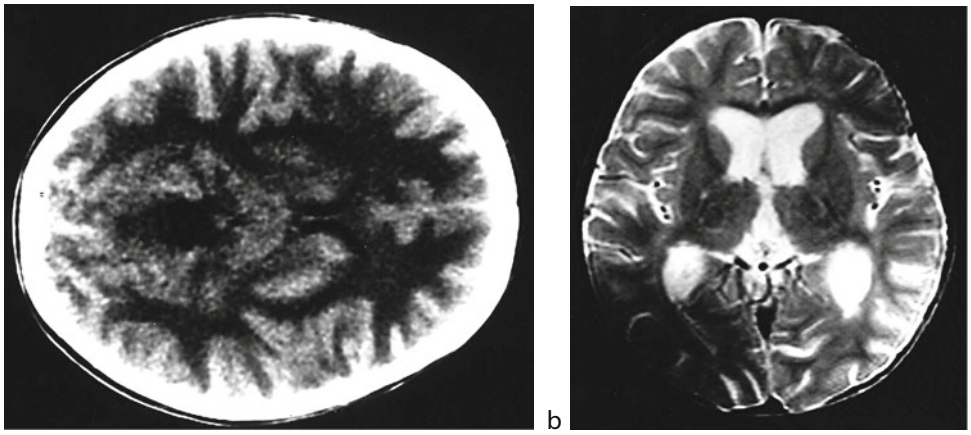

Figure 127.2
(a) CT of the brain of pt. with Griscelli syndrome. (b) MRI of the brain of pt. with Griscelli syndrome

Table 127.1
Clinical Findings in PAID (Griscelli disease)

		Findings
Total patients	18	Hypertonocity, ataxia-hyper reflexia, hemiparesis, facial palsy, coma, retinitis, mental retardation
Male/female	9/9	
CNS involvement	11(61%)	High protein mononuclear cells (50% B-cells, 50% CD4)
CFS involvement		
Abnormal EEG	11(61%)	Mild brain atrophy (two patients)
CT scan and MRI		White matter demyelination (11 patients)
Abnormal CT scan	11	Cerebellum alone (three patients)
Abnormal MRI	8	Generalized (four patients)

CNS involvement is at least partially reversible when treated early with a combination of immunosuppressive drugs.

Hematologic features: Very often these patients are anemic and they develop a picture reminiscent of the accelerated phase of Chediak–Higashi Syndrome. They develop pancytopenia, hepatosplenomegaly, and infiltration of the spleen, liver, bone marrow, and lungs with histiocytic mononuclear, atypical lymphocytes. CNS infiltration is evident by the presence of mononuclear cells in the CSF. Liver enzymes are elevated in all symptomatic patients.

Immunologic abnormalities: All patients with recurrent fever and infections have poor primary antibody response with very low isohemagglutinin antibody titer. They are anergic to recall antigens by skin test. As they become older, they develop a picture of combined immunodeficiency with low T- and B-cell count and defects in their function. Some patients had defective leukocyte chemotaxis.

Radiological findings: Computerized tomography (CT) and magnetic resonance imaging (MRI) may be normal in asymptomatic patients. Once the patient develops even mild neurologic manifestations, white matter changes will be detected. The early demyelination changes start in the cerebellum. As the disease progresses, the whole white matter disappears and the ventricles become dilated. This process is reversible when patients are treated early.

Histopathology findings: There is characteristic distribution of melanin pigment. The hair when examined under a high power lens shows areas of clumped pigment alternating with areas of no pigment. Skin biopsy shows melonocytes with short dendrites packed with mature pigment but very little pigment released in the epidermis. Langerhans cells may

be normal, decreased, or absent. The CSF cytology is 50% B-lymphocytes and 50% T-helper (CD4) lymphocytes. Over 78% of patients have high CSF proteins. Lungs, liver, and spleen and bone marrow are infiltrated by hemophogocytic histiocytes in symptomatic patients.

Epidemiology: The syndrome has been reported in case reports from different countries including Turkey, Mexico, Jordan, Kuwait, USA, and Europe but more than two thirds of the cases came from Saudi Arabia. Males and females are equally affected.

Pathogenesis and genetics: Consanguinity of parental marriages – usually first cousin – is the rule in all patients reported from the Arabian Peninsula. Mutations that have been identified are in MYO5A that encodes an unconventional myosin (GS1), mutation in RAB27A that encodes a GTP-binding protein of the Ras family (GS2), and MYO5A gene or gene that encodes for melanophilin (MLPH) in GS3.

Natural course: Untreated, patients die early in life, usually in the first decade of their lives. Before their demise patients become lethargic and stuporous followed by coma and death. They may develop septicemia or hepatitis with jaundice before they die. None of our patients survived beyond 6 years of age without BMT.

Diagnosis: Is made easy by the presence of the typical features confirmed by microscopic exam of the hair. The diagnosis can be made at birth.

Treatment: The disease is fatal if untreated. Rarely do patients survive beyond age 6–8 years. When patients are in accelerated phase with CNS involvement, chemotherapy with prednisolone, VPI6, with cyclosporine A, or antithymocyte immunoglobulins leads to temporary remission. If CNS is involved, intrathecal methotrexate can totally reverse the white matter changes, though partial response in relapse is the rule. The only curative treatment is allogeneic BMT or hematopoietic stem cell from a matched donor.

Prenatal diagnosis: Prenatal diagnosis can be achieved by examination of the fetal hair or and gene mutation of MYO5A or RAB27A in families with defined history.

128 Approach to the Child with Recurrent Infections

Mohammad Almutawa · Zaina H. Albalawi

Introduction

Newborns exhibit a physiological immature immune system. As they grow and interact with the environment, they encounter pathogens for the first time that trigger their immune system to mount a response and to develop an immunological memory. It is common for children to experience frequent infections; however, a concern should arise when these infections become severe, refractory to therapy, recurrent, or caused by unusual organisms. In this case, the physician should consider the possibility of an underlying primary immunodeficiency disorder (PID).

Primary immunodeficiencies are inherited disorders of the immune system function that predispose affected individuals to an increased rate and severity of infection, immune dysregulation with autoimmune disease, and malignancy. There are over 100 distinctive genetic disorders that have been identified up to date, but less than 20 probably account for more than 90% of cases.

They are classified according to the principle immunologic mechanisms that are disrupted. These subdivisions include humoral, cellular deficiencies, combined immunodeficiencies that affect both humoral and cellular mechanisms, phagocytic, and compliment system defects.

Individual immunodeficiencies are rare, but altogether they occur in as many as 1 in 2,000 live births. Of all the previously mentioned immune system components, antibody deficiencies account for about half of all primary immunodeficiency disorders (PIDs).

It is important for a physician faced with a child with recurrent infections to first consider other medical conditions, potentially resulting in secondary immunodeficiency and other anatomical or biochemical conditions predisposing to infection. Once those have been excluded, or are not considered sufficient to explain the observed degree of infectious susceptibility, the physician should proceed in a stepwise manner to search for a diagnosis of PID.

Knowing the principal clinical manifestations of each subtype of PID provides a useful way to narrow down the differential diagnoses (◉ *Table 128.1*). In general, the initial evaluation is guided by the clinical presentation. Screening tests are applied followed by advanced tests as indicated. Early diagnosis and therapy are key for improved survival and better quality of life for immunodeficient patients. It is therefore important to have an approach to identify those patients and effectively direct them to the appropriate route.

Classification of Primary Immunodeficiency

The immune system is a large organization of many interdependent cell types that work cooperatively to defend the human body from invading organisms such as bacteria, viruses, parasites, and fungi.

Inherited disorders of the immune system are classified according to the arm of the immune system that they predominantly affect. Immunity is subdivided into two major components, the *innate* "nonspecific" and the *adaptive* "specific." The former is characterized by its faster and immediate maximal generic response with no resulting immunologic memory. It is provided by the surface barrier of the skin and the mucous membranes. In addition, the inflammatory process attracts leukocytes by the release of cytokines that is triggered by injured cells. *The complement system* is the major humoral component of the innate immune response. It is a biochemical cascade that attacks the surfaces of foreign cells and is named so for its ability to "complement" the killing of pathogens by antibodies. Finally, the *Cellular Barriers* "Leukocytes" act like independent, single-celled organisms and are the second arm of the innate system. The innate leukocytes include the phagocytes (macrophages, neutrophils, and dendritic), mast cells, eosinophils, basophils, and natural killer cells. These cells identify and eliminate pathogens, either by attacking larger pathogens through contact or by engulfing and then killing microorganisms. Innate cells are also important mediators in the activation of the adaptive immune system. PIDs due to genetic defects in neutrophil development, toll-like receptor signaling and

Table 128.1

Primary immunodeficiency disorders: examples of typical clinical presentations (Adapted from Elsevier © with permission. Bonilla FA, Bernstein IL, Khan DA et al. (2005) Practice parameter for the diagnosis and management of primary immunodeficiency. Ann Allergy Asthma Immunol 94(5):S1–S63

Category of immunodeficiency and examples	Characteristic presentation
Antibody deficiencies	
XLA, ARA, CVID, SIGAD, IGGSD, SAD, THI, hypogam	Recurrent sinopulmonary infections with encapsulated bacteria
Cellular deficiencies	
IL-12/IFN-γ axis	Atypical mycobacterial and salmonella infections
AIRE mutations	Mucocutaneous candidiasis and autoimmune endocrinopathy
Combined deficiencies	
SCID	Failure to thrive, diarrhea, opportunistic infection, rash
Wiskott–Aldrich syndrome	Thrombocytopenia with bleeding and bruising, eczema, recurrent infection with encapsulated organisms
Ataxia telangiectasis	Chronic sinopulmonary disease, cerebellar ataxia, oculocutaneous telangiectasis, malignancy
DiGeorge syndrome	Hypocalcemic seizures due to hypoparathyroidism, cardiac disease, abnormal facies, infection
CD40 ligand deficiency	Recurrent, serious pyogenic infections (also opportunistic infections)
Phagocyte defects	
Chronic granulomatous disease	Deep-seated infection, abscess with granuloma formation
Leukocyte adhesion deficiency	Recurrent serious bacterial infections, delayed separation of the umbilical cord, poor wound healing, lack of pus
Hyper-IgE syndrome	Chronic dermatitis, recurrent serious infection of lungs with pneumatoceles, skin infections, bone fragility, failure to shed primary teeth
Complement deficiencies	
Early classical pathway components	Autoimmune disease and bacterial infections
Late components	Neisserial infection
C3 and regulatory components	Recurrent infections with encapsulated bacterial

Abbreviations: *AIRE* autoimmune regular, *ARA* autosomal recessive agammaglobulinemia, *CVID* common variable immunodeficiency, *hypogam* hypogammaglobulinemia, *IFN-γ* interferon-γ, *IGGSD* IgG subclass deficiency, *IL*-12 interleukin 12, *SAD* specific antibody deficiency, *SCID* severe combined immunodeficiency, *SIGAD* selective IgA deficiency, *THI* transient hypergammaglobulinemia of infancy, *XLA* X-linked agammaglobulinemia

complement reveal the protective role played by the innate immune system.

The second major component of the immune system is the adaptive immunity. It exhibits brisker and more specific responses on second and subsequent encounters to foreign antigen. It can also provide long-lasting protection through its capacity of immunologic memory. The responses are carried out by lymphocytes. There are two broad classes of such responses, antibody responses and cell-mediated immune responses, and they are carried out by different classes of lymphocytes, called B-cells and T-cells, respectively. T- and B-lymphocytes are the main self-defense weapons of this system. Unlike innate immune responses, the adaptive responses are highly specific to the particular pathogen that induced them.

Humoral or antibody deficiency is the most common type of PID and accounts for approximately 60% of all primary immunodeficiency. Five to ten percent of affected individuals have abnormalities of cell-mediated immunity (T-Cells), while a further 20–25% have combined defects of both humoral and cellular function. Disorders of phagocyte account for approximately 10–15% of all PIDs, while Complement deficiency is the rarest, comprising less than 2% of all PIDs.

Another classification for PID is presented by the International Union of Immunological Societies Expert

Committee on Primary Immunodeficiencies, published in 2009 by Notarangelo et al. It includes a detailed list of all the identified PIDs and their genetic basis. It serves as a useful reference for the immunologist. The classification adopted in this chapter is meant to facilitate the approach for the general pediatrician.

Clinical Features of Primary Immunodeficiency

History and Examination

In evaluating a child with recurrent infection, it is critical as much as possible to document carefully the foci of infections, the organisms, and the response to treatment. This is necessary to distinguish infectious disease from others noninfectious conditions such as allergic diseases. Any other conditions that may increase the patient's susceptibility to infection, including congenital defects, allergy, and metabolic disorders, should be considered when appropriate.

Careful evaluation of the family history of a similar condition can be helpful in determining the likelihood of PID. Consanguinity is suggestive of autosomal recessive diseases. Several PIDs are X-linked; a history of male infection or unexplained infective deaths in infancy or early childhood on the maternal side of the family is significant. Death from infection in infancy is highly suggestive of severe combined immunodeficiency (SCID) and should be taken seriously even in families where there is no consanguinity. The age at onset of infections of unusual frequency or severity may yield important insights into possible underlying immune deficiencies. In addition, pregnancy history, previous blood transfusions and vaccination history are also important. The latter is important from the diagnostic perspective of which antigens the patient's immune system has been exposed to, and secondarily important to document live vaccines that may become pathogenic in the immunocompromised host.

Growth parameters and the general state of health of the child should be evaluated as children with cell-mediated immunodeficiency tend to appear chronically unwell and have features of malnutrition. Ear examination with attention to the tympanic membranes should be carefully inspected for evidence of acute inflammation or scarring. Examination of the lymphatic system for the presence/absence and size of the lymph nodes, spleen and tonsils is important. The skin should also be examined for vascular abnormalities as well as rashes, which may or may not be infectious, due to malnutrition or graft-versus-host disease.

Humoral Immunodeficiency

Antibody deficiency is the most common form of PID. Among its subtypes, selective IgA deficiency (SIGAD) is very common, affecting approximately 1 in 500. Most patients with SIGAD are asymptomatic.

The principle clinical manifestations of humoral immunodeficiency are recurrent bacterial infections of the respiratory tract. These infections tend to be recurrent, pyogenic, and present after 6 months of age. On average, the majority of maternally acquired Immunoglobulin G (IgG) has disappeared by 6 months of age. IgG production begins shortly after birth and reaches adult levels by the fifth year of life. The common organisms infecting these children are polysaccharide-encapsulated organisms, such as *Haemophilus influenzae* and *Streptococcus pneumonia*. In general, patients with disorders of the humoral immune system tend to grow well; failure to thrive is not a feature of these diseases. An overview of selected humoral immunodeficiencies is presented in (*Table 128.2*).

Cellular Immunodeficiency

Cellular immunodeficiency accounts for 5–10% of PIDs. When T-cell function is impaired, antibody formation is also affected. Children suffering from defects of the cell-mediated immune system are predisposed to developing viral, bacterial, fungal, and parasitic infections. Infective organisms are mostly intracellular, such as *Mycobacteria* and *Salmonella*. They usually present between 3 and 6 months of age. A major feature of this group is failure to thrive associated with persistent diarrhea and malabsorption. Other features include diseases due to BCG vaccine, disseminated TB, and severe herpes infections. These children may also present with skin rashes and chronic, persistent candidal infection of the nail, skin, and mucous membranes, as seen in Chronic Mucocutaneous Candidiasis (CMCC). A list of cellular immunodeficiencies is presented in *Table 128.3*.

Combined Immunodeficiency

It comprises 20–25% of PIDs. This is a heterogeneous group, characterized by the presence of T- and B-cell dysfunction, often associated with decreased numbers of T lymphocytes and immunoglobulin levels. The "combined" nature of these immune deficiencies results from

Table 128.2
Characteristic features of selected humoral immunodeficiency

Humoral deficiency	Age of onset	Infections	Characteristic features
XLA	>6 months	Otitis media, sinusitis, and pneumonia	Absence of lymph nodes and tonsils Agammaglobulinemia and very low/absent B-cell count
		CNS infection with ECHO-virus	Paralytic polio with live vaccine Absence of BTK protein
CVID	Recurrent infection in children >2 years	Otitis media, sinusitis, pneumonia, bronchitis, and enteric infection	GI tract (20–25%): lymphonodular hyperplasia, IBD, and malabsorption Autoimmune diseases (20%): AIHA, ITP, seronegative arthritis, and vasculitidis Lymphoproliferative disorders: splenomegaly and peripheral lymphadenopathy Malignancies: NHL and gastric cancer
SIGAD	>4 years	Viral, otitis media, sinopulmonary infection and GI infection	Serum IgA level <0.07 g/L with normal IgG and IgM levels GI: Crohn's, UC, and celiac disease Atopy: allergies and asthma Autoimmune: lupus-like illness and arthritis Malignancies: GI and lymphoid malignancies later in life

Abbreviations: *XLA* X-linked agammaglobulinemia, *ECHO* enterocytopathic human orphan, *BTK* bruton tyrosine kinase, *CVID* common variable immunodeficiency, *GI* gastrointestinal, *IBD* inflammatory bowel disease, *AIHA* autoimmune hemolytic anemia, *ITP* idiopathic thrombocytopenic purpura, *NHL* Non-Hodgkin lymphoma, *SIGAD* selective IgA deficiency, *UC* ulcerative colitis

Table 128.3
Diseases of cellular immunodeficiencies

Defect of the IL-12/IFN-γ axis
IFN-γ receptor α chain
IFN-γ receptor β chain
IL-12 p40
IL-12 receptor β1 chain
Signal transducer and activator of transcription 1
CMCC
CD16 deficiency
Idiopathic CD4+ T Lymphocytopenia
NK cell deficiency due to unknown defect
Cellular immunodeficiency, unspecified

Abbreviations: *IL* interleukins, *INF* interferon, *CMCC* chronic mucocutaneous candidiasis, *NK* natural killer, *CD* cluster differentiation

the inability of T-cells to provide immunological "help" to the antibody producing B-cells or a direct impact on B-cell development, resulting in the combined clinical features of both T-cell and B-cell dysfunction. Patients with Combined Immunodeficiency (CID) present within the first few months of life with recurrent, persistent, or severe bacterial, viral, or fungal infections. Failure to thrive, diarrhea, and rashes are frequently seen features. Common

pathogens are most often seen, in addition to nonpathogenic organisms (opportunistic infections). Infections usually do not remain localized; disseminated disease is frequent in those patients.

It is critical to deal with even a suspicion of severe combined immunodeficiency (SCID) as a medical emergency because of the rapidity with which these infants succumb to life-threatening infections, and early management is life saving.

Newborn screening provides a promising method for identifying these children as early as possible. The feasibility of newborn screening for SCID has been demonstrated by Baker et al. in their experience in Wisconsin. *Table 128.4* presents features of some CIDs.

Phagocytic Cell Disorders

This entity constitutes approximately 10–15% of all PIDs. It includes defects in neutrophil and monocyte maturation and differentiation, chemotaxis, phagocytosis, and intracellular killing. Phagocytic cell defects may present with deep-seated abscesses due to infections with *Staphylococcus aureus* or gram-negative organisms such as *Klebsiella pneumonia*, *Serratia*, and *Proteus* species. These individuals are also predisposed to fungal infections, especially *Aspergillus fumigatus* pneumonia. Infections of the skin and viscera can also be manifestations of a phagocytic cell disorder. *Table 128.5* displays some of the characteristic features of selected phagocytic cell disorders.

Complement Disorders

Complement disorders account for a small percentage of PIDs (less than 2%) and may coexist with autoimmune diseases, such as systemic lupus erythematosus (SLE). The clinical features of these disorders vary depending on which complement proteins are affected. The complement system consists of 30 proteins that work synergistically in defending against invading organisms. Of these complement proteins, the commonest is deficiency of C1 inhibitor causing hereditary angioedema, but not infection. A deficiency of C2 is associated with SLE-like syndrome, vasculitis, dermatomyositis, and predispose individuals to recurrent bacterial infections. C3 is the most abundant protein of the complement system. Its products play

Table 128.4
Characteristic features of selected combined immunodeficiency

CID	Age of onset	Infections	Characteristic features
SCID	3–9 months	Pneumonia, septicemia, gastrointestinal	Absence of lymphoid tissue and thymus Failure to thrive and diarrhea Skin disorders and GVHD (due to maternal T-Cells) Disseminated BCG infection. Chronic hepatitis and neutropenia
WAS	<6 months	Otitis media, pneumonia, skin (herpes)	Triad: eczema, thrombocytopenia, and immune deficiency Recurrent and severe infections Autoimmune disease: colitis, vasculitis, and glomerulonephritis EBV-related B-cell lymphoma 10–15%. Average age 10 years
DiGeorge syndrome	Birth	Pneumonia and gastrointestinal	Cardiac abnormality, abnormal facies, thymic aplasia, cleft palate, and primary hypoparathyroidism 80–90% associated with 22q11.2 deletion
CD40 and CD40-L Deficiency (previously known HIgM)	Infancy	Pneumonia, otitis media, gastrointestinal, soft tissue	Gastrointestinal complaints with malabsorption associated with cryptosporidium infection and cholangitis Lymphoid hyperplasia Chronic anemia and neutropenia

Abbreviations: *SCID* severe combined immunodeficiency, *GVHD* graft-versus-host disease, *BCG* Bacillus Calmette–Guérin, *WAS* Wiskott–Aldrich syndrome, *EBV* Epstein–Barr virus, *HIgM* hyper-IgM

Table 128.5
Characteristic features of selected phagocyte disorders

Phagocyte disorders	Age of onset	Infections	Characteristic features
CGD	Infancy	Skin, pneumonia, perianal abscess, osteomyelitis, multiple ulcers infected with *Serratia* species in young adults	Granulomatous abscesses: lungs, lymph nodes, skin, liver, bones, and brain Hepatosplenomegaly, dermatitis, pneumonitis, suppurative lymphadenitis Obstructive granulomas in the GU and GI systems
HIES (Job syndrome)	Early childhood	Pneumonia, skin, otitis media, mastoiditis	Markedly elevated serum IgE and eosinophilia Severe papular and pruritic rash, becomes lichenified. Coarse facies Hyperextensible joints, polyarticular arthritis, reduced bone density, and recurrent fractures Recurrent pneumonia with pneumatocele formation Cold abscesses
LAD	Early in life	Cellulitis, abscesses, bacterial and fungal respiratory tract infection	Significant neutrophilia, recurrent infections, along with absence of pus formation LAD type I: poor wound healing, delayed separation of the umbilical cord LAD type II: pulmonary infections and chronic severe periodontitis. Characteristic facies, growth and developmental delay, and mental retardation
CHS	–	Pyogenic, affect mainly skin and respiratory tract	Partial oculocutaneous albinism and pleomorphic neurologic manifestations; cognitive impairment, photophobia, nystagmus, and central and peripheral neuropathies. Giant Azurophilic granules are characteristic Lymphoproliferative disorder known as the accelerated phase causing lymphadenopathy, hepatosplenomegaly, and bone marrow failure

Abbreviations: *CGD* chronic granulomatous disease, *GU* genitourinary, *HIES* hyper-IgE syndrome, *LAD* leukocyte adhesion deficiency, *CHS* Chediak–Higashi syndrome

an important role in chemotaxis, opsonization, and regulation of the complement cascade. Deficiency of C3 predisposes affected individuals to severe pyogenic infections. Disorders of the terminal complement cascade (C6 through C9) are associated with predisposition to Neisserial meningitis.

Laboratory Investigations

Laboratory investigations are heavily relied on to reach a specific diagnosis of PID. Before proceeding with immunological tests, basic tests should be applied to detect any electrolyte or metabolic imbalances the child may have due to intractable diarrhea, or malabsorption. A complete blood count with a differential, as well as a coagulation profile is essential. Efforts must also be made to identify any infection the patient may have.

The history and physical examination findings serve as a guide to which investigations to start with. The general rule is that screening tests are applied first followed by advanced tests. *Table 128.6* serves as an outline for this approach.

Consultation with physicians experienced in the diagnosis of PIDs is essential wherever uncertainty regarding evaluation occurs, to aid in reaching an accurate diagnosis as quickly as possible, and enable directed therapy. Wherever possible, diagnosis at the molecular level is desirable to establish a clear diagnosis and permit accurate genetic counseling. It also assists in better defining of genotype-phenotype association and to identify candidates for gene-specific therapies.

Table 128.6

Laboratory tests for evaluation of immunodeficiency (Adapted with permission from Elsevier ©. Bonilla FA, Bernstein IL, Khan DA et al. (2005) Practice parameter for the diagnosis and management of primary immunodeficiency. Ann Allergy Asthma Immunol 94(5):S1–S63)

B-cell function
Screening tests Serum immunoglobulin levels Serum specific antibody titers Advanced tests Antibody response to booster immunization Flow cytometry to enumerate B-cells In vitro immunoglobulin production in response to mitogen In vitro immunoglobulin production in response to anti-CD40 and cytokines Antibody response to immunization with ϕ X174
Cellular immune function
Screening tests Flow cytometry to enumerate T-cells and natural killer cells Cutaneous delayed hypersensitivity Advanced tests Enzyme assays (ADA, PNP) FISH for 22q11 and 10p11 deletion In vitro proliferative response to mitogens and antigens Natural killer-cell cytotoxicity Cytokine production in response to mitogen or antigen stimulation Expression of surface markers after mitogen stimulation
Phagocytic cell function
Screening tests Blood cell count with differential Neutrophil staining, morphology Advanced tests Oxidase function (dihydrorhodamine, nitroblue tetrazolium, chemiluminescence) Flow cytometry for adhesion molecules Chemotaxis Phagocytosis Enzyme assays (myeloperoxidase, G6PDH) WBC turnover Bacterial or fungal killing Bone marrow biopsy
Complement function
Screening tests CH_{50} (total hemolytic complement activity) AH_{50} (alternative pathway hemolytic activity) Advanced tests Level or function of individual complement components Chemotactic activity of complement split products
General
Advanced tests Molecular methods including southern, northern, and western blots, PCR/SSCP, DNA fingerprinting, and nucleotide sequencing

Abbreviations: *ADA* adenosine deaminase, *FISH* fluorescent in situ hybridization, *G6PDH* glucose-6-phosphate dehydrogenase, *PCR* polymerase chain reaction, *PNP* purine nucleoside phosphorylase, *SSCP* single-strand conformation polymorphism, *WBC* white blood cell

129 Primary Immunodeficiency Syndromes

Clinical Cases

Harb A. Harfi

Antibody Deficiency

Case History 1

Nada is a 12-year-old girl who was the product of a normal pregnancy and delivery, born to first-degree consanguineous cousins. At the age of 2 years, she had lobar pneumonia that required hospitalization for 15 days. At the age of 30 months, she had an episode of sinusitis and otitis media, which responded slowly to antibiotics. Between the ages of 3 and 5 years, she had several episodes of conjunctivitis, diarrhea, otitis media with bilateral ear canal discharge, and chronic productive cough. At the age of 5 years, she was diagnosed as having antibody deficiency. Her tonsils and adenoids were atrophic (*Fig. 129.1*). Her CD19 (B lymphocytes) was 3% and her serum IgM was 0.2 g/L (normal, 0.4–1.6 g/L), IgA was 0.3 g/L (slightly low), and IgG was 1.8 g/L (normal, 5–8 g/L). Chest and sinus x-rays showed a small area of bronchiectasis in the left lower lobe and bilateral maxillary sinusitis. She was started on trimethoprim/sulfamethoxazole (TMP/SMX) prophylaxis and monthly IVIG. She did well with no further infections other than mild conjunctivitis.

Nada has a 6-year-old sister and 4-year-old brother who were diagnosed with antibody deficiencies. Both are doing well on antibiotic prophylaxis and monthly IVIG.

Comment

The above case, with positive family history of both sexes and milder course, is an example of the autosomal recessive inheritance of antibody deficiency.

Case History 2

Mohammed is an 8-year-old boy who was well until the age of 2 years, when he started to have repeated episodes of fever and lymphadenopathy. He had one episode of pneumonia and two attacks of otitis media. He also presented with bilateral cervical and submandibular lymphadenopathy and organomegaly. He was anemic and had persistent neutropenia. He was hospitalized on four occasions because of fever. Lymph node biopsy on two occasions was nonspecific.

When the patient was referred to our Immunology Unit, he was small for his age, both in weight and height. He had splenomegaly of 6 cm and hepatomegaly of 5 cm below the costal margin. He had generalized lymphadenopathy of mediastinal, inguinal, axillary, and cervical areas. He had bull neck-like appearance, with hoarseness of his voice and inspiratory stridor. His eardrums looked thick and dull, and he had chronic sinusitis. His white blood cell count showed platelets of 120,000/mm^3 and his total neutrophils were 750/mm^3. His serum IgM ranged between 5.2 and 7.8 g/L (extremely high for his age). His serum IgG was 0.8 g/L and IgA less than 0.2 g/L. Lymph node biopsy from the cervical area on two occasions showed lymphoid hyperplasia. He was treated with TMP/SMX prophylaxis and monthly IVIG. Because of upper airway obstruction, dexamethasone was given orally for 10 days. His cervical lymphadenopathy decreased markedly in size and his spleen shrank to 2 cm below the costal margin. Both axillary and inguinal nodes became smaller. His upper airway obstruction and stridor cleared up. However, 6 months later, symptoms of upper airway obstruction with extremely large lymph nodes recurred. He responded modestly to dexamethasone. Flow cytometry with monoclonal antibody against CD40L showed lack of expression of the ligand on CD4+ cells, confirming the X-linked hyper-IgM syndrome. Repeat lymph node biopsy with DNA study showed B-cell lymphoma. Interferon alpha was added to his therapy and the patient did fairly well.

There is no family history of a similar case and the patient's parents are not consanguineous.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_129,

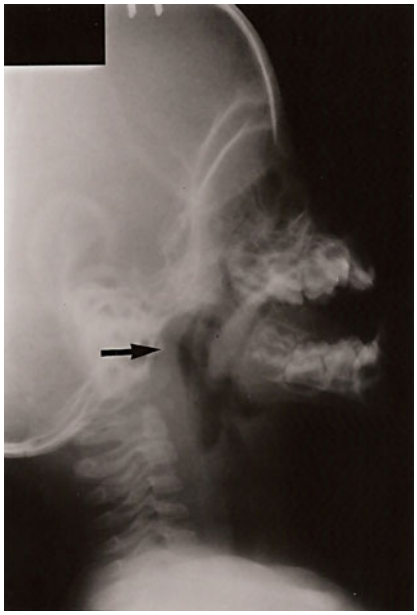

Figure 129.1
X-ray of the post nasal space shows atrophic adenoids in a patient with antibody deficiency

Case History 3

Othman is a 6-year-old boy referred because of recurrent meningitis. *Streptococcus pneumoniae* was isolated from the cerebrospinal fluid (CSF) on several occasions during his hospitalization. He was hospitalized on several occasions since the age of 2 years. As a consequence of recurrent meningitis, he became deaf. There was no history of trauma to the head. He had sepsis on one occasion and pneumonia on two occasions. Extensive radiologic and computerized tomography scans with thin cuts of the head, petrous bones, and cribriform plate failed to uncover communication with the CSF, nor were congenital anomalies detected. Serum IgG, IgA, and IgM were normal. Serum IgG subclass measurement showed IgG2 to be less than 0.01 mg/dL and IgG4 less than 0.001 mg/dL. No specific antibody was detected against *S. pneumoniae*. The patient was placed on antibiotic prophylaxis with TMP/SMX without much benefit. IVIG every 2 weeks reduced the frequency of meningitis to once every 9–12 months.

Comments

The above case is a classic example of the extreme presentation of IgG subclass deficiency. In such cases, trauma to the head and congenital skull bone defects should be excluded first before concluding that IgG subclass deficiency is the explanation for the recurrent meningitis.

Case History 4

Bander was 3 years old before he had his first episode of otitis media and left lobe pneumonia. He received a course of antibiotics and improved, though his improvement was slow. He continued to have low-grade cough with yellow, thick sputum. When he was evaluated in the Immunology Clinic at the age of 7 years, he was well developed with no apparent distress. His physical examination showed a few fine crepitations on the left lower lobe posteriorly. His serum IgG, IgA, and IgM levels were normal. IgG subclass assay showed his IgG3 level to be 0.1 mg/dL. Sputum and ear discharge cultures grew *Haemophilus influenzae* on several occasions. At the age of 11 years, he developed flat, hypopigmented maculopapular lesions on the forehead. Skin biopsy established verruca virus, a poxvirus, to be the cause of the skin lesion. Repeated extensive courses of antibiotics kept his lungs clean, except for a small area of bronchiectasis in the left lobe.

Comments

The above case illustrates another IgG subclass deficiency that ended up in mild bronchiectasis and failure to clear a viral infection. There was gradual improvement in the frequency and severity of infections as the patient grew older.

Case History 5

Abdulaziz was 14 months when he presented to the Immunology Clinic. According to his parents, his problems started at 10 months of age with upper respiratory tract infection and recurrent otitis media. He responded well to antibiotics. Since then, his history has been characterized by recurrent cough, fever, and sore throats. He had two episodes of bronchopneumonia between the ages of 14 and 24 months. He developed airway hyperreactivity with cough and wheezing that required bronchodilators. At the age of 14 months, his serum IgG was 2.1 g/L and the other immunoglobulins were normal. His serum IgG2 subclass was 0.15 mg/dL (normal, 0.28–0.8 mg/dL). Serial serum IgG and IgG subclass measurements showed gradual increase and normalization at 36 months, which

coincided with his clinical improvement. During this time he was placed on TMP/SMX three times per week.

During the follow-up, the parents had another boy, Saud. At the age of 4 months, Saud had his first upper respiratory tract infection. After that, he followed an identical course of clinical and laboratory findings as his brother. He recovered at 38 months of age.

Ataxia Telangiectasia

Case History 1

Shokri was a 2-year-old boy when he was examined because of unsteady gait and frequent falls. He was the product of a full-term pregnancy born to first-degree cousin parents. His examination showed expressionless face and ataxic (cerebellar) gait (*Fig. 129.2*). He also had telangiectasis of both conjunctivas (*Fig. 129.3*). As he grew older, he became more and more ataxic. He had horizontal and vertical nystagmus. He developed chronic cough and bronchiectasis. At age 21, he became wheelchair bound. Both weight and height were much below the fifth percentiles. His serum Alpha-FP was six times the upper normal value. His IgA is undetectable, and his serum IgG was 0.5 g/L. In vitro T-cell function was markedly depressed.

Figure 129.2
Patient with ataxia telangiectasia. Notice the expressionless face and masked appearance

His brother, Hussam, was seen at age 8 years with the same complaint of ataxia. On his initial visit, he was found to have matted, rubbery left cervical lymph nodes measuring 5 × 5 cm, which proved to be lymphoblastic lymphoma.

Case History 2

Abdulaziz and Abeer were two siblings, product of first-degree consanguineous cousin parents. They were diagnosed to have A-T at the age of 1 year. A third sibling, Bakr, was born and developed classic features of A-T at 10 months of age. All three siblings had classic immunologic and clinical features of A-T. Abdulaziz became wheelchair bound. He developed normal secondary sex characteristics at the age of 19 years, but his body was small. His sister, Abeer, developed cerebral infarction at the age of 10 years and became bedridden. None of the siblings suffered from serious infections other than mild sinusitis.

Case History 3

Noura is a 9-year-old girl who was diagnosed as having ataxia telangiectasia at 1 year of age. Since 7 years of age, she has been suffering from chronic sinopulmonary infections. Her IgG and IgG2 were very low, and her serum IgA was undetectable. Antibiotic therapy and TMP/SMX prophylaxis did not reduce her infections except temporarily. IVIG (400 mg/kg) was given slowly. Within minutes, the patient became diaphoretic and cyanotic with respiratory distress and expiratory wheezing. The infusion was stopped immediately and anti-anaphylactic treatment

Figure 129.3
Conjunctiva of a patient with ataxia telangiectasia. Notice the dilated Blood vessels

was given. The same reaction occurred when IVIG was attempted 1 month later. Therefore, replacement therapy with IVIG was abandoned.

DiGeorge Syndrome

Case History 1

Mabrook is an 8-year-old boy born to nonconsanguineous parents. Shortly after birth, he was observed to have abnormal congenital anomalies, including micrognathia, low-set deformed ears, broad depressed nasal bridge, high-arched palate, and Tetralogy of Fallot (*Fig. 129.4*) He developed hypocalcemic tetany 24 h after birth. His serum calcium was very low and his phosphorus was high. His parathyroid hormone was extremely low. Chest x-ray showed absent thymic shadow. The diagnosis of DiGeorge anomaly was made and he was started on calcium and vitamin D supplement; the latter was changed later on to calcitriol, 0.25 μ/day orally. His cardiac anomalies were corrected surgically at the age of 4 weeks.

Although in vitro assessment of his T and B lymphocyte function by culture with mitogens was normal, the patient had poor antibody response. He had several episodes of sepsis, otitis media, and oral thrush. He was placed on TMP/SMX prophylaxis and IVIG on a monthly basis. The patient did well, with no further pyogenic infections. He was slow in his language development and mental performance.

Figure 129.4
DiGeorge Syndrome notice the typical features

At the age of 5 years, the calcium and calcitriol were discontinued without the recurrence of tetany. His serum calcium and phosphorus remained normal. Repeated study of his T- and B-cell functions showed moderate in vitro suppression of his T cells when cultured with mitogens and allogenic cells.

Severe Combined Immunodeficiency (SCID)

Case History 1

Noura was 5 months old when she was referred to our Immunology Division. Her problem started in the second week of her life when she was noticed to have extensive oral thrush. She developed diarrhea and became emaciated. At 3 months of age, she developed a necrotic ulcer at the site of BCG vaccine on the left shoulder. She then developed generalized nodular cutaneous lesions. The lesions were 3–5 mm in diameter, and coppery red to dark brown in color, involving the scalp, palms, soles, and other areas of the body. Her lymph nodes were atrophic. She had hepatosplenomegaly, with her spleen being 5 cm below the costal margin. A complete blood count (CBC) showed extreme lymphopenia, with a white blood cell (WBC) count of 3,500/mm^3 and lymphocytes 8%. Total T cells were 185/mm^3, with CD4 less than 4 mm^3, CD8 84/mm^3, and B lymphocytes 21/mm^3. There were not enough lymphocytes for in vitro functional studies. X-ray of the chest showed absent thymic shadow. X-ray of the skull and long bones showed lytic small lesions with no bony reactions, involving all bones (*Fig. 129.5a*, *b*). Serum immunoglobulin levels were undetectable.

Biopsy of the skin nodules was full of acid-fast bacilli, confirmed by culture to be *Mycobacterium bovis*, compatible with disseminated BCG. The patient died shortly after admission before BMT could be given. Her parents were first-degree cousins. They lost two previous infants: a boy at the age of 4 months and a girl at the age of 7 months, both with a clinical history suggestive of SCID.

Case Histories 2 and 3

Abdulaziz and Abdulkareem were two full-term, identical twin brothers, born to first-degree cousins. The parents lost one boy at the age of 6 months with the diagnosis of

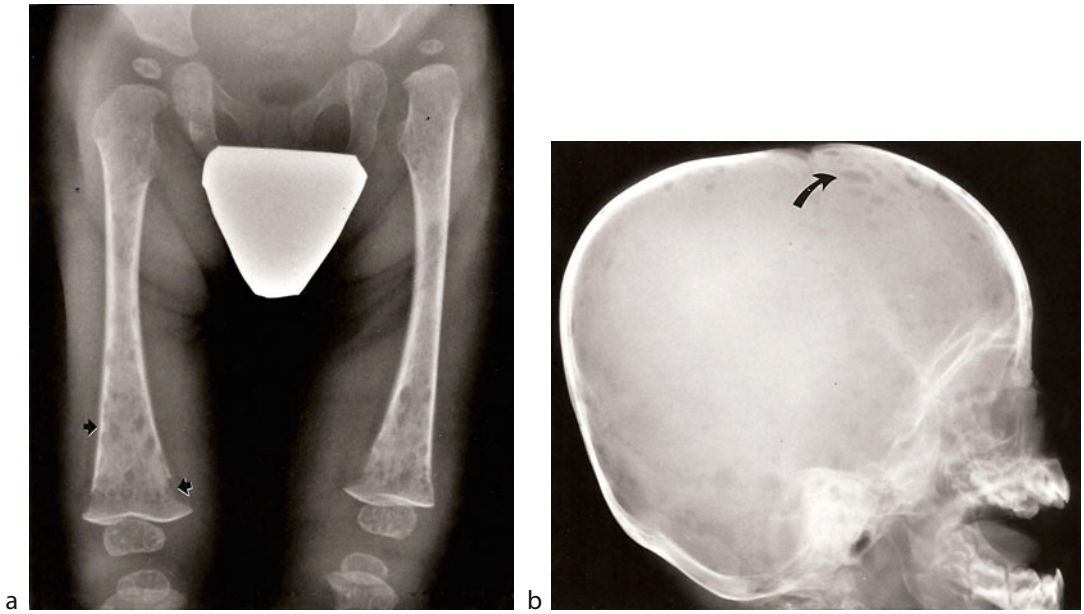

Figure 129.5
(a) X-ray of the long bones in a SCID patient with dessiminated BCG. Notice the lytic lesions due to absent immune. (b) X-ray of the skull in a SCID patient with dessiminated BCG. Notice the lytic lesions due to absent immune response

SCID. The twin brothers received BCG vaccine at the age of 24 h. Both developed oral thrush, recurrent otitis media, and lung infection. When they were examined at the age of 5 months, they were found to have atrophic lymphoid tissues, extensive oral thrush, and generalized dark brownish, nodular skin lesions. Both had hepatosplenomegaly but no BCG scar at the site of inoculation. Skin biopsies of the nodules were full of acid-fast bacilli; cultures grew *M. bovis*, compatible with BCG. Chest x-ray showed no thymic shadow; x-ray of other bones was negative. CBC showed extreme lymphopenia with very low percentages of CD4, CD8, CD3, and CD19 (B Cells). Serum immunoglobulin levels were undetectable. In vitro culture of lymphocytes with mitogens (phytohemagglutinin [PHA], concanavalin A [Con-A], pokeweed), pooled cells, and purified protein derivative (PPD) of tuberculin showed no response.

Human leukocyte antigen (HLA) typing of the patients and family members showed that the patients were full matches with their brother, Fahad. BMT was done on an emergency basis. Two weeks post-BMT, the patients became highly febrile with the appearance of more nodular lesions. Four weeks post-BMT, an abscess started to develop at the sites of BCG inoculation, coinciding with engraftment of bone marrow. Both patients were treated with a combination of four antituberculous drugs and biweekly IVIG and supportive therapy. During this time, the patients continued to be highly febrile, with temperatures ranging from 38–40°. They showed signs of engraftment 3 weeks post-BMT, with increasing lymphocyte count and normalization of serum immunoglobulins. Abdulkareem developed BCG osteomyelitis of the right metatarsal bone. At 4 months post-BMT, the skin lesions dried up and healed along with healing of the BCG inoculation site. Two years post-BMT, the two brothers were cured. They became immune competent with normal antibody response and normal in vitro T- and B-cell functions.

Comments

Disseminated BCG is uniformly fatal in SCID patients. The only chance for survival is aggressive antituberculosis therapy and emergency BMT form a full-match donor, such as what happened with these brothers. Once the patients engrafted, they started to be highly febrile. Localization of infection was reflected by the development of abscesses at the site of vaccination. The high fever reflects the response to endotoxin released from the dead organisms once the T cells became functionally competent and capable of mounting an immune response.

Case Histories 4 and 5

Amal is a 6-year-old girl, who had BMT at the age of 3 months. Because an older sister had SCID and died at the age of 6 months, Amal was diagnosed at 12 hours postnatally. She was placed in isolation and no BCG was given. Her CBC and leukocyte markers showed lymphopenia of both T and B lymphocytes. At the age of 3 months, her serum IgG, IgA, and IgM were undetectable. HLA and DR class typing showed her brother, Abdullah, to be a full match. She was transplanted without conditioning. Engraftment was apparent after 2 weeks. She reconstituted without complications.

The parents had another male child, Omar, who was diagnosed immediately after birth to have SCID. He was transplanted from his brother. He is alive and well 2 years post transplant. His transplant was across two A, B mismatch loci. He reconstituted for T cells but not for B cells. Currently, he is on IVIG replacement therapy.

Case History 6

Ahlam, a 5-month-old girl, was a product of a full-term, normal pregnancy and delivery. She was referred to the Immunology Service because of persistent thrush and recurrent febrile episodes. At the age of 2 months, she had gram-negative sepsis. At the age of 3 months, she had fever, anemia, and leukopenia. Her hemoglobin dropped to 6 g, and she was treated with nonirradiated packed red blood cells. She developed erythematous maculopapular rash on the cheeks, abdomen, and extensor surfaces of her upper and lower extremities. The rash was nonpruritic. She developed cough and low-grade fever. Her cough continued for 6 weeks until she was referred.

Her physical examination showed extensive oral thrush. She had no BCG scar at the site of inoculation. Her lymphoid system was atrophic, with very small adenoidal tissue. Her lungs were full of fine crepitations. A chest x-ray showed extensive interstitial pneumonia. CBC was remarkable with 15% eosinophilia and lymphopenia, with total T cells of 348/mm^3 and B cells of 108/mm^3. Skin biopsy was compatible with GVHD grade 2. Her serum immunoglobulin levels were extremely low. Lung biopsy was full of *Pneumocystis carinii*. The patient was treated with a combination of TMP/SMX and IVIG. She made a good recovery.

A search for a potential bone marrow donor was started. Her parents had no other children. Their first-born daughter died at the age of 7 months, with a history similar to Ahlam's. The patient received T-cell depleted marrow from her father, using soybean lectin. Her immediate post-BMT course was uncomplicated. She was continued on IVIG and *P. carinii* prophylaxis. There were no signs of engraftment 100 days post-BMT. Shortly after she went home, she developed fever, bilateral cervical lymphadenopathy, and hepatosplenomegaly. A chest x-ray showed bilateral lung infiltrate. The lymph nodes were matted together and rubbery. Cultures were negative. Lymph node biopsy showed lymphoproliferative disease with positive Epstein-Barr virus (EBV) capsid. Her condition deteriorated and she went into respiratory failure and died. Fine-needle aspiration from the lung was full of lymphoproliferative lymphoid cells, similar to histopathology of the lymph nodes.

Comments

This is a classic case of the autosomal recessive type of SCID. She developed a rare complication of depleted BMT (i.e., lymphoproliferative disease), which is uniformly fatal. She presented before 3 months of age and had opportunistic infection with *P. carinii*.

Bare Lymphocytic Syndrome

Case History 1

Bander was 9 months old when he presented to the Immunology Unit. He was the product of a full-term pregnancy, born to first-degree cousins. He had two brothers and four sisters. At the age of 2 months, he had one episode of fever, diarrhea, and dehydration. Since then, he had never been well; his life was characterized by chronic diarrhea and a distended abdomen, with both weight and height being below the fifth percentile. Recurrent fever, oral thrush, and chronically draining ears responded modestly to treatment.

At the age of 6 years, he developed extensive cutaneous atypical mycobacterial infection on both lower extremities (*Fig. 129.6*). The infection cleared up after 6 months of treatment with rifampin and isoniazid. Replacement with IVIG and prophylactic antibiotics reduced the severity and frequency of infections. CBC with differential showed normal numbers of T and B lymphocytes. His serum immunoglobulins were low, including IgG, IgA, and IgM. In vitro assessment of his T- and B-cell function showed moderate depression in response to both mitogens and antigens. HLA and DR typing failed because his cells

Figure 129.6
Atypical mycobacteria skin infection in a patient with Class II MHC deficiency (BARE Lymphocyte Syndrome)

were not typeable. He had class I and class II deficiency. The patient continued with ill health until he died outside the hospital at the age of 14 years. Since then, several members of the same tribe have been diagnosed with class II MHC deficiency (*Tables 129.1* and *129.2*).

Case History 2

Nahla was 3 months old when she was referred to the Immunology Unit. She was the product of a consanguineous marriage between two second-degree cousins. Early in life, she was noted to have erythematous skin rash that later became scaly. The rash involved the whole body, including the scalp. Her hair was sparse and she had generalized lymphadenopathy, mostly in the axillary areas. She also had hepatosplenomegaly. She developed otitis media and oral thrush. She had several episodes of fever and lung infections. Her in vitro lymphocyte blastogenesis was markedly depressed. Serum IgG was very low. Serum IgE was high; she had eosinophilia of 25% of the peripheral blood. Skin biopsy did not show evidence of GVHD.

The diagnosis of Omenn syndrome was made. HLA and DR class typing showed her mother to be a full match. She was transplanted after conditioning with busulfan and cyclophosphamide. The engraftment failed. Re-transplant was tried after adding radiation as part of her conditioning. The patient died with overwhelming sepsis during the acute stage of BMT.

After that, the parents had two healthy children, a boy and a girl. A third girl, Amal, was born with a clinical picture similar to Nahla at the age of 2 weeks. Successful BMT was performed at 2 months of age.

Table 129.1
Clinical features of 17 patients with the bare lymphocyte syndrome (MHC II & I)

Sex (M/F)	9/8
Clinical presentation in the first year	16/17
Parental consanguinity	15/17
MHC deficiency class II	16/17
MHC deficiency classes I & II	1/17

P. carinii	1/17
Cryptosporidium	1/17

Phagocytic Cell Disorders

Leukocyte Adhesion Defect (LAD)

Case History 1

Laila is a 5-year-old girl seen in the Immunology Unit with the following history. She was born full term to first-degree cousin parents. Her umbilical cord stump fell off at 21 days. At that time she had periumbilical cellulitis with sepsis. She had conjunctivitis and cellulitis of the inner canthus of the right eye. The lesion became necrotic. Pseudomonas species was isolated from the lesion. The cellulitis healed with a scar that led to obstruction of the right nasolacrimal duct. At 11 months of age she was seen in our hospital for diagnosis and management. Earlier she had perianal cellulitis and two episodes of sepsis and one episode of otitis media. She was also found to have persistent leukocytosis and neutrophilia. Immunologic studies showed CD11 and CD18 to be less than 1%. HLA and DR class typing of the patient and her family showed her 6-year-old brother to be a full match. After conditioning with a combination of busulfan and cyclophosphamide, Laila was transplanted from her brother with no complications. Engraftment was evident 3 weeks post BMT. Post-BMT immunologic studies, including in vitro lymphocyte blastogenesis response to mitogens and specific antigens and antibody response, were normal. Four years post-BMT the patient had no infection. Her chromosome analysis revealed 46, XY.

HyperIgE Syndrome

Case History 1

Khalid is a 5-year-old boy whose problem started around 6 weeks of age with skin rash, severe itching, and recurrent sinopulmonary infection. The skin rash was eczematoid and generalized. He had several boils and skin abscesses that grew *Staphylococcus aureus*. His WBC count showed eosinophilia of 17% with a platelet count of 645,000/mm^3. His serum IgE was 115,000 IU/ml (normal, up to 1,200 IU/ml). At the age of 3 years, he had pneumonia that progressed to lung abscess and pneumatoceles (◉ *Fig. 129.7*). He failed to respond to antibiotics. A right lobectomy was performed and histopathology showed extensive inflammation with abscesses; *S. aureus* was isolated. The patient failed to thrive and developed several episodes of lung infections and otitis media. He also developed oral thrush and *Candida* of the thumbs. In vitro culture of his peripheral lymphocytes with mitogens and specific antigens was moderately depressed. His serum IgG2, IgA, and IgM were normal. His serum IgG2 was less than 0.15 mg/dL. The patient was placed on prophylactic antibiotics and monthly IVIG, but continued to have recurrent sinopulmonary infections. His facial features became coarse (◉ *Fig. 129.8*).

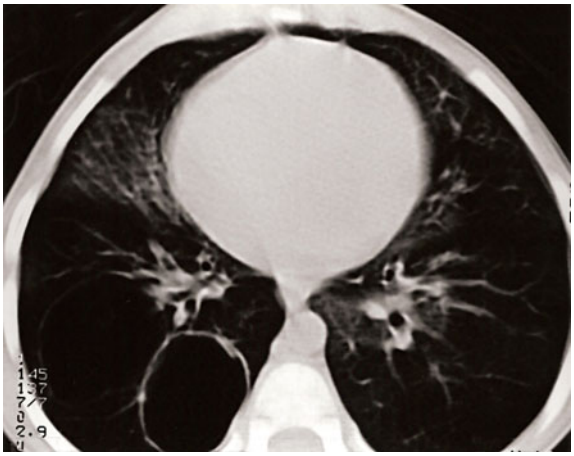

Figure 129.7
CT Chest showing pneumatocele in a patient with Hyper IgE

Chronic Granulomatous Disease (CGD)

Case History 1

Fatma is an 11-year-old girl who was diagnosed at the age of 3 years to have CGD. At the age of 6 weeks, she had perianal abscesses. After that she had several febrile episodes with cervical and gluteal abscesses that required surgical drainage and healed with scars. At the age of 3 years, she had another episode of perianal abscess that left a sinus track after it ruptured. She was found to have cervical and axillary lymphadenopathy. She had splenomegaly of 5 cm below the left costal margin. Her WBC count was 15,000/mm^3 with 78% neutrophils, her hemoglobin was 95 g/L, and her NBT test was 14% of the normal control. There was defective phagocytosis by chemiluminescence.

The patient was placed on prophylaxis with TMP/SMX on a daily basis. Between 3 and 6 years of age, the patient had

Figure 129.8
Coarse facial features in Hyper IgE

no serious infections. At the age of 7 she had fever and splenomegaly. Cultures were negative and antibiotics were given for 6 weeks with no response. On admission, she was found to have *Aspergillus* right lung pneumonia, empyema, and osteomyelitis of the seventh rib.

The patient was treated with a combination of surgical drainage and intravenous amphotericin B. She showed slow but steady improvement after 6 weeks of treatment. Her treatment was continued at home for 6 more weeks with 100 mg of itraconazole daily. The patient made a complete recovery. At the age of 8, she was placed on IFN-y, 50 $\mu g/m^2$ subcutaneously three times per week. While the patient was on IFN-y, she developed Salmonella sepsis, pneumonia on two occasions, one episode of liver abscess, and extensive pulmonary granulomas. The IFN-y was discontinued and the patient was placed on fluconazole and TMP/SMX prophylaxis. The patient failed to thrive and she looked small for her age.

Case History 2

Abdulrahman, a 3-year-old boy, is the product of nonconsanguineous parents. He was preferred at the age of 27 months because of persistent fever. He was noticed to have slight limping of the right leg and was complaining of abdominal pain in the pelvic area. There was tenderness to palpitation on the fourth and fifth lumbar vertebrae and on the pelvic area.

The WBC count was 18,000/mm^3 with 85% neutrophils. The erythrocyte sedimentation rate (ESR) was 120 mm in the first hour; the NBT test was 9% of the normal control. Magnetic resonance imaging of the abdomen and pelvic area, including vertebral column, showed pus collection in the spinal canal and the retroperitoneal space with osteomyelitis of the fourth and fifth vertebrae.

Laparatomy and drainage of the abscess grew *Aspergillus* species. The patient was treated with a combination of intravenous amphotericin B, leukocyte transfusion, and IFN-y. The response was very slow. The patient's ESR dropped gradually to 60 mm and then to 25 mm. After 6 months of therapy, the lesion started to heal with resolution of the abscess and osteomyelitis of the vertebrae with no residual neurologic deficit.

Case History 3

Sara is a 17-year-old black girl, diagnosed at the age of 6 years to have CGD because of recurrent folliculitis of her scalp and cervical lymphadenopathy. Her NBT test was 21% of the normal control. At the age of 12 years, she had a liver abscess that grew *S. aureus* though she was taking TMP/SMX and IFN-y prophylaxis. Her compliance with the treatment was poor. She developed bilateral pulmonary granulomas with fibrosis (*Fig. 129.9*). Sara had two other sisters, 3 and 5 years of age, diagnosed to have CGD. Their course is generally mild with no deep-seated abscesses. Their parents are first cousins and had five other healthy children, three girls and two boys.

Comments

The first case is a girl with an autosomal recessive disease with a mild course initially, but later on, she developed serious infections while on prophylactic treatment, including IFN-y. Case 2 is a classic X-linked CGD with very low NBT reduction. His disease was associated with abscesses and osteomyelitis early in life. His therapy was a combination of IFN-y, granulocyte transfusion, and antifungal treatment. There was no evidence that IFN-y made a difference in his response to treatment. Case 3 is an example of the mild autosomal recessive type of CGD. Three girls were affected in the family as a result of consanguineous marriage. Their NBT test results were higher than those in the X-linked CGD case, and their infections were generally milder.

Figure 129.9
CXR in a patient with CGD. Granuloma in right upper lobe

Complement Deficiency

Case History 1

Najla was 3 years old when she was diagnosed for the first time with hereditary angioneurotic edema (HANE). She had repeated attacks of painful, nonpitting edema at different parts of her body that occurred initially once a month (*Fig. 129.10*). Each attack lasted 2–3 days. She had one attack that involved the right temporal area, which left her with a mild visual defect. Her serum C4 was less than 0.2 mg/dL and C1-esterase inhibitor (CTINH) was less than 1% of normal.

She was started on ε-aminocaproic acid in a dose of 6 g daily, which later was reduced to 0.5 g daily. The frequency of the attacks was reduced to once every 2–3 months. During this therapy, the patient complained of some leg aches, muscle weakness, and hypertrichosis when she was on the higher dose. Later on, she was switched to danazol (100 mg/day). The frequency of the attacks dropped to one every 6 months. The frequency increased when the patient forgot to take her hormone. When in remission, her C4 stayed low while the C1-esterase inhibitor increased to 3–5%.

When the patient got married at the age of 18 years, she had more frequent attacks. One of the attacks was associated with respiratory distress. Recently, pure C1-esterase inhibitor was used for treatment of her acute attacks and as prophylaxis before delivery. She had two healthy children with no serious attacks.

Figure 129.10
Nonpitting edema in right hand in patient with HANE

Case History 2

Sara was 9 years old when she had her first attack of *Neisseria meningitidis*. Since that time, she had at least one attack every 9–12 months. Every time, meningococcal meningitis was diagnosed. Her family history was unremarkable, with no similar condition. CBC and serum immunoglobulin levels were normal. Total hemolytic complement (CH50) was zero. Her C6, C7, C8, and C9 levels were very low. Serum C7 was undetectable. The diagnosis of C7 deficiency was made. The patient was placed on rifampicin prophylaxis (200 mg/day) with no recurrence of her meningitis.

Miscellaneous Immunodeficiencies

Mucocutaneous Candidiasis with Immunodeficiency and Endocrinopathy

Case History 1

Yousef was 3 months old when he was seen for consultation because of persistent oral thrush that covered his tongue, buccal mucosa, and angle of the mouth. He also had *Candida* of the nails and the foreskin of the penis (*Candida* phimosis). There was no Bacille Calmette-Guerin (BCG) scar at the site of the inoculation, but he had left axillary

lymphadenitis. Fine-needle aspiration of the fluctuant lymph node grew acid-fast bacilli. The patient was treated for 6 months with rifampin and isoniazid. The lymph node was drained surgically and healed very slowly.

Skin test with *Candida albicans* antigen was negative. Lymphocyte culture with mitogens and purified protein derivative (PPD) of tuberculin and *Candida* showed moderate depression of the response to mitogens but flat response to *Candida* and PPD antigens. Serum immunoglobulin assay showed deficient IgG2 and IgG4. Endocrine function assessment showed hypothyroidism. At the age of 3 years, the patient developed diabetes mellitus. During this time, the patient developed several episodes of sinopulmonary infections. His *Candida* was resistant to mycostatin and miconazole but temporarily responded to itraconazole. The patient developed overwhelming gram-negative septicemia and died at the age of 3½ years.

Case History 2

Ali and Noura are 12 and 9 years old brother and sister, respectively. They had persistent oral thrush and maculopapular rash on the forehead and upper part of the chest and neck (*Fig. 129.11*). Culture of the oral and skin lesions grew *C. albicans*. Skin tests with *Candida* antigen were negative after 48 h. Screening for endocrine function was normal. Serum immunoglobulin assay was normal. In vitro culture of the lymphocytes with mitogens and *Candida* antigen showed normal response to mitogens but absent proliferation with *Candida*.

The oral mucosa cleared partially after topical applications of gentian violet, but there was no response to mycostatin. Oral and topical use of miconazole and ketoconazole was ineffective in clearing the lesions. Long-term treatment with ketoconazole and fluconazole led to limited improvement that relapsed after the treatment was stooped.

There was no problem with recurrent infections, and no complications with immunization. They had mild neutropenia and anemia. Ali developed a small patch of alopecia on the scalp and a limited area of vitiligo on the chest; otherwise continued to be in good general health. This case is mucocutaneous candidiasis without immunodeficiency or endocrinopathy.

Patient with mucocutaneous candidiasis

Wiskott–Aldrich Syndrome

Case History 1

Riyadh was 8 months old when he was referred because of recurrent infections, thrombocytopenia, and eczema. He was full term and a product of nonconsanguineous parents. Two brothers died at the ages of 7 and 10 months because of bleeding, anemia, recurrent respiratory infections, sepsis, and eczema. Those brothers had history of rectal bleeding in the first week of their lives.

Riyadh was found to have thrombocytopenia and rectal bleeding since the first week of his life. He was hospitalized on two occasions for treatment of bleeding and anemia. One month before his referral, he was hospitalized with left pectoralis muscle abscess. He had generalized petechiae and bleeding eczema on the back of the neck, chest, cubital areas, and ankles. He had bilaterally draining ears, the culture of which grew a mixture of *S. pneumoniae* and H. influenza. He had chronic sinusitis. His parents reported history of stools with streaks of blood. He also had nosebleeds and bleeding when scratching his skin. He had small adenoids and atrophic lymphoid tissues. His complete blood count showed lymphopenia and eosinophilia with thrombocytopenia. Serum IgM was less than 0.1 g/L, isohemagglutinin antibody titer was less than 1:1, serum IgE was 5,000 IU/ml (normal up to 72 IU/ml), IgA was 2.1 g/L (normal, 0.3–1.2 g/L), and IgG was 4.8 g/L. Platelet histogram showed 90% of the platelets to be between 2 and 6.2 fL.

The patient was placed on TMP/SMX prophylaxis, IVIG, and transfusion with irradiated blood when indicated. He developed crops of molluscum contagiosum on the face and upper extremities. The skin lesions were treated with local applications of acanthritine and curretting with minimal effect. His hepatitis screening was positive for hepatitis B surface antigen.

At the age of 18 months, he received BMT from his full-matched 4-year-old sister after conditioning with busulfan and cyclophosphamide. The patient developed mild GVHD on day 12, which responded well to treatment. At 3 months, his chromosome analysis showed 46 XX. At 6 months, he was immune competent, and his immunizations were given with good antibody response and without complications. At age 13 years, Riyadh is completely healthy, without bleeding eczema or infections. His serum IgG, IgA, IgM, and IgE all returned to normal values.

Case History 2

Mohammad was 12 h when the diagnosis of WAS was made. He was found to have small sized platelets and a count of 17,000/mm^3. His older brother, Sagr, was known to have WAS. Mohammad had rectal bleeding 48 h postnatally and he developed staphylococcus septicemia with a stormy course. He had two brothers, Rakan, who died at age 2 years with thrombocytopenia of unknown etiology, and 3-year-old Sagr, who was diagnosed to have WAS. Both Mohammad and Sagr had several episodes of bleeding, including per rectum, in the first week of their lives, as well as recurrent otitis media.

As no full-match donor was found, other than a 6-year-old sister with two loci on A and B mismatched, splenectomy was done on both boys. Mohammad had intracranial bleeding that was treated with ventriculoperitoneal shunt. Both brothers had eczema, skin infections, high serum IgE and IgA, and low serum IgM. Both patients were given pneumococcal vaccine before splenectomy and were placed on penicillin prophylaxis. During this time, the older brother, Sagr, developed pneumococcal septicemia and meningitis and died 6 h after admission.

Because of what happened to the two brothers, it was decided to transplant Mohammad, though there were two HLA loci mismatched. The patient was transplanted after conditioning with busulfan and cyclophosphamide. He engrafted with no complications. His chromosome study, post-BMT, showed 46 XX. His serum immunoglobulins returned to normal values, and his platelet count and size normalized. Three years post transplant, the patient is doing well with no infections or eczema.

Chediak–Higashi Syndrome

Case History 1

Atef was 3 months old when he was diagnosed as having CHS; his parents suspected the diagnosis at birth because four of his brothers died with the syndrome. He had typical findings of partially gray hair and freckled skin, and recurrent fever. His peripheral blood and bone marrow had the pathognomonic giant lysosomal cytoplasmic granules. The patient had several febrile episodes with sepsis and pyogenic arthritis. He was treated with antibiotics and ascorbic acid (0.5 g daily).

At the age of 5 years, he developed hepatosplenomegaly, lymphadenopathy, and pancytopenia. In vitro studies showed defective chemotaxis. Biopsy of the liver, bone marrow, and lymph nodes showed infiltration by mononuclear cells. His cerebrospinal fluid (CSF) showed atypical lymphocytes. The patient was prepared for BMT from his 8-year-old sister. Unfortunately, he died from intracranial hemorrhage before he was transplanted.

Close-up to show the typical hair and skin color in Griscelli Syndrome

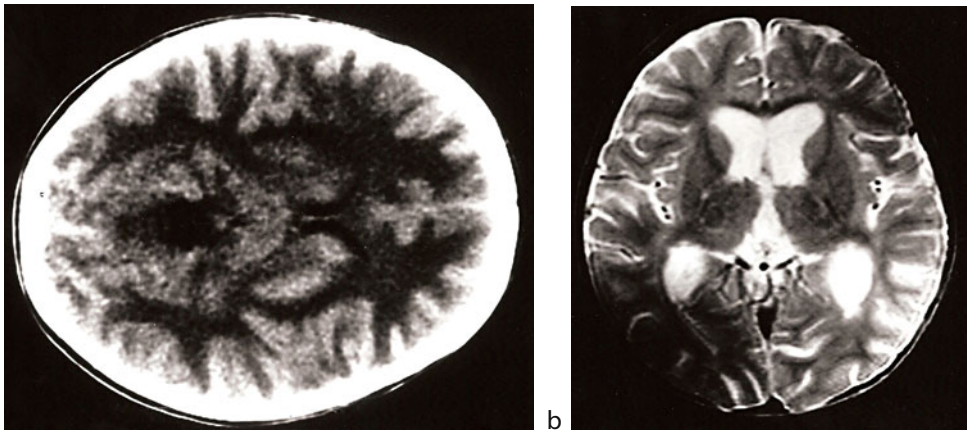

Figure 129.14
(a) CT of the brain of pt. with Griscelli Syndrome. (b) MRI of the brain of pt. with Griscelli Syndrome

Case History 2

Mohammad was a 10-year-old boy at the age of referral. He had lifelong history of recurrent fever and infections, viral, bacterial, and fungal. He was mentally retarded. His features were those of classic CHS, with partial oculocutaneous albinism (*Fig. 129.12*). His skin was very light in color compared to his parents. His white blood cells (WBCs) showed giant granules. He had peripheral neuropathy with foot drop. Sural nerve biopsy showed CHS cells infiltrating the nerve sheath. He had pancytopenia and giant splenomegaly. He required several blood transfusions with fresh frozen plasma, platelets, and packed red blood corpuscles, with no improvement. His leukocytes showed markedly depressed chemotactic activity. Splenectomy resulted in an immediate normalization of all blood elements. The histopathology of the spleen showed signs of hypersplenism and cells with cytoplasmic giant granules. Immunologic studies 6 weeks postsplenectomy showed reversal of the chemotactic activity, and no blood transfusion was needed. Six months postsplenectomy, the patient complained of sudden and severe headache and died within hours at home. The suspected cause of death was intracranial hemorrhage.

Griscelli Syndrome

Case History 1

Manal was 5 years old when she was referred to our hospital because of seizure, coma, and the suspected diagnosis of viral meningitis. She was the product of a

full-term pregnancy, born to first-degree cousin parents from the north of Saudi Arabia. She had four sisters and two brothers who were healthy. The parents lost two children, a 2-year-old boy and a 4-year-old girl with history of gray hair, light skin, recurrent fever, anemia, seizure, coma, and death. Their features and clinical history were similar to those of Manal.

Manal was noticed at birth to have freckles with areas of hypopigmented skin with alternating areas of normal skin. Her hair was golden to silvery gray in color, especially on the eyebrows. She had several episodes of fever and was found to have anemia and hepatosplenomegaly. She was given one blood transfusion. One month before her referral, she became febrile, complained of headache, and became lethargic. She also had three short attacks of clonic tonic seizures that lasted for 30 min each. The patient became unresponsive and comatose.

On examination, the patient had typical features of PAID (Griscelli/Harfi syndrome) (◉ *Fig. 129.13a*, *b*). She was deeply comatose and unresponsive to painful stimuli. Her pupils were sluggish in reaction, and her reflexes were depressed. Ophthalmologic exam showed bilateral optic neuritis. Complete blood count showed pancytopenia; her spleen was 8 cm below the costal margin and her liver was 6 cm down. Her alanine transaminase (ALT) was 120 U/L and aspartate transaminase (AST) was 95 U/L. Serum IgG, IgA, and IgM were normal. Isohemagglutinin antibody titer was less than 1:1, with blood group "O" positive. Her CSF showed a WBC count of 18/mm^3; all were lymphocytes. Cytospin and monoclonal study of these cells showed 50% to be B lymphocytes and 50% to be CD4 helper T lymphocytes. CSF protein was 980 mg/dL (normal, up to 450 mg/dL). CT scan and MRI of the head showed extensive white matter demyelination with ventricular dilation and brain atrophy (◉ *Fig. 129.14a*, *b*).

In vitro lymphocyte blastogenesis showed moderately depressed response to PHA, Con-A, and allogeneic pooled lymphocytes with a high response to pokeweed mitogen (2.5 times the control). A skin biopsy showed sparse Langerhans cells but a normal number of melanocytes, with very little melanin in the prickle cell layer of the epidermis. Microscopic examination of the hair showed characteristic distribution of melanin, with areas of clumping and areas of no pigment (◉ *Figs. 129.15* and ◉ *129.16*). The patient was started on a combination of prednisolone, methotrexate (12 mg/m^2 intrathecally, weekly for 6 weeks), and intravenous methotrexate (25 mg/kg every week). The patient started to respond gradually and was able to wake up from her coma. Repeat MRI of the head showed complete recovery of the white matter. The patient continued in remission for 6 months

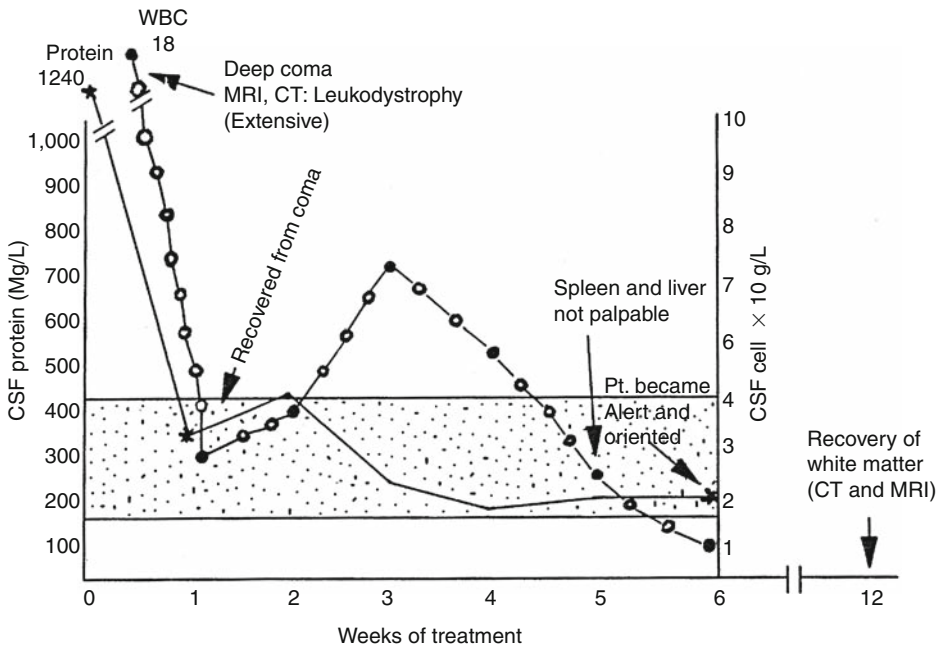

Figure 129.17
Clinical Course of a patient with Griscelli Syndrome

before she relapsed. Repeat of the same treatment failed to induce full remission, and the patient died at the age of 6½ years in a deep coma (Fig. 129.17).

During Manal's follow-up, her mother delivered another boy with the classic features of the syndrome. He was transplanted from his 4-year-old sister with good signs of early engraftment. Unfortunately, the baby developed gram-negative sepsis and died 28 days post-BMT. One year later, the parents had another boy with the same syndrome.

Case History 2

Lubna was the product of first-degree, double-consanguineous cousins. Because the parents had one son

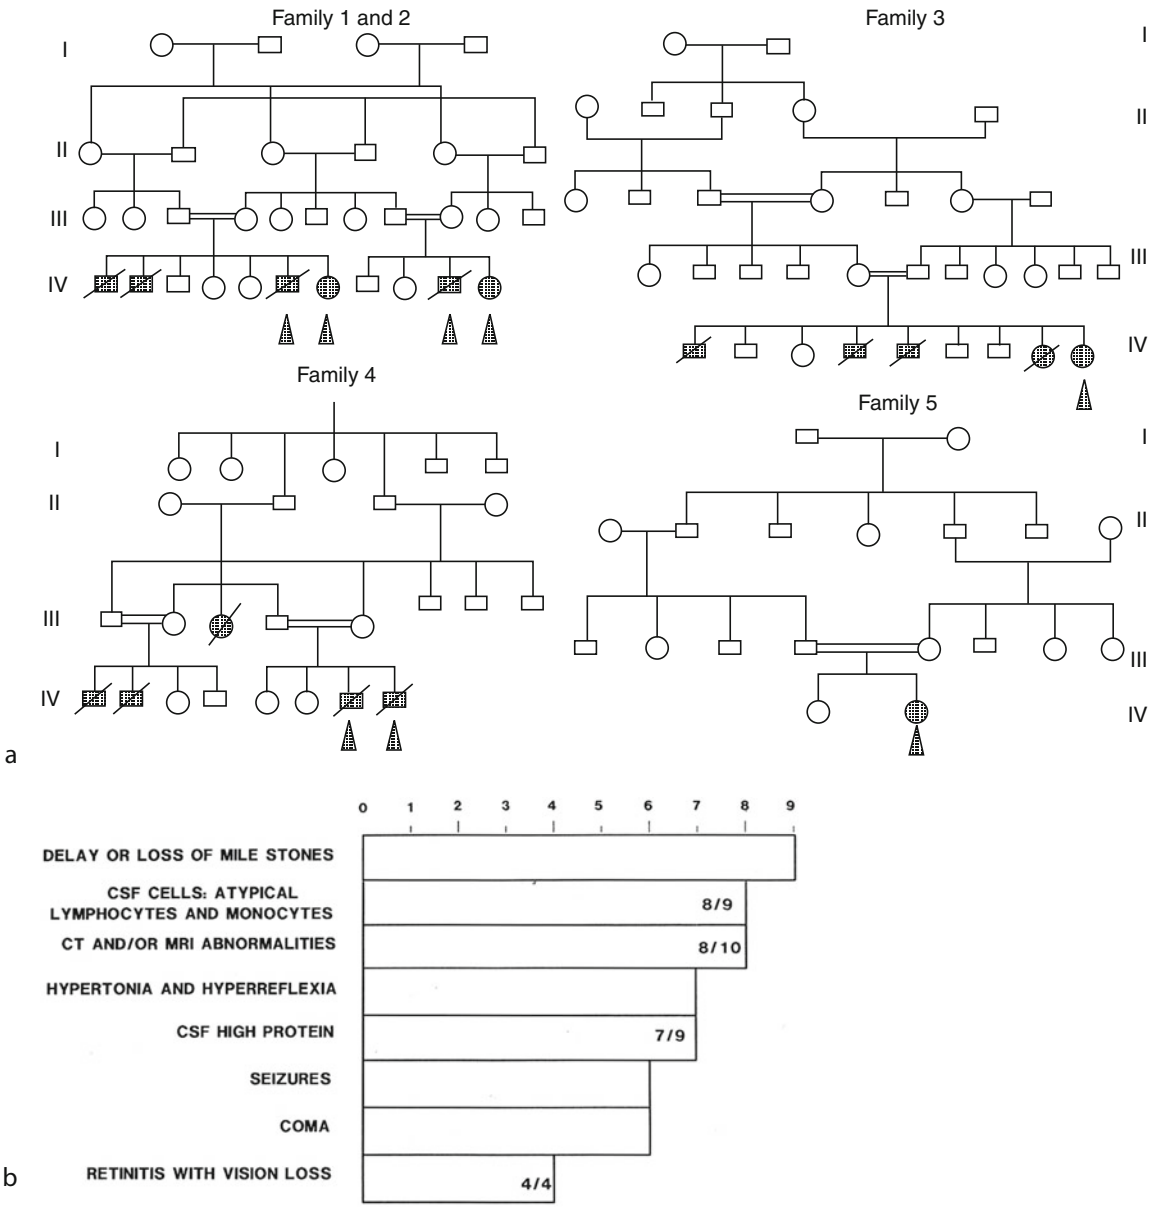

Figure 129.18
(a) Family pedigree of patients with Griscelli/PAID Syndrome. (b) CNS findings in 9 patients with Griscelli Syndrome

Table 129.3
Clinical findings in PAID (Griscelli disease)

Findings		
Total patients	18	Hypertonocity, ataxia-hyper reflexia, hemiparesis, facial palsy, coma, retinitis, mental retardation
Male /Female	9/9	
CNS involvement	11(61%)	High protein mononuclear cells (50% B-cells, 50% CD4)
CFS involvement		
Abnormal EEG	11(61%)	Mild brain atrophy (2 patients)
CT scan and MRI		White matter demyelination (11 patients)
Abnormal CT scan	11	Cerebellum alone (3 patients)
Abnormal MRI	8	generalized (4 patients)

who died a year earlier with the syndrome, and five of their nephews and nieces had the syndrome, they were able to make the diagnosis at birth (*Fig. 129.18*). When Lubna was seen at 1 month of age, she had the classic features of the syndrome. HLA and DR class typing showed one of her brothers to be a full match. After conditioning with busulfan and cyclophosphamide, Lubna was transplanted from her brother. She engrafted without complications. Four years post transplant, she is completely healthy with normal immune functions, but her phenotypic features in regard to hair and skin color did not change.

The father's sister was married to the mother's brother (Lubna's aunt and uncle) and both couples are from the southern part of the Arabian Peninsula. The second couple lost five children with the syndrome; one child died 3 years after BMT from overwhelming sepsis. Her four brothers died in coma as a result of CNS involvement. *Table 129.3* summarizes the clinical findings in 18 patients.

Comments

All 34 cases came from these two tribes, one from the far north and the other from the far south, with no blood relationships or intermarriage between the two tribes. It seems that the gene mutation occurred, probably simultaneously, in these two areas. Only one patient came from Bahrain and had no relationships to either tribe. The defect seems to be a stem cell defect, which can be corrected by early BMT from a full-match donor. *Figure 129.18* shows family pedigrees of some patients with Griscelli/PAID Syndrome.

Allergic Disorders

Harb A. Harfi

130 Allergy and the Allergic Diseases

Karthik Krishnan · William K. Dolen

The management of patients with the allergic diseases is a challenging and rewarding aspect of pediatric practice. It is estimated that 20% of the world's population suffer from one or more of the allergic diseases. For mysterious reasons, the prevalence of allergic diseases among children has increased significantly in the last few decades, resulting in considerable morbidity and mortality. Understanding basic concepts of the allergic diseases is essential to the timely diagnosis and effective management of children with these conditions and their comorbidities.

Definition of Allergy

In 1906, the Austrian pediatrician Clemens von Pirquet introduced the term "allergy" (from the Greek *allos*, "other," and *ergon*, "reaction") to describe a state of hypersensitivity, rather than simple immunity, to foreign proteins. Since then, the term has acquired many different meanings, in medicine, in pseudoscience, and in colloquial speech. Fundamentally, "allergy" is a state of sensitization of the immune system, a disease mechanism, rather than a specific disease entity.

Classification of Immunopathologic Mechanisms

In the modern era, Gell and Coombs have classified mechanisms of immunopathology for the purpose of study (*Table 130.1*). This classification remains very useful in the study of disease mechanisms, although a medical condition in an individual patient might simultaneously involve more than one mechanism. The European Academy of Allergology and Clinical Immunology (EAACI) defines the term "allergy" as inclusive of any of these mechanisms. In the United States, the term usually refers to Type I (IgE-mediated) hypersensitivity, unless otherwise qualified.

Type I Hypersensitivity

Type I hypersensitivity is IgE dependent. A sensitized patient has been exposed to an antigen and by a complex, highly regulated process has made a specific IgE antibody response. Antigens that produce IgE responses are called "allergens." These are typically protein antigens foreign to the body. IgE is a homocytotropic antibody that binds to various cells of the immune system via high-affinity and low-affinity receptors. In a sensitized patient, subsequent allergen exposure leads to cross-linking of allergen-specific IgE molecules bound to mast cells and basophils via high-affinity receptors. Receptor aggregation causes these cells to release preformed and newly synthesized mediators of immediate hypersensitivity, including histamine, tryptase, and leukotrienes (*Fig. 130.1*). In a patient who also has an allergic disease state (for example, anaphylaxis, rhinitis, asthma, and atopic dermatitis), these mediators will produce disease symptoms. Because the mast cell and basophil mediators are released so quickly (seconds to minutes) upon allergen exposure, these reactions are termed "immediate hypersensitivity."

Type II Hypersensitivity

These immunologic reactions are mediated by antigen-specific IgG or IgM class antibody bound to cell surfaces via specific receptors. Antigen binding by antibody causes lysis of sensitized cells, often by complement-dependent mechanisms. Clinical examples include hemolytic anemia of the newborn (which is not usually complement dependent), Goodpasture syndrome, and some types of transplant rejection.

Another disease mechanism now classified as Type II involves an autoantibody to a cell surface receptor. Antibody binding can either prevent receptor-mediated signaling, or induce it. In some cases of chronic urticaria, an autoantibody to a component of the high-affinity IgE receptor can cause mast cell activation in a non-IgE-mediated

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_130,

Table 130.1
The classic Gell and Coombs classification of hypersensitivity reactions

Class	Reaction type	Immunologic mechanism	Clinical disease example
Type I	Immediate hypersensitivity	IgE-mediated	Anaphylaxis
Type II[a]	Cytotoxic	Cell-bound IgG or IgM	Hemolytic anemia
Type III	Immune complex	IgG or IgM	Vasculitis
Type IV	Delayed hypersensitivity[b]	T lymphocyte mediated	Contact dermatitis

[a]A second mechanism now classified as Type II involves an autoantibody to a cell surface receptor
[b]Another mechanism involves T lymphocyte–dependent activation of eosinophils and other cells

manner. An autoantibody to the thyroid-stimulating hormone (TSH) receptor can cause unregulated thyroxin synthesis (Grave's disease), whereas a different autoantibody to the same receptor can block the action of TSH, resulting in hypothyroidism.

Type III Hypersensitivity

Type III hypersensitivity involves formation of immune complexes of antigen and antibody, of IgM or IgG class. The relative proportion of antigen and antibody determines immune complex size. When circulating immune complexes deposit in small blood vessels in tissue, they can activate the complement system, resulting in vasculitis with tissue destruction. Disease manifestations depend on which tissues are involved. Clinical examples include serum sickness, rheumatoid arthritis, and the Arthus reaction.

Type IV Hypersensitivity

Unlike the other three types of hypersensitivity, classic Type IV reactions are mediated by antigen-specific Th1 and cytotoxic T lymphocytes. Because T cell activation is a relatively slow process, it takes 1–3 days for disease manifestations to appear. Contact dermatitis is a clinical example. A different example of Type IV hypersensitivity involves T lymphocyte–dependent activation of eosinophils and other cells, resulting in non-IgE-mediated rhinitis or asthma.

Allergy and the Allergic Diseases

Sensitization to antigen, resulting in the formation of antigen-specific antibodies or T lymphocytes, is not necessarily a disease state. Sensitization is found in normal, asymptomatic individuals. In order for a sensitized individual to develop symptoms following antigen exposure, the patient must have a disease state in addition to immunologic sensitization. This concept will be explored in terms of Type I hypersensitivity.

The diseases commonly associated with Type I hypersensitivity are often called the "atopic diseases" or the "allergic diseases." The classic atopic diseases, which have a hereditary tendency, are rhinitis, asthma, and atopic dermatitis. These conditions are often called the "allergic triad" since they tend to occur together in the same patient at different stages of life. Disease symptoms can be produced by different immunologic mechanisms, primarily Type I IgE-mediated immediate hypersensitivity. However, they are not invariably IgE dependent; disease manifestations can be triggered by various immunologic and nonimmunologic mechanisms. For example, asthma can be triggered by respiratory virus infections (nonallergic, or "intrinsic," asthma) or by cat exposure in a cat-sensitized patient (allergic, or "extrinsic," asthma). Other diseases that can be triggered by IgE-dependent as well as non-IgE-dependent mechanisms include anaphylaxis, urticaria, and some types of conjunctivitis and gastroenteritis (in particular, eosinophilic gastroenteritis).

Risk Factors in the Development of the Allergic Diseases

The etiology and pathogenesis of the allergic diseases are the subject of worldwide research. The clinical manifestation of an allergic disease involves a complex interplay between host characteristics (i.e., race, gender), genetic influences, and a multitude of environmental factors. The contribution and interaction of these factors differ among the atopic diseases and are poorly understood.

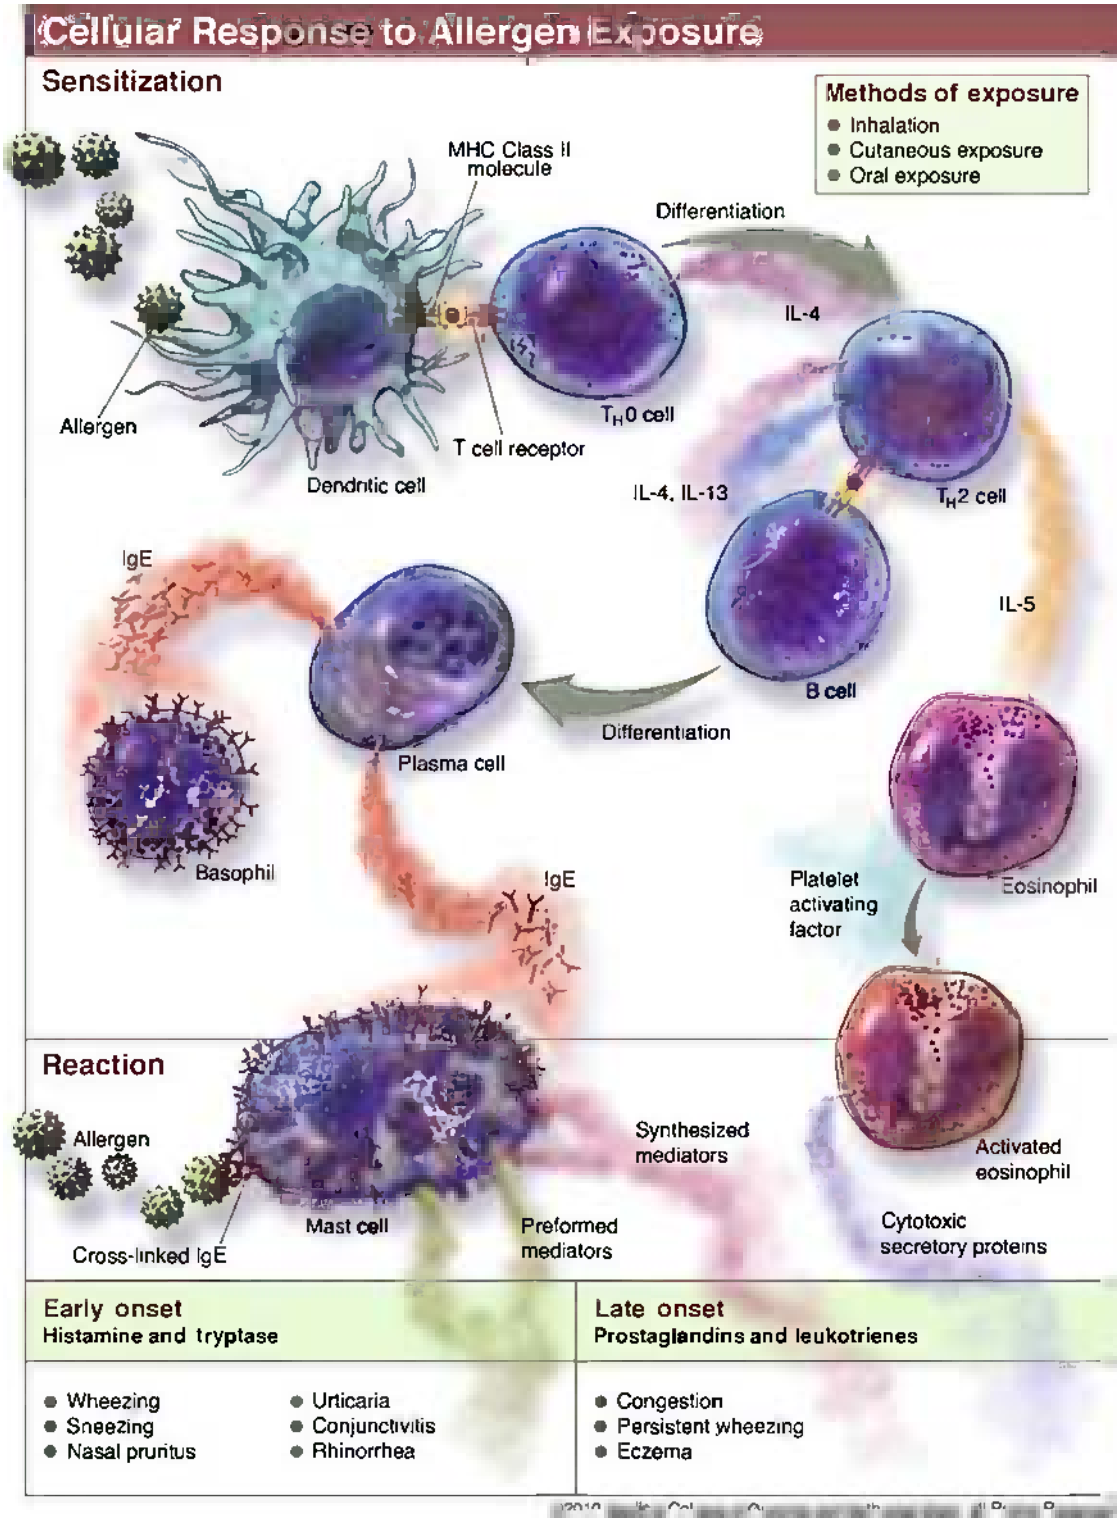

Figure 130.1
Cellular responses to allergen exposure: sensitization and reaction

Furthermore, whether an individual patient also has IgE-mediated allergic sensitization is an additional variable affecting disease expression.

The atopic diseases have a strong hereditary tendency, whereas the inheritance pattern of the other allergic diseases is highly variable, suggesting variable expression between different groups of genes. Certain individuals may co-express several atopic diseases while others manifest only one atopic disease. The atopic diseases can also occur without a family history of these diseases. The incidence of atopic disease is approximately 10% when neither parent has an atopic disease, 50% if one parent is atopic, and 66% when both parents have an atopic disease. Extensive genomic studies have identified specific genes associated with atopic diseases; however, no definitive casual genes have been discovered. Other factors involved in the development of atopic diseases are environmental factors such as allergens (both indoor and outdoor), animal exposure, air pollution, infections, gut flora and other microbes, antibiotics, air pollution (both indoor and outdoor), environmental tobacco smoke, maternal diet, obesity, and low vitamin D levels.

Children are not born with IgE-mediated allergic sensitization, but rather with the ability to produce specific IgE antibodies in response to environmental exposures. Reasons for this appear to be independent of, but somehow related to, mechanisms for developing the allergic disease state. External exposures are necessary for sensitization in susceptible individuals. Routes of exposure include inhalation, ingestion, or direct contact. The production of specific IgE antibody to allergens may take weeks to years of exposure.

Whether or not there is concomitant IgE-mediated allergic sensitization, a common feature of the chronic allergic diseases (such as rhinitis, asthma and atopic dermatitis) is eosinophilic inflammation. Successful management brings this inflammatory response under control.

Clinical Approach to Patients with Suspected Allergic Disease

Evaluation of all patients begins with a detailed medical history and physical examination, with the intent of establishing whether an allergic disease might be present, and determining what factors might be triggering acute symptoms and sustaining chronic inflammation. Symptoms of allergic diseases typically involve the eyes, nose, lungs, skin, and gastrointestinal system. Each symptom has a unique differential diagnosis based on the age of the patient. For instance, wheezing at birth is likely due to an anatomical defect, whereas the sudden onset of unilateral wheezing in a two-year-old is highly suspicious for a foreign body aspiration. Furthermore, symptoms such as wheezing, sneezing, and eczema are not specific for the allergic diseases but may be seen in many other conditions. The goal of the history and physical examination is to generate a differential diagnosis that will guide further evaluation, including any necessary diagnostic testing (laboratory or procedural).

A good medical history helps establish whether an allergic disease might be present, and identifies potential immunologic and nonimmunologic trigger factors. The history identifies which symptoms are (pertinent positive) or are not (pertinent negative) present, and carefully characterizes them by eliciting the onset, location, duration, characteristics, associated symptoms, relieving factors (including medications and other treatments), temporal factors, and severity of symptoms.

The history identifies the age at which symptoms began and how long they have been present. Atopic dermatitis begins in infancy, allergic rhinitis normally after two to three years of appropriate exposures, and eventually asthma. This sequence is commonly referred to as the "atopic march." The next line of questions should pertain to the symptom pattern. Are symptoms acute or chronic? Are they continuous (perennial), intermittent (seasonal), or intermittent exacerbations superimposed on a continuous background? Knowledge of pollination patterns of regional flora helps in correlating symptoms with the appropriate seasonal exposures. Environmental allergens such as house dust mites, animal dander, and fungi are present year round, albeit at different levels of exposure. An understanding of the frequency and severity of episodes reveals the impact on the quality of life of the patient. Children with mild symptoms that occur infrequently rarely come to the office. On the other hand, the allergic diseases can produce frequent episodes resulting in school absenteeism, considerable morbidity, and mortality. Symptom patterns that change in severity or character over the years may alter the diagnostic approach. For instance, a five-year-old who previously had nasal symptoms only in the spring, but now has symptoms in the fall, warrants repeat skin testing to identify sensitization to new triggers.

It is useful to ask the patient and parents what they suspect as triggers, exacerbating or precipitating symptoms such as pollens, dust, animals, foods, odors, and medications. Most patients are conscious of obvious triggers. Elicit whether symptoms are affected by infections, emotions, hormonal factors (pregnancy or menstruation), and changes in climate (humidity and temperature).

One asks whether symptoms occur at a particular time of day, such as upon awakening in the morning or worse at night. Are there particular locations where symptoms are worse or better such as a friend's home, school, hospital, indoors, or outdoors? Are the same symptoms present while visiting a different geographical location or while vacationing on a beach?

Details of timing and location of symptoms are relevant to correlating this information with suspected allergens and other trigger factors, allowing the clinician to identify potential causes of the patient's symptoms. Specific allergy testing, if indicated by the history, should confirm this impression. Positive skin test reactions with allergens are clinically relevant only if they correlate with the possibilities suggested by the history. If a skin test is negative to a particular allergen suspected to be relevant by history, this does not automatically dismiss the relevance of the history.

Information regarding previous and current medications should be reviewed. A detailed medication history should include dosage, frequency of usage, start date, efficacy, and adverse effects for all medications. A good response to medical therapy may suggest an allergic basis of the patient's symptoms. For instance, corticosteroids typically improve symptoms of allergic diseases. Lack of benefit may indicate other causes for the symptoms. However, medication failure may also result from improper use or lack of adherence. Certain medications, such as antihistamines, decongestants, and corticosteroids, may alter physical findings or skin test results. It is important to know when the last dose of antihistamine was taken since they can suppress skin test reactivity for days or weeks.

A detailed environmental history is a unique feature of an allergy history. An understanding of a patient's environment is important for identification of possible triggers and exposures to particular allergens (*Table 130.2*). It is also useful in planning environmental control measures. The indoor environment is the source for both allergens and non-specific irritants. The major indoor allergens include house dust mites, cockroaches, animal dander, and molds. A detailed description of indoor environment with special attention to the child's bedroom(s), pet exposures, and presence of a basement or water damage is helpful in determining the influence of the above indoor allergens in the home. Non-specific irritants include environmental tobacco smoke exposure, gas appliances, heating and cooling systems, and car exhaust fumes from attached garages.

The family history identifies the presence of atopic diseases in the parents and/or siblings. A family history of atopic disease increases the probability that the patient has an allergic disease. The social history should account normal daily activities, hobbies, and occupation of the patient. The past medical and surgical histories often reveal pertinent information. For instance, a history of extreme prematurity requiring prolonged assisted ventilation would be important in formulating the differential diagnosis of wheezing in a child. A thorough dietary history may reveal adverse food reactions that might be relevant to present symptoms. Hospitalizations and injuries should be documented. Operations such as tonsillectomy, adenoidectomy, and sinus surgery should be noted. The review of systems may uncover symptoms not reported in earlier parts of the history, suggest the presence of other diseases, or reveal comorbid conditions such as gastrointestinal reflux.

Table 130.2
Potential environmental triggers

Outdoor allergens	Indoor allergens	Irritants
Pollens	House dust mite	Tobacco smoke
Tree	Animal dander	Pollutants
Grass	Cockroach	Diesel exhaust particles
Weed	Other pests	Ozone
Fungi	Mouse	Cleaning chemicals
	Rat	Strong odors
	Molds	Perfumes
	Foods	Candles
		Air fresheners
		Temperature changes
		Cold air
		Humidity
		Emotions

The physical examination may provide additional clues for an accurate diagnosis. Vital signs and growth parameters warrant careful review. Children with chronic diseases may have poor growth either from the disease itself or from effects of therapy. The examination will report the overall general appearance of the child. Is he well developed and nourished? Does she have any obvious signs of allergic diseases? Following this brief visual inspection, an organized systematic approach to the examination is useful in identifying allergic manifestations in various organ systems. Particular features of the physical examination commonly seen in allergic diseases are conjunctival injection and edema, periorbital swelling, dark discoloration and/or wrinkles beneath the lower

eyelids, wrinkling of the nose, pale to blue mucosa with edematous nasal turbinates, pruritic, eczematous patches of skin, and presence of dermatographism. Abnormal findings on chest examination are usually seen in acutely sick children or children with severe, chronic asthma. The absence of lung findings does not exclude asthma.

Basic Testing

Laboratory and procedural evaluation should corroborate the clinical impression from a complete allergy history and physical examination. Basic testing is planned to address the differential diagnosis. Sometimes, no testing is indicated.

When asthma is suspected, spirometry, an objective measure of lung function, is indicated in children older than 4–5 years of age to evaluate for airway obstruction and reversibility. Regardless of pre-bronchodilator results, the initial evaluation should include a post-bronchodilator study to evaluate for reversibility of obstruction. Although no reversibility cutoff has been established in children, many have adopted the adult criterion of >12% reversibility (and >200 mL) in FEV1 following bronchodilator therapy to make a firm diagnosis of asthma. The lack of reversibility does not refute the diagnosis of asthma.

Bronchial provocation challenge can be used to assess airway responsiveness in patients with normal baseline spirometry. The agent most commonly used is methacholine, a potent non-specific bronchoconstrictor. Histamine, mannitol, exercise, and cold air are useful alternatives for some situations. Challenge testing determines the presence and magnitude of bronchial hyperreactivity in patients with normal or near-normal spirometry. The patient inhales increasing concentrations of methacholine until a 20% drop in FEV1 from baseline is noted. A negative methacholine challenge greatly lessens the likelihood of asthma; however, a positive challenge does not confirm the diagnosis of asthma, given the test's poor specificity.

The measurement of the level of fractional exhaled nitric oxide (FeNO) is being utilized both in asthma diagnosis and monitoring of asthma control. The FeNO level is a noninvasive biomarker of eosinophilic airway inflammation. Patients with uncontrolled asthma have higher levels of FeNO compared to those without asthma. FeNO concentrations acutely rise in conjunction with increased airway inflammation, sputum eosinophilia, and upper respiratory infections. Treatment of asthma with inhaled corticosteroids results in a decrease in FeNO levels. The equipment and supplies required to measure FeNO levels are affordable, simple to operate and maintain, and easily performed by most school-aged children, making it a very appealing tool. Reference values for FeNO concentration levels are based on age. FeNO levels are affected if performed after spirometry or after consuming foods high in nitrates.

However, the correlation between airway inflammation, FeNO levels, and asthma is not well delineated. It is not yet clear whether FeNO should be used as a diagnostic tool for asthma, to guide asthma management, or to monitor asthma control. Results of FeNO testing do have a high negative predictive value for the diagnosis of asthma (i.e., a low FeNO level lessens the likelihood of asthma), similar to methacholine challenge. There are conflicting results in the literature regarding the utility of serial FeNO levels to guide asthma management and predict asthma control following modifications in therapy. Further, controlled clinical trials may better define the role of FeNO measurement in the diagnosis and management of asthma.

Any child presenting with nasal obstruction warrants a detailed examination of the anterior and posterior nasal cavity. Rhinoscopy is a relatively simple and safe method for visualizing the upper airway anatomy in an office-based setting. Examiners can routinely identify the cause of the nasal obstruction, which may include mechanical obstruction from adenoidal hypertrophy, nasal polyps, or choanal stenosis.

In patients with suspected uncomplicated allergic disease, a complete blood count might show an elevated absolute peripheral eosinophil count (>500 cells per microliter). While this is a common finding in children with atopic diseases, it lacks diagnostic specificity. Other conditions associated with peripheral blood eosinophilia include malignancy, hypoadrenalism, drug reaction, collagen vascular disease, and parasitic infestation.

Allergy Testing

Because of the complexity of identifying triggers of allergic diseases, selecting appropriate test methods, performing testing, and interpreting results, allergy testing is fundamentally a subspecialty procedure. Various test methods are available.

Serum total IgE levels are not usually useful in the evaluation of patients with suspected allergic disease. While total IgE serum levels are often elevated in such patients, particularly in atopic dermatitis and asthma, an elevated serum total IgE level is not specific for the allergic

diseases. Consequently, this test has very limited value as a diagnostic tool for allergic disease.

Specific allergy testing by in vivo or in vitro methods is used to determine the presence of specific IgE to various allergens (*Table 130.3*). The presence of specific IgE indicates sensitization, not disease. The disease state occurs when only clinical symptoms correlate with results of allergy testing.

Allergen provocation testing is performed to determine the association between allergen exposure and the presence of symptoms. In provocation challenge testing, allergens are directly exposed to the skin, conjunctiva, nasal mucosa, or lungs.

Skin Testing (In Vivo)

When indicated, skin testing can be performed in patients of any age, including infants. The selection of allergen extracts (pollens, house dust mites, animal dander, molds, and foods) to be tested should be individualized based on the history. There are two skin testing techniques, namely, epicutaneous and intradermal, each with advantages and limitations. In the skin prick test, a drop of allergen extract is applied to the patient's skin, usually the back or ventral surface of the forearm. The allergen extract is introduced into the epidermis by a gentle needle prick or puncture through the drop of extract. A positive control (histamine) and a negative control (saline) are placed at the same time to assess skin reactivity. Patients with dermatographism may react to the skin pressure involved in performing testing, resulting in false-positive results. A poor histamine response indicates the presence of an antihistamine or related agent, resulting in false-negative results. The sizes of the wheal (swelling) and flare (erythema) are measured 15–20 min after test placement. There is international consensus that a wheal size at least 5 mm larger than the negative control is a "positive" result; some clinicians will accept smaller reactions as positive. The size of the reaction does not necessarily correlate with the severity of symptoms.

Intradermal skin testing is a more sensitive, but less specific, alternative to the skin prick test. A small amount (0.02 mL) of diluted allergen extract is injected into the dermis of the arm. It is often used for testing with low-potency extracts, such as drugs and insect venoms. Some clinicians apply intradermal tests when skin prick testing is negative, but the patient has a convincing history suggesting sensitization. It is controversial because of a lack of studies supporting clinical utility in this situation, and non-specific irritant reactions are commonly seen when concentrated extracts are used. Practice guidelines recommend not testing for food allergens by the intradermal technique due to the increased risk of systemic reactions (anaphylaxis). Skin testing is rapid, inexpensive, and correlates well with symptoms. Disadvantages include inconvenience of discontinuing antihistamine 3–7 days prior to testing, discomfort from pruritus, and minute risk of a systemic reaction.

In Vitro Testing

There are several immunoassay methods available to detect the presence of allergen-specific IgE antibody in the serum. The test is performed by incubating an allergen extract coupled to a solid phase matrix with a small amount of the patient's serum. Antibody present in the

Table 130.3
Comparison between specific allergy tests

	Skin test (in vivo)	Serum specific IgE (in vitro)
Test	Prick or intradermal test	Radioallergosorbent test (or modified version of assay)
Advantages	Immediate results	No risk of systemic reaction
	More sensitive than in vitro test	May continue antihistamine
	Inexpensive	
Disadvantages	Discontinue antihistamine use	Delayed results
	Risk of systemic reaction	Less sensitive than in vivo test
	Discomfort from pruritus	Increased cost
	Unable to perform in severe atopic dermatitis and dermatographism	

patient serum binds to the allergen-matrix. Specific IgE is detected by incubation with a labeled anti-human IgE antibody. The amount of IgE antibody bound to the allergen-matrix correlates to the quantity of serum allergen-specific IgE. Higher levels of allergen-specific IgE are more predictive of clinical symptoms. The main advantages of the blood allergy tests are safety (no risk of anaphylaxis, although there is a risk of phlebotomy-related syncope) and present no interference of results from medications, atopic dermatitis, or dermatographism. Although blood testing is less sensitive than skin testing, results correlate fairly well with skin testing. Disadvantages include cost and delay in results.

Food Challenge Testing

As noted above, allergen-specific IgE sensitization can occur without clinical manifestations. Oral food challenges determine whether a specific food has a causal relationship to symptoms and can help decide whether it is safe to re-introduce a specific food into a child's diet, given a history of an adverse reaction. There are three forms of oral food challenges: open, single blind, and double blind placebo-controlled. The latter is the gold standard for research, and is most appropriate clinically when the patient's symptoms are vague or subjective. In blinded studies, the smell and taste of the food being challenged is disguised. The patient is gradually challenged with increasing amounts of food at set time intervals until a reaction occurs or the patient tolerates an entire meal. Challenges are not commonly used to evaluate patients who have had severe anaphylaxis. In patients at risk, challenges should be performed in a medical facility with trained personnel equipped to treat anaphylaxis.

Unproven Tests

In the lay press and the pseudoscientific literature, various vague or subjective symptoms such as hyperactivity, fatigue, myalgia, and learning difficulties have been empirically attributed to "allergy." Specific IgE testing by any accepted method is not helpful in such situations. Unproven diagnostic tests, not based on sound scientific principles, are sometimes used to identify environmental triggers (inhalants and chemicals) or foods in order to explain a constellation of poorly characterized symptoms. The diagnostic value of these tests has not been examined or validated in rigorous controlled clinical trials. Furthermore, many of these tests are expensive and not covered by insurance companies. Examples of unproven tests include exposing various substances to the patient in an attempt to reproduce symptoms (provocation testing); presence of morphologic changes in peripheral blood leukocytes exposed to an allergen (the cytotoxic test); measuring changes in leukocyte cell volumes following allergen exposure; measuring electrical impedance of the skin exposed to various food or inhalant extracts (electrodermal testing); and estimating muscle strength while holding allergens (applied kinesiology).

Managing Patients with Allergic Diseases

General Principles of Management

There is presently no cure for any of the allergic diseases, whether allergen-specific IgE is playing a role, or not. Thus, the basic goals in the management of allergic diseases include symptom control, decreasing exacerbations, and improving quality of life. In patients with IgE-mediated sensitization, these goals are achieved by avoidance of allergens and irritants, appropriate pharmacotherapy, and allergen immunotherapy. For patients with allergic diseases without evidence of IgE-mediated sensitization, management focuses on avoidance of nonallergic triggers (such as irritants), and pharmacotherapy.

When symptoms are only triggered by IgE-dependent mechanisms, the most effective mode of treatment is avoidance of known allergens, which is possible for many foods and drugs. However, strict avoidance of other trigger factors is difficult and not practical. Pharmacotherapy offers a wide selection of medications and minimal side effects, providing control of underlying inflammation and relief of symptoms. Immunotherapy is the only treatment option that can alter the natural history of the disease, producing a long-term remission of symptoms. Immunotherapy demands a time commitment from the patient and is expensive. Symptoms of allergic diseases can be successfully controlled with a combination of management options along with regular patient education.

Allergen Avoidance

Patients with the allergic diseases report allergic (IgE-dependent) and nonallergic triggers. Environmental control measures are the most effective means of reducing symptoms precipitated by trigger factors. Most children spend the majority of their day indoors, at home, or school. House dust mites, cat, and cockroach are the most

significant triggers in the indoor environment. Other pets, pests, fungi, and non-specific irritants (tobacco smoke and strong odors) can also be problematic.

Although no measures are available to completely eradicate house dust mites, significant reduction in exposure can be achieved. In sensitized patients, dust mite avoidance practices should be emphasized in the child's bedroom and bed since one-third of their day is spent in this one room. Appropriate and effective control measures include impermeable encasings on pillows, the mattress, and box spring; washing beddings weekly in bleach and hot water; and minimizing or removing items that collect dust (i.e., carpet, drapes, upholstered furniture, and stuffed animals). Other possible measures include removing room humidifiers since dust mites do not survive in <50% relative humidity and vacuuming floors and furniture weekly.

Many families own pets, most commonly a cat or dog. The major allergen source for these animals is hair, dander, and saliva. When a family member is allergic to a beloved pet, some families will remove the pet from the home, and others will not. Even after pet removal, pet allergen may be present for many months. The major cat allergen, Fel d 1, is particularly problematic since it is highly charged and sticks to a variety of surfaces. As a result, cat allergen is ubiquitous and is commonly transported to public places, including schools where cat allergen can be found on clothes of children who do not have pets.

Non-specific irritants in the home are often overlooked as symptom triggers. The use of products that generate strong odors (e.g., candles, perfumes), kerosene heaters, and wood burning stoves should be discouraged. Environmental tobacco smoke is a major indoor pollutant, and smoking cessation should be encouraged and discussed on a regular basis.

Avoidance of outdoor allergens is impractical, although certain measures will limit exposure. Limiting certain outdoor activities such as mowing the lawn during the grass pollen season significantly decreases exposures. Windows and doors should be kept closed during periods of high pollen levels to minimize exposures.

Pharmacotherapy

For all of the allergic diseases, the goal of pharmacotherapy is to control the disease by reducing underlying inflammation, and to provide relief from breakthrough symptoms. At the same time, it is important to minimize adverse effects from therapy. Drugs alleviate symptoms in allergic diseases by inhibiting or downregulating inflammatory mediator production and/or release, acting as mediator receptor antagonists, or promoting sympathomimetic effects. Certain medication classes are used for controller (preventive) therapy while others are more appropriate for relief (rescue) therapy. Controller medications are taken on a regular basis while reliever drugs are used as needed for acute symptom relief. It is very important to educate patients about the difference between "controller" and "reliever" medications, so that they will be used appropriately. The allergic diseases affect different organ systems. The concepts of therapy are similar, but the specific medications differ (Table 130.4). Most importantly, regardless of which medications are used, adherence and education on the proper use of these medications is the key to successful management.

Controller Therapy

Asthma controller medications include inhaled corticosteroids, leukotriene synthesis inhibitors and receptor antagonists ("antileukotrienes"), and cromolyn. Long-acting beta-2 receptor agonists, and theophylline have some anti-inflammatory action, and are sometimes classified as asthma controller therapy. Inhaled corticosteroids are recommended as first-line therapy for persistent asthma symptoms because of their potent anti-inflammatory properties. The other medications listed above are alternatives or add-on therapy to gain improved control of symptoms. Antileukotrienes and long-acting beta agonists are the most common add-on controller medications used. Cromolyn and theophylline are less frequently used due to compliance issues and safety concerns, respectively. Anti-IgE therapy, using recombinant humanized monoclonal antibody to IgE, is used in patients with allergic asthma, and is being studied in other conditions.

Controller medications for allergic rhinitis include intranasal corticosteroids, intranasal cromolyn, and leukotriene synthesis inhibitors and receptor antagonists ("antileukotrienes"). The most effective first-line therapy for control of nasal symptoms is a topical intranasal corticosteroid. Intranasal cromolyn is effective and safe but requires frequent dosing. Antileukotrienes have most thoroughly been studied as reliever therapy for rhinitis symptoms, and seem to be effective controller therapy in a subset of patients. Oral and topical intranasal antihistamines are most often used as symptom reliever therapy, but some products do have some degree of anti-inflammatory effect. Regular therapy is an alternative to intranasal corticosteroid therapy. For patients with problematic ocular symptoms, an antihistamine and a mast cell stabilizer are most effective in controlling symptoms.

Table 130.4
Pharmacotherapy options

Disease	Controller therapy		Reliever therapy
	First-line	Add-on	
Asthma	Inhaled corticosteroid	Long-acting beta agonist	Short-acting beta agonist
		Antileukotriene	Anticholinergic agent
		Theophylline	
		Cromolyn	
Rhinitis	Intranasal corticosteroid	Antileukotriene	Oral or intranasal antihistamine
		Intranasal cromolyn	Decongestant
			Intranasal anticholinergic
Atopic dermatitis	Oral antihistamine	Calcineurin inhibitor	Oral antihistamine
	Topical corticosteroid		

Regular antihistamine therapy, and non-specific skin hydration measures can decrease pruritus in patients with atopic dermatitis. When needed to control an exacerbation, topical corticosteroids are appropriate controller medication for atopic dermatitis. Different potencies of topical corticosteroids are used based on the severity of disease. Topical calcineurin inhibitors are used as add-on therapy in cases of severe atopic dermatitis. Some experts recommend systemic immunosuppression for the most severe cases.

Reliever Therapy

Short-acting beta agonists are the medication of choice for acute relief of asthma symptoms. Anticholinergics have been used as reliever medications in asthma, benefitting a select group of patients. Some antihistamines have a mild bronchodilator effect, but none are used as reliever therapy in asthma.

Antihistamines (oral and intranasal), and sympathomimetic decongestants are most commonly used for acute relief of nasal symptoms. Oral decongestants should be used sparingly for short periods of time with caution in children due to concerns of side effects. Topical decongestant sprays are also only for short-term therapy. Anticholinergics are effective against rhinorrhea of various etiologies.

Immunotherapy

Specific allergen immunotherapy modifies the immune response to limit or prevent symptoms upon exposure to the putative allergen. Because of the complexity involved in identifying appropriate patients for treatment, identifying allergen extracts for therapy, and writing the immunotherapy prescription, it is primarily a subspecialty procedure. However, while subspecialists should prescribe immunotherapy, patients may prefer to receive injections in their pediatrician's office. Current practice guidelines do not support the giving of injections at home because of the complexity of treating anaphylaxis.

Three routes of administration that have been used for immunotherapy, subcutaneous, sublingual, and oral immunotherapy, have proven to be effective in inducing tolerance (*Table 130.5*). In the United States, subcutaneous immunotherapy is the most established and widely practiced, whereas sublingual immunotherapy is considered investigational. Oral immunotherapy for severe food allergy is in clinical trials with encouraging results. Each of these forms will be discussed.

Subcutaneous Immunotherapy

Conventional immunotherapy is a clearly effective treatment option for both seasonal and perennial allergic rhinitis, allergic asthma, and insect venom anaphylaxis. It has not been well-studied for food anaphylaxis, atopic dermatitis, or urticaria, and its use in treatment of these conditions is controversial. Immunotherapy involves the subcutaneous injection of increasing doses of specific allergens in individuals to induce tolerance upon natural exposure to the offending allergen. Successful immunotherapy diminishes and prevents symptoms by inducing immunologic changes, hence modifying disease duration and progression. Immunotherapy increases production of specific IgG-blocking antibodies, increases activity of specific regulatory

Table 130.5
Comparison between three forms of immunotherapy

Subcutaneous	Sublingual	Oral
Weekly to monthly injections	Daily doses of allergen under tongue	Variable food ingestion schedule
Multiple components can easily be given simultaneously	Usually given as monotherapy (one type of allergen)	Monotherapy (single food)
Low prevalence of systemic reaction (including fatal reactions)	Very low prevalence of systemic reactions	Safety, administration schedules, and dosing under investigation in clinical trials
Established schedules and allergen dosing ranges	Schedules and dosing under investigation	Administered in medical facility
Injection administered in medical facility	Self-administration at home	Must continue daily intake of sensitized food
3–5 year treatment course	Likely 3–5 year treatment course	
Documented long-term efficacy	Long-term benefits not known	

(suppressor) cells, causes a lymphocyte differentiation shift from the T_H2 phenotype to the T_H1 phenotype, decreases allergen-specific IgE levels; and decreases mediator release from sensitized mast cells and basophils.

Effective immunotherapy depends upon selection of appropriate patients whose disease is mostly triggered by IgE-dependent mechanisms, and upon administration of clinically relevant allergen extracts. Immunotherapy is appropriate when symptoms are not controlled with avoidance measures and a trial of pharmacotherapy for an appropriate length of time at recommended doses. The severity and duration of symptoms should justify the time commitment, cost, and risks associated with immunotherapy. Another important consideration is the age of the patient. Immunotherapy is not usually recommended for infants and small children due to the increased risk and difficulty in communicating systemic reactions and emotional distress associated with repeated injections. Other factors to consider prior to initiating immunotherapy include compliance of frequent injections over a 5-year time period and accessibility to a nearby medical facility willing and equipped to administer immunotherapy. The benefits versus risks of immunotherapy warrant careful consideration in children on beta-blocker therapy, with autoimmune disorders, psychiatric disorders, and other chronic medical conditions (or therapies) that would place the patient at increased risk for a severe systemic anaphylactic reaction.

The allergist should discuss benefits and risks of immunotherapy with the patient and family prior to initiating therapy. They should know exactly what to expect over the next 3–5 years, understanding that the benefits from immunotherapy are not immediate; rather immunotherapy is a long-term plan. The types of immunotherapy reactions, including fatal anaphylaxis, should be discussed. Reactions can be local or systemic (generalized); immediate or delayed. Local shot reactions consist of swelling or erythema at the site of injection and do not predict future systemic reactions. Systemic reactions involve two or more separate organ systems (e.g., skin and lungs) and can be fatal. Because of this, injections should only be given in a medical facility with personnel trained to administer shots and equipped to handle medical emergencies. Most systemic reactions occur within 30 min of receiving an injection; as a result, patients should be monitored in the office for 30 min following an injection. Current practice guidelines recommend that injections should not be given at home or by untrained personnel. Patients with an asthma exacerbation are at increased risk for an adverse reaction.

The mixture of allergen extracts administered in immunotherapy is based on the patient's history and the allergy test results. Immunotherapy vials may contain single component allergen extracts, or mixtures of pollens (tree, grass, and weeds), dust mite, cockroach, animal dander, or molds. High protease extracts (dust mite, cockroach, and molds) are mixed and stored separately from low protease extracts (pollens) to prevent degradation and loss of potency.

The prescribing allergist will provide a dosage schedule for administering injections. The basic principle of immunotherapy is to gradually inject increasing doses of an allergen extract mixture until a maintenance dose is achieved. Initial injections are typically given every 3–7 days until maximum ("maintenance") doses are reached. This usually requires 6 months, at which point the interval may be increased to every 2–4 weeks. The physician supervising the injections should ensure that reactions are monitored throughout the immunotherapy course, consulting with the prescribing allergist when reactions occur. Local reactions do not necessitate dose

reduction, unlike systemic reactions, which may require up to a 50% reduction in dose prior to the next injection. The typical course of immunotherapy lasts 5 years.

The response to therapy should also be monitored throughout the course of immunotherapy. Successful results include reduction in symptoms, decreased reliance on medications for symptomatic relief, and increased tolerance upon natural exposure of the offending allergen. If no significant clinical benefit is achieved after 1 year of maintenance therapy, the supervising physician should consult with the prescribing allergist to determine whether there should be a reassessment of sensitivities or a discontinuation of immunotherapy. When a course of immunotherapy has been successful, the majority of patients benefit from continued improvement after discontinuing immunotherapy, while some experience a gradual relapse of symptoms. Such patients may benefit from reevaluation and another course of treatment.

Sublingual Immunotherapy

Sublingual immunotherapy (SLIT) involves the application of high doses of allergen extracts under the tongue, followed by swallowing. Compared to placebo therapy, SLIT is effective, but less effective than conventional subcutaneous immunotherapy. SLIT has been used mostly in patients sensitized to one type of allergenic substance. The appeal of sublingual immunotherapy includes lower rates of systemic reactions and patient convenience. Although there is a risk of systemic reactions, particular when high doses of mixtures containing multiple components are used in highly sensitive individuals, patients are usually permitted to self-administer SLIT at home. The main complaint from patients is local adverse reactions. Further investigation is required regarding optimal dosing, administration schedules, safety and efficacy of complex allergen mixtures, and long-term benefits.

Oral Immunotherapy (Desensitization): Food Allergy

Oral immunotherapy is a promising treatment option for children with severe food allergy manifesting as anaphylaxis or cutaneous symptoms. The use of oral desensitization in controlled clinical trials conducted in children with milk, egg, and peanut allergy has been effective. It is a potentially dangerous therapy, although it has been safe when used by highly experienced researchers. Treatment protocols involve gradually challenging patients with increasing amounts of the offending food allergen in rigorously supervised medical settings. Preliminary studies indicate oral tolerance to food allergens may be mediated by the same mechanisms involved in conventional immunotherapy.

Oral Desensitization: Drug Allergy

Oral desensitization is a form of immunotherapy used to induce clinical tolerance, primarily in patients with adverse drug reactions, IgE-mediated and non-IgE-mediated. Escalating doses of the offending drug are given in a fixed period of time until a tolerable, therapeutic drug dose is reached. Specific protocols for various drugs are available, including penicillin, aspirin, and trimethoprim/sulfamethoxazole. Following desensitization, patients must remain on the desensitized drug to preserve tolerance, or have repeat desensitization prior to future use.

Unproven Therapies

Unproven treatment methods are those that lack scientific validation in controlled clinical trials, or have not been studied to documented clinical efficacy and safety. Unproven treatments have been endorsed to alleviate or eliminate allergic diseases without scientific credibility. Examples of these methods include self-administration of a "neutralizing" substance when symptoms appear or prior to anticipated exposure to relieve symptoms (neutralization therapy); injecting a mixture of low-dose allergen with beta-glucuronidase prior to pollen season or every 2–6 months (enzyme-potentiated desensitization), chemical detoxification to remove toxic, synthetic chemicals in the body; injecting the patient's own urine to reduce symptoms (autogenous urine therapy); acupuncture, chiropractic manipulation, yoga, and homeopathic remedies. Perceived benefit from these therapies is likely placebo effect, and not physiologic. The clinician should be aware of these therapies to provide proper counseling of patients.

131 Allergic Rhinitis

Michael S. Blaiss · Cyrus Nozad · Jeremy Katcher

Allergic rhinitis (AR) has become a global health problem affecting 10–25% of the population with the highest rate in the pediatric population. This figure underestimates the true prevalence of AR primarily secondary to under diagnosis, misdiagnosis, and patients not seeking medical attention. Allergic rhinitis affects 20–40 million people in the United States with its frequency continuing to increase especially in the younger population. Allergic rhinitis is one of the most common chronic allergic diseases of childhood, and one of the top ten reasons for visits to primary care physicians. The prevalence of seasonal AR (SAR) is higher in children and adolescents than adults, and according to the International Study of Asthma and Allergy in Children (ISAAC) Phase I study, the prevalence is 0.8–14.9% in 6- to 7-year-olds and 1.4–39.7 % in 13- to 14-year-olds. According to ISAAC, the prevalence of AR varies worldwide with the lowest prevalence rates in countries such as Indonesia, Greece, and Albania while the highest rates are seen in countries including the United States, United Kingdom, Australia, New Zealand, Nigeria, and Paraguay.

AR is rare below the age of 1, but 20% of the cases develop before the age of 3 years and 40% by the age of 6. In fact, 80% of people that are going to have symptoms of AR do so by the age of 20.

Classification

Allergic rhinitis is an IgE-mediated reaction triggered by allergens in nose that leads to the classic symptoms of sneezing, nasal itching, rhinorrhea, and nasal congestion (*Table 131.1*). The sneezing is usually repetitive and worse during the early morning hours. Rhinorrhea is profuse and watery. Nasal obstruction is worse at night and can interfere with sleep. Along with nasal symptoms, most children with allergic rhinitis will have eye involvement, which consists of itching, watering, and redness of the conjunctiva. Other less common symptoms that occur in children with allergic rhinitis include post-nasal drip, which leads to frequent clearing of the throat, cough, and headache. Children may also complain of itching of the soft palate and ears as accompanying symptoms of allergic rhinitis.

Classification of the types of allergic rhinitis has been going through a revision. Until recently, allergic rhinitis has been divided into two primary types, seasonal and perennial, which is based on the allergen(s), which lead to the symptoms. Seasonal allergic rhinitis is due to pollen that typically occurs during a particular season. In general, trees pollinate in the early spring, grass in the late spring and summer, and weeds in the fall. In certain climates, mold or fungus may be primarily found in the air during the summer. It is important to know what pollinates in your area at which time of year in making the diagnosis of seasonal allergic rhinitis in a patient. In contrast, perennial allergic rhinitis is due to allergens which are present on a year-round basis. The most common allergens leading to perennial disease are animal danders, dust mites, mold spores, and insect particles. In rare cases, foods may be a factor in perennial disease, but it appears to be restricted to infants. Seasonal allergy symptoms may differ with perennial ones, in that children with seasonal disease tend to have more sneezing and rhinorrhea with eye involvement where perennial disease is characterized by more nasal congestion and post-nasal drip.

In 1999, The World Health Organization commissioned a panel of global experts in the field of allergy to review the impact of allergic rhinitis, develop guidelines for management, and propose a new classification for allergic rhinitis (*Fig. 131.1*). Their classification divides allergic rhinitis into two subgroups, intermittent and persistent based on duration of symptoms. Intermittent allergic rhinitis means that symptoms are present for less than 4 days a week or for less than 4 consecutive weeks. Persistent allergic rhinitis is defined as symptoms for more than 4 days a week and for more than 4 consecutive weeks. Also under each classification, the patient is rated due to severity of symptoms and its effect on quality of life. It is mild disease if the patient has none of the following present: sleep disturbance, impairment of daily activities, leisure, and/or sports, impairment of work or school, and symptoms present but not troublesome. In contrast, moderate or severe disease has at least one of the above. This classification based on duration of symptoms and severity may be more accurate since the pathophysiology of allergic rhinitis is the same for seasonal and perennial disease

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_131,

ARIA classifications of allergic rhinitis

and in some climates patients may have exposure to "seasonal" allergens throughout the year while some patients may have exposure to "perennial" allergens for only a short period of time each year, such as visiting a house with a pet.

Pathophysiology

Allergic rhinitis can manifest as an early-phase response characterized by itching and sneezing within seconds or minutes followed by nasal discharge and congestion at 15–30 min, but can also involve a late-phase response of nasal obstruction usually around 6–12 h post-exposure. The early allergic response is largely mast cell/basophil-dependent, and occurs when cross-linking of adjacent IgE molecules on the mast cell/basophil surface by allergen results in cell degranulation. This degranulation causes the release of immediate hypersensitivity mediators such as histamine and tryptase. In addition, there is neosynthesis of membrane-derived leukotrienes C4, D4, E4, and prostaglandin D2 (PGD2), as well as platelet-activating factor (PAF), TNF-α, IL-3, IL-4, IL-5, and IL-13. Histamine stimulates H1 receptors on sensory nerves causing vasodilation and increased vascular permeability; bradykinin production leading to nasal congestion. Tryptase indirectly leads to inflammation/tissue damage. Leukotrienes increase vascular permeability and induce mucus secretion from nasal glands, while PGD2 causes vasodilation and neutrophil chemotaxis. PAF causes chemotaxis, leukocyte activation, and vasodilation, while TNF-α promotes overall inflammation. IL-3 and IL-5 promote mast cell proliferation and eosinophil production/activation, while IL-4 and IL-13 promote Th2 differentiation.

Unlike the immediate response, the late-phase response is characterized by T cell recruitment and activation and tissue eosinophilia. Eosinophils degranulate and release tissue-damaging mediators such as major basic protein and peroxidases. Similar to the mast cell, eosinophils also generate leukotrienes C4, D4, E4, IL-3, and IL-5. However, they also secrete their unique set of cytokines that promote eosinophil activation and production, inflammation, and leukocyte chemotaxis. These cytokines include GM-CSF, IL-10, IL-8, RANTES, and eotaxin.

The development of allergic rhinitis involves a complex interaction between genetic predisposition and environmental exposures. Though allergic rhinitis does not exhibit a Mendelian hereditary pattern, twin studies have demonstrated a hereditary component (45–60% concordance for monozygous twins, 25% concordance for dizygous twins). It has been estimated that allergic rhinitis exhibits an inheritability of 0.33–0.75.

Diagnosis

Diagnosis of allergic rhinitis in the child is dependent on an accurate history and physical examination. As previously mentioned, the typical symptoms are repetitive sneezing, nasal itching, profuse rhinorrhea, and nasal congestion. Age of onset of symptoms and time of year that symptoms occur should be elicited from the parent/caregiver. Along with nasal symptoms, it is important to know question about the possibility of headaches, cough, and itching of the soft palate and ears in the child. Because of the nasal congestion, it is not uncommon for the child to have snoring associated with their nasal allergies. Also due to nasal congestion, children with allergic rhinitis have decreased sleep time and poorer quality of sleep, which can lead to poorer school performance and worsen their quality of life. Children with nasal allergies frequently have epistaxis due to fragility and congestion of the nasal

mucosa. A history of previous medications used for treatment of nasal symptoms can be beneficial in determining future treatment in the child.

Family history is pertinent as the child's risk of allergies is much higher than the general population if a first-degree relative has allergies. If one parent has allergies, a child's estimated risk of developing allergies increases to about 30%. If both parents have allergies, the child's risk nearly doubles again to 50–60%. The environmental history is paramount in learning about possible triggers of a child's allergy. Are there pets in the house? Is there carpet in the bedroom? Is there a basement or flooding in the home, which may suggest a mold problem? Are there smokers in the home? Though cigarette smoke is not an allergen, it is an irritant that can make nasal allergies worse.

On physical examination, numerous organ systems should be assessed in the child with AR (◉ *Table 131.2*) The child should also be observed for mouth breathing, repeated nose wiggling, wiping, and pushing up the tip of the nose (allergic salute), and a nasal crease, a transverse line across the bridge of the nose due to repeated allergic salutes for at least 2 years. Chronic mouth breathing due to nasal congestion can lead to allergic facies with development of an elevated upper lip and overbite along with a high arched palate.

Table 131.2
Physical examination characteristics of allergic rhinitis

Where to look	Relevant signs
General Observations	• Facial pallor • Allergic shiners • Allergic salute • Mouth breathing • Nasal (allergic) crease
Nose	• Pale, "boggy," swollen nasal mucosa • "Cobblestoning" of the posterior pharynx • Clear, watery discharge (but can be thick and white/yellow-green if concomitant sinusitis is present)
Eyes	• Conjunctivitis
Mouth	• Elevation of upper lip • Overbite (malocclusion) • High arched palate
Ears	• Abnormal tympanic membranes (retraction or immobility) • Serous fluid collection
Chest	• Persistent cough • Wheezing
Skin	• Eczema

Some children may have allergic shiners. These are dark circles in the eyes due to nasal blockage that acts as a dam in impeding venous drainage.

It is important to do an intranasal exam. Typically in children with allergic rhinitis, the turbinates are pale, boggy, and swollen with profuse serous drainage. On throat examination, it is not uncommon to see thick post-nasal drip and cobblestone appearance of posterior pharyngeal wall.

Because of the numerous co-morbidities associated with allergic rhinitis, other important organ systems should always be assessed. Eye symptoms are especially common with seasonal allergies. The conjunctiva may be inflamed and swollen. Skin manifestations that may be seen in children with nasal allergies are atopic dermatitis and urticaria. Examination of the tympanic membranes is needed to check for serous otitis media. Auscultation of the chest should be done to assess the possibility of expiratory wheezing as children with allergic rhinitis are three times more likely to develop asthma than children without allergies.

The most important diagnostic test is skin prick test using common allergens pertinent to the patient's history. Linking the history and physical examination with the positive skin prick tests will give an accurate diagnosis that can lead to proper management of the child's nasal allergies. In vitro diagnosis of specific allergens with the RAST is useful if a skin test cannot be performed or as a confirmatory test. Another diagnostic test is a nasal smear, which will contain eosinophils in an allergic patient, but does not differentiate from non-allergic eosinophillic rhinitis. In rare patients, there may be a need for CT or sinus x-ray when chronic or recurrent rhinosinusitis is suspected as a complicating factor.

Complications

Asthma

There is a strong epidemiologic link between allergic rhinitis and asthma with allergic rhinitis occurring in the vast majority of asthma patients. Allergic rhinitis often precedes the development of asthma in children, which is commonly called the "atopic march." Wright et al. showed that the presence of physician-diagnosed AR in infancy was independently associated with doubling the risk of developing asthma by the age of 11. They found that 32% of the children with rhinitis developed asthma while only 5% were without rhinitic symptoms. In the classic work by Greisner and Settipane, they followed 1,836 college freshman at Brown University for 23 years. They were evaluated

prospectively by questionnaires, interviews, and physical examinations, and allergy skin tests for the presence of asthma and allergic rhinitis for 23 years. It was found that allergic rhinitis and positive allergy skin tests are significant risk factors for developing new asthma. The freshman were three times more likely to develop asthma that had allergic rhinitis than the ones that did not have allergies

Numerous studies have documented that treatment of allergic rhinitis will improve asthma outcomes. Intranasal corticosteroids have been shown to decrease asthma symptoms and airway hyperreactivity. Leukotriene modifier agents, such as montelukast, have also been demonstrated to show efficacy in both allergic rhinitis and asthma.

Sinusitis

Sinusitis is a potential complication of allergic rhinitis. The relationship between rhinitis and sinusitis may involve inflammation in one compartment leading to secondary inflammation in the other compartment, such as in the case of rhinitis leading to obstruction of the osteomeatal complex. The relationship may also involve individual manifestations of a shared process, such as allergic disease. In a Los Angeles population of 70 children 3–16 years of age with allergic rhinitis, 53% had abnormal sinus radiography. In this subgroup, 4 children (6%) had marked thickening (>6 mm) of the maxillary sinus walls, and 15 children (21%) had complete opacification of 1 or more sinus cavity. Huang et al. studied 413 children for 5 years, of whom 215 had perennial allergic rhinitis and 198 had seasonal allergic rhinitis, to examine the prevalence of sinusitis in these patients. They found that the prevalence of sinusitis was significantly higher among patients with PAR than among those with SAR regardless of age or season, and that mold allergy is an important risk factor for sinusitis in these children.

The clinical presentation of chronic sinusitis in children can be very vague. Most commonly, it is associated with chronic post-nasal drip, cough, especially at night, and headaches. Though headaches are seen in children with chronic sinus disease, the symptoms are usually mild and not intense. Confirmatory diagnosis of chronic sinusitis requires CT scans of the paranasal sinuses.

Chronic Otitis Media with Effusion (OME)

Otitis media with effusion is a significant medical problem in the pediatric population. It is estimated that more than 80% of all children have at least one episode of otitis media by the age of 3 and that 40% will have three or more episodes.

Tomonaga et al. showed that in children with a primary diagnosis of allergic rhinitis, 21% had OME; in the control group representing the general population, only 6% had OME ($P < 0.01$). In children with a primary diagnosis of OME, 50% had allergic rhinitis; in the general population, only 17% had allergic rhinitis ($P < 0.01$). These results suggest that allergic rhinitis affects tubal function (even temporarily) and that allergic rhinitis may be a risk factor in children prone to OME.

Caffarelli et al. evaluated 172 children with OME and a control group of 200 children using a questionnaire for atopy, allergy skin tests, and a clinical evaluation of allergic symptoms and hypersensitivity to aeroallergens. They found that symptoms associated with atopy occurred significantly more frequently in the group with OME ($P<0.001$), and concluded that the association of OME with symptoms associated with atopy might play a part in the pathogenesis of the disorder.

Even though there is data suggesting a linkage between OME and allergic rhinitis, there is controversy on whether routine evaluation for allergies should be done in children with OME. A recent guideline on management of OME by The American Academy of Pediatrics, American Academy of Family Physicians, and American Academy of Otolaryngology-Head and Neck Surgery made no recommendations for allergy management as a treatment for OME. They based their recommendation on insufficient evidence of therapeutic efficacy or a causal relationship between allergy and OME. It appears prudent that if the child with OME has significant symptoms of allergic rhinitis, then evaluation of allergy as a factor in the child's OME should be entertained.

Snoring and Sleep Apnea

Another complication to consider in children with allergic rhinitis is snoring. Chng et al. administered a questionnaire on snoring to parents of 11,114 children aged 4–7 years in randomly selected preschools and primary schools in Singapore. They found that snoring and habitual snoring (snoring three or more time a week) were reported in 28.1% and in 6.0% of the children, respectively. On multivariate logistic regression analysis, it was found that one of the significant associations with snoring was atopy (asthma, allergic rhinitis, or atopic dermatitis). In fact, atopy was the strongest risk factor for habitual snoring. In children with snoring secondary to allergic rhinitis, obstructive sleep apnea syndrome may be present and

may lead to further medical problems. McColley et al. did a prospective study of 39 children with habitual snoring who were referred for polysomnography. RAST was performed to check for allergen sensitization. They found that 14 subjects (36%) demonstrated sensitivity to allergens; this is higher than expected for the general pediatric population. The frequency of sleep apnea was increased in subjects with positive RAST results compared to those with negative RAST results (57% vs 40%; $\chi^2 = 9.11$; $P < 0.01$) suggesting that allergy may be a risk for habitual snoring in children. Of course, not all snoring in children is due to allergic rhinitis, but it is important to include it in the differential diagnosis for evaluating the child that snores.

Differential Diagnosis

The differential diagnosis of allergic rhinitis is vast. Non-allergic rhinitis encompasses a large list of causes of rhinitis that do not have an allergic stimulus. Vasomotor or idiopathic rhinitis is the most frequent form of non-allergic rhinitis. It is characterized by sporadic or persistent nasal symptoms that are trigged by: strong smells, cold air, changes in temperature, humidity, barometric pressure, strong emotions, alcohol and changes in hormone levels. Diagnosis is made clinically and typically is adult onset.

Rhinitis medicamentosa is severe nasal congestion due to a rebound effect with overuse of topical decongestants, such as oxymetazoline and phenylephrine. Other medications that can lead to nasal symptoms, especially congestion, are ACE inhibitors, β-blockers, aspirin, and NSAIDs. Gustatory rhinitis occurs after eating heated foods, spicy foods, or alcohol. It may be vagally mediated, food allergy, and/or other undefined mechanisms. Hormonal-induced rhinitis includes menstrual cycle–related rhinitis and rhinitis of pregnancy. This condition typical begins in the 2nd trimester with severe congestion and resolves about 2 weeks postpartum. Infectious rhinitis may be acute or chronic. Symptoms include nasal congestion, mucopurulent nasal discharge, pain and pressure, headache, olfactory disturbance, post-nasal drainage, and cough. Viral infections account for as many as 98% of acute infectious rhinitis in young children. Non-allergic rhinitis with eosinophils (NARES) usually develops in adults and is characterized by year-round nasal symptoms primarily congestion with negative allergy skins and normal serum IgE levels. Classically, nasal smears on these patients have 20% or greater eosinophils. Many of these patients may develop ASA sensitivity, nasal polyps, and asthma. (◉ *Table 131.3*)

◉ **Table 131.3**
Differential of rhinitis in children

Differential	Examples
Allergic rhinitis	
Non-allergic rhinitis	Vasomotor Drug Induced Gustatory Hormonal Infectious NARES
Nasal polyps – may occur in conjunction with allergic rhinitis, chronic rhinitis, or sinusitis	
Anatomic abnormalities: Structural changes may cause symptoms	Deviated septum/ septal wall anomalies Adenoidal Hypertrophy Trauma Nasal tumors (Benign or Malignant)
CSF rhinorrhea: From accidental head trauma, surgery, tumors, or spontaneous	
Primary ciliary dykinesia: Autosomal recessive impairment of mucociliary clearance. Nasal polyposis is often present leading to nasal congestion, as well as failure of the frontal sinuses to develop	
Autoimmune: May be the cause of rhinosinusitis, which is seen in some vasculitities	SLE Churg–Straus syndrome Wegener's granulomatoisis
Foreign body	
Metabolic: Hormonal related, e.g., excess growth hormone	Hypothyroidism Acromegaly
Cystic fibrosis: Chronic rhinosinusitis may be associated with CFTR gene mutations. 10–32% develop nasal polyps, leading to nasal congestion	

Treatment

Allergen Avoidance

Treatment of allergic rhinitis requires education of the patient/parent/caregiver and is a threefold approach-allergen avoidance, appropriate pharmacotherapy, and allergen immunotherapy (in selected children).

The initial step in treatment of allergic rhinitis is to educate the patient/parent/caregiver about their condition and complications associated with allergic rhinitis. After allergic triggers have been identified, either through the patient's history or through diagnostic testing, the physician or office staff person can educate the patient on how to avoid specific allergens (*Table 131.4*). The most common allergens are house dust mites, cockroaches, molds, animal dander, and pollen.

Table 131.4
Allergen avoidance measures (Adapted from Urval, 1998)

Allergen	Control measure
House dust mites	• Remove dust collectors from bedroom. • Cover mattress, box springs, and pillow with allergen-proof coverings. • Wash uncovered bedding in 130°F at least once a week. • Maintain indoor humidity at less than 40%. • Remove carpeting throughout house, or at least in the bedroom.
Animal dander	• Remove the pet. • Keep pets out of bedroom at all times. • Note: No hypoallergenic dog or cat breeds have been identified.
Cockroaches	• Wash dishes promptly. • Keep garbage contained outside of the home. • Wipe up food spills immediately. • Keep food tightly sealed in containers. • Repair or remove sources of standing water.
Molds	• Avoid damp, musty basements. • Use a dehumidifier in areas of high humidity. • Avoid activities (such as raking leaves) that increase exposure to molds. • Houseplants should be kept at a minimum. Apply fungicides to appropriate surfaces with obvious contamination.
Pollens	• Monitor pollen forecasts and avoid high pollen areas. • Keep windows closed in the home and car. • Avoid activities (such as mowing the lawn) that increase pollen exposure. • Use air conditioning both in the house and car. • Immediately shower after being outside for an extended period of time.

House dust mites. These allergens are among the most common perennial allergens. They survive in all climates, except at high altitudes where reproduction is halted. While the entire home can be a source of dust mites, the bedroom should be of particular concern. Mattresses, box springs, and pillows should be encased in zippered, allergen-proof encasings. Bedding should be washed weekly in hot water. Ordinary dusting and vacuuming have little effect on dust mite control. If vacuuming is done, it should be done using a vacuum cleaner with an efficient double filtration system or a high-efficiency particulate air (HEPA) filter. When dusting, a damp cloth should be used, as it better picks up dust. Because it takes approximately 40 min for dust mites to settle after cleaning, the patient should leave the area immediately after cleaning. Ideally, the house should be cleaned when the patient is not home.

Dust collectors, such as stuffed animals and should be removed from the bedroom. When practical, carpeting should be removed throughout the house, or at least in the bedroom.

Animal dander. While cat and dog dander are the most common animal allergens, most other warm-blooded animals, including mice, rats, guinea pigs, horses and birds, can also cause allergic reactions. The best method of allergen avoidance in this case is removal of the animal from the home. However, because most people have strong attachments to their pets, this is often an unreasonable request. Also, it can take up to four months for all the dander to decompose after the pet is removed, so improvement in symptoms will not be immediate. After discussion, if the decision is made to keep the animal in the house, several steps can be taken. The pet should be kept out of the patient's bedroom at all times. Routine vacuuming of furniture and carpeting can also help. Ideally, the carpet should be removed from the bedroom floor and allergen-proof covering used for dust mite avoidance should also be used. Use of a HEPA filtering system in the bedroom can help decrease the level of animal dander in the air. At this time, no hypoallergenic breeds of cats or dogs have been identified.

Cockroaches. Cockroach allergy is a major trigger of allergic rhinitis. This is particularly evident in the inner cities. Although exposure to cockroaches is usually limited to the kitchen or dining rooms, the allergen can be passively transferred on clothing and shoes. Eradication of cockroaches may prove to be difficult, as the allergenic proteins can persist in the environment for months or even years. In addition, problems will often persist until food and garbage are disposed and packaged properly. Cockroaches also require water for survival. Therefore, it

is essential to repair leaking faucets or to clean up standing water in the basement.

Molds. Mold spores can be a source of both perennial and seasonal allergies. To avoid exposure to outdoor molds, keep car and house windows closed at all times. Outdoor activities that bring greater exposure to molds, such as raking leaves, should be avoided. In patients with mold allergies, limitation of outdoor activities during specific times may be necessary. Spore counts are often at their highest early in the morning or late in the evening when dampness is present. Numerous precautions can be taken indoors. Damp musty basements should be avoided, and the humidity level should be reduced within the house. A dehumidifier can be helpful during periods of high humidity. Live plants should be kept to a minimum, as they can promote the growth of mold. Finally, because mold spores can accumulate in bedding and carpeting, techniques such as those used for dust mites can be used.

Pollens. Pollen-induced allergy is probably the most difficult to control through allergen avoidance, because simply being exposed to outside air can trigger an attack. Patients should be given resources that allow them to monitor daily pollen counts and be advised to stay indoors on days when pollen counts are particularly high. Because remaining entirely indoors is impractical, the best prevention is to keep windows closed at all times, both in the house and in the car. Don't dry clothing outside, as the pollens will collect on the clothes. If available, air conditioning should be used both in the car and house; air filters should be replaced or cleaned on a regular basis. Certain activities that increase exposure, such as mowing the lawn, should be avoided. Finally, showering after spending time outdoors can remove pollen from hair and skin and avoids contamination of bedding.

Pharmacologic Agents in AR

There are several pharmacologic agents available: oral and topical H_1-antihistamines, intranasal glucocorticosteroids, leukotriene receptor antagonists, mast cell stabilizers, anticholinergic agents, and oral and topical decongestants (*Table 131.5*).

Medications used for AR are typically administered orally or intranasally. The intranasal route allows for higher concentrations of the drug to be delivered, thus minimizing the systemic side effects. However, many children with AR have an aversion using nasal spray and oral medications are typically used in these patients.

Oral H_1-Antihistamines

Histamine is an important chemical mediator of allergic inflammation and is released in large quantities from tissue mast cells and basophils.

H_1-antihistamines are inverse agonists, rather than H_1-antagonists, that combine with and stabilize the inactive form of the H_1 receptor, leading toward a shift in equilibrium to the inactive state. In addition to the inverse agonist effect at the H_1 receptor, the newer second-generation agents have both anti-allergic and anti-inflammatory properties.

The first-generation H_1 antihistamines such as diphenhydramine, chlorpheniramine, brompheniramine and hydroxyzine are also referred to as the sedating antihistamines. These agents are effective at controlling the rhinorrhea, sneezing, and pruritus associated with AR. Unfortunately, these agents cross the blood–brain barrier, thus producing undesirable side effects such as central

Table 131.5
Estimated symptom efficacy of agents used in management of AR

Drug class	Sneezing	Itching	Rhinorrhea	Congestion
Oral antihistamines	++	++	++	+
Intranasal antihistamines	+++	+++	+++	+++
Intranasal corticosteroids	++++	++++	++++	++++
Decongestants	_	_	_	++++
Cromolyn	+	+	+	+
Leukotriene receptor antagonists	++	++	++	+
Anticholinergic	_	_	++++	_

Excellent efficacy, ++++; Good efficacy, +++; Mild efficacy, ++; Questionable efficacy, +; No efficacy, –

nervous system depression, sedation leading to impaired performance at home, work, and school, and cardiotoxicity. There are no long-term safety studies on the first-generation antihistamines. These agents have poor H_1 receptor selectivity and act on muscarinic receptors, causing anticholinergic effects such as dry mouth, urinary retention, constipation, and tachycardia. The high risk to benefit ratio makes the first-generation H_1 antihistamines a less attractive therapeutic option and are not recommended as first-line therapy in AR.

The second-generation antihistamines developed in the early 1980s have improved H_1 receptor selectivity, absent or decreased sedation, faster onset and longer duration of action, and fewer adverse effects. To date, no clinically significant cardiotoxic effects have been reported for loratadine, desloratadine, fexofenadine, cetirizine, and levocetirizine. In general, second-generation antihistamines exhibit favorable pharmacokinetics. They have a relatively quick onset of action, near complete absorption, widespread tissue distribution with minimal CNS penetration unlike first-generation antihistamines and relatively long half-life allowing for once daily dosing.

Intranasal H_1-Antihistamines

Topical second-generation H_1-antihistamines are considered to be similar in efficacy to oral antihistamines and are also considered as first-line therapy for mild-moderate AR. Studies have shown that azelastine and olopatadine improved all symptoms in SAR and PAR including ocular symptoms and can also reduce nasal congestion. These agents have a quicker onset of action than oral antihistamines and intranasal corticosteroids. The most common side effects associated are mild sedation and bad taste.

Corticosteroids

Intranasal corticosteroids are recommended as first-line therapy for moderate-severe AR. Corticosteroids target the inflammatory mechanism of the early- and late-phase allergic processes and are therefore effective in treating most symptoms of AR including: congestion, sneezing, rhinorrhea, and nasal pruritus. They may also decrease eye symptoms by blocking the nasal-ocular reflex. Studies show that these agents are superior to all other classes of allergic rhinitis medications in controlling symptoms of AR.

Epistaxis, secondary to irritation of the nasal mucosa, is the most common adverse effect but diminishes over time. Therefore, patients should be instructed on proper technique for administration, which is to direct the spray away from the septum.

In children, there is a concern regarding suppression of linear growth, and, therefore, they should receive the lowest possible dose of intranasal corticosteroid and routine height monitoring.

Systemic corticosteroids should not be used for chronic management of allergic rhinitis due to their poor side effect profile. In moderate to severe flare-ups of AR, systemic corticosteroids may be used for a short course (3–7 days).

Leukotriene Receptor Antagonists

Leukotrienes appear to be important mediators of nasal allergic reactions, and their presence in the nose induces nasal obstruction. Montelukast has been generally accepted for treatment of mild to moderate AR with efficacy comparable to oral antihistamines. However, there are no data supporting the use of leukotriene receptor antagonists combined with oral or intranasal antihistamines, intranasal corticosteroids, or both in the treatment of AR.

Cromolyn

Mast cell stabilizers inhibit mast cell degranulation and thus inhibit the release of histamine and other mediators of the early phase of allergic inflammation. Cromolyn sodium is generally not as effective as antihistamines or intranasal corticosteroids but has been shown to be superior to placebo in reducing symptoms of the early phase. Although the safety profile of cromolyn is very good, the dosing interval of four times a day makes this a less attractive option.

Anticholinergics

Double-blind, placebo-controlled studies have shown that ipratropium bromide is effective in controlling watery nasal discharge, but that it does not affect sneezing or nasal obstruction. Anticholinergic side effects are uncommon and usually dose-dependent.

Decongestants

Decongestants reduce nasal congestion by activating α-adrenergic receptors on the nasal vasculature leading to vasoconstriction. Decongestants have not been shown to be effective with other symptoms of AR. Common side effects in children seen with oral decongestants include insomnia and agitation.

Topical decongestants, oxymetazoline and phenylephrine, are also available for the treatment of nasal congestion. Unfortunately, rebound nasal congestion, termed rhinitis medicamentosa, can occur if they are used for greater than 3–5 days.

Allergen Immunotherapy

Allergen immunotherapy is the only disease-modifying treatment for AR. During allergen immunotherapy, patients can be desensitized to their allergen triggers. During this process, the patient is injected subcutaneously or given sublingually increasing amounts of allergen until either a symptom-relieving dose is reached or a maximum tolerance dose is reached.

Children should be considered candidates for allergen immunotherapy when they fail to respond to a combination of allergen avoidance and pharmacotherapy. Also, patients with severe and persistent nasal symptoms are commonly referred for immunotherapy. Another indication for allergen immunotherapy would be a child with significant complications associated with their allergic rhinitis, such as asthma and chronic sinusitis.

Recent studies have suggested that allergen immunotherapy in children with allergic rhinitis may reduce the risk of developing asthma. Recent research has demonstrated that the use of allergen immunotherapy in children with allergic rhinitis can decrease the risk of development of asthma. Novembre et al. evaluated 113 children aged 5–14 years allergic rhinitis to grass pollen and no other clinically important allergies were randomized in an open study to receive specific sublingual immunotherapy (SLIT) for 3 years or standard symptomatic therapy. The children on SLIT were 3.8 times less likely to develop asthma after 3 years than the control subjects. Jacobsen et al recently published a 7-year follow-up of children treated for 3 years with specific subcutaneous immunotherapy for allergic rhinitis to grass and/or birch pollen. These children were compared to a control group of allergic rhinitis children for allergy symptoms and the development of asthma. The immunotherapy-treated children had significantly less asthma after 7 years as evaluated by clinical symptoms [odds ratio 4.6 (1.5–13.7)] in favor of specific subcutaneous immunotherapy for prevention of development of asthma.

Allergic Conjunctivitis

The most common associated condition with allergic rhinitis is allergic conjunctivitis. Studies suggest that all 90% of children with allergic rhinitis have eye symptoms especially those with seasonal pollen sensitivity. Typically, the child complains of itching, redness of the conjunctiva, and watering of the eyes. On examination, the conjunctiva is usually inflamed and in severe cases, swelling or chemosis of the conjunctiva can occur.

As with allergic rhinitis, the first step toward successful management of allergic conjunctivitis is to limit the exposure to the known allergens. Once symptoms have occurred, the use of cold compresses may provide temporary relief of symptoms. Lubricating the eye with saline solutions may help to alleviate the symptoms, as well as assist in the removal and dilution of allergens that may be in contact with ocular tissue.

There are a number of medications currently available to treat the symptoms of allergic conjunctivitis. Systemic first- and second-generation antihistamines may help stop the itching associated with allergic conjunctivitis though they are usually not effective for more moderate to severe eye symptoms. Topical antihistamines, such as emedastine and levocabastine, are effective in relieving symptoms of itching and redness. Topical non-steroidal anti-inflammatory agents such as ketorolac are effective in relieving not only the itching associated with allergic conjunctivitis, but also the redness, swelling, and tearing that often accompany the allergic reaction. Topical mast cell stabilizers such as cromolyn sodium, lodoxamide, or nedocromil are effective in relieving the itching, tearing, and redness associated with allergic rhinitis; however, as with the nasal products, mast cell stabilizers do not offer rapid relief. Instead, they must be used prophylactically. Some of the more effective treatments are dual-action antihistamines/mast cell stabilizers such as olopatadine, ketotifen, epinastine, bepotastine and azelastine. These agents have a rapid onset of action and relieve all the symptoms associated with allergic conjunctivitis. In addition, they are both very long lasting, and so compliance is easier to attain. In more severe cases of conjunctivitis, topical ocular corticosteroids may be used. However, these agents should be prescribed only by an eye specialist,

and only after a slit-lamp examination has been performed to make sure there is no evidence of a herpes infection. Use of a topical ocular corticosteroid in a patient with herpes infection in the eye can lead to severe complications, including blindness.

Christina E. Ciaccio · Mercedes C. Amado · Jay M. Portnoy

Introduction

A mother brings in her 3-year-old son because he has recurrent respiratory symptoms.

He coughs at night, when he laughs or cries, or runs outside. He has had post-tussive emesis on occasion. Colds settle into his chest and he has been diagnosed with bronchitis, croup, and pneumonia several times.

He is usually treated with antibiotics and has been given albuterol breathing treatments on several occasions which helped his symptoms. The last time he was sick he received 5 days of oral steroids, which was very beneficial. He is nasally congested on most days. His mother states he seems to be susceptible to colds and he is sick more frequently than he is well.

He was full term and his immunizations are up to date. He has not been hospitalized nor has he had surgical procedures. When he was an infant he had hives and vomiting with cow's milk formula and scrambled eggs. He tolerates dairy and eggs now.

He is an only child and he attends day care 5 days a week.

His mother has allergies and his father had asthma when he was a child. His maternal cousin has eczema and peanut allergy.

He is not presently on medications.

Physical exam reveals a well nourished happy 3 year old with height and weight at the 75%.

He has pale swollen nasal turbinates with clear discharge bilaterally. He has mild scarring of the tympanic membranes and shotty posterior cervical lymph nodes bilaterally. Cardiovascular exam is normal. His chest has normal configuration and his lungs are clear to auscultation; however, after running in the exam room he begins to cough.

The skin demonstrates dry, erythematous patches in the antecubital and popliteal fossae.

He does not have clubbing or cyanosis or edema of the extremities.

Does this child have asthma? Does he have risk factors for asthma? What is the differential diagnosis of a child with these recurrent respiratory symptoms? What is the severity classification? What is appropriate workup and treatment plan for this child?

Will his symptoms remit or persist over time?

Definition/Classification

The Global Initiative for Asthma (GINA) guidelines define asthma descriptively as "a chronic inflammatory disorder of the airways in which many cells and cellular elements play a role. The chronic inflammation is associated with airway hyperresponsiveness that leads to recurrent episodes of wheezing, breathlessness, chest tightness, and cough, particularly at night or in early morning. These episodes are usually associated with widespread but variable airflow obstruction which often is reversible either spontaneously or with treatment."

Asthma is a syndrome. A syndrome is defined as "an aggregate or set of concurrent symptoms indicating the presence and nature of a disease." Such an aggregate can be recognized only if it is associated with clear criteria for doing so. Asthma is a syndrome because there is no readily available genetic, blood, or pulmonary function test that can be used to objectively diagnose it, particularly in young children in whom it usually starts. Consequently, it is not surprising that a variety of underlying physiologic disorders may result in the constellation of symptoms that are consistent with asthma.

The diagnosis of asthma is usually made clinically based upon the history and response to asthma medications. In older children and adults, pulmonary function studies (spirometry) may be done before and after bronchodilator; however, many patients particularly those with cough variant asthma do not demonstrate obstruction on spirometry. To assist in making the diagnosis, the GINA guidelines recommend that the following questions be asked with positive responses increasing the likelihood that the patient has asthma.

- Has the patient had an attack or recurrent attacks of wheezing?
- Does the patient have a troublesome cough at night?
- Does the patient wheeze or cough after exercise?

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_132,

- Does the patient experience wheezing, chest tightness, or cough after exposure to airborne allergens or pollutants?
- Do the patient's colds "go to the chest" or take more than 10 days to clear up?
- Are symptoms improved by appropriate asthma treatment?

Etiology

Atopy

Many studies such as the Tucson study and the PEAK trial have shown that allergy plays an important role in the development of asthma. In addition, total IgE is a strongly heritable trait. In a genome-wide association study, functional variants in the gene encoding the alpha chain of the high affinity receptor for IgE (FCER1A) on chromosome 1q23 (rs2251746 and rs2427837) were strongly associated with total IgE. The most significant single nucleotide polymorphism (SNP) influenced the cell surface expression of FCER1A on basophiles, and genome-wide expression profiles indicated an interesting novel regulatory mechanism of FCER1A expression via GATA-2. Polymorphisms within the RAD50 gene on chromosome 5q31 were consistently associated with IgE levels and increased the risk for atopic eczema and asthma and STAT6 was confirmed as susceptibility locus modulating IgE levels.

Obesity

Obesity has been shown to be a risk factor for the development of asthma. Infant weight gain has been shown to be associated with the development of asthma later in childhood. Though weight gain is not associated with daily asthma symptoms or lung function it is associated with an increased need for prednisone and urgent care visits. Conversely, smaller weight gain is associated with fewer exacerbations.

Obese patients with asthma are more likely to report continuous symptoms, miss more work days, use short acting beta agonists, use inhaled corticosteroids (ICS), and use controller medication than matched nonobese asthmatics. They also are less likely to be in asthma remission and are more likely to have severe persistent asthma.

Environmental Factors

Environmental tobacco smoke (ETS) is the best understood and likely the most significant indoor air pollutant. It not only confers a significant increase in risk of developing asthma, it also causes an increase in IgE sensitization as well as an increase in asthma severity. Asthma is more severe in former smokers both before and after treatment than in those who have never smoked. Though smoking cessation is an important goal in treatment of asthmatic patients, smoking initiation needs to be reduced, especially in teenagers. This is because cigarette smoking has a persistent, dose-dependent, negative impact on the response to treatment in patients with uncontrolled asthma even after smoking cessation.

Outdoor air pollutants with significant impact on asthma include nitrogen oxides (NO_x), sulfur oxides (SO_x), and ozone along with particulates. Sensitivity to these exposures does vary and has a genetic component. For example, arginases (encoded by ARG1 and ARG2 genes) have an important effect on asthma pathogenesis through effects on nitrosative stress. Arginase expression is upregulated in asthma and varies with TH2 cytokine levels and oxidative stress. Both ARG1 and ARG2 genetic loci are significantly associated with asthma. Within each locus, the ARG1 haplotype is associated with reduced risk and the ARG2 haplotype is associated with increased risk of asthma. The effect of the ARG1 haplotype is associated with the presence of atopy and ambient ozone. Atopic children living in high-ozone communities with the ARG1 haplotype have a reduced asthma risk.

Infections

Many common respiratory viruses have been linked to recurrent wheezing in infancy and early childhood, including rhinovirus and respiratory syncytial virus. In addition, some of these viruses are linked to as high as a 40% increase in risk for asthma later in childhood. The "hygiene hypothesis" suggests, however, that infections during early childhood influence the immune system in such a way that the risk of developing asthma is reduced.

In the childhood origins of asthma study (COAST), 289 newborns were followed prospectively. The investigators found that even one moderate to severe rhinovirus infection during infancy drastically increases the risk of recurrent wheezing and possibly of the subsequent development of asthma. Apparently, healthy infants who experience repetitive severe viral respiratory infections develop recurrent wheezing, possibly as a consequence of lung damage and/or airway remodeling. It also seems that infants born with poor antiviral responses and/or airway hyperresponsiveness (AHR) are prone to have repetitive severe illnesses which may increase their risk of

developing asthma. This effect is most pronounced if the infants wheeze with rhinovirus infections as opposed to infections with RSV which is less specific for development of asthma.

Epidemiology

The world wide prevalence of asthma is increasing. Epidemiological studies based upon symptom questionnaires of parents of young children (6–7 years old) and older children (13–14 years old) in the ISAAC study Phase I (International Study of Asthma and Allergies in Children) show variability between countries with highest prevalence rates of asthma symptoms in 12 months in UK, Ireland, New Zealand, and Australia followed by South, Central, and North America, Kuwait, and South Africa. The lowest rates were reported in several Eastern European countries (Romania, Georgia, Albania, Uzbekistan), Greece, China, India, and Ethiopia. In Southeast Asia the lowest prevalence of symptoms was in Malaysia and China and the highest in Japan, Thailand, Philippines, and Hong Kong.

Studies show patterns of increasing prevalence of asthma worldwide especially in Western countries and as communities become more urbanized. Asthma symptoms in Chinese adolescents was lowest among residents of mainland China and greater for those in Hong Kong and for those who immigrated to Canada and was highest for those born in Canada. A significant increase in the prevalence of asthma in the Kingdom of Saudia Arabia was noted from 8% in 1985 to 23% in 1995 in a questionnaire of children between 8 and 16 years which was hypothesized to be related to changes in environmental factors of increased tobacco smoke and indoor animal exposure. Although the prevalence of asthma symptoms tends to be more common in affluent countries, the symptoms are more severe in less affluent countries.

According to data from the US National Center for Health Statistics, the burden from childhood asthma seems to have leveled off after many years of increasing. Asthma prevalence in the USA increased by an average of 4.3% per year (from 3.6% to 6.2%) between 1980 and 1996. Asthma attack prevalence remained constant between 1997 and 2000. After a decrease between 1980 and 1989, the asthma office visit rate increased by an average of 3.8% per year from 1989 to 1999. The asthma hospitalization rate grew by 1.4% per year from 1980 to 1999. Although childhood asthma deaths are rare, the asthma death rate increased by 3.4% per year from 1980 to 1998. Children aged 0–4 years had the largest increase in prevalence and had greater health care use, but adolescents had the highest mortality.

Unfortunately, racial and ethnic disparities remain large for asthma utilization and mortality. The asthma burden is borne disproportionately by black children. Racial disparities were largest for asthma hospitalizations and mortality: compared with white children. In 1998–1999, black children were more than three times as likely to be hospitalized, and in 1997–1998 they were more than four times as likely to die from asthma.

In the USA, the Centers for Disease Control and Surveillance published data from surveys of 2001–2003 reporting higher rates for current asthma for children (8.5%) than for adults (6.7%), for blacks (9.2%) than whites (6.9%) and for those of Puerto Rican descent (14.5%) than those of Mexican descent (3.9%) and the rates of asthma deaths in the USA increased during 1980–1990, but have decreased each year since 2000. In the2007 report of The National Health Interview Survey, the greater prevalence of asthma in minority populations occurred in non-Hispanic black children more likely to have ever been diagnosed with asthma (20%) than Hispanic children (13%) or non-Hispanic white children 11%).

In early childhood, asthma is twice as prevalent among boys as girls. As the asthma rate among young girls increases, however, the gap in prevalence of asthma in early childhood between boys and girls decreases. The ratio reverses in adolescence and early adulthood with asthma becoming more common in women though the reasons for this gender-related difference is unclear.

In a survey of randomly chosen adult patients and parents of children with current asthma in the USA, surveyors asked about short-term symptoms (4-week recall), long-term symptoms (past year), and activity limitation. The surveyors found that 10.7% had mild intermittent disease while 77.3% had moderate to severe persistent disease suggesting that a majority of the US population with asthma experiences persistent rather than intermittent asthma.

Pathogenesis: Including Genetics

Asthma is known to be an inheritable condition. Whole genome screens are beginning to identify gene-rich regions that are of special relevance to the development of asthma and atopy. Candidate genes for the development of asthma include the many genes that regulate IgE production, the proliferation and maturation of eosinophils and mast cells, and epithelial barrier function. Some

of the better defined genes contributing to the development of asthma, include Arg/Gly, 17q12–21, ADAM-33, and the filaggrin (FLG) gene. In addition, several genes have been identified that effect patient response to medications. These genes include Arg/Gly alleles of the beta2 receptor as well as components of the leukotriene pathway. The identification of novel genes for asthma suggests that many genes with small effects rather than few genes with strong effects contribute to the development of asthma. These genetic effects are modified interactions with a person's environmental exposures, though some genetic influences also operate independently of environmental factors. A number of important gene–environment interactions have been identified which may aid in the identification of individuals who are particularly susceptible to environmental hazards.

Since asthma is an inflammatory airway disease that is associated with upregulation of TH2-type cytokines, genes encoded in the corresponding cluster on chromosome 5q on T cells and inflammatory cells are of particular interest. This upregulation along with local airway susceptibility factors leads to airways hyperresponsiveness, variable airflow obstruction, and in some cases to airways remodeling. Two examples are polymorphisms involving IL-4 receptors and the enzymes controlling cysteinyl leukotriene production.

In addition to inflammation of the airways caused by atopy, interactions between the respiratory epithelium and other environmental factors such as virus infections, ETS, and pollutants also contribute to tissue damage and abnormal repair responses that can lead to remodeling. Previously unknown genes involved in this interaction have recently been identified. Dipeptidyl peptidase 10 (DPP10) and disintegrin and metalloproteinase-33 (ADAM-33) are examples of newly identified genes that are associated with asthma that are preferentially expressed in the airway epithelium and underlying mesenchyme.

Leukotrienes contribute to the inflammatory process in asthma, to the extent that leukotriene modifiers are mainstays in the therapy of asthma. Leukotriene pathway genes have been shown to be involved in the pathogenesis of and treatment response in asthma. Certain genetic variants in these pathway genes also appear to be associated with the development of aspirin-exacerbated respiratory disease, and pharmacogenetic response. Those specific variants include two variants in the 5-lipoxygenase gene that are both associated with response to 5-lipoxygenase inhibition and to leukotriene receptor antagonists (LTRA), variants in genes encoding the two cysteinyl LTRA, and a leukotriene C4 synthase promoter polymorphism that has been associated with the risk of asthma exacerbations.

Transcription factors control the development of TH1 and TH2 T-cells. Two of these, the T-box transcription factor and GATA3, appear to be involved in the development of asthma and atopic diseases. Another homeobox transcription factor H.20-like homeobox 1 (HLX1) interacts closely with the T-box transcription factor. Nineteen polymorphisms have been identified in this gene, and seven of these are associated with increased likelihood of developing childhood asthma. These appear to work by decreasing promoter transactivation disrupting specificity protein-transcription factor binding.

Another T cell-specific T-box transcription factor (TBX21) induces the differentiation of T-cells to a TH1 phenotype and prevents the formation of TH2 cells in combination with the homeobox transcription factor HLX1. Three SNPs in this gene increased the risk of developing childhood asthma significantly. In addition, two polymorphisms in the promoter region influence TBX21 promoter activity. A specific combination of TBX21 and HLX1 polymorphisms increases the asthma risk by more than threefold, which demonstrates a synergistic effect on asthma risk.

Null mutations in the FLG gene have been shown to be major risk factor for. A meta-analysis of 24 studies on FLG mutations, eczema, and asthma showed strong associations with eczema and also that certain mutations are significantly associated with asthma though the strongest effects were for the combination of asthma and eczema. No association between FLG mutations and asthma in the absence of eczema. The two common FLG-null mutations R501X and 2282del4 and three recently identified rare FLG variants (R2447X, S3247X, 3702delG) increased the risk for eczema more than threefold, conferred a substantial risk for allergic rhinitis, and increased the risk of asthma occurring in the context of eczema but not of asthma alone.

In addition to pathogenesis, genetic factors also may explain ethnic disparities not explained otherwise by environmental, social, cultural, or economic factors. In particular, differences in susceptibility allele frequencies have been observed that increase the risk of asthma in certain populations. A meta-analysis of African-ancestry populations yielded three SNPs in genes of potential biologic relevance to asthma and allergic disease: rs10515807, mapping to the alpha-1B-adrenergic receptor (ADRA1B) gene on chromosome 5q33; rs6052761, mapping to the prion-related protein (PRNP) gene on chromosome 20; and rs1435879, mapping to the DPP10 gene on chromosome 2q12.3–q14.2. Though certain forms of these SNPs are associated with minority populations in the USA, their

significance with respect to disparities remains to be determined.

Bronchial hyperresponsiveness (BHR) and asthma are linked to chromosome 5q31–q33 with some evidence that the protocadherin 1 gene (PCDH1) has several novel sequence variants. In seven out of eight populations from The Netherlands, UK, and USA, PCHD1 gene variants were significantly associated with BHR both in families with asthma and in general populations. PCDH1 mRNA and protein are expressed in airway epithelial cells and in macrophages.

Several studies have suggested that chromosome 19q13.1–3 contains asthma susceptibility genes. In particular, support has been found for an asthma/lung function susceptibility locus (48.9–49.1 Mbps) which apparently is localized to the plasma urokinase plasminogen activator receptor (PLAUR) gene. PLAUR SNPs in the 5′ region, intron 3, and 3′ region are associated with asthma and BHR susceptibility and predict FEV_1 and plasma PLAUR concentrations. SNPs in the 5′ region showed an association with asthma, FEV_1, and BHR. These same were associated with plasma PLAUR levels as well as with FEV_1 decline in subjects with asthma. The association of PLAUR with lung function decline appears to support a role for PLAUR in airway remodeling in asthma.

Pathology

The GINA guidelines first recommend that asthma severity be classified as intermittent, or as mild, moderate, or severe persistent based on specific criteria (Table 132.1). This classification is determined with the assumption that the patient has yet been treated since once treatment is initiated the symptoms are expected to improve. The NHLBI guidelines have similar criteria for the four categories of asthma severity.

Once treatment is initiated, both guidelines recommend that the degree of asthma control should be monitored to determine whether treatment needs to be increased, remains the same, or even decreases. The criteria for asthma control outlined in the GINA guidelines are shown in Table 132.2. In clinical practice, the need for simple methods to assess asthma control has led to investigation of a variety of candidate measures. The method that is most effective depends on the outcome that is to be achieved. If the goal is to minimize symptoms and exacerbations, then the measurement should utilize standardized measures of symptoms such as the Asthma Control Test (ACT). On the other hand, if reduction of eosinophilic pulmonary inflammation is the goal, then measures such as eosinophilic cationic protein (ECP) should be used. The question is how the various measures relate to each other and how well they lead to the ultimate asthma outcome, which is a reduction in long-term morbidity and mortality while maximizing the patient's quality of life.

Both the NHBLI guidelines and the GINA guidelines emphasize the need to monitor and maximize asthma control as a major goal of treatment. The main reason for this new emphasis on control is due to the recognition that the adverse effects of taking medications when they are not necessary may offset the advantage of complete medical control. It may be easy to prescribe all of the medicine all of the time; however, it is not as easy to prescribe just the right amount of treatment to reach a balance between the benefits of medical control and the

Table 132.1
Classification of asthma before treatment * (Gina Guidelines 2008, P23)

Intermittent Asthma
Symptoms less than once a week
Brief exacerbations
Nocturnal symptoms not more than twice a month
FEV1 or PEF >80% predicted
PEF or FEV1 variability <20%
Mild Persistent
Symptoms more than once a week but less than once a day
Exacerbations may affect activity and sleep
Nocturnal symptoms more than twice a month
FEV1 or PEF >80% predicted
PEF or FEV1 variability <20–30%
Moderate Persistent
Symptoms daily
Exacerbations may affect activity and sleep
Nocturnal symptoms more than once a week
Daily use of inhaled short-acting B2-agonist
FEV1 or PEF 60–80% predicted
PEF or FEV1 variability >30%
Severe Persistent
Symptoms daily
Frequent exacerbations
Frequent nocturnal asthma symptoms
Limitation of physical activities
FEV1 or PEF <60% predicted
PEF or FEV1 variability >30%

*The worst feature determines the severity classification

Table 132.2
Levels of asthma control (Gina Guidelines 2008, Chapter 2 Diagnosis and Classification P 23)

Characteristic	Controlled	Partly Controlled	Uncontrolled
Daytime symptoms	None (twice or less/week)	More than twice/week	Three or more features of partly controlled asthma present in any week
Limitations of activities	None	Any	
Nocturnal symptoms/ awakenings	None	Any	
Need for reliever/ Rescue treatment	None (twice or less/week)	More than twice/week	
Lung Functions (FEV or FEV1)	Normal	<80% predicted or personal best (if known)	
Exacerbations	None One or more/ year*	One in any week+	

*Any exacerbation should prompt review of maintenance treatment to ensure that it is adequate

+By definition, an exacerbation in any week makes that an uncontrolled asthma week

Lung function is not a reliable test for children 5 years and younger

There are several validated questionnaires which may be used to access asthma control including the Asthma Control Test (ACT) and Childhood Asthma Control Test (C-ACT) (http://www.asthmacontrol.com), the Asthma Therapy Assessment Questionnaire (ATAQ) (http://www.ataqinstrument.com), the Asthma Control Questionnaire (ACQ) (http://www.goltech.co.uk/Asthma1.htm).1 The questionnaires may be used by researchers and clinicians in the assessment of patient asthma control at follow up visits

harms of treatment. Patients have been asserting their desire to take less medicine for a long time by choosing to be nonadherent to recommendations made by their physicians. Their volitional decisions to take less medicine while physicians prescribe more medicine leads to a question of what the best method is for measuring asthma control and what effect such measurements could have on outcomes. For this reason, it is essential that any treatment of asthma consider both the reduced burden of disease while at the same time recognized reduction in the burden of treatment.

The measures of asthma control that will be considered in this chapter include validated measures of symptoms (e.g., ACT), pulmonary function testing (PFT), airway hyperresponsiveness (AHR), exhaled nitric oxide (eNO), induced sputum for eosinophils, ECP and exhaled breath condensates (EBC). Though other measures such as bronchial alveolar lavage and bronchial biopsy may provide a more definitive assessment of airways inflammation, they are not appropriate for routine clinical use in an outpatient setting.

Clinical Manifestations: Symptoms, Signs

The NHBLI guidelines emphasize the need for assessment of daytime and nighttime asthma symptoms as a measure of control. Symptoms of asthma generally consist of recurrent cough, wheeze, and difficulty breathing that vary in intensity spontaneously, or in response to bronchodilators or to provoking agents. To facilitate quantification of asthma symptoms as a measure of control, the five-item ACT was developed. As a screening tool, the ACT shows good agreement with specialist's rating of asthma control. The test has been validated for identifying patients with poorly controlled asthma. It also has been found to be a useful tool for helping physicians to identify patients with uncontrolled asthma and to help them follow patients' progress. It has been found to be internally consistent, repeatable, and sensitive to changes in asthma control. It correlates well with specialists' ratings of asthma control, pulmonary function tests, and with treatment recommendations. An ACT score of 19 or less provides an optimum balance of sensitivity and specificity for detecting uncontrolled asthma.

Pulmonary Function Testing

Asthma is a condition that is manifested by airways obstruction due to cellular infiltration and edema leading to narrowing. Since it is not practical to directly measure the degree of narrowing in a patient's airways, it is necessary to use surrogate measures of airflow resistance such as FEV_1 and FEV_1/FVC. Even so, there is some debate about the utility of measures of airflow limitation in patients with asthma. The NHLBI recommends that objective measures of airflow limitation be obtained at regular intervals and has included them as a component of asthma severity and control. The measurements are easy to perform, noninvasive, and relatively inexpensive. For these reasons, PFT has become the standard test used in clinical trials and it has achieved widespread use in clinical

practice. Use of PFT does have its limitations, however. Though patients with decreased FEV_1 have been shown to have an increased risk of having an asthma exacerbation, even patients with an $FEV_1 > 80\%$ predicted have a 20% of having an exacerbation.

Airway Hyperresponsiveness

AHR is defined as the concentration of a provoking agent that is required to reduce FEV_1 by 20% from baseline. This can be expressed either as the provocation concentration (PC20) or the provocation dose (PD20), which is the concentration multiplied by the volume delivered. AHR is used to measure the sensitivity of airways to provoking agents and also to define underlying mechanisms of drug action and bronchoconstriction. The most common agents used for AHR include methacholine, histamine, AMP, exercise, cold air, and dry air (eucapnic hyperpnea). Recently, hyperosmolar mannitol also has been used. Allergens can also be used to determine the sensitivity of an allergic individual over time in response to a new treatment.

In general, methacholine, an agent that directly activates smooth muscle cells in the lung, is used for making the diagnosis of asthma by identifying AHR and to guide treatment. Exercise is used as a model of exercise-induced asthma, though eucapnic hyperpnea also is being tested as a surrogate to identify exercise-induced asthma. These techniques indirectly cause AHR by enhancing the release of prostaglandins, leukotrienes, and histamine. There is increasing interest in agents that act indirectly to release mediators to better define the underlying mechanisms of inflammation.

To determine predictors for failed reduction of ICS in patients with well-controlled asthma taking a stable dose of an ICS, the ICS was halved every 8 weeks in a clinical trial. The significant predictors of a failure of ICS reduction were AHR to both histamine and mannitol at baseline and during the dose-reduction phase. Response to mannitol and percent sputum eosinophils were significantly greater before a failed ICS reduction than before the last successful ICS reduction, whereas there were no significant differences in symptoms, spirometry, or eNO.

Tests of AHR are well suited to monitor the success of a treatment strategy. In one study comparing AHR-guided treatment using methacholine with recommendations from the NHLBI guidelines, investigators found that the AHR-guided strategy led to more effective asthma control and greater improvement of airways inflammation. In particular, patients treated according to the AHR strategy had a 1.8-fold lower rate of mild exacerbations than did patients treated with the reference strategy. In addition, FEV_1 improved more and there was a greater reduction in thickness of the subepithelial reticular layer in the AHR strategy group.

Eosinophil Cationic Protein

Eosinophil cationic protein (ECP) is another measure that has been studied as a potential biomarker of eosinophilic airway inflammation. ECP has been measured in serum, plasma, sputum, saliva, and bronchoalveolar lavage (BAL) fluid; however, serum and sputum are the most common sources. The concentration of ECP correlates well with airway inflammation but not with AHR. Since it can be elevated in other atopic diseases, measurement of ECP is not diagnostic for asthma, though it has been shown to be useful for assessing asthma severity and compliance with anti-inflammatory medications. ECP also has the potential to be used as a guide for managing ICS therapy.

Serum concentrations of ECP are significantly higher during acute asthma exacerbations than during clinical remissions. In addition, patients with an FEV_1 less than 75% predicted have higher ECP concentrations than those with a higher FEV_1. ECP also is higher in children with chronic asthma symptoms compared with non-asthmatic, non-atopic children.

Induced Sputum

The value of sputum induction in pediatric asthma lies in its potential to directly and noninvasively assess airway inflammation in children. Induced sputum is one way to determine which types of cells (neutrophils or eosinophils) are predominant in the airways of a patient with asthma. The challenge is to get a good sample that is reflective of the pulmonary cellularity and that is not too contaminated by saliva. For adults, this is relatively straight forward though it is less easy in children due to their lack of cooperation in the maneuver and to their tendency to swallow sputum rather than spit it out. In one study using induced sputum neutrophil and eosinophil counts as markers of inflammation, the presence of sputum neutrophils but not eosinophils was associated with lower postbronchodilator FEV_1 suggesting that neutrophilic airway inflammation is associated with poorer response to treatment.

Since exacerbations of asthma are likely to be due to an increase in airway inflammation, an increase in the number of cells in induced sputum may prove to be a marker of an impending exacerbation. Both increases in sputum eosinophils and eNO correlate with decreased morning peak flows and FEV1. In addition, higher sputum percentage eosinophils are associated with atopy, increased bronchodilator reversibility, lower FEV_1/FVC ratio, higher eNO levels, circulating eosinophils, sputum and serum eosinophil cationic protein, and greater asthma severity. Tailored asthma interventions based on sputum eosinophils are beneficial in reducing the frequency of asthma exacerbations in patients with asthma.

Exhaled Breath Analysis

International asthma guidelines recommend that a variety of clinical tests be used to monitor asthma control. These have focused largely on identifying variable airflow obstruction and responses to provoking agents, bronchodilator, or corticosteroids. A growing interest has recently been directed toward identifying noninvasive markers of airway inflammation including gases such as nitric oxide and EBC collection. Exhaled breath analysis is used to measure inflammation and oxidative stress in the respiratory tract, to make a diagnosis of airway disease and as a guide to monitor and adjust therapy. EBC is obtained by cooling exhaled air. Its composition is believed to mirror that of the fluid lining the airways. While EBC is still considered to be a research tool, other exhaled components such as eNO measurement are closer to clinical practice.

Exhaled Nitric Oxide

Fractional eNO (FeNO) is a gas that is increased in atopic asthma, correlates with various inflammatory markers, and is reduced by treatment with corticosteroids and antileukotrienes but not by beta2-agonists. Since NO is a gas at room temperature, it does not liquefy on cooling and therefore it is not an EBC. FeNO is a reliable marker of eosinophilic airway inflammation that can be measured using standardized techniques in children as young as 4 years. FeNO is believed to be another surrogate marker of inflammation. Until recently, measurement of FeNO was limited to research facilities and secondary care institutions. With the development of portable nitric oxide analyzers (MINO; Aerocrine AB; Smidesvagen, Sweden) routine measurement of FeNO is more available for clinical practice without the need for the more expensive units (NIOX; Aerocrine) without losing any accuracy in measurement.

FeNO appears to represent a distinct parameter from other, more clinically based measurements. The concentration of FeNO is significantly elevated in uncontrolled asthma and decreases after anti-inflammatory therapy. A low eNO appears to be predictive of not having an exacerbation of asthma in the near term. An elevated FeNO in preschool-aged children with moderate-to-severe intermittent wheezing also is associated with an increased risk of respiratory tract infections and with aeroallergen sensitization.

Current asthma guidelines recommend adjusting treatment on the basis of lung function tests and symptoms. Unfortunately, neither of these has been shown to be closely associated with airway inflammation. This leads to the question of whether FeNO can be used to manage asthma as effectively as the more standard measurements. FeNO concentrations do seem to change more rapidly in response to administration of ICS than FEV_1 or AHR suggesting that it is more sensitive to changes in inflammation than these other measures. By using it to guide step-down treatment, FeNO measurement seems to reduce the use of ICS without compromising asthma control. There have been studies with different results. Clearly, further research is needed to fully define the value of FeNO measurements as a guide to asthma treatment.

Exhaled Breath Condensates

Collection of EBC is a noninvasive method for obtaining samples from the lungs to assess airway inflammation and oxidative stress and may be useful in the assessment of childhood asthma. EBC contains large number of mediators including adenosine, ammonia, hydrogen peroxide, isoprostanes, leukotrienes, nitrogen oxides, peptides, and cytokines. Concentrations of these mediators are affected by lung diseases and can be altered by therapeutic interventions. In addition, the pH of EBC changes in response to the presence of respiratory diseases. Recently, the American Thoracic Society/European Respiratory Society Task Force on EBC provided recommendations for the collection and measurement of EBC. The recommendations included instructions to "collect EBC during tidal breathing using a noseclip and a saliva trap; define

cooling temperature and collection time (10 min is generally sufficient to obtain 1–2 mL of sample and well tolerated by patients); use inert material for condenser; do not use resistor and do not use filter between the subject and the condenser."

Increased concentrations of 8-isoprostane, hydrogen peroxide, nitrite, and 3-nitrotyrosine are found in EBC in inflammatory lung diseases. Increased levels of lipid mediators are found in these diseases, with a differential pattern depending on the nature of the disease process. With the development of smaller, less expensive, and more sensitive analyzers, exhaled breath analysis may become available for diagnosis and monitoring of asthma in the routine clinical practice.

Exhaled 8-isoprostane is a stable marker of oxidative stress. Mean exhaled 8-isoprostane concentrations are significantly higher in steroid-naive asthmatic children than in healthy children. Children with asthma who take ICS also have higher 8-isoprostane levels than normal children suggesting that it is not normalized by inhaled steroid therapy. Exhaled 8-isoprostane also does not correlate with duration of asthma, dose of inhaled steroids, or FeNO.

Aldehydes and glutathione are additional biomarkers of oxidant and antioxidant status in asthma, respectively. Children with exacerbations had higher concentrations of malondialdehyde (an oxidant), that decreased after steroid therapy, than healthy controls. Conversely, glutathione (an antioxidant) concentrations are decreased during exacerbations and increased with steroid therapy.

Cysteinyl leukotrienes (Cys-LT) and isoprostanes are inflammatory metabolites derived from arachidonic acid whose levels are increased in the airways of asthmatic patients. Isoprostanes are relatively stable and specific for lipid peroxidation, which makes them potentially reliable biomarkers for oxidative stress found during asthma exacerbations. Both substances decrease with prednisone treatment but not as much as FeNO suggesting that corticosteroids may not be fully effective in reducing oxidative stress in children who are having an exacerbation of asthma.

EBC pH and ammonia concentrations have been used as a noninvasive method to measure acid-base status in the airways of asthmatics. Both pH and ammonia are lower in patients with asthma than in healthy control groups. In addition, both values increase with ICS-treatment. At low pH values found in the airways, nitrite, which is an endogenous airway compound, is converted to nitric oxide (NO) in quantities that may be sufficient to account for the concentrations of NO found in the expired air of asthmatics.

Diagnosis

2007 NHLBI Guidelines

In 2007, the NHLBI published the third complete update of its guidelines for the diagnosis and treatment of asthma. Though previous versions emphasized careful diagnosis of asthma, categorization of severity and treatment based on that severity, little emphasis was placed on long-term assessment of asthma control. The third update corrected that oversight with its emphasis on ongoing measurement of asthma control with corresponding modification of treatment. There are a number of reasons for this including a growing recognition that maintaining asthma control is an important component of prevention of adverse outcomes such as emergency department (ED) visits, hospitalizations, and death.

Since asthma is a heterogeneous syndrome with some phenotypes responding better to certain treatments than others, identification of markers that can help to predict asthma exacerbations is an important component of control, particularly since asthma severity changes frequently over time. This heterogeneity includes variability in clinical, physiologic, and pathologic parameters. Children with asthma frequently move between severity categories, particularly if they start with inadequate asthma control to begin with.

To achieve the best control, asthma severity needs to be determined repeatedly using assessments of lung function, albuterol use, and asthma symptoms along with new markers of eosinophilic airway inflammation. There is increasing evidence that management guided by measures of inflammation is superior to other measures leading to a reduction in exacerbation frequency and a reduction of inhaled corticosteroid dosage.

International GINA Guidelines

In addition to the NHLBI guidelines in the USA, the GINA guidelines have been accepted as an international set of asthma guidelines. Since it was formed in 1993, the GINA, a network of individuals, organizations, and public health officials, has played a leading role in disseminating information about the care of patients with asthma based on a process of continuous review of published scientific investigations. A comprehensive workshop report entitled "A Global Strategy for Asthma Management and Prevention," first published in 1995, has been widely adopted, translated, and reproduced, and forms the basis for many national guidelines. The 2006 report contains important

new themes. First, it asserts that "it is reasonable to expect that in most patients with asthma, control of the disease can and should be achieved and maintained," and recommends a change in approach to asthma management, with asthma control, rather than asthma severity, being the focus of treatment decisions. The importance of the patient–care giver partnership and guided self-management, along with setting goals for treatment, are also emphasized. Management of asthma according to the GINA guidelines has been shown to be associated with a decrease in asthma morbidity and mortality.

Differential Diagnosis

Since asthma is a heterogeneous syndrome that is defined clinically, a number of related diseases can have similar symptoms. It is important to distinguish between alternative diagnoses and conditions that trigger underlying asthma. For example, Respiratory Syncytial Virus and Rhinovirus are common triggers of asthma in young children. Though it is possible for a child with RSV to wheeze, it is more common for a patient with asthma to wheeze when infected with these viruses than for a nonasthmatic person. These viruses therefore are triggers of asthma and not alternative conditions. Similarly, Gastroesophageal Reflux Disease (GERD) is a trigger for asthma as opposed to an alternative disease since most children with this condition do not wheeze.

The most common alternative disorders in children include Cystic Fibrosis which often manifests as a chronic obstructive lung disease, Vocal cord dysfunction (VCD), congenital abnormalities of the lower airways (bronchogenic cysts, abnormal blood vessels, TE fistulae, etc.), Cardiac asthma which is actually congestive heart failure manifesting with wheezing, immotile cilia syndrome (Kartagener's syndrome if associated with situs inversus), and immunodeficiency. Other conditions such as foreign body aspiration must be considered along with various conditions associated with chronic cough such as post-viral cough, habit cough, and exposure to irritants. Children with alpha-1-antitrypsin deficiency usually present with liver disease, and COPD in a child is very rare.

Since most of these alternative diagnoses can be excluded either by history or simple diagnostic tests and most obstructive wheezing lung disorders in children actually are manifestations of asthma, it is not necessary to perform exhaustive testing in every child to rule out alternative conditions. Instead it is reasonable to prescribe a short trial of asthma treatment and evaluate the response to it. If the patient fails to improve significantly after a reasonable treatment trial, alternative conditions should then be considered.

Treatment

General Care

Trigger Avoidance

Allergen exposure in children with asthma with known sensitivity not only can increase asthma symptoms but can also trigger an asthma exacerbation. Therefore, patients with persistent asthma should be evaluated for atopy for potential of allergen exposure. This should be done by taking a careful allergy history and with either skin prick testing or in vitro testing for allergen-specific IgE. Sensitized patients should be encouraged to limit their allergen exposure.

The most common indoor allergens are dust mite, fungi, and animal dander. When indoor allergens are suspected to be present, consideration should be given to requesting an environmental home or school assessment by an environmental hygienist. Such assessments may help to identify the types and amount of exposure and can help guide avoidance recommendations.

Dust mites are considered to be an important trigger of asthma. These acarids are found in upholstered furniture, bedding, and carpeting and they feed on shed skin cells, fungi, and each other. They produce 5 μm fecal pellets that contain dust mite allergens and that become airborne when disturbed. Suggested methods for reducing exposure to dust mites include air filtration, reduction of humidity, chemical acaracides, and use of dust-mite impermeable mattress covers. Because the fecal pellets settle out of the air relatively quickly, air filtration has not been shown to be very effective for reducing dust mite exposure. Reduction of humidity to 35% can reduce dust mite populations but is hard to consistently achieve in microenvironments such as a bed because of respiration and perspiration by its human occupants. There is limited evidence that these simple interventions such as dust mite covers and chemical acaracides are effective for treating asthma. Instead, a comprehensive set of environmental control measures is likely to be required.

Exposure to pet dander from furry animals is another important trigger of asthma. There is some evidence that individuals born into houses with cats can become desensitized; however, once sensitization has occurred it is important to avoid exposure. While

avoidance would seem to be easily accomplished for sensitized individuals, the reality is that most households consider their pet to be a member of the family that they are very reluctant to part with. For that reason, a number of strategies have been evaluated for reducing pet allergen while retaining the dog or cat. The most effective has been to simply wash the dog or cat regularly to remove most of the allergen. Denaturants such as tannic acid and dilute bleach also have been proposed as ways to reduce allergen exposure. Regular use of a high-efficiency vacuum such as a HEPA or cyclonic vacuum also has been proposed as a way to reduce pet allergen exposure. Ultimately, it is likely that a combination of these approaches will be necessary to sufficiently reduce exposure so that the pet can remain in the home without triggering asthma.

Irritants trigger asthma symptoms by non-immunologic mechanisms. ETS is one of the most important indoor irritants. For that reason, all patients with asthma should be evaluated for exposure to ETS and referrals to smoking cessation programs should be offered when appropriate. Avoidance of smoke from wood burning stoves, fireplaces, and grills should be advised, as well as avoidance of strong odors, volatile organic compounds, and other respiratory irritants. Adolescents should also be screened for possible occupational exposures, particularly those who have new onset asthma.

Finally, a detailed history should be taken to identify possible, treatable comorbid conditions that may cause increased symptoms. Examples of these conditions include gastrointestinal reflux disease, aspirin sensitivity, rhinosinusitis, obesity, sleep apnea, and stress. If identified as a contributing factor, comorbid conditions should be aggressively treated.

Vaccinations

Patients with asthma are more likely to have serious health problems as the result of many infections. As a result, immunizations should be kept up-to-date with current recommendations. In particular, inactivated influenza vaccinations should be offered to all children greater than 6 months of age with asthma every fall. Children with asthma should not receive the live attenuated influenza vaccine. The 23-valent pneumococcal polysaccharide vaccine is currently only routinely recommended for adults with asthma. Children should continue to receive the 7-valent pneumococcal vaccine as part of their routine immunization schedule but it is not considered to be part of asthma treatment.

Asthma Self-management

Asthma education is an essential component of asthma management. Asthma care providers should teach patients and families the basics of asthma and medication techniques in simple language. Patients should be taught about asthma and step-down treatment. In addition, clinicians should provide written asthma action plans that include the patient's daily controller medications as well as how to recognize and handle worsening asthma symptoms. Action plans based on peak flow meter readings are no more effective than plans based on symptoms.

The Acute Intervention Management Strategies (AIMS) trial attempted to determine what management strategies are effective by following children with a variety of allergy, asthma, environmental, and quality of life assessments. They found that episodic use both of ICS and LTRA led to reductions in trouble breathing and interference with activity during episodes. This suggests that parents can use symptoms to guide the need for controller medications for long-term management of asthma.

The question of what intervention would be effective for treating an exacerbation of asthma has been extensively reviewed. There is limited evidence for the addition of a long acting beta-agonist (LABA) during an episode of asthma to prevent the need for oral steroids. Addition of or doubling the dose of an inhaled corticosteroid has not been shown to be effective. The one intervention that has been shown to be effective is to quadruple the dose of the inhaled corticosteroid at the onset of respiratory symptoms. If needed for an exacerbation, a short course of oral steroids has been found to effectively prevent relapses of asthma.

Spacers

Spacers should be considered for use with all metered dose inhalers (MDIs) when the patient is unable to coordinate an inhalation and actuation. In particular, spacers should be considered for infants and very young children. Though there does not appear to be a significant difference between the different types of spacer, it is important that it be fitted to the patient so that it can be used properly. Holding chambers, when used correctly, are as effective for

delivering an aerosol as is nebulizer delivery and they may be more effective for treating acute episodes of asthma.

The Future of Asthma

While asthma continues to be a significant global health problem, the future of asthma management appears to be bright. Over the next decade it is likely that genetic tests will identify individuals who are at high risk for developing asthma and that new treatments will be developed based on those new insights. Treatment will be personalized based on knowledge of a person's genetic makeup eliminating the "one size fits all" approach that is used today. In addition, asthma control will be monitored using sensitive biomarkers that relate to outcomes that are important. And finally, it is possible that preventative approaches to asthma will be developed so that the prevalence of this troublesome disease will decline.

Specific Treatment

The 2007 NHLBI guidelines for the diagnosis and management of asthma outline a stepwise approach to initiating various pharmacologic treatments. While initiation of treatment is based on the severity of asthma, long-term management is based on control. The recommendations are for patients to step-up treatment if control is inadequate and to maintain or step-down treatment when control is achieved to determine the least amount of treatment necessary to maintain optimal control. The specific medications recommended for each step are shown in *Table 132.3*.

Table 132.3
Stepwise approach for managing asthma

Stepwise approach for managing asthma in children 0–4 years of age	
	Preferred medications
Step 1	SABA PRN
Step 2	Low-dose ICS
Step 3	Medium-dose ICS
Step 4	Medium-dose ICS and either LABA or montelukast
Step 5	High-dose ICS and either LABA or montelukast
Step 6	High-dose ICS and either LABA or montelukast and oral systemic corticosteroid
Stepwise approach for managing asthma in children 5–11 years of age	
	Preferred medications
Step 1	SABA PRN
Step 2	Low-dose ICS
Step 3	Low-dose ICS and either LABA, LTRA, or theophylline or medium-dose ICS
Step 4	Medium-dose ICS and LABA
Step 5	High-dose ICS and LABA
Step 6	High-dose ICS and LABA and oral systemic corticosteroid
Stepwise approach for managing asthma in children >12 years of age	
	Preferred medications
Step 1	SABA PRN
Step 2	Low-dose ICS
Step 3	Low-dose ICS and LABA or medium-dose ICS
Step 4	Medium-dose ICS and LABA
Step 5	High-dose ICS and LABA and consider omalizumab
Step 6	High-dose ICS and LABA and oral systemic corticosteroid and consider omalizumab

Relievers

Short acting beta-agonists (SABAs) include albuterol, levalbuterol, and pirbuterol. These medications quickly relax bronchial smooth muscles leading to bronchodilation. These drugs are also beneficial for prevention of exercise-induced bronchospasm when used 15–20 min before exercise. The mechanism of action involves activation of adenlycyclase resulting in an increase in cAMP which in turn leads to activation of protein Kinase A which inhibits phosphorylation of myosin and lowers intracellular calcium resulting in relaxation of bronchial smooth muscle. Other benefits include reduced vascular permeability and edema and increased cillary beat frequency. Side effects include tremor, increase in heart rate, prolongation of QT interval and hypokalemia and hyperglycemia especially with frequent use.

Asthma mortality epidemics occurred in 6 countries in the early 1960s associated with the introduction of isoprenaline forte and in the 1970s in New Zealand with the introduction of fenoterol. Both of these beta adrenergic agents are nonselective with enhanced cardiovascular side effects especially in high doses and with frequent administration in persons with hypoxemia from asthma. Selective beta adrenergic agents currently in the market such as albuterol, salbuterol, and levalbuterol have not been associated with epidemics of asthma mortality.

In patients with mild asthma, scheduled use of albuterol does not provide either beneficial or deleterious effects on asthma control. Consequently, SABAs should be used as rescue medication and ideally should be necessary infrequently if the asthma is under good control. An increased need for SABA use should be viewed as a marker for increased inflammation and to signify the need to increase daily controller medications. A patient who requires frequent SABA use and is not controlled should receive stepped-up therapy with an inhaled corticosteroid and/or systemic corticosteroids because beta adrenergic agents do not provide the needed anti-inflammatory activity.

Inhaled Corticosteroids

ICS are the most potent and effective maintenance treatment of asthma and should be used in all patients who require more than infrequent use of SABA. ICS reduce airway inflammation and hyperresponsiveness. There are a large number of ICS currently available for the treatment of asthma. These medications can be increased in a stepwise fashion to obtain improved asthma control though most have a limited dose-response range. The NHBLI recommendations for the comparative daily doses of various ICS are shown in *Table 132.4*.

Table 132.4
Estimated comparative daily doses of inhaled corticosteroids

Drug	Low dose (mcg per day)			Medium dose (mcg per day)			High dose (mcg per day)		
	Age 0–4	Age 5–11	Age ≥ 12	Age 0–4	Age 5–11	Age ≥ 12	Age 0–4	Age 5–11	Age ≥ 12
Beclomethasone HFA 40 or 80 mcg/puff	N/A	80–160	80–240	N/A	>160–320	>240–480	N/A	>320	>480
Budesonide 90, 180, or 200 mcg/DPI	N/A	180–400	180–600	N/A	>400–800	>600–1,200	N/A	>800	>1,200
Budesonide inhalation suspension	250–500	500	N/A	>500–1,000	1,000	N/A	>1,000	2,000	N/A
Flunisolide 250 mcg/puff	N/A	500–750	500–1,000	N/A	1,000–1,250	1,000–2,000	N/A	>1,250	2,000
Fluticasone HFA 44, 110, or 220 mcg/puff	176	88–176	88–264	>176–352	>176–352	>264–440	>352	>352	>440
Mometasone 110 or 220 mcg/DPI	N/A	110	220	N/A	110	440	N/A	110	>440
Triamcinolone acetonide 75 mcg/puff	N/A	300–600	300–750	N/A	>600–900	>75–1,500	N/A	>900	>1,500

Source: Reproduced from the NHLBI Asthma Guidelines 2007

Though ICSs are the most commonly used asthma controller medications, responses to corticosteroids vary widely between individuals. Though it is difficult to predict who will respond and who will not, a genetic cause in the form of variations in corticotropin-releasing hormone receptor 1 (CRHR1) has been shown to be associated with enhanced response with individuals homozygous for the variants showing increased lung function response to corticosteroids.

Long Acting Beta-Agonists

LABAs are defined as beta-agonists whose half-lives are at least 12 h duration. LABAs are more lipophilic secondary to their extended side chain which leads to a longer duration of action. Medications in this class include salmeterol and formoterol. Formoterol has an onset of action within 15 min and salmeterol within 30 min. LABAs are used in combination with ICS in the maintenance of asthma and are not recommended for use as monotherapy. In the USA, packaging of LABA includes a black box warning from the Food and Drug Administration in which practitioners are advised to weigh the risks and benefits of this medication prior to use.

The GINA guidelines recommend increasing inhaled corticosteroid doses in all children with asthma not controlled on low-dose ICS before adding a long-acting beta2-adrenergic agonist, whereas NHLBI guidelines have different age-based recommendations for children. In patients younger than 5 years, NHLBI guidelines recommend increasing the inhaled corticosteroid dose before adding a LABA; in children aged 5–11 years, equal weight is given to increasing the inhaled corticosteroid dose or including add-on therapy to low-dose ICS. In adults and adolescents aged 12 years and older, GINA recommends adding a LABA to low-dose ICS in preference to increasing the dose of inhaled corticosteroid. The NHLBI guidelines give equal weight to these choices, with alternative, although not preferred, therapies including the addition of theophylline, zileuton, or LTRA to low-dose ICS.

A number of concerns were voiced in 2006 regarding the safety of the use of LABAs for treatment of asthma. These concerns included whether use of this class of drug increases the risk for hospitalization, near death, or death due to asthma, whether the increased risk was greater in African Americans, and whether individuals who are homozygous for arginine at the 16th codon of the beta2-adrenergic receptor have a poorer response or even deteriorate when prescribed LABAs. Subsequent studies addressed each of these concerns and have been consistently reassuring.

Leukotriene Modifiers

This class of medications include both LTRA (montelukast and zafirlukast) as well as a 5-lipoxygenase inhibitor (5-LO; zileuton). The NHLBI guidelines consider LTRAs to be an alternative, but not preferred monotherapy for the treatment of mild persistent asthma. They also are considered to be effective for adjunct therapy in children <12 years; however, LABAs are the preferred adjunct therapy in adults and children >12. Finally, LTRAs are indicated for treatment of exercise-induced bronchospasm. Zileuton is less preferred to LTRAs in children >12 years because of the need for liver function monitoring. LTRAs and Zileuton also may attenuate bronchoconstriction in aspirin sensitive individuals.

Oral Corticosteroids

Oral corticosteroids are potent anti-inflammatory agents whose efficacy in the treatment of asthma is well documented. Because of the many side effects, however, every consideration must be given to administering the lowest dose of oral corticosteroids for the shortest amount of time. Before prescribing oral corticosteroids for maintenance therapy it is important that the use of all other conventional asthma medications be maximized.

Short courses of oral corticosteroids have been shown to be effective for treatment of acute asthma exacerbations. In particular, when taken at the onset of a respiratory infection, a 3–5 days course of an oral steroid can reduce the risk of an ED visit or hospitalization for asthma. Once an asthma exacerbation has taken place, oral steroids are effective for treatment in the ED to reduce the likelihood of hospitalization, though they need to be given as early as possible.

Other Agents

Cromolyn sodium and nedocromil are similar but distinct medications whose anti-inflammatory properties are felt to occur via mast cell stabilization. They may be used as an alternative, but are not preferred treatment in mild persistent asthma. They also may be useful as preventative treatments prior to exercise and when a predictable

exposure to an allergen is unavoidable. Both of these agents are considered to have relatively weak anti-inflammatory effects that take time to become apparent. Their main benefit is their extremely low side effect profile.

Theophylline is a nonselective phophodiesterase inhibitor that provides some bronchodilation. Sustained-release theophylline is an alternative, but not preferred treatment of mild persistent asthma in children >5 years old. Theophylline was widely prescribed for treatment of asthma in the 1980s but fell into disuse in favor of ICS. The main drawback to theophylline is its relatively narrow therapeutic index and well-known side effects that include tachycardia, arrhythmias, nausea, hyperactivity and at higher concentrations, seizures. If theophylline is used it is necessary to monitor serum theophylline concentrations to ensure that the levels are therapeutic without becoming toxic. A number of medications interact with theophylline metabolism including cimetadine, ketaconazole, and many macrolide antibiotics.

Omalizumab

Omalizumab is a recombinant, humanized, monoclonal antibody directed to the portion of the IgE molecule that binds to mast cells and basophiles, thus preventing binding of IgE and subsequent degranulation of these cells. Omalizumab is considered to be an effective adjunct therapy in asthma patients >12 years old with moderate to severe persistent asthma and allergies documented by skin prick testing or in vitro testing. The safety and efficacy of omalizumab in children of ages 6–11 is currently under investigation.

Combinations

Given the extensive list of treatment options for controlling asthma, the question is how to determine which treatment is most appropriate for a particular individual. Both ICSs and LTRAs lead to improvement in most measures of asthma control. However, clinical outcomes, pulmonary responses, and inflammatory biomarkers such as exhaled nitric oxide eNO improve significantly more with ICS treatment than with LTRAs treatment. In addition, elevated FeNO seems to be a predictor of better response to ICS compared with an LTRA.

For moderate persistent asthma, ICSs are more effective. This was confirmed by the Pediatric Asthma Controller Trial (PACT) which found that fluticasone monotherapy and combination fluticasone/salmeterol combination provided greater improvements in asthma control days than montelukast alone. These results are not surprising given the greater anti-inflammatory effects of ICS; however, there is limited information comparing the two agents for patients with mild asthma where the anti-inflammatory effect required for control may be less.

For mild asthma it is possible that both ICS and LTRA would provide sufficient control assuming that patients respond to them equally. To determine how frequently children with asthma do respond to ICS or LTRA, a comparison study was performed in children 6–17 years of age with mild-to-moderate persistent asthma. While 17% responded to both medications, 23% responded only to fluticasone, 5% responded only to montelukast alone and surprisingly, 55% responded to neither medication. Since most patients with asthma improve with treatment, this result suggests that there is more going on than simple anti-inflammatory treatment with medications.

The GINA guidelines are similar to the NHLBI guidelines with an important difference. In the GINA and NHLBI guidelines, patients with moderate to severe asthma are advised to use ICS or an ICS/LABA combination with a SABA as reliever. Because some patients still fail to achieve guideline-defined asthma control leading to overuse of SABA reliever medication at the expense of ICS, the GINA guidelines recommend that such patients use an ICS/LABA combination for both maintenance and reliever therapy. This clearly is contrary to recommendations from the NHLBI guidelines. The GINA treatment strategy has been shown to significantly reduce the rate of severe asthma exacerbations compared with ICS/LABA plus SABA while achieving equivalent daily symptom control with a lower overall steroid load.

Finally, there has been controversy over whether ICS can modify the subsequent development of asthma in children at high risk for asthma. This is important because if ICS does modify subsequent disease development and severity, a stronger case can be made for more aggressive ICS use in young children even when they are asymptomatic. On the other hand, if disease progression is not affected by regular ICS use, it is hard to recommend that asymptomatic children receive aggressive treatment given the potential harms, both physiologic and psychological, that are associated with such treatment. In the one study that addressed this question in preschool children at high risk for asthma, 2 years of inhaled-corticosteroid therapy did not change the development of asthma symptoms or lung function during a third, treatment-free year. These findings suggest that ICS treatment does not lead to a subsequent disease-modifying effect after ICS treatment is discontinued.

Allergen Immunotherapy

Patients who do not respond adequately to pharmacotherapy or who wish to avoid long-term use of medications should be considered for allergen immunotherapy. Injection immunotherapy has been shown to be effective for the treatment of asthma in children in a meta-analysis of clinical trials In addition, sublingual immunotherapy has also shown substantial efficacy for treatment of asthma in children and may be as effective as an inhaled corticosteorid for mild persistent asthma.

Prognosis

Although many children wheeze within the first 3 years of life with viral infections, not all of these children continue to have asthma symptoms as they age. A prospective study of 6-year-old children in Tucson, Arizona found that 51% never wheezed, 19.9% wheezed at least once with viral illness during the first 3 years of life but not at 6 years (transient wheezing), 15% did not wheeze at 3 years but had wheezing at 6 years (late onset), and 13.7% had wheezing both at 3 and 6 years (persistent). Smoking by mother, lack of history of maternal atopy, and lower lung function of the child in the first 3 years of life were risk factors for transient wheezing whereas children who continued to wheeze at 6 years were more likely to have mothers with allergy and to have elevated serum IgE levels. In addition, young children were more likely to continue to wheeze at 6 and 13 years of age if they had risk factors including parental history of asthma or eczema, eosinophilia, wheezing apart from colds, and allergic rhinitis, and over 95% of children without these criteria never wheezed actively between 6 and 13 years.

Patterns of wheezing prevalence and levels of lung function appear to be established by age 6 years and do not change much after that. In a follow-up report, the prevalence of atopy and wheeze by age 16 years was similar for never and transient wheezers and for persistent and late-onset wheezers. Both transient early, and persistent wheezers had significantly lower FEF(25–75), FEV_1, and FEV_1:FVC ratio, respectively when compared to never wheezers.

The natural history of asthma is one of periods of remission followed by reemergence of symptoms in some individuals. A New Zealand cohort study of children with asthma followed into adulthood found that 14.5% continued to wheeze to age 26 years, 27.4% had remission at age 26 years, and 12.4% had a remission but relapsed by age 26 years. Risk factors for persistence and relapse of asthma were earlier onset of wheezing, sensitivity to dust mites, BHR, female sex, and smoking.

Another cohort study of babies at risk for atopy in the UK in which most of the children who wheezed before the age of 2 years and did not wheeze at 11 years did not develop allergies or bronchial hyperresponsiveness whereas 20 of 23 children who wheezed at 11 years had atopy and increased bronchial hyperresponsiveness. Those with positive skin test to egg and milk as infants correlated with asthma at 22 years of age.

Persistence of childhood asthma correlated with severity of asthma in a Canadian study. Children who were hospitalized during the first year after the diagnosis of asthma had a threefold risk of persistent asthma and those with at least four physician visits for asthma had a 2.6-fold increased risk of persistent asthma at age 12 years.

As to the long-term natural history, 30–80% of asthma patients seem to develop symptoms again later in life. This is because some patients who outgrow their asthma continue to have persistent airway eosinophilic inflammation, AHR and airway narrowing. In summary, family history of allergies, personal history of allergic rhinitis, wheezing apart from colds, more severe asthma symptoms in childhood, and lower lung function in childhood tends to be associated with persistence or relapse of asthma as adults.

Prevention

According to the NHLBI guidelines as outlined in *Table 132.5*, the goal for asthma treatment is to control asthma by reducing impairment and risk. This can be done using a stepwise approach to medications in which treatment increases as symptoms increase and decreases when symptoms decrease. To do this it is essential that patients be taught to monitor their degree of asthma control. Because asthma is a chronic disease, it is likely that the relationship between a patient and the asthma provider will be long-term necessitating that the two approach management of the asthma as partners. Referral to an asthma specialist should be considered for patients with persistent asthma for possible comanagement. Patients should receive information about identifying and avoiding asthma triggers including testing for specific IgE, environmental control and when indicated specific allergen immunotherapy. And finally, all patients with asthma should receive a written action plan so that they can control their asthma if and when it flares to reduce the likelihood of an ED visit, hospitalization, and most importantly, avoidance of death. By following these steps it

Table 132.5
Managing asthma long-term

• The goal for therapy is to control asthma by reducing impairment and risk (Evidence A).
• A stepwise approach to pharmacologic therapy is recommended to gain and maintain control of asthma in both the impairment and risk domains (Evidence A).
• Monitoring and follow-up is essential (Evidence B).
• Because asthma is a chronic inflammatory disorder of the airway, persistent asthma is most effectively controlled with daily long-term control medication directed toward suppression of airway inflammation (Evidence A).
• Therapeutic strategies should be considered in concert with clinician–patient partnership strategies; education of patients is essential for achieving optimal pharmacologic therapy (Evidence A).
• At each step, patients should be advised to avoid or control allergens (Evidence A), irritants, or comorbid conditions that make the patient's asthma worse (Evidence B).
• A written asthma action plan detailing for the individual patient the daily management (medications and environmental control strategies) and how to recognize and handle worsening asthma is recommended for all patients; it is particularly recommended for patients who have moderate or severe asthma, a history of severe exacerbations, or poorly controlled asthma (Evidence B). The written asthma action plan can be either symptom-based or peak-flow-based; evidence shows similar benefits for each (Evidence B).
• Referral to an asthma specialist for consultation or comanagement of the patient is recommended if there are difficulties achieving or maintaining control of asthma; if additional education is needed to improve adherence; if the patient requires step 4 care or higher (step 3 care or higher for children 0–4 years of age); or if the patient has had an exacerbation requiring hospitalization. Consider referral if a patient requires step 3 care (step 2 care for children 0–4 years of age) or if additional testing for the role of allergy is indicated (Evidence D).

Source: Reproduced from the NHLBI Asthma Guidelines 2007

should be possible for all patients with asthma to have well-controlled disease with little or no impairment.

133 Atopic Dermatitis

Harb A. Harfi

Definition

Atopic dermatitis or infantile eczema is a skin inflammation characterized by intense pruritus and scratching, which result in skin damage. The skin lesions manifest in the form of papulation, excoriation, oozing, crusting, and secondary infection. The severity and intensity of symptoms vary from one patient to another. The hallmark of atopic dermatitis (AD) is itching. The skin changes that follow are due to traumatization of the skin by persistent scratching. The symptoms are made worse by increased heat, perspiration, excessive dryness, irritation, psychological tension, and secondary infections.

Epidemiology

Although AD is a common allergic disease of infancy and childhood, its exact incidence is not known. But the incidence seems to be increasing. There are no racial or geographical differences and girls may be slightly more affected. It may affect 5–20% of children, but some studies estimate the incidence to be between 1% and 4%, depending on the population studied and the methodology of the study. The higher figures are in urban population. Most infants develop AD below the age of 1 in 60% of cases and by the age of 5 in another 30%. It is unusual for an infant below 2 months of age to develop AD. The occurrence of AD is much higher in families with a history of allergy. About 75% of infants and children with AD either have another allergy or have a strong family history of atopy.

Pathogenesis and Genetics

The pathogenesis of AD is more complex than it was previously thought. This includes impaired epidermal barrier function, immune disorders in which T-cells, Langerhans cells, and immune effector cells induce inflammatory response to various environmental factors such as irritants, infections, chemicals, and allergens. The integrity of the epidermis is important for a healthy skin. This integrity is kept by the interaction of keratinocytes and a variety of proteins such as Filaggrin, enzymes, and lipids. Disruption of this barrier allows foreign antigen to penetrate and come in contact with immune cells and release proinflammatory agents that lead to the clinical and pathological manifestations of AD. Atopic skin keratinocytes are defective in binding water, which is important for a healthy epidermal barrier. This dryness leads to pruritus with scratching, skin trauma, and inflammation. Several genetic factors involved in the epidermal permeability barrier defect have been described. These include Filaggrin mutation that leads to icthyosin (R 501X and 2282dL4), and defective Spink5 that leads to cleavage of intercellular attachments, and hence, the corneocyte cohesion, which weakens the skin barrier function. The defects open the way for foreign antigens to enter through the epidermis and interact with immune cells, leading to sensitization and inflammation. AD is a genetic disease based on twin studies and family history. The trait is more often inherited through a maternal gene rather than a paternal one. Many patients have Filaggrin mutations.

Clinical Manifestations

Clinical features of atopic dermatitis depend on the severity and chronicity of inflammation. The most prominent feature of atopic dermatitis is itching. The skin is usually dry or erythematous with some degree of lichenification, or oozing, crusting, and acutely inflamed, depending on the stage of inflammation. Skin manifestations go through different stages, depending on the chronicity of symptoms and the age of the patient. Classification of atopic dermatitis in relation to age is divided into three groups:

1. Infantile – from 2 months to 2 years
2. Childhood – from 2 to 10 years
3. Adolescent – from 11 to 20 years

In infants, the early feature is dry erythema on the cheeks, which may become oozy with crust formation and secondary infection. The eczema may spread to involve the forehead, scalp, and postauricular areas. It may also

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_133,

involve the extensor surfaces of the upper and lower extremities and may become generalized. The baby is usually irritable and scratches the skin constantly. The baby may look unhappy due to severe itching, which may interfere with feeding and sleep. This stage has a tendency to improve as infants grow older. Once an infant starts crawling, the skin's dryness increases and the papules tend to become larger, confluent, and crusty. In older children, the skin lesions have a tendency to involve the flexural areas, with the antecubital and popliteal fossae and the back of the neck being the preferred areas. Skin infection may complicate the picture further and leads to confusion in diagnosis. In chronic severe eczema, the skin of the eyelids becomes thickened and forms transverse lines known as Dennie–Morgan lines.

Complications

Complications of atopic dermatitis in both infants and children include

1. Secondary infections with *Staphylococcus aureus*, herpes simplex, herpes zoster (eczema herpeticum), and molluscum contagiosum. Herpes simplex may become disseminated, causing serious consequences.
2. Subcapsular cataract occurs in about 16%.
3. Keratoconus and ulceration of the cornea.
4. In cases of severe generalized eczema, psychological complications may lead to withdrawal of the child from social activities.

Differential Diagnosis

Seborrheic dermatitis is easy to differentiate; it usually starts as cradle cap with thick, greasy, yellowish scales. It begins before the age of 2 months and causes minimal or no itching. In comparison, atopic dermatitis starts after the age of 2 months with intense itching. Classic seborrheic dermatitis follows the hairline with slight erythema, while atopic dermatitis is inflamed mostly at the center, and when scales are present, they are usually dry. In addition, the smell of seborrheic dermatitis (mouse-like) is characteristic.

Contact dermatitis is rather uncommon in infants and children. The common causes are earrings, wristwatches, and metal buttons in trousers. The site of dermatitis correlates with the size and site of the causative metal.

Primary immunodeficiency syndromes include *Wiskott–Aldrich syndrome*, which is characterized by eczema, immunodeficiency, thrombocytopenia, and bleeding early in infancy. It is X-linked, and there is usually a history of similar cases in the family. *Severe combined immunodeficiency (SCID)* is very easy to differentiate from atopic dermatitis. The history of severe infections with low virulence and uncommon organisms makes the diagnosis easy. The dermatitis in SCID is due to graft-versus-host disease, and pruritus is unusual. *Hyper-IgE syndrome* (Job syndrome) is very easily confused with atopic dermatitis. In hyper-IgE syndrome, the level of serum IgE is extremely high, and the infant has a history of deep-seated infections, including sinusitis and skin and pulmonary abscesses. The distribution of the eczematoid eruption in hyper-IgE syndrome is different from that of severe atopic dermatitis. The first involves the entire skin from head to toe, and patients have coarse facial features. The color of the eczema ranges from coppery red to violaceous red, with distribution mostly on the extensor surfaces. ➤ *Table 133.1* summarizes the most important differential points between atopic dermatitis and other conditions.

Diagnosis

History and physical examination are usually enough to make the diagnosis of atopic dermatitis. The minimal criteria to establish the diagnosis should include the followings: chronic or recurrent dermatitis with itching, characteristic distribution in relation to age, and white dermographism. The history should include detailed questioning regarding the age of onset, severity of symptoms, and manifestations of other allergic diseases, both in the patient and relatives. Evolution of the skin eruption, the presence of pruritus, and the effect of seasonal variations are pertinent questions in history taking. Triggers such as foods, clothes, drugs, and changes in weather should be inquired into. If food is suspected to be a trigger for the patient's symptoms, confirmation by oral challenge and appropriate tests, performed by a physician experienced in the field of allergy, should be sought. Frequency of bathing and showers are important to know, because of their drying effect on the skin. By physical examination, the patient may have a classic appearance and distribution of atopic dermatitis; in addition, other stigmata of allergy may be present.

Diagnostic procedures include skin prick test. Allergens should include inhalants and common foods consumed by the patient. All positive tests should be confirmed by elimination and oral challenge. Other diagnostic tests include complete blood count, serum IgE level, and culture from surfaces of the infected skin. If the child has extensive skin involvement, skin testing may not be possible. In this case,

Table 133.1
Differential diagnosis of atopic dermatitis

	AD	Seborrhea	Contact dermatitis	WAS	SCID/GVHD	HIE
Itching	+ + + +	+	+ + +	+ + +	0	+ + +
Age of onset	Early (>2 months)	<2 months	Late	V. early	<2 months	V. early

Prognosis	Good; development of other allergies	Excellent	Excellent	Guarded unless transplanted	Guarded unless transplanted	Poor
Inheritance	±Atophy	0	0	X-linked	X-linked or autosomal recessive	Autosomal recessive

AD, atopic dermatitis; *WAS,* Wiskott–Aldrich syndrome; *SCID*, severe combined immunodeficiency; *GUHD,* graft-versus-host disease; *HIE*, hyper IgE

a radio allergo sorbent tes (RAST) for the common foods and inhalants allergens is an alternative diagnostic tool. Although the majority of infants and children with atopic dermatitis react to foods, the results should not be taken as cause and effect unless confirmed by elimination and challenge.

Management

Patients with atopic dermatitis live in a vicious cycle of scratching and skin inflammation, which aggravate each other. Therefore, the management of atopic dermatitis should attack two points in this vicious cycle: (1) stopping the itching and (2) healing the inflamed skin.

General Management

Excessive dryness, perspiration, and overheating should be avoided as much as possible. Rough fabrics in clothing should be avoided and soft fabrics made of cotton or silk should replace them. Nails should always be kept trimmed to minimize trauma to the skin from scratching.

To bathe or not to bathe? It is a known fact that frequent bathing with soap and water increases skin dryness and, hence, pruritus and scratching of the skin. The traditional teaching to the patient is not to bathe or at least to minimize bathing and showers to once a week. From a practical point of view, it is extremely difficult for the patient and family to accept this recommendation due to hygienic reasons. Therefore, the recommendations in this regard should take into account the social habits and living conditions of the patient and the family. The parents should follow their usual practice of bathing their child as long as they apply moisturizing creams and lotions immediately after the bath or shower. Soap that has a high content of fat is preferred, and it is also preferable not to use scented or perfumed soap. The parents should be encouraged to use creams and lotions of their choice as liberally and as often as they desire.

Antipruritic Medications

Any of the following antihistamines can be used to relieve itching. cyproheptadine (Periactin) in a dose of 2 mg every

6–8 h, or hydroxyzine 5 mg every 6 h, can be used in infants younger than 6 months. The dose can be increased to 10 mg every 6 h in older children. The latter drug is tolerated very well, and the dose can be increased by 6 mg every 5–7 days. Because itching is worse at night, it is advisable to double the dosage at bedtime. If hydroxyzine is not enough to relieve the symptoms, diphenhydramine (Benadryl) in a dose of 0.5–1 mg/kg (maximum 25 mg) every 6 h can be added. The treatment with antihistamines should be given on a continuous basis rather than intermittently. Relieving the itch will help the skin to heal faster, and therefore the need for anti-inflammatory drugs will decrease.

Control of Infection

If there is evidence of skin infection, antibiotics that are active against *S. aureus* should be used. Topical antibiotics should be completely avoided in patients with dermatitis. Patients with a history of frequent skin infections may benefit from prophylaxis with long-term antibiotics active against *S. aureus.* Erythromycin is an alternative drug when the patient is allergic to penicillins.

Dietary Manipulation

Dietary restriction should be reserved for those infants who have definite evidence of allergy to food. If there is evidence of coexistence of respiratory allergy, such as allergic rhinoconjunctivitis and/or bronchial asthma, and the allergen cannot be avoided, immunotherapy guided by history and skin tests may be added to the treatment.

Local Treatment

In the acute weeping phase, topical application of a wet dressing should be used at least four times a day on the oozing areas. Burow's solution is aluminum acetate 1:40 and can be prepared by dissolving Domeboro in 500 mL of tap water. A clean gauze is then soaked in the solution and applied to the oozing area. Once the skin becomes relatively dry and less inflamed, with no oozing, corticosteroid creams can be applied once to twice a day. In cases where the skin is thick and lichenified with no signs of infection, corticosteroid ointment can be applied but avoid skin folds and facial areas. Extremely thick eczematous areas on the extremities need an occlusive dressing with steroid ointment. In very severe cases, systemic, short-acting corticosteroid administration may become necessary for the control of inflammation. Ultraviolet light (PUVA) or cyclosporin A may be used in extremely resistant generalized dermatitis.

In some patients with atopic dermatitis, hypopigmented or discolored areas appear after healing and may be of concern to them. In these cases, reassurance is all that is needed, because the skin color will go back to normal in due time. Topical potent fluorinated corticosteroids should never be applied to facial areas, especially around the eyes. The preferred corticosteroid is 0.5–1% hydrocortisone cream applied twice to three times a day for facial dermatitis. Topical calcineurin inhibitors such as tacrolimus and pimecrolimus applied twice daily have been introduced recently. In very severe cases, oral cyclosporine A may be used with caution.

Prognosis and Prevention

Although prognosis depends on the severity and extent of skin involvement, at least 50% of infants with atopic dermatitis become asymptomatic as they grow older. If there is a positive family history of allergy, atopic dermatitis in early infancy is an indication that other forms of allergy will follow. This knowledge is useful to the treating physician and the family in planning treatment and prophylaxis. Approximately 70% of infants and children who start with atopic dermatitis and have a positive family history of atopy end up with bronchial asthma and allergic rhinitis. If the cord blood IgE level of an infant is greater than 1 U/mL along with a positive family history, the chances of development of atopic dermatitis and other allergies in that infant are extremely high. Mothers of such infants should be advised to breast-feed their babies and to be cautious in introducing solid foods or cow's milk formula into their infant's diet before the age of 6 months. Mothers should also avoid potentially allergenic foods such as milk, eggs, peanuts, and fish in their diet while nursing their infants.

134 Food Allergy

Justin Skripak · Hugh A. Sampson

Definition/Classification

Food allergy is broadly defined as an adverse reaction to a food resulting from an abnormal immunologic mechanism. "Food hypersensitivity" is generally used interchangeably with "food allergy." However, a European Academy of Allergy and Clinical Immunology subcommittee recently recommended using the term food hypersensitivity to describe any type of adverse reaction to a food, not just immunologically mediated reactions. There are indeed many types of adverse reactions to foods with no immunologic cause. These are best categorized as food intolerances. There are many examples of food intolerance, such as lactase deficiency, scombroid poisoning, or food poisoning when infectious bacteria are present (*Table 134.1*). Food allergy can be subdivided into three categories, based on various possible immunologic mechanisms, which are also described in *Table 134.1*.

Etiology

As food passes through the gastrointestinal tract, it is digested and subsequently presented to the immune system. This normally results in immunologic tolerance to the antigens in that food. A failure of this process to proceed normally is likely a contributing mechanism by which food allergy develops. Genetic and environmental influences on the development of allergic disease have been extensively studied, and the associations appear to be a complex web of multiple factors.

There clearly is a genetic component to the development of food allergy. A child with a food allergic first-degree relative has a significantly increased risk of being food allergic. Additionally, monozygotic twins have an estimated food allergy concordance rate of 64.3%, compared to only 6.8% for dizygotic twins. Lastly, although there have not been any "food allergy-specific" genes identified, there are some candidate genes for increased risk of food allergy, as well as other atopic diseases.

In addition, there are environmental exposures that likely influence the risk of developing food allergy. Vitamin D deficiency, exposure to certain microbes, and timing of food exposures have all been demonstrated in certain studies to contribute to the development of food allergy, but with limited degrees of association. However, all of these factors seem to rely on other complementary environmental, as well as genetic factors, being present simultaneously. The significance of early exposure to foods, in particular, has been challenging to sort out. An alternative to the long-standing approach of early avoidance of allergens in high-risk children has been challenged and is being studied. Some early evidence suggests that the opposite approach, that is, early exposure to allergens, may be beneficial.

Epidemiology

The prevalence of specific food allergies is not uniform around the globe. In Western countries, studies identify milk, egg, peanut, tree nuts, soy, and wheat as the most common allergens. In Spanish children, while egg and milk are also the two most common food allergens, fish may be the third most common one. Israeli children have also been found to be most commonly allergic to cow's milk and eggs, but in this case, sesame allergy appears to be the third most common. In a recent study of Turkish school-aged children, the most common food allergens were found to be beef, cow's milk, cocoa, egg, and kiwi.

Pathogenesis

There are a few aspects of the infant's or young child's *gastrointestinal tract* that differ from that of an adult. These include decreased acidity, decreased proteolytic activity, and an immature microvillus membrane. These factors may contribute to altering the process of food antigen uptake and subsequent presentation to the immune system, which reduces the normal tendency toward tolerance induction. Every individual who ingests food will subsequently have those antigens presented to their immune system. Normally, there is no immunologic

response, as the process of *oral tolerance induction* to food antigens occurs. In children who acquire food allergies, this normal development of tolerance fails to occur. Exactly how this normal process fails is yet to be elucidated. It appears that T lymphocytes are intimately involved in the process. Induction of anergic T lymphocytes or T regulatory lymphocytes is essential for the development of oral tolerance.

One factor that clearly is involved in the development of food allergy is the presence of a *Th2*-type immune response. Th2 lymphocytes are defined by their production of certain cytokines that promote an allergic inflammatory response. (It is the interaction of the immune system with dietary antigen in the context of this Th2-type milieu that drives the development of sensitization and subsequent clinical allergy.)

Not all allergic disease is created equal. The IgE-mediated allergic response, such as those seen with typical allergic rhinitis or with anaphylaxis, is the classic pathway associated with allergic disease. However, there are other allergic disorders that appear to develop through a T cell-mediated pathway and do not involve allergen-specific IgE. Examples of such disorders include food protein-induced enterocolitis syndrome and food protein-induced proctocolitis. Finally, some allergic disorders appear to operate through both IgE-mediated and non-IgE-mediated mechanisms. Atopic dermatitis and eosinophilic esophagitis are conditions of this nature.

Clinical Manifestations

The most feared manifestation of food allergy is *anaphylaxis*. Although a precise definition for anaphylaxis remains debated, a working group assembled by the National Institute of Allergy and Infectious Disease and Food Allergy and Anaphylaxis Network in the USA defined it as a "serious allergic reaction that is rapid in onset and may cause death." Along with this definition, a set of diagnostic criteria were also put forth to aid in the diagnosis of anaphylaxis (Table 134.2). In general, these criteria state that symptoms involving two or more body systems must occur following the ingestion of a known allergen for a given patient.

Anaphylaxis typically occurs within minutes to a few hours of ingesting an allergenic food. One variation on this is food-dependent exercise-induced anaphylaxis. This condition requires the presence of two triggers: (1) a food allergen and (2) physical activity above a certain threshold, in order for anaphylaxis to develop. If the food allergen is ingested in the absence of significant physical activity, or if there is physical activity in the absence of the food allergen, no symptoms will develop. Symptoms are typical of those seen with conventional anaphylaxis.

Symptoms are not infrequently isolated to the *skin* during food IgE-mediated allergic reactions. These symptoms can include localized erythematous or urticarial rashes, or facial angioedema at the site of food contact. These symptoms can also develop as part of a systemic reaction. Another skin manifestation of food allergy can be atopic dermatitis. This is often a confusing clinical problem, since atopic dermatitis can be present in addition to food allergy and not necessarily always provoked by it. Additionally, false positive food-specific IgE tests are not uncommon in cases of significant atopic dermatitis. Therefore, attributing a given food as a factor in the exacerbation of atopic dermatitis must be based on symptoms that specifically improve with food elimination and recur with reintroduction of the particular food.

Gastrointestinal symptoms associated with food allergy can be separated into two large categories: those symptoms whose onset repeatedly follows each food allergen exposure, and those that are chronic and not temporally related to food allergen ingestion. In the first category, the abdominal pain, vomiting, and/or diarrhea associated with anaphylactic reactions would be included. The oral cavity sensations of pruritus or scratchiness associated with *oral allergy syndrome* would as well. Finally, although involving a different immunologic mechanism, the delayed onset of severe vomiting and diarrhea associated with *food protein-induced enterocolitis syndrome* also reliably follows each exposure to a given allergen.

Other food allergic conditions manifest as chronic symptoms that do not necessarily follow or are not recognized following each ingestion of a given allergen. *Food protein-induced proctocolitis* usually presents in infants, with bloody stools. Onset of these symptoms may not occur for hours, days, or even weeks following initial exposure to and repeated ingestion of a food. *Food protein-induced enteropathy* typically presents with diarrhea, vomiting, poor feeding, failure to thrive, and steatorrhea. *Allergic eosinophilic disease of the esophagus or gastrointestinal tract* may present at any age. Symptoms of *allergic eosinophilic esophagitis* in infants and young children typically include poor feeding, irritability, spitting-up [reflux], food refusal or early satiety, and sometimes failure to thrive. In older children and adults, difficulty in swallowing, abdominal pain, and impaction are common

Table 134.2
Diagnosing anaphylaxis

Anaphylaxis should meet one of these three criteria		
1. Acute onset of:	2. Acutely following a *likely* exposure to a known allergen (any two below):	3. Acutely reduced BP following a *known* allergen exposure
• Skin or mucosal symptoms *AND* • Respiratory compromise	• Skin or mucosal symptoms	• For infants and children, low age-specific systolic BP, *or* >30% decrease in systolic BP
OR • Reduced BP or symptoms of cardiovascular dysfunction	• Respiratory compromise	• For adults, systolic BP <90 mmHg or >30% decrease from the individual's baseline
	• Reduced BP or symptoms of cardiovascular dysfunction	
	• Persistent gastrointestinal symptoms	

symptoms. *Allergic eosinophilic gastroenteritis* may present with intermittent abdominal pain, poor appetite, and failure to thrive, and edema, hypoproteinemia, and anemia are not infrequent complications.

Respiratory symptoms and/or *cardiovascular* symptoms, such as throat tightness, coughing, wheezing, chest tightness, paleness, cyanosis, or passing out, are unusual as isolated symptoms of food allergy. These symptoms can occur during severe reactions, typically with other more common skin and/or gastrointestinal symptoms, as described above.

Diagnosis

As with all good medical practice, the diagnosis of food allergy is heavily dependent on obtaining a thorough *history.* Critical questions should include, but are not limited to the following: what are the symptoms of concern, when do they occur in relation to exposure to a given food, can the food be eaten without these symptoms occurring, and have the symptoms been present at times other than after exposure to a given food. Because children with food allergy are at significantly increased risk for the development of other atopic diseases, screening questions addressing those concerns should be posed as well. A *physical examination* should cover any areas of concern, with particular attention paid to body weight and height, rashes, and upper or lower respiratory stigmata of allergic disease or asthma.

When there is a suspicion of one or more food allergies, diagnostic testing can be used to help in the diagnosis. *Skin prick testing* and *serum food-specific IgE* levels are the two most appropriate tests to be utilized, although these test results often require careful interpretation. While the sensitivity is generally very good, clinically irrelevant (false-positive) tests are not uncommon. However, studies have indicated that increasing skin prick test wheal diameters or food-specific IgE levels correlate with an increasing likelihood of clinical reactivity. This concept is illustrated in further detail in ❯ *Fig. 134.1.*

Other forms of testing may be employed at times in food allergy evaluation. *Atopy skin patch testing* may have some limited value in assessing food allergies manifesting as delayed hypersensitivity reactions, atopic dermatitis, or eosinophilic esophagitis. Others have found that utilizing atopy patch testing in addition to skin prick and serum-specific IgE testing provides only a marginal increase in positive predictive values. Additionally, extracts for food testing are not standardized, nor is the interpretation of test results. This has resulted in patch testing not being considered a routine or reliable part of the evaluation of food-allergic patients at this time.

Food-specific IgG testing has been utilized from time to time by some physicians. However, there is no evidence that there is any clinical significance to the presence of food-specific IgG antibodies, and this test is not indicated in the routine evaluation of food allergy.

Differential Diagnosis

The key point in the accurate diagnosis of a food allergy is that reactions typically occur *consistently* with exposure to the particular food proteins. A deficiency of one of several enzymes responsible for carbohydrate digestion can result in the onset of gastrointestinal symptoms with or without rashes in some cases. However, symptoms will occur with exposures to foods containing various unrelated proteins. Symptoms occurring as a result of the ingestion of a food contaminant can mimic symptoms seen during anaphylaxis. This can be especially true with scombroid, following ingestion of contaminated fish. However, these reactions are sporadic, following many previous ingestions of the food with no problems, and frequently occur in more than one individual eating the meal. Again, the diagnosis of scombroid poisoning can be difficult since fish allergy is one of the few foods (along with shellfish) that cannot uncommonly have an onset during adulthood. Some foods have pharmacologically active substances, which that can cause symptoms as well. Examples of these include caffeine, histamine (e.g., in strawberries), or tyramine (e.g., in wine, dried cheeses, or sausages). Celiac disease can also present with a food allergy-like constellation of gastrointestinal symptoms. However, there are distinct diagnostic findings on serum testing (IgA anti-endomysial and anti-tissue transglutaminase antibodies) and histology of intestinal biopsies (flattened villi). Lastly, food phobias can cause multiple symptoms, including flushing, oropharyngeal sensations, chest tightness, light-headedness, and diaphoresis, which are similar to those seen with food allergy. A careful history and judicial use of diagnostic testing are important in making the appropriate diagnosis.

Treatment

For as long as food allergy has been recognized, the standard management has been total *avoidance* of responsible food allergens. This usually means not just avoidance of a given food in a concentrated form (e.g., a glass of milk

for a milk-allergic child), but avoiding even trace amounts (e.g., incompletely refined lactose [with protein contaminant] as an ingredient in a cookie). The latter can be quite difficult when deciding what packaged food products are safe to consume. The U.S. Government attempted to lessen the burden on parents by enacting legislation in 2004 requiring that the presence of any of eight "major" allergens be clearly indicated on a food's ingredient label (Food Allergen Labeling and Consumer Protection Act of 2004). Similar legislation was passed in the European Common Market countries. In addition to this, parents must be advised that certain types of foods (e.g., baked goods or candies), or types of cuisines (e.g., those of certain Asian countries), carry a relatively high risk of containing a particular food allergen (e.g., peanut).

It is no longer uncommon for children to have multiple food allergies. One common example in the USA is the infant who is allergic to milk, egg, and peanut. Although the prognosis for spontaneous resolution of cow's milk allergy has always been thought to be good, some studies have found more patients with milk allergies persisting through adolescence. Some combinations of food allergies can severely limit dietary options, placing those children at increased risk for the development of nutritional deficiencies. Since it appears that more and more children are developing food allergies, and that they may be lasting longer in some of those children, it is essential that adequate *nutritional counseling* be provided when necessary.

Even among the most well-educated and well-intentioned patients and their families, accidental exposures to food allergens occur. In fact, they are not uncommon, and when they do occur, can be relatively severe in about 10–15% of cases. Therefore, once the diagnosis of an IgE-mediated food allergy is made, families must be counseled on the signs and symptoms of anaphylaxis, and on how to treat such reactions appropriately. In the case of acute anaphylactic reactions, the primary treatment remains intramuscular epinephrine. In addition to this, antihistamines (oral, intramuscular, or intravenous depending upon the patient's symptoms), intravenous fluids, systemic corticosteroids, and inhaled beta-agonists should be used as clinically indicated.

It is worth noting that recently there has been a major increase in clinical trials investigating various forms of treatment for food allergy. Clinical trials of oral and sublingual immunotherapy, involving the administration of extremely small amounts of the food protein, and then progressively increasing the dose over time, have shown promising results. The majority of participants in these studies became "desensitized" to the particular food. However, most were not permanently cured, that is, "tolerized," and required continued regular exposure to the food to maintain the desensitized state. Allergic reactions to the treatment are common side effects: anaphylactic reactions occur in up to 10% of cases. Future research will attempt to improve on these initial trials, by improving both safety and efficacy of the approach. Another approach of interest involves the consumption of cow's milk or egg proteins in extensively heated (baked) forms, such as when they are contained in muffins, cakes, and cookies. It appears that a majority of children allergic to milk and eggs in the unheated form can tolerate them when extensively heated. The same is not likely to be effective for foods such as peanut, in which proteins are not similarly heat-labile. Most importantly though, these treatments are still considered experimental, and should only be implemented under the careful supervision of clinical trials at this time.

Prognosis

While allergies to milk, soy, egg, and wheat commonly present during the first or second year of life, they also tend to resolve spontaneously in the majority of cases. However, some recent retrospective studies of selected cohorts have found even milk, egg, and wheat allergies persisting into adolescence in a significant number of children with these allergies. Peanut, tree nuts, fish, and shellfish allergies, on the other hand, most often persist into adulthood. The natural history for other food allergens is not well studied. However, our clinical experience in the USA is that among other common allergens, allergies to meats, fruits, and vegetables are often outgrown during childhood. Allergy to seed proteins may be more likely to persist into adulthood, for example, sesame and mustard seed. One qualified exception to this is the oral allergy syndrome, a type of food allergy to raw fruits and vegetables, which typically has an onset in late childhood or adulthood, and is likely to persist. These allergies are not primary food allergies, but rather, allergies to plant pollens with secondary cross-reactivity to certain fruit and plant-based proteins, for example, birch pollen and apples, potatoes, carrots, etc., ragweed, and melons and bananas.

Prevention

There are no current measures that provide a clear and significant protective effect against the development of food allergies. A 2007 American Academy of Pediatrics report and an earlier report from European Society of

Pediatric Allergy and Clinical Immunology recommended breastfeeding until the age of 4 months, and delaying the introduction of solids until the age of 4–6 months because of a possible small impact on decreasing the risk for developing atopic disease. Infants who are not breastfed may gain some protection against the development of atopy when fed a hydrolyzed formula until the age of 4–6 months. Of note, neither organization's review of the literature found a discernible protective effect conferred by maternal food allergen avoidance during pregnancy or lactation.

Conclusion

Food allergy affects up to 6% of the pediatric population in the USA and Europe, and up to 2–3% of the general population, figures that may be on the increase. The diagnosis is established by typical history, laboratory studies, and food challenges. The prognosis for IgE-mediated food allergies in young children is for the eventual acquisition of tolerance. Although food allergen avoidance and counseling about how to treat reactions caused by accidental ingestions remains the mainstay of therapy, there has been a recent increase in clinical trials investigating various forms of immunotherapy.

135 Urticaria

Harb A. Harfi

Definition

Urticaria is an intensely itchy, circumscribed, raised erythematous plaques usually pale in the center. Lesions may coalesce to form giant lesions. The lesions are usually evanescent and disappear in hours, rarely lasting more than 48 hours. The urticarial lesions clear up without leaving residual marks unless the skin is damaged by scratching.

In relation to the clinical course, urticaria can be divided into:

1. *Acute urticaria*: Acute urticaria is defined if the outbreak of the lesions does not last more than 6 weeks. This form is common and affects about 20% of the population, at least once in their lives. Usually, the cause of acute urticaria can be identified in most cases.
2. *Chronic urticaria*: Chronic urticaria is defined by urtical lesions that last more than 6 weeks and present most of the time. Chronic urticaria makes about one-third of all urticarial cases, both acute and chronic. In most cases of chronic urticaria, an underlying etiology is difficult to identify. Nearly 40% of patients with chronic urticaria have associated angioedema of lips, eyelids, cheeks, and extremities. Sometimes, angioedema also affects the tongue and genitalia.

Etiology

Anything under the sun can cause urticaria including the sun itself. Among the many causes of urticaria, drugs of all kinds are the most common. Others include insect stings, foods, food additives, pollens, parasitic infestations, contact allergens, and transfusion reactions and physical agents such as heat, cold, pressure, exercise, vibrations, water, and sunlight. Other causes include immune complex diseases and serum sickness, viral and bacterial infections, or it can be idiopathic or secondary to autoimmune thyroiditis.

Children with urticaria usually have manifestations of other atopic diseases such as allergic asthma, allergic rhinitis, and positive family history of allergy. Children with contact urticaria due to latex have other manifestations of allergy. Although chronic urticaria is not common in children, parasitic infections, drugs, physical factors, and foods are likely to cause it among them. In some studies, autoantibodies to high affinity IgE receptors were present in as high as 47% of the cases, similar to adults. Food allergy in children may contribute to 7–11% of the cases of urticaria. In a recent study, children with chronic urticaria, physical urticaria such as dermographism, cholinergic and mixed, formed 70% of the subtypes and 13% reported respiratory allergy.

Epidemiology

There are very few studies that define the prevalence of urticaria in children. The figure of 20% within the general population involves both adults and children. In one study, autoimmune chronic urticaria is found in 30% of children who have urticaria. Another study estimates the figure to be 47%. Chronic urticaria alone affects 1% of the general population.

Pathogenesis and Genetics

Several theories regarding the pathogenesis of chronic urticaria have been proposed such as autoimmunity, defective basophils signaling or function. But none of those theories have been helpful in investigating the disease.

Pathology

The pathology is usually heterogeneous, but usually there is interstitial edema and perivascular cellular infiltrates, including eosinophils, lymphocytes, neutrophils, and basophils.

Clinical Manifestations

The urticarial lesions are intensely pruritic, well defined, raised, red or pinkish in color, and usually pale in the

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_135,

center. The lesions can be a few millimeters or centimeters in diameter and may coalesce and form giant lesions. Very frequently, urticaria is associated with angioedema of the lips, tongue, or eyelids. Benign urticarial lesions are evanescent lasting few hours to less than 48 hours. It can involve any part of the body.

Diagnosis

The urticarial lesions are easy to identify. In acute urticaria, a careful history taking is important in identifying the cause. In children, food allergy, or drugs are the most likely causes. In endemic regions and areas of poor hygiene, stool examination for ova and parasites is indicated. In chronic urticaria, a careful history and limited laboratory testing may help to identify an underlying disease: CBC, ESR, TSH, and antithyroid antibodies are recommended. Serum IgE and specific IgE for foods and inhalants are recommended, especially if there is history of respiratory allergy. If the lesions last more than 48 hours, a punch biopsy to rule out vasculitis is indicated.

Differential Diagnosis

The pruritic skin lesions that need to be differential from urticaria include:

Drug eruptions, contact dermatitis, atopic dermatitis, pityriasis rosea, insect bites, Henoch–Schonlein purpura, plant-induced dermatitis, and erythema multiformed

Treatment

The most important part of the treatment is identification of the underlying cause and its elimination. However, in the majority of cases, the etiology of urticaria is difficult or impossible to identify. In these cases, pharmacological therapy is indicated. However, most cases of urticaria clear up spontaneously. Administration of antihistamines that relieve itching and suppress the lesions is the main treatment. In severe cases, corticosteroids may be used with other drugs. In autoimmune thyroid disease, with hypothyroidism, thyroxine replacement may be helpful. H1 and H2 antihistamines may be combined in resistant cases. Antileukotrienes, cyclosporine, and calcium channel blockers may be helpful in some difficult cases.

Prognosis and Prevention

Most cases of acute urticaria in children clear up with or without treatment. If urticaria is related to foods, pollens, or drugs, elimination and treatment of the etiology leads to cure. In most cases related to autoimmune thyroiditis, chronic urticaria usually clears up in weeks or years, usually less than 5 years.

Prevention of urticaria depends on recognition of the underlying cause or causes and treating it, or avoidance especially if it is food or drug.

136 Anaphylaxis

Harb A. Harfi

Definition

As defined by international expert consensus, "Anaphylaxis is a serious allergic reaction that is rapid in onset and may cause death".

Etiology

Food is the most common cause of anaphylaxis, especially in infants. Other causes include medications, insect stings, rubber latex; vaccines, and idiopathic anaphylaxis are relatively rare in the pediatric age group. Other uncommon triggers of anaphylaxis in infants and children include inhalant allergens, especially animals and exposure to cold temperature.

Epidemiology of Anaphylaxis in Children

The true incidence of anaphylaxis in infants and children is not exactly known. In one study, it has been estimated to be 1/3,000 for both children and adults. In a recent study questionnaire in German children below 12 years, 103 cases were found. Foods were the most common, followed by insect stings and immunotherapy. The occurrence is increasing in industrialized countries.

Pathophysiology of Anaphylaxis

In anaphylaxis, there is massive and sudden release of mediators from mast cells and basophils into the circulation. The reaction results from immunologic response to foods, insect stings, or drugs, or foreign proteins. However, nonimmune mechanisms by contrast media or drugs can also lead to release of mediators. Genetic factors also may play a role. The immunologic reactions that lead to release of multiple mediators from mast cells and basophils are IgE-dependent. Sensitization by foreign proteins leads to formation of specific IgE. The IgE becomes cell bound to the surfaces of mast cells and basophils. On reexposure to the foreign protein, the protein (allergen) binds to the cell-bound IgE, leading to release of the mediators responsible for anaphylaxis. These include heparin, histamine, tryptase, chemochynes, leukotrienes, prostagladins, and platlets activating factor (PAF). These are responsible for signs and symptoms of anaphylactic reactions.

Pathology

In autopsy of fatal anaphylaxis, there are few or no pathological findings. This is related to the rapid onset of anaphylaxis. When pathologic findings are present, they include edema and hyperemia of the upper airway, hyperinflations of the lungs, cerebral edema, and urticaria on cutaneous erythema.

Clinical Manifestations

The clinical manifestations of anaphylaxis in infants up to 2 years can be difficult to recognize. Many of the signs are nonspecific, such as drooling, crying, vomiting and diarrhea after feedings, flushing, colics, and irritability, which can also be found in healthy infants. But in some infants, the onset of anaphylaxis can be seen in the form of sudden onset of lethargy or hypotonia and cessation of activity. Because food is the most important cause of anaphylaxis in infants, sudden onset of lethargy, irritability, colics, crying, flushing, and angioedema or cessation of activity should alert the mother or the caregiver to the possibility of anaphylaxis, and immediate resuscitative measures undertaken. In older children and adolescents, the clinical features of anaphylaxis are not different from those in adults. These include generalized hives, flushing, pruritus, vomiting, diarrhea, respiratory distress, sneezing, rhinorrhea, and nasal congestion, hoarseness, strider, laryngeal edema, wheezing, cough, dyspnea and cyanosis, dizziness, syncope, seizure, and, in severe cases, a sense of doom. There may be arrhythmia, tachycardia, hypotension or bradycardia, cardiac arrest, and death in very severe anaphylaxis.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_136,

Diagnosis

The diagnosis of anaphylaxis is based on the clear history of exposure to a known allergen, followed by the symptoms such as, respiratory distress, angioedema, urticaria, tachycardia, choking, etc. Since foods and insect stings, in addition to drugs are the most common causes of anaphylaxis in infants and children, parents, caregivers, and physicians should suspect anaphylaxis if symptoms occur shortly after food ingestion or insect sting or drug administrator. Laboratory tests such as serum tryptase and serum IgE measurement for specific allergens are not much helpful.

Differential Diagnosis of Anaphylaxis

The conditions that may be confused with anaphylaxis include acute generalized urticaria and angioedema, acute asthma, vasovagal and syncope attacks, acute anxiety disorders, shock, and vocal cord dysfunction. In infants, inborn errors of metabolism and sudden infant death syndrome have to be considered in differential diagnosis.

Treatment

Immediate and effective treatment of anaphylaxis starts with assessment of the airway, skin, circulation, and response, followed by immediate administration of epinephrine intramuscular and intravenous fluids, in addition to antihistamines and corticosteroids.

To establish the diagnosis and differentiate it from other conditions in order to establish proper treatment, three criteria must be met:

1. Acute onset of an illness involving the skin, mucosal tissue or both and respiratory distress, and reduced blood pressure.
2. Two or more of the following occurring shortly after the exposure to an allergen: generalized hives and angioedema, respiratory compromise, hypotension, and gastrointestinal symptoms.
3. Hypotension after exposure to a known allergen for that patient, within minutes or hours. Hypotension in infants and children is defined as systolic pressure of 30% less for age normal BP.

Treatment of anaphylaxis has to be immediate. This includes administration of epinephrines, immediate intubation, and establishment of IV line if airway obstruction is anticipated, oxygen and intravenous bolous fluids, and inhalation of salbutamol if there is bronchospasm, and antihistamine diphenhydramine 1–2 mg/kg. Ranitidine 1 mg/kg can be given IV, and methylprednisolone 2 mg/kg to be given iv. In refractory cases, epinephrine and dopamine should be given, especially in hypotension. After recovery, the patient should be kept under observation at least for 6 hours.

Prognosis

If treated immediately with epinephrine the prognosis is good. However, fatalities and near fatalities occur in children if treatment is delayed or anaphylaxis is not recognized early. Fatalities are more common in patients who had asthma. Most fatalities followed ingestion of foods such as peanuts or tree nuts. Recurrence of anaphylaxis can be as high as 40–60% if the trigger is not avoided.

Prevention of Anaphylaxis

The most important measure is to identify the cause of the reaction and avoid future exposure. In case of food allergy, the parents and caregivers should be given a list of the foods that caused the reaction. Reading the labels of processed foods for ingredients is critical in prevention. If the trigger is a drug, an alternative drug should be prescribed in case it is needed. Avoidance of insect nestings and places of attraction is important. Epinephrine autoinjections should be kept on hand at home and school, and the patient should learn to inject himself. Patients who receive allergens immunotherapy should stay under observation in the physician's office at least for 20–30 min while the treatment is being updosed.

137 Drug Allergy

Harb A. Harfi

Introduction

Drug hypersensitivity in children is not as common as in adults. The estimated occurrence of adverse drug reactions is more common in adults, especially hospitalized patients. The occurrence of drug reactions from different epidemiological studies ranges from 6% to 10%. True allergic drug reactions in children based on questionnaires and confirmation by skin testing, in vitro specific IgE antibodies, and challenge is rather low 3–5.8%. The most common drugs to cause allergic reactions are the beta-lactam group. Other drugs include anticonvulsants, sulfa, biological agents, chemotherapeutic agents, protamines, and others.

Clinical Manifestations of Drug Allergy

Skin eruptions are the most common presentation of drug allergy in children. The rash can be morbilliform, urticarial, bullous lesions or exathematous, or in the form of eczema or fixed drug eruptions. In some severe cases, it can be in the form of Stevens–Johnson syndrome or epidermolysis. Anaphylaxis with respiratory distress, angioedema, hypotension, and even death may occur in some cases, especially with beta-lactam antibiotics. Toxic immunologic reaction such as hemolysis may occur. Some patients may develop immune complex reactions such as serum sickness and vasculitis. Sometimes, drug fever may be the presenting symptom. Other clinical manifestations are fixed drug eruptions.

Diagnosis and Differential Diagnosis of Drug Allergy

Drug allergy is a great imitator of many skin diseases, especially viral exanthema. In case of skin eruptions, differential diagnosis should include measles, chicken pox, eczema, other causes of urticaria, and in patients with bone marrow transplant for immunodeficiency with graft versus host reactions.

The diagnosis of drug allergy is usually easy in children if the reaction occurs after the administration of a single drug.

The difficulty arises when a patient is taking multiple drugs when the reaction occurs.

- Practical approach to a child with suspected drug allergy
  1. Get a detailed medical history.
  2. Get history of atopy in the child or his family. Allergic drug reactions are more common in atopic families.
  3. Get information on the start and stop of each drug. Allergic reactions are more likely to occur with the lately introduced drug.
  4. Get history of previous reactions to a drug, dosage, and route of administration.
- Tests to establish the diagnosis of drug allergy.
  1. Skin Prick test: Very few drugs are available for skin test. These are mostly the beta-lactam antibiotics, insulin, and very few other drugs. Tests should not be done earlier than 2 weeks after anaphylaxis.
  2. Specific IgE in vitro using ImmunoCAP system or ELISA.
  3. Oral challenge, if feasible and no danger of anaphylaxis.

Management of Drug Allergy

The most important thing to do is to stop and withdraw the suspected drug. If the reaction is mild type 1 allergic reaction that is usually enough. However, in severe cases with anaphylaxis, resuscitative measures should be started immediately. These include administration of adrenaline, antihistamines, and corticosteroids, in addition to intravenous fluids, if there is hypotension. If the drug is life-saving such as the case of bacterial endocarditis, the patient should be desensitized and continued on penicillin. But in milder cases, an alternative antibiotic should be given. If the drug is very necessary and no alternative the patient should be desensitized under close observation

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_137,

in a hospital setting by an allergist or an experienced physician.

Once the culprit drug is identified, the patient should carry a card or a bracelet and his chart labeled "allergy to", with the name of the drug.

138 Insect Allergy

Harb A. Harfi

Stinging insects are widespread and are of different orders. Most belong to hymenoptera. The hymenoptera that are important in allergy belong to three families: Vespidae, Apidae, and Formicidae. The Vespidae has the following subfamilies: yellow jacket, yellow hornet, paper wasp, and white-faced hornet. The Apidae has the honey bee, bumble bee, and sweet bee. The Formicidae has fire ant, harvester ant, jack jumper ant, and samsum (Mayr), Pachycondla sennaarensis ant. Usually, it is the female that stings, most often in defense of its nests.

The incidence of allergic reactions to insect stings in children is not exactly known. But figures from epidemiological studies in general populations showed allergic reactions in children to be around 3% of all those who reported history of insect stings.

Children have a different pattern of allergic reactions to insect stings compared to adults. Systemic reactions are less severe and mostly cutaneous in the form of urticaria. Honey bee is the commonest culprit. It is estimated that 60% of systemic reactions in children are mild. But 30% of those who have moderate to severe reaction will have a similar reaction 2 decades later. Although previous studies did not show correlationship between atopy and increased severity of reactions to insect stings, a recent study showed that school-age children with atopic diseases are at a higher risk of having more severe reactions.

Clinical Manifestations

Most insect stings in children cause painful local swelling, with redness and itching. This may last a few hours or a few days. Generalized or systemic reactions are mostly cutaneous: urticaria, flushing, and/or angioedema with pruritus. A small number of older children may develop respiratory symptoms in the form of hoarseness, shortness of breath, and wheezing. Only 30% of children may develop light-headedness, hypotension, and shock, with cardiopulmonary symptoms.

Diagnosis

The diagnosis of insect allergy is essentially clinical. History of exposure to outdoor insects, feeling of sudden pain at the site of sting, and identification of the insect are enough to establish the diagnosis. But, sometimes, identifying the insect may be difficult. Redness and itching at an exposed area of the skin point to an insect sting. Symptoms of anaphylaxis should be recognized immediately by the patient and the physician and the family members. It is very important to recognize symptoms such as nausea, light-headedness, vomiting or cramps, and diarrhea and flushing early after sting in order to establish diagnosis and start treatment immediately.

Laboratory diagnosis is limited to skin test with venom or whole body extract, or in vitro by specific IgE. In case of anaphylaxis, serum tryptase and histamine measurements can be helpful, but negative results do not exclude the diagnosis because they are transient.

Management

In children less than 16 years of age do not give epinephrine unless the reaction is more than cutaneous. For local reactions apply cold compresses. If the local reaction is large and troublesome to the child, give either one dose of prednisolone 2 mg/kg or tapering dose over 2–3 days. If the reaction is painful, a nonesteroidal anti-inflammatory drug should be given. If the lesion is pruritic, antihistamine may be given.

In cases of anaphylaxis, epinephrine intramuscular should be given immediately, in addition to other resuscitation measures with intravenous fluids, corticosteroids, antihistamines, and oxygen. Once these patients recover, they should be referred to an allergist for long-term management. Autoinjectable epinephrine such as EpiPen should be available at all times. Immunotherapy with venom vaccine did not show any difference in the course of insect stings in children, except in the small number with history of anaphylaxis. In the majority of children, venom immunotherapy is not indicated except in moderate to severe reactions. Children who received venom immunotherapy for 3–5 years fared better and had milder reactions on subsequent stings.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_138,

Prognosis

Children aged less than 16 years who suffered a systemic reaction have about a 10% chance of a similar systemic reaction on subsequent sting. Children who were followed for 10–20 years, irrespective of whether they had received venom immunotherapy or not, continued to have reactions on subsequent stings. But those with moderate to severe reactions and venom immunotherapy fared better than those who did not receive venom immunotherapy. The effect of venom immunotherapy in these cases was long lasting.

Prevention

Hymenoptera, whether they are winged or nonwinged, are attracted to bright colors, perfumes, and rotten fruits. Some of them nest on the ground, such as ants and some wasps. Children with history of insect allergy should avoid wearing floral shirts and perfume when they are outdoors. In picnic areas and areas with vegetation, they should avoid walking barefoot and sitting next to garbage cans. Autoinjectable epinephrine such as EpiPen can be lifesaving in case of severe reactions and should be carried by the patient or the child's parents all the time when they are outdoors.

Summary

Allergic reactions to hymenoptera stings are usually mild and mostly cutaneous in nature in the majority of children. The incidence is not exactly known, but it is less than in adults. Long-term follow-up showed that children continue to have reactions on subsequent stings either the same or milder. In those who had moderate to severe reactions should be referred to a qualified allergist for care. Venom immunotherapy is not indicated in the majority of children with insect allergy. But those with moderate to severe reactions on subsequent stings may benefit from venom immunotherapy. Prognosis is generally good. Prevention is important and EpiPen is necessary in cases of severe reactions.

139 Miscellaneous Allergies

Harb A. Harfi

Prevention of Sensitization and Allergic Diseases

Numerous publications dealt with ways of preventing the occurrence of allergic diseases in infants and children.

Breast Feedings

Numerous studies showed that breast feeding alone, at least in the first 4–6 months, delays or even prevents the early development of atopic dermatitis and respiratory allergy in high-risk infants. However, this issue is controversial since other studies showed breast feedings did not prevent the occurrence of allergic symptoms. However, it is generally recommended, in high-risk families for allergy, that mothers nurse their babies for the first 6 months. Also delay of introducing solid foods in infant's diet may help in delaying development of allergy symptoms. If breast milk is not available, an alternative is a highly hydrolyzed formula that may help in delaying or even decreasing the development of sensitization.

Smoking

Cigarette smoking in doors is a major pollutant factor that enhances the occurrence of allergy, especially asthma. In children of smoking parents, asthma symptoms and severity improve when parents quit smoking.

Dust-Mite-Sensitization Prevention

Early studies showed that exposure to house dust mite early in life is responsible for the development of respiratory allergy. Avoidance of exposure to dust mite allergens tends to result in less wheezing and other respiratory allergy. However, other studies showed dust mite avoidance reduced the indoor allergen level, but has no effect on respiratory symptoms or other atopic diseases and no effect on total or specific IgE level. So, encasing of beddings and expensive equipments and the use of acaricidal sprays do not seem to have big impact on reducing development of allergy in genetically susceptible infants and children.

Latex Allergy in Children

Latex is extracted from the tree *Heavia brasiliensis*. Rubber gloves and balloons are made of latex. The occurrence of sensitization to latex protein is very common in children with spina bifida. This is due to frequent exposure intermittently during surgery, catheterization, or removal of impacted stool. These children may develop urticaria, contact eczema, rhinitis, asthma, or even anaphylaxis. The higher the number of procedures, the greater the chance of allergic reactions. It is recommended that surgeons should use an alternative with non-latex gloves and catheters when they operate on these children.

Allergic Reactions to Vaccines

Anaphylaxis to vaccines in children is very rare and the estimated figures are between 0.65 and 1.53 per million. Most cases of vaccine allergic reactions are due to preservatives, such as gelatin, in the vaccine. Mumps and measles vaccines are grown in chick embryo fibroblast culture. Hundreds of thousands of children who are allergic to eggs are given the vaccine without reactions. Therefore, MMR vaccine can be given safely to egg allergic children if they can eat eggs without anaphylaxis. However, in influenza and yellow fever vaccines, patients who are egg allergic should be tested with the vaccine before it is administered. Reactions to meningococcus, pertussis, pneumococcus, rabies, tetanus, and varicella have rarely been reported. Most of those reactions were due to preservatives.

Disorders of the Skin

Zbigniew Ruszczak

140 Pediatric Dermatology: Scope and Challenges

Zbigniew Ruszczak

Skin is the largest organ of the body and a very complex and dynamic structure consisting of many parts and appendages. The actual condition of the skin may reflect not only skin-specific or skin-limited disorders, but – in most cases – is a mirror of either the somatic or psychological status of the patient.

The outermost layer of the skin surface – the epidermis – is an effective barrier to the penetration of irritants, toxins, and organisms, as well as a membrane that holds in body fluids. It acts also as an immunologically active organ responding to external and internal stimuli, communicating with other parts of the skin and, through signaling molecules, transmitters, and neural connections, with different body structures including the central nervous system.

Beside the main cellular component – keratinocytes – epidermis contains specific and sophisticated cells such as melanocytes, which are important for protection against the harmful effects of ultraviolet (UV) light, and the Langerhans cells, a part of the body's first-line immunologic defense. In its basal layer epidermis also contains multipotent stem cells, which in physiologic condition reassure the normal turnover of this skin layer.

The dermis, consisting largely of fibroblasts and collagen, is a tough, leathery, mechanical barrier against cuts, bites, and bruises. Its collagenous matrix also provides structural support for a number of cutaneous appendages.

Hair, which grows from follicles deep within the dermis, is important for cosmesis as well as for protection from sunlight and particulate matter. The bulb part of a hair follicle is also the place from which the epidermis and hair regenerate, being the part of the skin richest in stem cells.

Sebaceous glands arise as an outgrowth of the hair follicles. Oil produced by these glands helps to lubricate the skin and contributes to the protective function of the ceramide-rich epidermal barrier.

The nails are specialized organs of manipulation that also protect sensitive digits.

Eccrine sweat glands accomplish skin thermoregulation.

Glomus cells regulate changes in the cutaneous blood flow.

The skin also contains specialized receptors for heat, pain, touch, and pressure, and the input from these structures helps to protect the skin surface against environmental influence or trauma.

Below the dermis, in the subcutaneous tissue, fat is stored as a source of energy, a reservoir of biologically active substances, vitamins, and hormones, and also acts as a soft protective cushion.

The newborn and neonatal skin is of special interest not only because the transition from an aqueous and sterile atmosphere to a dry and pathogen-rich environment is a tremendous challenge to the young skin. The functioning epidermal barrier is of great importance for the prevention of water loss and for the interaction with numerous microorganisms that colonize the neonatal skin from the moment of birth.

The anatomy of the epidermal and dermal components of the newborn and neonatal skin is the same as that of older skin. However, the process of postnatal maturation and adaptation to environmental stimuli is crucial for the further physiological condition of the skin. It is also important to know that the young skin is much more permeable than the skin of an older person, which implicates the need for appropriate dose adaptation of topically used agents.

The importance of appropriate neonatal skin care and treatment to maintain the protective function of the skin will be discussed later in this section.

Disorders of the skin in infants and young children vary from the occurrence and presentation of the same symptoms in older children and adults. Both diagnosis and treatment may be influenced by the more sensitive pattern of reaction and, in many cases, therapeutic regiments differ from those of adults.

In the beginning of any diagnostic process, a careful and adequate patient and family history should be obtained followed by a detailed physical examination of the child's body. Easy visibility of the lesion may sometimes lead to cursory examination and hasty diagnosis.

Examination of the entire skin including the scalp, oral and anogenital regions, periorbital skin and conjunctiva,

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_140,

palms and soles, as well as nails and hair should be routinely performed to obtain a clue for final diagnosis.

Examination should always be performed in a well-temperatured room. Overwarming or overcooling of sensitive skin, especially that of newborns and neonates may lead to wrong impressions and misdiagnosis of physiological skin response to environmental stimuli as a specific pathologic condition (i.e., vascular phenomenon).

The morphology and configuration of cutaneous lesions are not always specific, but are of great importance to the classification and, consequently, correct diagnosis of skin diseases. Therefore, understanding dermatologic terminology is of great importance to a physician who is not a dermatologist. This also helps to eliminate barriers in communication and misunderstandings if specific dermatologic consultation is requested and when a dermatologist is responding to pediatrician consultation using his or her specific "skin-derived" language.

It is important to understand that most dermatologic terms are descriptions of the morphology of the lesion and applicable to many different diseases. Appropriate description of the lesion, timeline of its appearance, changes over time, and associated symptoms (i.e., itching or burning versus asymptomatic course) are crucial in distinguishing between different pathologic conditions.

Annular, nummular, circinate, or *ring-shaped lesions* (ringworm-like) may most often be found in superficial fungal infections. However, ringed lesions can be seen in seborrheic dermatitis, nummular eczema, pityriasis rosea, erythema anulare, erythema migrans, erythema multiforme, lupus erythematosus, urticaria, lupus vulgaris, leprosy, tinea versicolor, secondary syphilis, and many others.

Lesions that have an arc-like configuration are named *arciform* or *arcuate*; if they show a tendency to merge they are described as *confluent* and most commonly occur in exanthemas, pityriasis rosea, urticaria, and erythema exsudativum multiforme.

Distribution of the lesion over specific dermatome (single or multiple) is described as *dermatomal* because it is most commonly seen in HSV-3 infection.

Lesions that are solid, infiltrated, and discus-shaped (solitary or multiple) are named *discoid*, as in lupus erythematosus, discoid eczema, granulomas.

If skin lesions are drop-like, infiltrated, and showing a covering scale, they are called *guttate* and are often seen in childhood psoriasis or in adolescents and often follow acute respiratory tract infections (i.e., early pityriasis rosea).

Lesions showing spiral-like, coiled, or twisted appearance are described as *gyrate* (i.e., in urticaria, erythema anulare).

If such lesions have more than one kind of shape, they are considered to be *multiform* or *polycyclic* (i.e., urticaria, erythema multiforme, polymorphous light eruption).

Serpentine or snake-like morphology is named *serpiginous* and is most commonly seen in larva migrans and elastosis perforans serpiginosa.

Lesions presenting with a central depression and shaped like an umbilicus are termed *umbilicated*, as is the case in molluscum contagiosum, varicella, variola, eczema herpeticum, or HSV-III infection.

Vesicular and papular lesions localized in clusters are referred to as *grouped*, as in cases of HSV infection (HSV-I, -II or -III), insect bites, bullous dermatosis of childhood, and less commonly in contact dermatitis.

Iris-like or *target* lesions are those having a concentric, ringed appearance most characteristic of erythema exsudativum multiforme and Stevens-Johnson syndrome.

Lesions having line or stripe form are defined as *linear* or *band-like* and are most commonly seen in epidermal nevi, linear morphea, lichen striatus, incontinentia pigmenti, hypomelanosis of Ito, acanthosis nigricans, etc.

Lesions demonstrating a *net-like* or *murmur-like* pattern are described as reticulated – i.e., in livedo reticularis, curis marmorata, and cutis telangiectatica congenital.

An important pattern of skin morphology often indicating a specific disease is called *isomorphic response* or *Koebner phenomenon*. This term describes the appearance of new lesions along the site of a superficial injury. The most prominent example is a linear development of new lesions in psoriasis vulgaris, lichen planus, or keratosis folicularis. Linear spreading of warts or molusca contagiosa after scratch inoculation is also an example of this phenomenon.

The morphological configuration and regional distribution of skin lesions, presence or absence of mucous membrane involvement, or coincidence of skin and nail lesions may also be of importance in the finding of correct diagnosis.

Dependence from exposure to UV light (i.e., sun exposure areas) is important in estimating a possible photosensitive background or establishing a relationship between medication and the appearance of skin lesions.

Coexistence of itching and aggravation of symptoms in a warm environment (e.g., nights at bedtime) together with specific localization (i.e., intertriginous areas, genitalia, interdigital spaces) and coexistence of similar symptoms in other family members in close contact with each other is specifically suggestive of infestations such as, scabies. However, in infants and small children this diagnosis may be difficult because the lesions are typically

localized on the palms and soles and often on the neck and the head. A change of skin color frequently helps in making the correct diagnosis.

Brown or brownish discolorations are often associated with postinflammatory hyperpigmentation, pigmented nevi, incontinentia pigmenti, café-au-lait spots, epidermal nevi (together with hyperkeratotic, villous-like structure), photodermatitis and phytophotodermatitis, acanthosis nigricans, or as iatrogenic-induced hyperpigmentation by use of local irritants or concentrated fragrances (melasma, chloasma).

Yellow discoloration, especially in infants, is often connected with the presence of carotene derived from food, particularly yellow vegetables and carrots. Examination of sclera helps in distinguishing this phenomenon from an icterus.

Red or purple lesions are usually of vascular origin like superficial hemangiomas, naevi flamei, or spider telangiectasias.

Rose color is often characteristic for active inflammation or in development of inflammatory lesions such as atopic dermatitis or psoriasis. The latter often show superficial scaling and pinpoint bleeding known as the Auspitz phenomenon.

Lesions with decreased pigmentation (hypopigmentation or depigmentation) may be seen in several pathologic conditions. Superficial tinea, pityriasis versicolor may be easily distinguished by Wood's lamp. Localized depigmentation in different shape and form may be seen in vitiligo, piebaldism (clinical picture, family history, and dynamics of lesion are important distinguishing factors), and chemically induced pigment loss or progressive macular hypomelanosis.

Postinflammatory lesions may also appear hypopigmented. In children with atopic constitution or atopic dermatitis, multiforme hypopigmentation is described as pityriasis alba. Generalized decrease in skin pigmentation may be seen in albinism or untreated phenyloketonuria.

Ethnic variations need to be taken into consideration in assessment of skin changes. Erythema or inflammation may be difficult to see in children with black skin; postinflammatory hyperpigmentation or hypopigmentation is usually much more prominent in black, Mediterranean, Arabic, and Asian populations.

Hyperpigmentation of flexure areas (neck, axilla, inguinal region, perianal region) are considered to be physiologic in children with colored skin. However, physicians may be confronted with the pressure of parents who are not willing to accept that their children have such normally occurring skin discoloration, even if the parents have the same skin symptoms.

Qualities of hair may also differ among individuals of different ethnic origins. African-American and African hair tends to be extensively curly, to tangle when dry, and becomes matte when wet. Due to the naturally curly or spiral nature of the hair and appearance of so-called bushy hair, folliculitis and pseudofolliculitis are more common in children of African, African-American and in some groups of Asian descent.

Prolonged and continuous traction on hair results more commonly in traction alopecia in African, Asian, and Arabic populations.

Wound healing complications, especially development of keloids and hypertrophic scars after surgery or burns, are reported more often in children of African, Asian, or Arabic origin. Similarly, keloid complications of acne or other follicular disorders are more prominent in children and adolescents with colored skin.

Skin is not just a cover of the human body. It helps to adapt to environmental conditions; communicate with the surrounding world in a physical, chemical, and immunologic manner; and is an organ of interpersonal communication.

Most important for appropriate skin function is to keep the skin barrier intact and to restore it as quickly as possible if the barrier function is impaired.

Interruption of disruption of the barrier may lead not only to skin dysfunction, but also to impaired function of other organs, i.e., to immunologic defects. Skin and mucous membranes are the targets of airborne and contact allergens.

There is a common belief that the best way to keep the skin barrier and skin itself in good shape is to make it moist and fat. However, this widely believed thinking is not correct. Use of fat lubricants (i.e., vaseline or liquid paraffin) may seal the skin surface, which increases the accumulation of water and heat below the applied product and leads to increased itching and worsening of skin lesions. This is of particular importance in hot and humid climate areas.

Many nondermatologists may be hesitant to use some specific agents in younger patients because of safety concerns.

Two groups of topical skin medication are of special interest: topical corticosteroids and emollients.

Emollients and moisturizers are of particular interest because fragile, young skin needs them more than adult skin and – because of high permeability – it may absorb applied ingredients in much higher concentrations.

Children's skin should be kept "not too dry" and "not too moist (fat)," and achieving this balance has become a science in itself.

In this section, dermatologic conditions most relevant in a pediatrician's daily practice are reviewed. Our goal is to give a practical overview and to help in the assessment and management of common skin diseases in neonatal, child, and adolescent populations. The intent is to not to deeply discuss etiologic, genetic or therapeutic issues, especially if they are in an experimental stage of medical knowledge or if only a single clinical report describes specific clinical outcome.

For detailed reviews and further studies, pediatric dermatology textbooks and monographs are recommended. A short list of such fundamental recent books is given below.

141 Cutaneous Disorders of the Newborn

Shaden Abdel Hadi

Neonatal dermatology encompasses the spectrum of cutaneous conditions observed during the first 4 weeks of life. As it is practically impossible to discuss the full spectrum of neonatal dermatoses in one chapter, we have elected to focus on conditions that are most common in clinical practice.

Physiology of Neonatal Skin

From the moment at birth, the skin of the neonate is confronted with a significant challenge of transition from a sterile, thermally stable aqueous environment to a dry one, rich in pathogens, undergoing temperature changes, and exposed to friction. Therefore, the neonate's skin undergoes several changes in adapting to the new extrauterine environment. The stabilization of the epidermal barrier is the highlight of this dynamic adaptation process that involves acceleration of the stratum corneum maturation by increasing its thickness and normalizing the skin pH, stratum corneum hydration, and changing the lipid composition. Thus, the majority of premature infants develop intact barrier function by 2–3 weeks of age.

In addition to epidermal thickness, the neonatal skin differs from that of an adult in many other aspects. It is less hairy, secretes less sweat and sebum, has weaker intercellular and dermo-epidermal attachments, has fewer melanosomes, lacks protective skin flora at birth, and forms a higher surface area–body mass ratio. All these factors combined make the neonatal skin more vulnerable to external stresses and toxins than the adult skin.

Skin of the Premature Infant

The number of epidermal layers increases with fetal age along with stratum corneum thickness, which makes the extent of skin fragility in premature neonates directly proportional to the degree of prematurity. Infants born prior to 32–34 weeks of estimated gestational age have markedly decreased epidermal barrier function with a higher surface area–body mass ratio than that of full-term infants. Heat regulation, on the other hand, is dysfunctional in premature neonates due to reduced sweating, thin subcutaneous fat layer, and underdeveloped autonomic control of the skin vasculature. Moreover, immature organs of premature neonates may affect the metabolism of chemical agents administered topically or systemically.

The above-mentioned features of premature skin put it at a higher risk of thermal instability, percutaneous toxicity, mechanical injury, infections, and, finally, increased transepidermal water loss. The latter is particularly accompanied by increased morbidity, as it can lead to dehydration and electrolyte imbalance.

In extremely premature infants (<24 weeks), the skin is sticky, friable, and transparent, and lanugo hair is absent.

Skin of the Full-Term Infant

The skin of full-term infants seems to have a relatively sufficient barrier function; however, they still stand the risk of toxicity from topically applied products. As mentioned above, this is due to the high surface area–body mass ratio and the underdeveloped metabolism pathways.

Skin of the Postmature Infant

Postmature infants born at >40 weeks of gestation have a dry peeling skin soon after birth. This physiological shedding is usually superficial and much more prominent in postdate infants than in others, and may last for a maximum of 1 month.

Skin Care of the Newborn

Removal of Vernix Caseosa

In utero, fetal skin is covered by a protective biofilm known as vernix caseosa that prevents it from maceration in amniotic fluid. It is composed mainly of water, proteins, lipids

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_141,

from sebaceous gland secretions, and debris of fetal epidermal decomposition.

The thickness of this gray-white greasy layer varies depending on the gestational age at which the baby was born. It is thicker in full-term infants than in pre- or postmature ones. It is usually wiped off gently with a clean towel soon after delivery.

Washing and Bathing

There is a general consensus that cleansers used for washing newborns should be gentle, nontoxic, nonabrasive, pH-neutral, and free of dyes and fragrances. Antiseptic baths containing hexachlorophene, chlorhexidine, or iodine are not indicated in daily care due to the risk of absorption and systemic toxicity. Immersion of the newborn in water baths for more than 5 min increases skin fragility due to hyperhydration and therefore it should be avoided.

There is no single ideal method for umbilical cord care; however, a recent study revealed that wiping with sterile water and allowing it to dry naturally is superior to using isopropyl alcohol.

Ears should be cleaned gently with water, and ear swabs, if used, should never be inserted into the external ear canal.

Finally, too frequent washing with multiple products not only leads to irritation and dryness but also exposes the infant to a wide range of potentially allergenic chemicals and puts the infant at risk of sensitization. So, bathing the whole body twice a week might be enough, using the least needed number of topical products.

Napkin Change

Changing infant's napkin should be done frequently and as soon as it gets soiled. The area should be washed with running lukewarm water and dried carefully without rubbing, and then covered with a barrier product before placing a new diaper.

For more details, the reader is refered to standards of diaper area care shown in *Table 141.2*.

General Care of Newborn Skin

Emollients are generally used to enhance skin flexibility and reduce transepidermal water loss. The use of thick fatty products is generally discouraged for daily care, specifically in warm and humid climates, and incorporating these products into emulsions consisting of W/O (water in oil) appears to be more logical in terms of achieving skin hydration without paradoxical increase of occlusion.

Powder use is undesirable in infants due to the hazard of accidental inhalation and subsequent lung inflammation.

The skin of the newborn tends to be less pigmented in the first few months and, therefore, has less natural protection from sunlight. Considering the general concern around using topical sunscreens before the age of 6 months, it is appropriate to avoid prolonged sun exposure and use protective clothing whenever necessary.

Evidence-based guidelines for standard care of neonatal skin were recently published in the *Journal of Obstetric Gynecology and Neonatal Nursing*. A recent review of moisturizers and emollients used for appropriate skin care is given in the dermatology section of the *eMedicine* journal (see reference list for details).

Transient Benign Neonatal Dermatoses

The exact etiology behind many transient neonatal dermatoses remains unclear. Clinical recognition of these cutaneous lesions is essential not only to reassure the parents but also to rule out serious infections. When in doubt, skin scrapings and swab cultures taken from the lesions should be performed, and antimicrobial therapy should be initiated accordingly.

The most common transient skin findings in neonates include: desquamation (seen in 15–65% of the neonates, depending on their ethnic and geographic origin), Epstein' and Bohn's pearls (56–88% of neonates, depending on the study region), hyperplasia of sebaceous glands (32–48% of assessed children, depending on the geographic localization), milia (19–48% of the patients, depending on ethnic and geographic origin), toxic erythema (seen between 16% in Indian and 40% in Japanese neonates), perianal dermatitis (seen between 7% in African-Americans and 19% in Japanese patients), miliaria cristalina (seen between 3.1% in white skin children in the USA and 17% in neonates of African-American origin), and miliaria rubra (seen between 4% in Japanese and 5.5% in African neonates in the USA). Genital hyperpigmentation has been reported, for example, in 5% of Caucasian neonates and 20% of Mongolians. The phenomenon of cutis marmorata is a phenomenon described in 6.7% of neonates in France. Other transient skin changes that may affect neonatal population are sucking blisters (reported in approximately 10% of the children), acne neonatorum

(affecting approximately 1.2% of newborns in the USA) as well as harlequin color changes, jaundice, and undefined skin redness.

Vernix Caseosa

Vernix caseosa presents as a chalky white film covering the skin of infants at birth. It is a mixture of shed epithelial cells, sebum, and lanugo hair.

The vernix serves as a protective lubricant covering the infant from amniotic fluid and also as a natural defense from microbes due to its content of antimicrobial peptides and lipids. In infants who have suffered fetal distress, vernix might be stained with meconium (a yellow-brown color).

Neonatal Desquamation

Postmature infants (over 40 weeks of gestation) are often born with cracking and peeling of the skin that are much more clinically prominent in them in full-term or premature neonates. In severe cases, congenital ichthyosis can be considered as the condition might mimic collodion baby syndrome without ectropion, eclabion, or gloved appearance. Topical care is usually sufficient to control the desquamation and includes moisturization and avoidance of over-bathing.

Transient Vascular Phenomena

Harlequin Color Change

Harlequin color change is a rare phenomenon in which the amount of blood flow differs markedly between the right and left sides of the infant's body, particularly when lying on one side. A transient erythema appears on the dependent side due to vasodilatation while the upper half of the body exhibits simultaneous blanching with a sharp demarcation on the midline (◉ *Fig. 141.1*).

This phenomenon is believed to be related to abnormal hypothalamic control of skin vasculature within the first few weeks of life. It has also been observed in infants with severe intracranial injury that could have contributed to hypothalamic dysfunction.

The condition is more common in, but not limited to, premature/low-weight infants, usually in good general health. It typically occurs around days 3–5 of life and may last up to 3 weeks of age. The face and genitalia of the infant may be spared. Color changes are transient, lasting 20–30 min in each attack, and rapidly reversible when the infant's position is changed.

Figure 141.1
Harlequin color skin changes. Unilateral, transient net-like erythema

Harlequin color change is self-limiting, completely benign, and usually subsides after the third week of life without any treatment.

Acrocyanosis and Cutis Marmorata

Acrocyanosis is a condition in which the hands, feet, and/or lips become variably blue or violaceous in color without associated edema or other notable skin changes.

Cutis marmorata presents as a marble-like pattern or bluish mottling of the skin. This reticulated cyanosis is usually blanchable, symmetrically involving the trunk and extremities. Both patterns reflect an underlying vasoconstriction in a physiologic response to cold stress and usually resolve with warming of the skin.

If cutis marmorata persists over 1 month of age, other central nervous system–induced neurovascular dysfunctions (e.g., Down syndrome, Cornelia de Large syndrome, and hypothyroidism) should be considered.

Cutis marmorata telangiectatica congenita (CMTC) may also mimic cutis marmorata, but it is persistent in the form of localized patches on the trunk or extremities.

Erythema Toxicum Neonatorum (Toxic Erythema of the Newborn)

Erythema toxicum neonatorum is the most common, transient rash in neonates, occurring in approximately 50% of all full-term newborns, but virtually never seen in premature infants. Lesions may be seen at birth, but they usually appear in the first 2 days of life or later; some cases that appear at the age of 10 days have been reported. Lesions then wax and wane and rarely last for more than a week. They are clinically characterized by small erythematous macules with or without a central papule or pustule. These 1–3-mm sterile lesions show a follicular-based distribution and, therefore, can appear anywhere on the body except palms and soles. Histologically, pilosebaceous apparatus is filled with eosinophils, and therefore their pathogenesis has been mistakenly related to a fleabite.

The etiology of erythema toxicum neonatorum is not yet established and it has been considered to be idiopathic. Currently, there are several unproven etiological hypotheses including skin reaction to absorbed enterotoxines, hence the name "toxicum," an allergic reaction because of eosinophilia in lesions (and in peripheral blood of some patients); however, an allergic agent has so far never been identified. Transient adjustment of the skin of the newborn to mechanical/thermal stimuli, a decrease in corticosteroid blood levels following neonatal stress enhancing the eosinophilic response, maternofetal transfer of lymphocytes prior to, or during, delivery causing a minor transient form of acute GvH reaction, and activation of skin antimicrobial system prior to birth and strengthened in the first few days of life, all have also been postulated as factors causing this acute inflammatory response.

The disease is self-limiting and no therapy is needed. The parents can be reassured.

Transient Neonatal Pustular Melanosis

Transient neonatal pustular melanosis (TNPM) is clinically characterized by pustules that are present at birth but rapidly resolve leaving a fine colarette of scales rather than healing with hyperpigmented macules. The content of the pustule is mainly neutrophilic and sterile. The condition is more common among full-term neonates of African descent and is usually located on the chin, forehead, neck, nape, chest, back, and thighs. It can occasionally be found on the scalp, palms, and soles.

TNPM has no clear etiology. It is self-limiting in nature; pigmented freckles or lentigines may persist for a few months.

Transient neonatal pustular melanosis is considered to be a harmless condition that requires no treatment.

Miliaria

Miliaria is a general term that describes a group of transient eccrine disorders in which the sweat ducts are occluded by keratotic plugs at various levels, resulting in leakage of sweat to the surrounding tissue.

The pathophysiology is closely related to warm conditions (i.e., when an infant is overheated, over-wrapped with occlusive agents/materials, or febrile). It has been suggested that *Staphylococcus epidermidis* may have produced an occlusive substance that obstructed the delivery of sweat to the skin surface. Relative immaturity of the eccrine ducts favors the poral closure and subsequent sweat retention.

Several subtypes of miliaria have been described:

- *Miliaria crystallina (Sudamina)* is common during the summer and in neonates placed in incubators. Ductal obstruction occurs at the stratum corneum level. It is clinically characterized by 1–2 mm asymptomatic superficial clear noninflammatory vesicles, which desquamate in few days. They usually appear 1 week after delivery, mostly on the forehead and then the scalp, sparing the skin of palms, soles, and the mucosa. Rare congential cases have been reported and attributed to the occlusive environment of amniotic fluid and vernix caseosa.
- *Miliaria rubra (Prickly Heat)* typically occurs later than *Miliaria crystallina*, mostly between the 11th and the 15th day of life, usually in hot and humid conditions. It may be preceded by *Miliaria crystallina*. The level of ductal obstruction is still intraepidermal, but lower than that of *Miliaria crystallina*. It presents as nonfollicular erythematous 1–3-mm papules or pustules (*Miliaria pustulosa)* on the head, neck, trunk, diaper region, or any intertriginous area. Erythema reflects dermal inflammation around the occluded eccrine duct.
- *Miliaria profunda* is an obstruction at or below the dermo-epidermal junction. It presents as a firm pale papule on the trunk or extremities and may follow *Miliaria rubra*. It is unusual in a newborn.

Treatment for miliaria includes avoiding or correcting the overheating. In febrile condition, treating the underlying fever is helpful. Lightweight cotton clothing, cool baths, and air conditioning are all supportive measures.

Milia

Milia are small epidermal cysts commonly occurring on the face of newborns as a result of retention of keratin within the dermis. They present as pinpoint to 1-mm pearly white papules, more prominently on the nose, chin, cheeks, and forehead. They are usually spontaneously extruded in a few weeks, requiring no therapy.

Lesions may also be located in the oral cavity on the hard palate where they are called Epstein's pearls. These are present in the majority of newborn infants.

When such lesions occur on the alveolar gum margins, they are termed Bohn's cysts.

Similar to skin lesions, oral lesions also resolve spontaneously within few weeks.

Neonatal Acne (Neonatal Cephalic Pustulosis)

Acne neonatorum is a commonly observed, benign condition affecting many newborns. Historically, appearance of the lesions has been thought to be mediated hormonally. Recently, however, it has been proposed that the term "neonatal acne" should be replaced by "neonatal cephalic pustulosis," because there is no relation to androgen secretion, and classical acne comedones are usually absent. Latest hypotheses favor the theory that an inflammatory reaction to malassezia species (both *M. furfur* and *M. sympodialis*) may promote the development of such acneiform skin lesions in neonates.

Clinically, erythematous papules and pustules appear mainly on the cheeks, face, and sometimes on the scalp, either at birth or within the first few weeks of life, only to resolve spontaneously without requiring any treatment (*Fig. 141.2*).

In contrast to acne neonatorum, infantile acne presenting in children of 2–3 months of age has been considered to be androgen driven. The morphology of the lesions exhibits the classical picture of papules, pustules, and comedones located on the face. This condition may be severe and may require systemic treatment to prevent scar formation (*Fig. 141.3*).

Sebaceous Hyperplasia

Sebaceous hyperplasia is common in term neonates, but premature infants are less affected. It is present as follicular, regularly spaced smooth white papules grouped into plaques without surrounding erythema. In such cases, androgenic stimulation in utero, coming from either the mother or the infant, leads to hypertrophy of the sebaceous glands occurring in the last month of pregnancy. The lesions are found typically on the nose, cheeks, upper lip, and forehead. They gradually involute in the first few weeks of life.

Figure 141.2
Neonatal cephalic pustulosis. Disseminated pustular lesion on the face and scalp

Figure 141.3
Infantile acne. Multiple acneiform lesions on the face of a 3 months old boy

Umbilical Granuloma

Failure of the umbilical stump to heal after the cord sloughs off may cause hyperproliferation of the endothelial cells in that area, clinically resulting in pink-gray

papules or nodules growing over the stump that are extremely friable and bleeding easily, resembling pyogenic granuloma. The term "granuloma" is, however, a misnomer as the condition is not related to any granulomatous skin reaction. A traditional treatment consists in gently touching the surface of the lesions with silver nitrate, and the lesion resolves without scaring.

Sucking Blisters

Sucking blisters are apparent at birth as a result of vigorous intrauterine sucking of a finger, thumb, wrist, lip, or forearm. It is an uncommon finding in a newborn and presents as a solitary oval-shaped 0.5–2-cm blister or erosion seen on noninflamed skin of the dorsal aspect of the affected site. It resolves rapidly without sequelae.

Disorders of Subcutaneous Tissue in the Newborn

A well-developed layer of subcutaneous fat (panniculus) is normally present at birth in the neonate, even when premature, which then grows until about 9 months of age giving the traditional chubby appearance to the healthy newborn.

A number of subcutaneous fat disorders have been described and recognized based on their distinctive clinical patterns, course, and both histopathological and biochemical markers. The neonatologist must differentiate disorders that have an innocent and self-limiting behavior from those that have systemic implications and are associated with significant morbidity.

Subcutaneous Fat Necrosis of the Newborn

Subcutaneous fat necrosis (SCFN) of the newborn is an uncommon skin disorder, which appears during the first few weeks of life, primarily in full-term and postmature infants. This condition may develop in infants with a normal delivery; however, it has been observed mostly in neonates who have suffered from perinatal complications.

The exact etiology of this disorder remains uncertain; however, some investigators have suggested that it occurs as a result of ischemic injury of fat by local trauma during or after delivery. The observation that lesions are commonly located over bony prominences supports this theory. Many affected neonates have had perinatal asphyxia with poor American Pediatric Gross Assessment Record (APGAR) scores, hypothermia, meconium aspiration, and fetal distress.

Other authors have hypothesized that the disorder may be related to an underlying defect in fat composition and metabolism in the newborn.

Neonatal fat is mainly composed of saturated fatty acids (stearic and palmitic) with a relatively high melting point when compared to adult fat, which is rich in unsaturated fatty acids (oleic acid) with a much lower melting point. This causes the neonatal fat to be more susceptible to crystallization and adipocyte damage in response to hypothermia.

Fat necrosis has been associated with hypercalcemia. It has been proposed that this is related to production of 1,25 dihydroxy-vitamin-D by macrophages in the granulomatous reaction around fat necrosis, subsequently increasing intestinal calcium uptake.

Another hypothesis tries to explain increased calcium serum level as a result of elevated levels of prostaglandin E2 which may have caused excess bone resorption. An increased level of parathyroid hormone has also been postulated as a potential promoting factor.

Overall, it seems that all of these mechanisms combined result in this fat necrosis. An abnormal fat composition in the newborn makes it susceptible to necrosis under a stressful event leading to a granulomatous skin reaction, which in turn predisposes the child to hypercalcemia.

Affected infants are usually in a good clinical condition. Lesions appear during the first month of life as single or multiple firm nodules or plaques that are localized and freely mobile (not attached to deeper structures), with or without erythema. These are usually painless, but may become tender. Sites of predilection are areas of trauma or ischemia including cheeks, back, buttocks, arms, and thighs (*Fig. 141.4*). The anterior trunk is usually spared. Lesions resolve spontaneously within weeks to months; however, they may occasionally calcify or ulcerate leaving mild atrophy of the skin after resolution.

Diagnosis is usually made clinically, but histological examinations reveal lobular panniculitis (inflammation of subcutaneous fat lobules) with granulomatous inflammatory infiltrate and characteristic needle-shaped clefts within adipocytes and calcification.

The prognosis for subcutaneous fat necrosis of the newborn is excellent. Most lesions undergo spontaneous resolution within several weeks to months.

Hypercalcemia is a rare association, but may be life threatening. The onset may be delayed for several months

Figure 141.4
Subcutaneous fat necrosis. Atrophic changes in subcutaneous disuse in a newborn (Courtesy of Arti Nanda, MD)

after the appearance of skin lesions. Therefore, it is recommended to check the calcium level, vitamin-D level and parathyroid functions, and renal function for up to 6 months after appearance of the lesions. Children should also be observed closely for symptoms such as anorexia, vomiting, constipation, irritability, failure to thrive, and seizures. Unclear transient thrombocytopenia has been reported in a few cases.

In most cases, reassurance is the key due to the self-healing nature of the disease. If hypercalcemia occurs, treatment should include good hydration to increase renal excretions of calcium with or without calcium-wasting diuretics (e.g., furosemide). Systemic corticosteroids or etidronates are rarely needed.

Sclerema Neonatorum

Sclerema neonatorum is a diffuse, rapidly spreading hardening of the skin and subcutis that affects very sick, debilitated neonates in the first 1–2 weeks of life. This condition is becoming rare as neonatal care is improving worldwide.

The cause of this disorder seems to be multifactorial; it appears to represent a nonspecific sign of severe illness rather than a primary disease. Infants are characteristically small or premature, debilitated, cyanotic, and lethargic.

Immaturity of the neonatal lipoenzymes that are responsible for converting saturated fatty acids (palmitic and stearic) into unsaturated acids (oleic) is further compromised by hypothermia, severe metabolic disorders, infections, shock, or any other environmental stress. This enhances the subcutaneous fat predisposition for solidification (because of a defect in fatty acid mobilization) and subsequent development of sclerema.

Sudden diffuse hardening of the skin usually appears during the first week of life, from legs to thighs and buttocks to cheeks and trunk until it eventually involves most of the infant's skin except the palms, soles, and genitals. This woody-hard nonpitting induration renders the skin cold, smooth, and bound down, the joints immobile, and the face masklike. Prognosis is poor, with a high mortality rate in affected infants. In surviving infants, the skin findings resolve without residual sequelae.

No specific treatment is beneficial for sclerema neonatorum. Attention should be paid to the underlying general disorder (i.e., sepsis, dehydration, etc.) and adequately correcting it may improve the skin condition. The role of systemic steroids is still controversial. Exchange transfusion with fresh whole blood may improve the outcome. Comparison between sclerema neonatorum and subcutaneous fat necrosis of the newborn is shown in *Table 141.1*.

Table 141.1
Comparison between clinical features of sclerema neonatorum and subcutaneous fat necrosis of the newborn

	Sclerema neonatorum	Subcutaneous fat necrosis of the newborn
Affected neonates	Premature, critically ill newborns	Generally healthy full-term newborns, may have history of perinatal complications
Morphology	Diffuse, rapid hardening of skin and subcutis	Localized indurated nodules
Distribution	Whole body, sparing palms, soles, and genitals	Buttocks, cheeks, arms, and thighs
Prognosis	Poor	Excellent

Pedal Papules of Infancy (Congenital Pedal Papules)

Pedal papules of infancy are uncommon, soft, asymptomatic lesions located on the heels of the newborn's feet.

The etiology of pedal papules of infancy is unknown. This condition is considered to be distinct from the more common adult piezogenic pedal papules in which gravity on the heels leads to fat herniation through a defect in the dermis.

The presence of these papules at birth speaks clearly against this gravitational theory. The only plausible etiology is probably a developmental defect in the plantar fibrous fat trabeculae that allows fat herniation through it. The histological picture supports this theory showing normal fat globules protruding from the reticular dermis without inflammation.

Clinically, pedal papules of infancy are solitary asymptomatic, soft, skin-colored nodules seen on the medial plantar surface of a newborn's heel. It does not seem to accentuate with position.

Prognosis is unknown, and it is not clear if pedal papules of infancy predispose the child to painful piezogenic pedal papules. Pedal papules of infancy usually do not require treatment.

Iatrogenic and Traumatic Skin Disorders of the Newborn

Iatrogenic and traumatic skin disorders can occur before, during, or after delivery. Skin injury caused by medical procedures may be complicated by infection or scarring.

Iatrogenic Injuries During Pregnancy

Antenatal procedures performed for diagnostic or therapeutic purposes may be complicated by fetal skin injuries. There have been several observations that these wounds may heal without scarring. This could be attributed to either the presence of amniotic fluid or the nature of fetal skin, or both. The amniotic fluid provides a moist, sterile environment that is rich in growth factors and extracellular matrix components. On the other hand, fetal skin is covered, between 4 and 24 weeks of gestation, with a unique layer called "periderm" that is highly proliferative, facilitating wound closure by regeneration and growth rather than scarring. Despite this hypothesis, scars are often observed in newborns undergoing antenatal procedures.

Marks Related to Amniocentesis

Aspiration of amniotic fluid is a widely used procedure in obstetric practice. Since the introduction of ultrasound guidance under which amniocentesis is performed nowadays, fetal injuries have been greatly reduced.

Mid-trimester amniocentesis has the lowest risk of fetal injury since the fetus occupies only half of the amniotic cavity, whereas in the first and third trimesters there is less room to maneuver.

Marks caused by amniocentesis injuries are present at birth, but may go unnoticed for weeks. These marks may be scars, lacerations, depressions, or dimples, and may be solitary or multiple, located on the extremities, head, neck, or chest.

Serious complications are exceptional, and if they occur, include peripheral nerve damage, ocular penetration and blindness, arteriocutaneous fistulization, and exsanguinations of the fetus.

Injuries due to Chorionic Villus Sampling

Chorionic villus sampling is obtaining a small biopsy of villi from chorion fundosum under ultrasound guidance to analyze its DNA.

It has been reported that this procedure might be associated with increased risk of limb and jaw malformations; however, this notion has been disputed and confirmation is still lacking.

An increased risk of hemangioma has been reported in infants exposed to chorionic villus sampling antenatally, especially when performed by the transcervical route as opposed to the transabdominal approach. However, this association is now considered to be controversial.

Other Antenatal Procedures

Other procedures performed antenatally, which may leave marks on the skin of the newborn, include:

- Fetal biopsies taken for prenatal diagnosis of severe genodermatosis
- Fetal liver biopsy
- Fetal tumor biopsy
- Aspiration of fluid collection, such as fetal urine from bladder or pleural effusion
- Therapeutic procedures such as shunting of obstructive uropathy or hydrocephalus

Iatrogenic Injuries During Labor

Injuries due to Fetal Monitoring

Monitoring of the fetal heart rate during labor is a standard obstetric practice. This can be achieved either by placing an ultrasonic transducer on the mother's abdominal wall or by using an electrode attached to the presenting part of the fetus. The latter method is generally safe; infrequent complications include bleeding at various levels in the scalp, lacerations, ulcerations, scalp abscesses, and herpetic infections. Although herpes simplex virus infection is an extremely rare complication, it might become life threatening.

Scalp puncture for fetal blood gas sampling is less frequently performed, but it may cause scalp lacerations. Scalp abscess formation is an unusual complication.

Caput Succedaneum

A caput succedaneum is a diffuse soft-tissue edema with or without bruising involving the fetal presenting part (scalp, face, and scrotum). This occurs as a result of venous congestion during a prolonged labor. Accumulation of the fluid is external to the periosteum, which explains why the edema crosses the midline and is not limited to the suture lines.

The condition clears spontaneously in few days. No treatment is required except in the case of extensive bruising when early phototherapy for hyperbilirubinemia may be indicated. Another possible complication is the development of an annular alopecia presenting in a circumferential ring around the scalp, reflecting a pressure necrosis phenomenon (scalp ring halo) which may occasionally persist.

Cephalohematoma

A cephalohematoma is a subperiostial hematoma caused by rupture of skull veins due to shearing forces during prolonged delivery, particularly vacuum-assisted vaginal deliveries. Due to the slow process of periosteal bleeding, cephalohematoma may not become visible until several hours or even days after birth.

Cephalohematoma appears as a nonpulsating, often fluctuant, lump on one side of the scalp limited by cranial sutures, with a normal colored overlying scalp. Although the parietal bone is most commonly affected, occipital and frontal bones may also rarely be involved.

The cephalohematoma has no long-term implication, although it may last for months before it disappears. Treatment is not required, except in rare cases when it is complicated by infection or severe hemorrhage. In these cases, antibiotic treatment, blood transfusions, or phototherapy for eventual hyperbilirubinemia may be indicated.

Injuries due to Forceps Deliveries

Forceps deliveries can cause many injuries to the soft tissues of the face or scalp, corresponding to the area of application of the forceps. These injuries range from minimal erythema or bruising to abrasions or subcutaneous fat necrosis.

Injuries due to Vacuum Extractors

Vacuum extractors are occasionally used when there is slow progress of labor. Introduction of softer silicone cups has reduced the risk of fetal injuries.

When the fetal scalp is sucked inside the cup, a "chignon" might be produced; this is a small swelling of the scalp with a diameter larger than the rim of the vacuum cup. A chignon is a benign lesion which disappears in a few days in the majority of cases without scarring. In rare cases, it may become lacerated and infected that may end up in a localized alopecia. Abrasions of the scalp may also be seen especially with the rotation of the cup on the skin, or due to sudden detachment from the infant.

Injuries due to Cesarean Section

A potential injury from a cesarean section is lacerations to the infant caused by the scalpel, which may be deep enough to require suturing. This can be complicated by infection, scarring, and linear alopecia.

Iatrogenic Skin Disorders After Birth

Several untoward events may be related to technological advances that have become standard nursery practice. When describing these iatrogenic complications, one should keep in mind that these diagnostic and therapeutic procedures have significantly reduced morbidity and mortality in many infants. Injuries related to these procedures, if they occur, are minor and easily manageable in most cases (*Fig. 141.5*).

Figure 141.5
Iatrogenic skin injury. Skin ulceration after peri-partum superficial skin injury

Conditions Related to Arterial Catheterization

Catheterization of umbilical or peripheral arteries is a commonly performed procedure in neonatal intensive care units.

Damage or thrombosis of the artery caused by cannulation may lead to ischemia of the distal part of the limb. These are frequently seen on feet, hands, or buttocks.

Early skin changes include transient blanching, erythema, and bulla formation. Usually, this is reversible after early removal of the line. It may, however, progress to extensive skin necrosis and gangrene if the diagnosis and subsequent removal of the line were delayed.

Drug-Related Complications

Neonatal skin is uniquely vulnerable to the toxic effects of chemical substances. This has been attributed to their immature hepatic, renal, and central nervous systems, and to the high body surface to volume ratio.

Skin damage, burns, sloughing, and blistering have been reported from topical application of alcohol-based skin cleansers such as isopropyl alcohol and chlorhexidine gluconate. Moreover, toxic side effects of systemic absorption have been noted with some drugs such as neomycin, aniline dye, iodine, and hexachlorophene.

Infants born at 37 weeks of gestation or later seem to have an effective skin barrier as compared to infants born at 32 weeks or before. At 2 weeks of age, the skin of the most immature infant begins to function like that of full-term infants.

Skin Damage due to Adhesive Dressings

Adhesive tapes used frequently to secure intravenous catheters, endotracheal tubes, nasogastric tubes, monitor leads, or chest drains may damage the skin, especially that of premature infants. As a result, skin sloughing, blistering, and even hemorrhage, scarring, and pigmentary changes have been reported. Using pectin-based skin barriers directly on the skin under the adhesive tape may prevent these injuries. Careful and gentle removal of the tape is also helpful.

Needle Marks

Hypopigmented, pinhead-sized lesions, grouped together giving a speckled appearance, are frequently seen on distal extremities at sites of venous or arterial catheterization.

Heel prick marks may appear as dimpling, hard calcified nodules, hypertrophic scars, or even gangrene of the heel.

Anetoderma of Prematurity

Depressed atrophic patches or outpouching of the skin of a premature infant resulting from thinning of the dermis with loss of elastic fibers have been described, especially with extreme prematurity (less than 29 weeks of gestation). Lesions develop without a preceding inflammation 1–10 months after birth. These are mainly seen on the anterior trunk and proximal extremities, at sites of placement of adhesives or monitoring leads. The exact cause is not well understood, and lesions are believed to have lasted indefinitely.

Calcinosis Cutis

Calcinosis cutis is the deposition of hydroxyapatite crystals and calcium phosphate within the skin's soft tissue. Iatrogenic calcinosis cutis occurs as a result of tissue damage followed by deposition of these crystals with a normal calcium/phosphorus ratio. This usually occurs at sites of heel pricks, calcium administration for correction of hypocalcemia, electrocardiograph electrode placement, or any injury resulting in subcutaneous fat necrosis. Calcified nodules appear initially as depressed small macules, growing over months to turn into white-yellow papules or nodules and eventually extruding their content to the skin surface. These lesions disappear generally within 2–3 years.

Children may occasionally show signs of discomfort while standing. In such cases, gentle cryosurgery or curettage may be helpful. Using electrode pastes that do not contain calcium chloride may prevent calcinosis cutis secondary to electrode placement.

Bronze Baby Syndrome

The term "bronze baby syndrome" is used to describe infants who develop a diffuse gray-brown discoloration of the skin, serum, and urine 1–7 days after starting phototherapy for hyperbilirubinemia. This is considered to be a rare complication of phototherapy, developing particularly in infants with liver impairment, especially cholestasis. The pathophysiology seems to be related to photoisomers of bilirubin or biliverdin or to a copper-bound porphyrin photoproduct. This discoloration fades over weeks after phototherapy is discontinued without significant sequelae.

Bronze baby syndrome can easily be distinguished from transient porphyrinemia after phototherapy, as the latter causes a purpuric eruption sharply confined to the exposed skin areas.

Complications of Neonatal Circumcision

Meatal ulceration is a complication of circumcision that often goes unrecognized. This is probably due to its potentially delayed occurrence. Removal of the prepuce exposes the glans penis epithelium to diaper irritation, which in turn may lead to erosions and sometimes healing with stenosis.

Bleeding, infections, and direct injury to the glans penis or urethra are some of the uncommon complications of circumcision.

Dermatoses of Diaper Area

"Diaper dermatitis" is probably the most common dermatologic disorder in infancy and early childhood. The term is broadly used to describe any acute inflammatory skin reaction affecting the anogenital area of napkin-wearing infants. Thus, the term "diaper rash" should not be used as a specific diagnosis, but rather as a descriptive regional term that encompasses various skin disorders of multifactoral etiology. A prolonged contact with urine and feces, hydration, friction, occlusion and heat, allergic and irritant agents, and secondary infections may all play a causative role in napkin dermatitis, either separately or in combination with each other.

Eruptions of the diaper area may be classified into disorders that are directly related to the wearing of diapers in which the diaper environment plays a central role, disorders aggravated by wearing diapers, and disorders occurring in the diaper area regardless of the presence of diapers. This chapter will mainly review the first group of diseases directly related to diapers.

Clinical presentations of different diaper dermatoses may overlap significantly, and a specific diagnosis can be a real challenge in some cases. As a general rule, a diaper rash that does not respond to standard therapeutic measures or develop as expected should draw the physician's attention to alternative uncommon diagnoses, and further diagnostic evaluation should be performed.

Standard Care of the Diaper Area

The advent of superabsorbent disposable diapers in the 1990s has significantly reduced the frequency and severity of diaper rashes.

Normal care should be aimed at frequent changing of the diapers as soon as they get soiled, gently removing the residual feces preferably with running lukewarm water with or without a soap-free cleanser, drying the area gently without rubbing, applying a mild nonocclusive barrier product with every diaper change, and removing the diaper whenever possible to allow drying of the skin. Using baby wipes is generally not recommended, but, if needed, they should be free from fragrance and alcohol (*Table 141.2*).

It is not recommended to use talcum or baby powders due to their potential toxicities and the risk of inhalation by the infant.

Table 141.2
Simplified rules of diaper area care (ABCDE-rules)

ABCs of diaper area care
Air: Diapers should be left open when possible to allow aeration of area
Barrier ointments (zinc oxide paste) should be applied with each diaper change
Cleansing gently with plain water and a gentle cleanser without rubbing
Diapers changed frequently as soon as they get soiled
Education of parents and caregivers

Modified from Boiko S: Making rash decisions in the diaper area. Pediatr Ann 29:50, 2000.

Finally, parents can be reassured that even the most severe or extensive rash related to napkin wearing will resolve once toilet training is achieved.

Disorders Directly Related to the Use of Diaper

Irritant Contact Dermatitis

Chafing or frictional napkin dermatitis is by far the most prevalent type of diaper dermatoses affecting almost every infant at some point in his/her life. The disorder seems to be attributed to a combination of factors such as contact with proteolytic enzymes of the stool, especially in cases of diarrhea, irritant chemicals or soaps, moisture and occlusion leading to sweat retention, the warm environment of the diaper, and constant friction and rubbing. All these factors compromise the skin integrity and impair its barrier function. Although ammonia from urine was initially thought to cause irritant diaper dermatitis, subsequent evidence refers to feces as the principal culprit.

Clinically, the condition is characterized by shiny confluent erythema with or without shallow erosions and swelling involving the convexities of the perineum, genitals, and buttocks (areas of closest contact with irritants), and sparing creases of intertriginous areas. Rarely, in infants over 4 months of age, it may present with perianal erythema. A subtype of irritant contact dermatitis is the simple intertrigo that affects overweight infants, mostly on moist skin folds (*Fig. 141.6*).

Figure 141.6
Contact dermatitis and secondary intertrigo in diaper area. (Courtesy of Arti Nanda, MD)

A severe form of irritant contact dermatitis is known as Jacquet's erosive dermatitis. This presents as well-demarcated punched out ulcers and erosions with elevated borders. Irritant contact dermatitis may occur any time during the diaper period. This condition has become uncommon since the advent of superabsorbent diapers.

Treatment includes minimizing contact with irritants by following the instructions previously mentioned (keeping the area clean and dry). A mild topical corticosteroid therapy (1% hydrocortisone cream for a short period of time) with a barrier product (zinc oxide soft paste) applied two to three times a day clears the condition rapidly. Stronger topical steroids should be avoided under diaper occlusion as it maximizes systemic absorption.

Allergic Contact Dermatitis of the Diaper Area

Allergic contact dermatitis is less common than irritant contact dermatitis in the diaper area, arising de novo or as a complication of another form of napkin rash. However, it should be considered if the infant does not respond to the usual therapeutic measures.

Offending agents include fragrance, dyes, and preservatives in topical baby products or other components of the diaper itself. An infant usually needs time to be sensitized, which is why this type of dermatitis is not generally seen in the first 6 months of life. Morphologically, it begins with erythema, small vesicles that rupture, giving the classical picture of an eczematous eruption. It mainly affects the convex surfaces under occlusion if the allergen was in the diaper, or may be more prominent in the flexural surfaces if the reaction is due to a topically applied product.

"Lucky Luke" dermatitis is a specific form of allergic contact dermatitis affecting the outer buttocks and hips, waistline, and proximal thighs. It indicates an allergy to rubber components in the elastic bands of the diaper. This is known as the holster sign (named after a cartoon character that carried its gun holster in the same area).

Strict avoidance of the suspected allergen with judicious use of topical corticosteroids is usually efficient in clearing this reaction in several days.

Granuloma Gluteale Infantum

Granuloma gluteale infantum is a rare condition characterized by firm, painless red-brown to purple dermal nodules varying in size from 0.5 to 4 cm, localized on the gluteal and convex surfaces of the diaper area in infants

between 2 and 9 months of age. It usually arises within the area of preexisting diaper dermatitis. The etiology is unclear, but it seems to be related to a combination of factors as an abnormal skin response to inflammation, local infection with candida, and the use of topical fluorinated steroids. Treatment is directed at correcting the underlying diaper rash and avoiding topical steroids and all irritants. Resolution occurs in several months, sometimes leaving atrophic skin patches.

Candida Diaper Dermatitis

Candidiasis is the most common infection in newborns. Candida diaper dermatitis in particular is the second most common type of diaper dermatitis. Provided there is sufficient warmth and moisture, candidiasis from lower intestinal flora frequently contaminates any form of diaper rash that lasts for over 3 days. Moreover, candidiasis is a possible sequela of systemic antibiotic therapy and should be considered when the rash develops during or shortly after antibiotic administration. Diarrhea also makes the infant more susceptible to candidiasis. Maternal mastitis during breast-feeding or presence of vaginitis at vaginal delivery could also be other sources.

Characteristic morphology is seldom seen before 6 weeks of age and presents as beefy red erythematous moist papules, patches, and plaques with pathognomonic satellite lesions, sharply defined with peripheral scale over the buttocks, abdomen, and the entire perineal area involving creases as well as convex surfaces. Oral thrush can also be associated with this type of diaper rash and it should be examined when candida is suspected.

The diagnosis is usually based on the characteristic clinical picture; however, potassium hydroxide scraping from peripheral scales may confirm it by revealing pseudohyphae and/or egg-shaped budding yeast.

Rarely, a psoriasiform skin eczematid ("Id reaction") may complicate a severe candidal napkin rash with scaly psoriasiform lesions appearing rapidly on the trunk and extremities.

Diaper candidiasis responds rapidly to topical antifungals such as nystatine, imidazoles, and ciclopirox. A brief course of low-potency topical steroids may speed up clinical improvement.

Perianal Pseudoverrucous Papules and Nodules

"Perianal pseudoverrucous papules and nodules" is a term used to describe a rare entity that represents a severe skin reaction following a chronic, unremitting irritation with feces, urine, or both. Therefore, it affects infants and older children with chronic diarrhea much more than newborns. Clinically, it presents as wart-like papules and nodules in the perianal and suprapubic areas. The lesions are usually red in color, moist, shiny, smooth, and flat topped.

Once the chronic irritation is removed, lesions regress spontaneously. The clinical importance of this condition lies in differentiating it from other serious dermatosis, especially candyloma accuminata.

Granular Parakeratosis

Infantile granular parakeratosis represents a rare, peculiar, idiopathic form of retention hyperkeratosis in diaper-wearing infants, rather than newborns.

There are two clinical patterns for this condition. The first one presents with asymptomatic geometric yellow-brown plaques with characteristic thick flake-like scales and underlying erythema over areas of friction or pressure. The second pattern presents with bilateral linear plaques appearing in the inguinal folds.

Treatment aims at reducing friction and following standard care of the diaper area; however, response is variable and spontaneous resolution after several months seems to be the rule.

Dermatoses Aggravated by Diaper Environment

Infantile Seborrheic Dermatitis

Infantile seborrheic dermatitis is an inflammatory skin disease, which may commonly affect the diaper area of infants, starting at 3–6 weeks of age and lasting for several months.

The condition occurs in "seborrheic areas" where sebum secretion is active, most commonly on the scalp, intertriginous areas of the diaper region, and may also involve the face, retroauricular area, neck, and axilla.

Classical presentation of infantile seborrheic diaper dermatitis includes a well-defined asymptomatic salmon-colored patch starting from the creases to the convex surfaces. Although classical seborrheic dermatitis is covered with thick greasy yellow scales, this feature in diaper areas is minimal or unusual, unless candida is secondarily involved. A major clue in the diagnosis is the characteristic sparing of the anogenital area.

The etiology of infantile seborrheic dermatitis is probably due to colonization of the yeast Malassiza furfur

(pityrosporum ovale) that thrives in an oily environment, explaining the special distribution of the patches.

The prognosis for infantile seborrheic dermatitis is generally good. It resolves spontaneously in most cases within the first year of life. Topical ketokonazole used two to three times daily may be useful.

Psoriasis

Psoriasis occasionally begins as a persistent diaper rash, with potential overlap with seborrheic dermatitis (sebopsoriasis). The appearance of psoriasis in the diaper area is attributed to the Koebner phenomenon caused by other types of diaper rashes.

Clinically, psoriasis presents as sharply defined erythematous plaques with much less scaliness than the classical psoriasis lesions due to hydration under the diaper (psoriasis inversa). These plaques involve both convex surfaces and inguinal folds. The lesions can potentially spread to the trunk and extremities or remain confined to the diaper region. Lesions tend to persist or heal and recur over months. Topical steroids usually achieve temporary improvement; new topical immunomodulators (pimecrolimus/tacrolimus) are also promising.

Other Dermatoses Affecting the Diaper Area

Acrodermatitis Enteropathica

Acrodermatitis enteropathica is another rare disease that can cause atypical or persistent diaper rash as a part of periorificial distribution of the disease. In the recessively inherited form of the disease, there is an inborn defect in intestinal absorption of zinc. This typically affects infants when weaned from breast milk, which contains a zinc-ligand-binding protein. The other form of the disease is transient and is acquired due to nutritional zinc deficiency for any reason (e.g., low zinc in mother's breast milk, malabsorption, prematurity, etc.). Both types clinically present with crusting–scaling erosive diaper dermatitis, diarrhea, and hair loss. Affected infants are usually irritable and suffer from recurrent infections and failure to thrive. Eczematous lesions typically involve the face periorally and periorbitally with the acral areas of the digits (*Fig. 141.7*). Oral zinc supplementation clears the rash within several days. Infants with inherited forms require this supplementation for life, with dose adaptation according to the zinc serum levels.

Many other dermatoses may also affect the diaper area with or without affecting other areas of the infant's body that are not directly in contact with the diaper. These include:

- Atopic dermatitis
- Bullous impetigo
- Staphylococcal scalded skin syndrome
- Ecthyma gangrenosum
- Diaper dermatophytosis
- Herpes simplex
- HPV infection
- Molluscum contagiocum
- Coxsackie viral infection
- Cystic fibrosis
- Chronic bullous disease of childhood
- Langerhans cell histiocytosis (Letterer–Siwe disease)

Figure 141.7
Acrodermatitis enteropathica. Typical erosive lesions on palms and genital area

- Kawasaki disease
- Hemangiomas
- Lichen sclerosus
- Pyoderma gangrenosum
- Bullous pemphigoid
- Child abuse
- Bullous mastocytosis
- Incontinentia pigmenti
- Congenital syphilis
- Scabies
- Perianal streptococcal disease and streptococcal intertrigo
- Perioral dermatitis with genital manifestations Crohn's disease
- Epidermolytic hyperkeratosis
- Epidermolysis bullosa

These diseases are much less common and relate to various etiologies, and therefore, are not discussed in this chapter. The reader is referred to the list of recommended references for further information.

142 Eczematous Skin Disorders and Atopic Dermatitis in Childhood

Douglas W. Kress

Definition and Epidemiology

Atopic dermatitis (AD) is a genetically inherited papulosquamous skin disease most commonly seen in children. Seventy to ninety-five percent of cases present before the age of 5 years. The prevalence of AD in the western world is now between 10% and 20%, with the ratio of girls to boys being 1.3:1. Additionally, it is more likely for a child to inherit atopic dermatitis from a mother with atopy than from a father with atopy. This prevalence has steadily increased in North America and Europe since World War II. There are many theories that attempt to explain this increase ranging from environmental factors to the "Hygiene Hypothesis," many of which will be discussed later on in this chapter. The prevalence of AD varies worldwide. One very large study which looked at over 700,000 children in over 150 centers across the world showed the lowest prevalence in 6–7 year olds to be 2% in Iran and the highest prevalence in this age group to be 16% in Japan. In children 13–14 years of age, the lowest prevalence was 1% in Albania and the highest was over 17% in Nigeria.

Atopic dermatitis is commonly associated with asthma and allergic rhinitis, and the three together have historically been referred to as the "atopic triad." More recently, the finding of eosinophilic enteritis associated with severe food allergies has also been linked to these diseases. Food allergies can be seen in 40% of infants and children with moderate to severe AD. Eighty percent of individuals with AD will go on to develop either asthma or allergic rhinitis later on in life.

Etiology and Pathogenesis

From an etiologic perspective, AD is a multifactorial disease. First, there are several aspects of immune dysregulation. Seventy to eighty percent of patients with AD show elevated levels of IgE and eosinophilia. Biopsies of active skin lesions show a predominance of TH2 lymphocytes. Additionally, the skin of patients with AD produces lower levels of two families of antibacterial peptides known as B-defensins and cathelicidins. This is just one reason why atopics are much more susceptible to viral and bacterial infections than are non-atopics. Up to 90% of patients with AD will grow pathogenic *Staphylococcus aureus* from swab cultures taken from exudative skin lesions. *Staphylococcus* proteins can act as superantigens that can also flare AD.

Another pathomechanism, and another reason why atopics are so prone to infection, is that they have deficient epidermal skin barrier function. The stratum corneum of the skin of atopics contains much lower levels of ceramide proteins and filagrin than does the skin of non-atopics. Ceramides and filagrin are proteins that function to help the skin retain its moisture content. A hydrated epidermis keeps transepidermal water loss to a minimum, and also provides the best barrier against infection. There are many new topical products now available, both over the counter and by prescription, which contain both ceramides and filagrin. Their appropriate use as part of an overall treatment regimen for AD will be discussed at length in the treatment section to follow.

Clinical Manifestations

Clinically AD usually manifests itself in three phases, infantile, childhood, and an adolescent/adult phase. Infantile AD usually presents with a diffuse red scaly dermatitis mainly limited to the face and scalp (*Fig. 142.1*). Within the first 6–12 months of life, AD can overlap clinically with Seborrheic Dermatitis, also known as cradle cap. Usually, sometime between 12 and 18 months, the rash of AD leaves the face and scalp, and becomes more prominent on the popliteal (*Fig. 142.2*) and antecubital fossas (*Fig. 142.3*). This phase usually persists up through the early teenage years, by which point approximately 60% of patients will have grown out of their disease. In the up to 40% of atopics who carry their skin disease into adulthood, a number of different clinical patterns can be seen. These can include a chronic hand dermatitis, eyelid or neck eczema, or nipple eczema in young women. Many other clinical features can be seen

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_142,

Figure 142.1
Facial atopic dermatitis in an infant

Figure 142.2

at any age and make up a number of the minor criteria used to diagnose atopic dermatitis (see list below). From a morphological perspective, clinical lesions at each phase can also present in three different stages, acute, subacute, and chronic, which vary both clinically and histologically.

Major and minor criteria for the diagnosis of atopic dermatitis (adapted from Hanifin and Rajka's article) are as follows:

Major features

Pruritus
Typical morphology/distribution
Chronic and relapsing
Personal or family history

Figure 142.3
Antecubital fossa atopic dermatitis

Minor features

Xerosis
Ichthyosis/keratosis pilaris
Immediate Type 1 hypersensitivity
Elevated serum IgE
Early age of onset
Increased skin infections
Non-specific hand foot dermatitis
Nipple eczema
Chelitis
Recurrent conjunctivitis
Dennie–Morgan folds
Keratoconus
Anterior subcapsular cataracts
Orbital darkening
Facial pallor/erythema
Pityriasis alba
Anterior neck folds
Pruritus with sweating
Intolerance to wool
Perifollicular accentuation
Food intolerance
Influenced by environment
White dermatographism

Pathology

Histopathology varies at each stage. Acute eczema shows intraepidermal edema with microvesicles, also known as spongiosis. There is a perivascular lymphocytic infiltrate predominantly composed of CD4+ T cells extending from

the upper dermis into the epidermis. Langerhans cells and macrophages may also be seen in the infiltrate of acute eczema. Subacute eczema still shows some spongiosis and a less prominent lymphocytic infiltrate. Additionally, some epidermal thickening may be noted at this stage. Chronic eczema, which clinically appears as lichenification, shows only sparse to absent inflammation and spongiosis, with psoriasiform epidermal hyperplasia. Even the normal skin of patients with atopic dermatitis can show abnormal pathology, including a sparse perivascular infiltrate of T lymphocytes, eosinophils, and macrophages.

Differential Diagnosis

The differential diagnosis of AD is quite broad and is different for each phase, infantile, childhood, and adult. The differential includes other chronic dermatosis, infections and infestations, immunodeficiency syndromes, metabolic, genetic and autoimmune disorders, drug eruptions, and malignancies (*Table 142.1*).

Treatment

Once the diagnosis is made, the treatment of AD varies based on the patient's age, the location of the eczematous lesions, and their morphology. Treatment of infantile AD, which mainly involves the face and scalp, should begin with mild soap-free cleansers, known as syndets, and with moisturizers which contain ceramides and/or filaggrin. If those are not effective, very mild topical steroids should be added. There are seven classes of topical steroids available to treat all types of skin disease in patients of all ages. Class 1 steroids are the strongest and Class 7 steroids are the weakest. Several agents in Classes 5–7 are approved for use as young as 3 months of age in the United States, including certain strengths of hydrocortisone, desonide, and fluticasone. These are the agents that should be used to treat eczema in young infants. The topical steroids should be used for no more than 2 weeks without taking a break to minimize their side effects, including the possibility of hypothalamic–pituitary–adrenal (HPA) axis suppression. They should be used in conjunction with the above cleansers and moisturizers. Pruritus can be seen in association with AD at any age. If numerous excoriations are noted, or the parents report poor sleep hygiene, a low nightly dose of a sedating antihistamine, such as hydroxizine, should be considered. Sometimes there is a clinical overlap between AD and seborrheic dermatitis. If this overlap is suspected, the addition of ketoconazole shampoo applied three times per week can be very helpful.

At some point between 12 and 18 months, most facial and scalp AD resolves, and many young children are left with a flexural dermatitis involving the popliteal and antecubital fossas. These skin lesions often exhibit accentuation of the skin lines, a clinical finding known as lichenification. Once lichenification is noted, it will probably become necessary to increase the strength of the topical steroid to one of mid potency, such as triamcinolone. As above, it continues to be important to use

soap-free cleansers and ceramide and filaggrin containing moisturizers. As the strength of the topical steroid use is increased, it is especially important to find ways to give the skin a break from steroid use. Twice daily use of a Class 4 steroid for only 2 weeks on greater than 10% of the body surface area of a child can be associated with statistically significant HPA axis suppression. If, as a clinician, one finds patients for whom the moisturizers and cleansers are not enough to allow the patient to not use topical steroids for at least 1 week per month, that patient may be a candidate for the use of one of the two calcineurin inhibitors/topical immunomodulators (TIMs), pimecrolimus or tacrolimus. In the United States, these two agents carry a Black Box Warning against the theoretical increased malignancy risk of using these agents in children under 2 years of age. This warning stems from the fact that the transplant patients taking oral tacrolimus for more than 5 years have an increased risk of malignancy, especially skin cancers and lymphomas. No malignancies have been definitively causally linked to the use of either topical pimecrolimus or topical tacrolimus.

For a very small percentage of patients who do not respond to aggressive moisturization, mid to high potently topical steroid use, oral antihistamines, and the addition of one of the TIMs, systemic therapy is sometimes necessary. Systemic therapy may also be appropriate for those patients with such a large percentage of body surface area involved (i.e., >20%) that topical therapy is not a tenable option. There are numerous systemic therapies ranging from oral antibiotics and oral steroids, threw light therapy, and up to other oral and injectable immunosuppressive agents such as Cyclosporin, Azathioprine, Methotrexate, Mycophenolate mofetil (MM), Intravenous immunoglobulin (IVIG), and Interferon gamma.

Prospective clinical trials evidence exists only for Cyclosporin, Azathioprine, Interferon gamma, Broadband UVB, and PUVA. Evidence at the level of retrospective clinical trials or large case series exists for systemic steroids, narrowband UVB, methotrexate, mycophenolate mofetil (MM), and intravenous immunoglobulin (IVIG). Although the scientific evidence for oral prednisone is not as strong as for some other agents, based on decades of clinical experience, many pediatric dermatologists will first try a 2–3 week taper of oral prednisone from a starting dose of 1 mg/kg/day. It is often necessary to overlap a 10–14-day course of a penicillin or cephalosporin antibiotic with the prednisone in these patients with severe atopic dermatitis due to their high risk of secondary bacterial infection. If the prednisone is either not effective or significant rebound in disease activity is noted rapidly, one of the steroid sparing agents should be considered.

Cyclosporin is the most effective of these other agents and should be given at a dose of 3–5 mg/kg/day for 3–6 months. Close monitoring of patients on cyclosporine is very important, and includes monthly blood pressure checks, complete blood counts, lipid profiles, BUN, creatinine, magnesium, and urinalysis. Azathioprine can also be very effective, but produces a slower clinical response. Dosing should be determined based on the patient's level of thiopurine methyl transferase. It is necessary to follow hepatic function tests and complete blood counts monthly. If cyclosporine and azathioprine are either ineffective or too toxic for a given individual, either methotrexate or MM can be given. Methotrexate is dosed weekly at 0.2–0.8 mg/kg/week, while MM is given daily at a dose of 10–30 mg/kg/day. It is important to follow hepatic function and complete blood counts monthly in patients on both of these drugs. Although there is a good evidence for the efficacy of several different types of light therapy in the treatment of atopic dermatitis, the technical difficulties involved in providing it to young children usually puts it far down the therapeutic ladder. Lastly, Interferon gamma and IVIG, although both effective, must be considered treatments of last resort due to their extremely high costs.

Prognosis and Prevention

Approximately 60% of individuals with AD will grow out of it by the early teenage years. Unfortunately, a small percentage of these patients will carry their tendencies toward asthma and food and environmental allergies into adulthood. Prevention can be viewed as either keeping the disease from ever developing or minimizing the level of disease activity once it has developed. Complete prevention has only been reported in a few small trials in the British medical literature that looked at the use of probiotics in pregnant and nursing mothers, and the incidence of AD in their infant children. From the point of view of prevention of active disease, once the diagnosis has been made, ceramide and filaggrin containing moisturizers have been shown in numerous studies to fill this roll.

143 Acne and Related Disorders

Harald P. M. Gollnick

Introduction

Acne is a disease which encompasses a variety of clinical features and variants of which the most known is acne vulgaris. However, different courses exist due to several grades of severity, distribution in body areas, age, gender, and internal and external factors manifesting, exacerbating, or prolonging it. Acne is seen today as a chronic disease which continuously needs medical counseling. Physical and psychological scarring often accompanies the disease, and emotional distress is very commonly seen in all ages with manifestation of acne.

Historical Remarks

In the "Papyrus Eber," a disease named "Aku-t" was mentioned which was characterized by lesions well fitting the clinical picture of acne: boiling, blains, sores, pustules, and inflammation. The famous Greek physicians Hippocrates and Aristoteles saw an association with puberty. The Greeks named the disease "ionthos," the Latins "Varus." The pharao King Tut (135–1337 A.D.) undoubtedly had suffered from severe scarring. Most probably Atius, physician at the court of Justinian in East-Rom, used the term "acne" for the first time. Acne most probably arises from the greek "akme" but have been misspelled. It could also derive from aknesis, a rash which does not itch or from the greek word "akun." Lastly the Greeks took most probably over the term "aku-t" and then the word was introduced and finally came into medical latin language "acne."

Genetics and Epidemiology of Acne

Acne has a familial background, but a clear genetic inheritance has not been described yet. Genes encoding for cytochrome P450-1A1 and steroid-21-hydroxylase as well as 11- or 3-HSD may be involved. Environmental factors also appear to be of relevance. Especially, diet has recently gained attention. Populations with a balanced lifestyle seem not to develop significant acne and recent epidemiologic and investigative studies correlate acne with Western diets. The course of the disease in homozygotic twins is very similar, the sebum excretion rate is the same in more than 90%, whereas in heterozygotic ones it drops down to 40% and the severity is different. It has clearly been shown that seborrheic and acne patients have more lobules per single gland in the sebaceous apparatus than people with normal skin, which indicates a genetically prone situation. Nodulocystic courses of acne are more frequently seen in patients with the XYY genotype.

Acne today is regarded as one of the most frequent skin diseases worldwide in all ethnic groups. Epidemiologic studies in Western industrialized countries estimated the prevalence of acne in adolescents to be between 50% and 95%, depending on the method of lesion counting. In the USA, the prevalence in 15–17-year-old children is around 85%. If mild manifestations were excluded and only moderate or severe manifestations were considered, the frequency was still 20–35%. Acne is a disease primarily of adolescence. It is in parallel emerging in children at the start of puberty by the initiation of androgen production by the adrenal glands and gonads, and it usually subsides after the end of the growth period. Although comedo formation decreases significantly, the hyperseborrhea still exists up to the fourth or fifth life decade. However, to some degree, acne is going to persist beyond teenage in a significant proportion of individuals (*Fig. 143.1*).

There are not only cases with persisting acne, but also those with reoccurrence or with a first manifestation in the third decade of life. Even after the adolescent type of acne has ceased, scarring and hyper- and hypopigmentation are long-term visible postacne features affecting the patients with negative physical outcome needing further medical and cosmetic care. Recent publications show a higher incidence of facial and persisting acne in certain families with an odds ratio of about >4 in the UK and Han Chinese. The course of disease stops more abruptly in males as compared to

Acne epidemiology

females in whom there is today up to 30% persisting acne cases. Interestingly these observations have been already made in a doctoral thesis from Breslau in the early 1900 on female medical students. This means it is not a clear observation in females today, however, it is increasing in number.

Acne is in general considered a disease starting in adolescence; however, acne lesions may already precede the natural signs of puberty and little tiny comedones like milia (acne miliaris) can be seen mostly in children from the seventh to ninth year of life at the sides of the upper nose/glabellar area and lateral cheeks. Rarely, inflammatory lesions are detected. In girls, it may precede the menarche by up to 2.5 years.

A special subtype of acne occurring in early childhood is acne neonatorum during the second and fourth week of life and acne infantum manifesting after the second or third months after birth. Whereas in the first case maternal androgens or intrauterine stress-induced adrenal androgens are responsible, in the second case a temporarily adrenal functional hyperplasia is the cause, which under normal circumstances will fade away after the 9th month of life. Persisting cases, however, are suspicious for adrenal or gonadal androgen–producing tumors or misfunction of 3-, 7-, 11-, or 21-steroidhydroxylases and a pubertas precox.

Prognostic Factors of Disease

A number of prognostic factors have to be considered and are more or less related to the severe courses of the disease. These are outlined and evidenced in a review paper published by Holland and Jeremy (2005) and Dreno et al. and include family history, course of inflammation, persistent or late onset disease, hyperseborrhea, androgenic triggers, scaring, truncal acne, and/or psychological sequelae. Infantile acne may also correlate with resurgence of acne at puberty and one should be aware – even though not clearly proven by statistical evidence that early age of onset with mid-facial comedones, early and more severe seborrhea, and earlier presentation relative to the menarche are connected to the incidence of acne as a baby.

Scarring Assessment/Potential for Scarring Influence on Management

Scarring usually follows deep-seated inflammatory lesions but may also occur as a result of more superficial inflamed lesions in scar-prone patients. Holland and Jeremy published their findings that patients with more severe inflammatory infiltrate in the biopsy have less scarring

than those with a less inflammatory one. If this can be used as a predictor is not clear yet. Ethnic predisposition plays, in addition, an important fact having more scarring in black and Indian skin. More recent results by S. Kang point toward the fact that scars may even arise from skin areas not having involved by a visible lesion at all. This implies that treatment has to be done as early and as sufficient as possible.

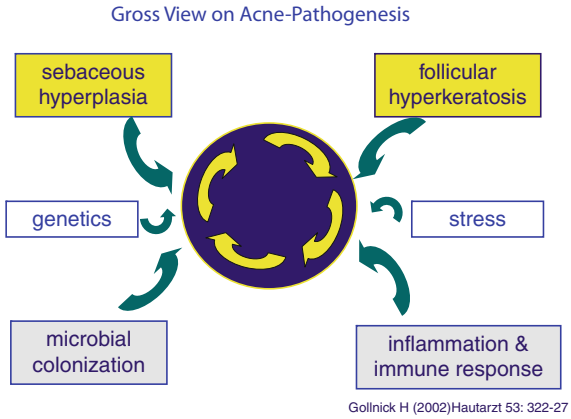
Acne scarring of different types, albeit mild, has been identified in up to 90% of patients attending a dermatology setting. Scars may show increased collagen (hypertrophic and keloid scars) or be associated with collagen loss (ice-pick, boxcar and rolling type of scars). The presence of scarring should support immediate onset of an interventional aggressive management and therapy should be considered as early as possible in the disease process. In the postacne situation, patients suffer long-standing sequelae and ask for additional support by peelings and lasers as well as psychological help.

Pathophysiology

Acne is an androgen-dependent and androgen-driven disorder of the pilosebaceous apparatus. At the beginning of its manifestation, the first nonvisible lesion is the microcomedo in which the colonization with *P. acnes* does not play any role, but sebaceous hyperplasia and increased pathologic cohesion of follicular corneocytes have led to the microscopic changes of the follicular milieu.

Today, four primary pathogenic factors are accepted in different grades of expression and at different time points involved or intermingled in the pathogenesis of acne. These are as follows: (1) increased sebum production by the sebaceous gland, (2) hyperproliferation and disturbed keratinization with increased cohesion of corneocytes in the follicular canal, (3) colonization with Propionibacterium acnes in the lower part of the infundibulum, and (4) release of several inflammatory mediators involved in innate and acquired immunity (◉ *Fig. 143.2*).

Patients with seborrhea and acne have a significantly higher number of lobules per gland as compared to normal healthy persons who never developed acne or seborrhea (so called genetically prone "Anlage"). This means that the androgenic event in puberty acts on a different Anlage. Inflammatory responses occur prior to hyperproliferation of keratinocytes. IL-1α upregulation participates in the development of comedones independent of the colonization with *P. acnes.* A relative linoleic acid



◘ Figure 143.2
Gross view on acne pathogenesis

deficiency has been described by Downing and Strauss, but this can only be a contributing factor because the deficit appearing in the lobules of the gland and consequently in the follicular corneocytes with less barrier function (ceramides) persists despite resolution of comedones in the third life decade when acne resolves but seborrhoea persists (◉ *Fig. 143.3*).

Cycling of the sebaceous follicle is an important part in the cascade of mechanisms interacting in the pathophysiology, leading to certain time points when the microcomedo formation becomes disposed to form a sensitive moment for an injury as a starting point of new lesions.

P. acnes colonizes the skin right after birth and an immune response with IgM and IgG follows. It seems that *P. acnes* at this time point is of a planctonic type, whereas later in puberty it becomes pathologic and starts biofilm production and increases its virulence. Acting on the inflammatory cascade of NF kappa and the proinflammatory cytokines via Toll-like receptor 2 it contributes to a continuous self-perpetuating vicious cycle. Activation of AP-1 induces matrix metalloproteinase genes, whose products degrade and alter the dermal matrix.

However, it should be noticed that inflamed follicles exist showing no *P. acnes* colonization at all. Oxidized squalene (squalene peroxide) can stimulate hyperproliferation in keratinocytes and those lipoperoxides can produce leukotriene B4, a powerful chemoattractant.

The role of free fatty acids formed after the splitting of triglycerides into FFAs and diglycerols has been long overestimated but still contributes to the different factors working in concert in the follicular milieu (◉ *Fig. 143.4*).

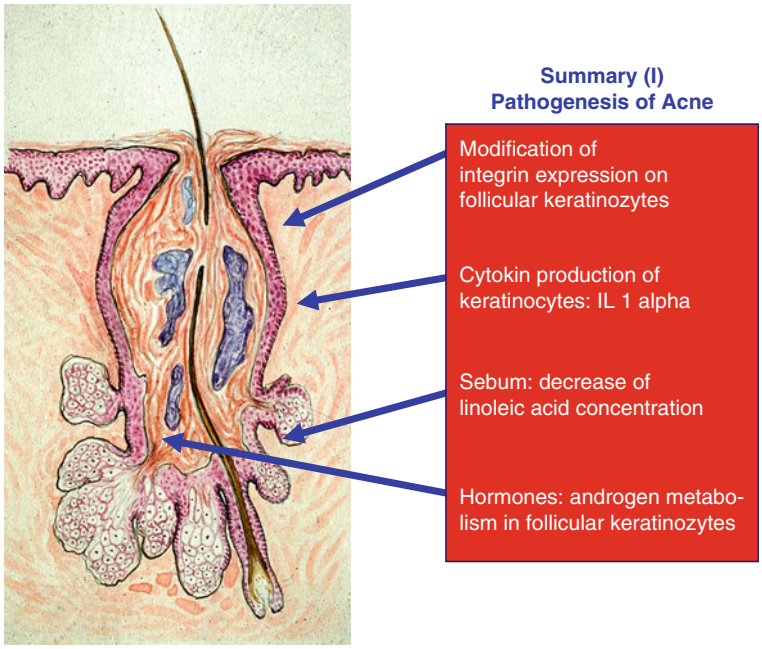


Figure 143.3
Summary of the pathogenesis of disturbed follicular keratinization processes in the follicular infundibulum

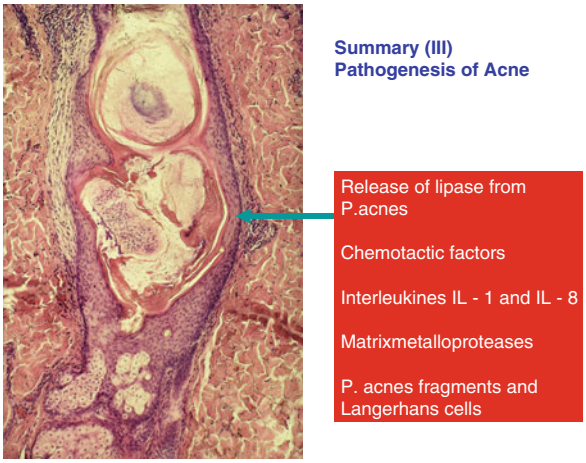

Figure 143.4
Summary of pathogenetic processes in the infundibulum related to P.acnes

Sebaceous lipids are regulated by peroxisome proliferator-activated receptors gamma and alpha (PPAR's) which act in concert with retinoid X receptors to regulate epidermal growth and differentiation as well as lipid metabolism. Sterol response element binding proteins (SREBP) mediate the increase in sebaceous lipid formation induced by insulin-like growth factor-1 via the PIK-3 or/and Akt-pathways. Substance P receptors, neuropeptidases, α-melanocyte stimulating hormone, IGF-1R, and CRH-R1 are also involved in regulating sebocyte activity, and finally the ectopeptidases such as dipeptidylpeptidase IV and animopeptidase N, which are distributed on activated keratinocytes, sebocytes, and T-cells in the inflammatory infiltrate. The sebaceous gland acts on the whole as an endocrine organ in response to changes in androgens and hormones (*Figs. 143.5* and *143.6*).

The role of FoxO1 and the relation of nuclear to cytoplasmic shifting with stimulation of the PPAR gamma and of the androgen receptor are not yet fully discovered; however, a connection to the IGF and insulin-related stimulation of this cascade is a further evidence for research (*Fig. 143.7*).

The improved understanding of acne development on a molecular level suggests that acne is a disease that involves the innate and adaptive immune system and inflammatory events as well as the local and systemic hormonal network. The "Switch-Off Signal" of acne, however, is not understood yet (*Fig. 143.8*).

Detailed scheme on acne pathogenesis

Clinical Features and Variants

Vulgar acne, synonymous with "acne vulgaris," is a polymorphic, in the very beginning noninflammatory but then characteristically inflammatory skin disease most commonly affecting the face (in 99% of cases) and to a lesser extent the back (60%) and chest (15%). Seborrhea is a hallmark of acne.

The clinical picture embraces a spectrum of signs, ranging from mild comedonal acne, with or without sparse inflammatory lesions, to aggressive fulminate disease with deep-seated inflammation, nodules, and in some cases associated systemic upset. In addition, certain clinical subtypes provoked by internal and/or external factors exist (◉ *Fig. 143.9*).

Comedonal Acne

Clinically, noninflamed lesions develop from the subclinical microcomedo which is evident on histological examination early in acne development. At very early stage of puberty, the comedones are very small and monomorphic, white miliaria like, closely located at the sides of the cheeks at the nose and the outer cheek near the maxilla-orbital area and forehead near the hair margin. Noninflamed lesions encompass both open (blackheads) and closed (whiteheads) comedones which increase in size over the years. These comedones frequently appear in a mid-facial glabellar distribution in childhood and when evident early in the course of the disease; this pattern is probably indicative of poor prognosis. Closed comedones are often inconspicuous with no visible follicular opening and become more visible when stretching the skin or may be prominent producing a sandpaper-like pattern (◉ *Figs. 143.4*, ◉ *143.10*, ◉ *143.11*).

Papulo-Pustular Acne

Most patients with acne vulgaris (A.pap.pustulosa I–III according to Plewig and Kligman) have a mixture of noninflammatory and inflammatory lesions. Inflammatory lesions arise from the invisible microcomedo or noninflammatory lesions and may be superficial or deep in nature. Superficial inflammatory lesions include papules and pustules (5 mm or less in diameter) and these may evolve into deep pustules or nodules in more severe disease. Lesions with a size of 0.5–1 cm are small nodules and characterize the subtype of Acne pap.-pust.nodosa often in the course of the disease developing in addition nodes >1cm. Inflammatory macules represent either initial precursor lesions existing for a short time or regressing lesions that may persist for many weeks and contribute markedly to the general inflammatory erythematous pattern of acne. Scarring may even develop from macules (◉ *Figs. 143.12–143.15*).

Conglobate Acne

Small nodules are defined as firm, inflamed lesions >5 mm in diameter, painful already by palpation; large nodules are >1 cm in size and may extend to the subcutaneous tissue and confluate over large areas, frequently resulting in painful and exudative sinus tracts and tissue destruction. Conglobate acne (*A. conglobata*) is a rare but severe special form of acne found most commonly in adult males with no or little systemic involvement. Lesions

Figure 143.15
Acne papulo-pustulosa nodosa (grade IV accord.Plewig & Kligman)

usually occur on the trunk and upper limbs and frequently extend to the buttocks. In contrast to classic acne, facial lesions are less common or may be missing and only back or chest are involved, however, poor nodular pattern of the face without trunc involvement exists, however, severe only in the face localized cases with sinuses at the cheeks can be observed. The condition often presents in the second to third decade and may persist even into the sixth decade of life. Conglobate acne is characterized by multiple, grouped comedones amid inflammatory papules, tender, suppurative nodules which commonly coalesce to form sinus tracts or a network of rabbit-warren like small undermining fistules.

Extensive and disfiguring scarring of the hypertrophic and keloid type as well as icepick scars, boxcar scars and rolling scars in the face are frequent postacne sequelae (*Fig. 143.16*).

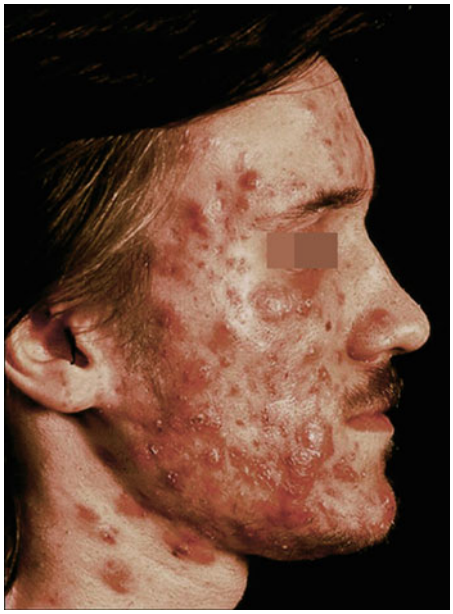

Figure 143.16
Conglobate acne of the face

Other Acne Variants

There are several mild to moderate to severe and clinical different variants or complications of the course of acne. These include acne conglobata as described earlier, but in particular acne fulminans, gram-negative folliculitis, pyoderma fulminans, vasculitic/pyoderma gangrenosum, acne mechanica, oil/tar acne, chloracne, acne in neonates and infants and late onset, adrenogenital syndromes, including HAIR-AN syndrome, Sapho-syndrome, and other rare syndromal manifestations, persistent acne sometimes associated to underlying inborn or iatrogenic-induced endocrinopathies as well as occupational derived provocations.

Therapy

General Remarks

Therapy in acne has changed over the last two decades significantly because new drugs and new formulations have become available. In general, there is a differentiation in acute intervention treatment and maintenance treatment with topical and systemic agents and a combination of both. In addition, adjunctive treatment procedures are available such as lasers and light and chemical peelings as well as cosmeceuticals for postacne or concomitant treatment. More and more guidelines and consensus papers with evidenced-based medicine-related studies support therapeutic decisions today. Acne treatment is long term. Not more than 50% improvement in a moderate acne under oral tetracycline plus topical benzoylperoxide can be achieved in 3 months, for milder cases earlier and for more severe cases even longer. Because of the relapsing character of acne as a chronic disease over 5–10 years, continuous medical counseling and prescriptions and additional adjunctive including psychologic counseling procedures are necessary (*Fig. 143.17*).

Topical Treatment

Topical treatment is based on three out of the four main pathophysiologic factors in acne which are normalization of the disturbed keratinization in the follicular apparatus, the reduction of hypercolonization of *P. acnes*, and anti-inflammatory actions. Until now, no effective drug is available which influences by the topical route the activity of gland hyperplasia with consecutive reduction of hyperseborrhea. Lasers and photodynamic therapy unfortunately reduce seborrhea by complete or partly irreversible damage to the gland followed by subclinical microscarring.

Three main classes of topical substances are on the market worldwide: the different generations of retinoids, benzoyl-peroxide (BPO), azelaic acid (AzA), and antibiotics. Retinoids and BPO function as so-called basic topical agents. Peeling substances are not well evidenced yet based on the interventional phase of treatment.

Retinoids

Within the classes of retinoids, the oldest (first reported in 1962) still in use is tretinoin (all-trans retinoic acid); later isotretinoin (13-cis retinoic acid) came on the market followed by tazarotene and adapalene.

All of them have very good efficacy in normalizing of the disturbed keratinization in the follicular canal by being comedolytic and anticomedogenic. The increased cohesion of corneocytes, filaggrin macroaggregates, tonofilaments, and lipid droplets is reduced. Upregulated and downregulated genes are directly influenced by the retinoids. In addition, there is evidence of an additional anti-inflammatory efficacy of adapalene and tretinoin in

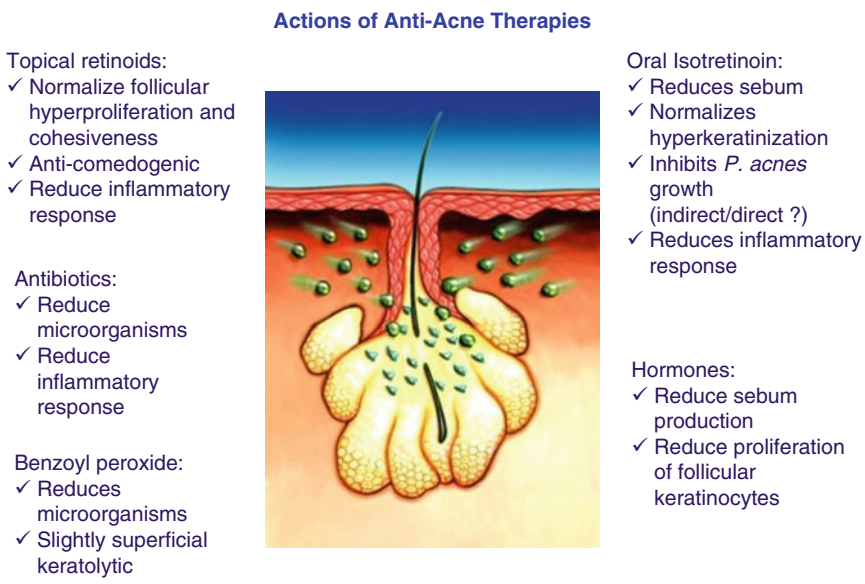

Figure 143.17
Overview of therapeutic armamentarium in acne

downregulating the activity of Toll-like receptor 2 (TLR-2) stimulated by *P. acnes* which finally leads to the activation of proinflammatory cytokines such as IL-6, IL-8, or TNFalpha. Adapalene is, in addition, capable of species-specific inhibition in humans certain lipoxygenases. The additional positive influence on postinflammatory hyperpigmentation and on the collagen matrix in the upper dermis is well known.

All retinoids significantly reduce the number of open and closed comedones and microcomedones as well. After 3 months of treatment, more than 50% of comedones are reduced. There are several types of formulations on the market which vary from country to country but are mostly gels and creams or solutions. All retinoids available are effective as single agents in mild to moderate acne. Tazarotene 0.1% is more effective than tretinoin 0.025% or the more modern galenic formulation 0.1% microsphere gel or adapalene 0.1% gel or cream (EBM level 2c). Adapalene 0.1% is equally effective as the above-mentioned tretinoin gel concentration or tretinoin 0.05% cream or isotretinoin 0.05% (EBM level 2c).

Retinoids are recommended as a monotherapy in comedonal acne and mild acne papulo-pustulosa. Grade II and III of papular-pustular acne according to the Plewig and Kligmans classification should be treated in sequential or fixed combinations with BPO or with topical antibiotics. In those combinations, in addition to the retinoid effects, a reduction of *P. acnes* is markedly achieved. There is one fixed combination of adapalene and BPO 2.5% on the market available now, the first combination of a retinoid with BPO that is pharmacologically compatible. Alternatively, one can use a topical antibiotic or BPO in the morning, followed by the application of the retinoid in the evening.

In severe forms of acne, retinoids are ideal partners in combination with oral antibiotics or in young females already under prescription for an antiandrogenic hormonal pill.

The irritative potential is the mildest with adapalene, followed by isotretinoin and tretinoin and tazarotene, respectively. One can mostly see an initial flare-up of lesions for a couple of days, in particular with tretinoin and tazarotene; erythema, desquamation, and dryness are common to all generations of retinoids. All adverse events fade away over the duration of treatment. In dry atmospheres in the house or in hot temperatures, a moisturizer should be applied in addition. Adapalene has nearly no phototoxicity compared to tretinoin or tazarotene which is important for treating patients in sunny countries. In young females of childbearing age and who wish to become pregnant, a retinoid should not be chosen because of the risk of teratogenicity (*Fig. 143.18*).

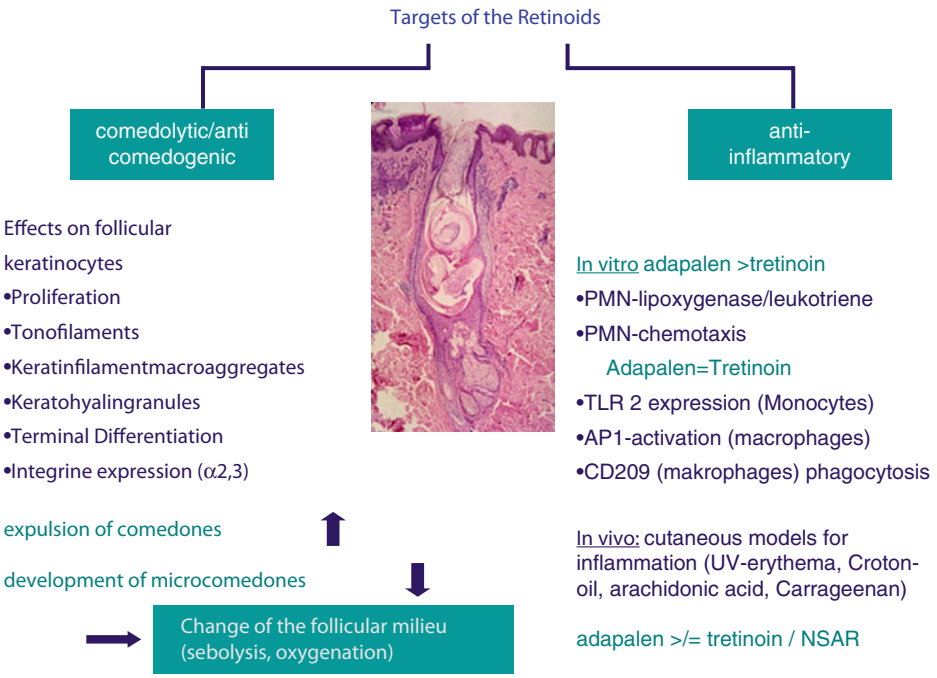

Figure 143.18
Targets for the actions of topical retinoids

Benzoyl-Peroxide

Benzoyl-peroxide is one of the oldest but very effective topical acne drugs introduced already in 1934. It is available in concentrations between 1% and 10% for acne treatment. Controlled studies revealed that a dose of 2.5% is enough for topical treatment in the face. For back and chest, a 5% concentration with more irritation can be applied, which is here better tolerated than in the face. One can use gels, lotions, or washes, the last also as a short contact therapy. As a monotherapy, BPO can be used in mild inflammatory acne, in moderate acne combinations with adapalene in a fixed form, or in sequential applications together with topical antibiotics or retinoids, as has been well documented and evidenced.

The efficacy of BPO is based on its strong antimicrobial potency which is achieved within 2 weeks by reducing *P. acnes* on two log scales from skin samples and in in vitro cultures. It does not allow the development of any resistance of *P. acnes* or staphylococci on the skin. Benzoyl-peroxide is the gold standard of antimicrobial acne treatment. It has only a slight anticomedolytic action by desquamating the upper corneocyte layers at the orifice of the follicular channel, but it is not anticomedogenic.

Depending on the concentration and galenic formulation, one can see a dose-dependent dryness and desquamation of the skin accompanied by burning and redness, which the patient will adapt to over time. Moisturizers will reduce adverse events. Bleaching of hair and clothes can occur and contact sensitization in acne is rare. Benzoyl-peroxide can be used during pregnancy.

In moderate forms in which internal drugs are not applied, as a first step, the combination with adapalene or other retinoids is to be preferred (see above), or the combination in either fixed ones or sequential ones with antibiotics (either erythromycin or clindamycin). Resistances toward topical antibiotics are reduced by these combinations.

For severe forms of acne, BPO can easily be combined with oral antibiotics which lead to an additional antimicrobial effect and a faster onset of therapeutic success. Resistant bacterial strains on the skin under oral antibiotics are reduced. The efficacy of the combination is enhanced and the treatment goal achieved faster.

Antibiotics

Currently, there are two antibiotics which are used most for the topical route: erythromycin and clindamycin. Tetracycline should not be used anymore on the topical way because of high bacterial resistances and phototoxicity. Nadifloxacin is chemically synthesized and belongs to the group of quinolones acting against gram-positive bacteria and gram-negative bacteria. Its use is critically seen because of the possibility of inducing quinolone-resistant staphylococci strains with consequences for negative systemic treatment outcomes.

Both antibiotics erythromycin and clindamycin are macrolides and act via bacteriostatic mechanisms using ribosomal protein synthesis inhibition.

Erythromycin and clindamycin are indicated for the mild papular-pustular acne; however, recent evidence-based guidelines do not recommend these agents as monotherapy but in combination with retinoids, BPO, or AzA. Fixed combinations are available on the market or a sequential use in the morning and the combination partner in the evening. The efficacy is significantly enhanced with reduction of the time course of treatment. A combination with oral antibiotics is obsolete and they should also not be used in comedonal acne. The efficacy of topical erythromycin and clindamycin monotherapy in mild inflammatory acne is evidence based on level 2b.

The local side-effect profile of topical antibiotics is different; on one side, they have a low irritative potential, on the other, they induce resistance in the skin bacterial populations and may even be resorbed and have systemic adverse events. Clindamycin in pregnancy should not be used because of rarely reported colitis events.

Azelaic Acid

Azelaic acid has been available since the beginning of 1980. It is a dicarbonic acid that occurs physiologically in the body. It reduces comedones by repairing the corneocyte dysfunction in the follicle, reducing the increased keratohyalin macroaggregates, and acts by reducing protein synthesis in the pathological proliferating cell. It has an antibacterial effect in reducing the *P. acnes* amount in vitro by one log step. In addition, it is an ROS scavenger and reduces the hyperreactivity of neutrophils. Recent evidence indicates a reduction of certain proinflammatory cytokines. It also restores the postinflammatory hyperpigmentation, similar to retinoids.

AzA is available in creams and gel or lotion in 20% and 15% formulations. It is indicated in comedonal acne and in inflammatory mild acne as a monotherapy. Evidenced studies show a 2b level of similar efficacy when the drug was compared to clindamycin, BPO, or tretinoin. In moderate acne it should be combined with topical antibiotics and retinoids or BPO. It can be well combined with oral

tetracyclines or with oral antiandrogenic drugs. In conglobate acne, a controlled study of minocycline and AzA with oral isotretinoin showed a similar efficacy, however, the long-term outcome was better with isotretinoin. When AzA was used as a maintenance topical treatment, it prevented the relapse to some extent.

The adverse drug profile shows, in particular, a stinging and burning or itching sensation at the beginning of treatment which persists for 10–20 min after application and generally fades within 1–2 weeks. It induces no bacterial resistances and can be used during pregnancy.

Other Topical Treatments

Local abrasives have additional value in comedonal acne, in particular to open the closed comedones to allow topical drugs to better penetrate and to desquamate the comedonal plug.

Topical dapsone is released on the market in the US, however, the efficacy is of minor value compared to other topicals mentioned before.

A large pile of topicals exist from the medico-comeceutical site, but good controlled studies are missing. Except the preparation of retynal ester and glycolic ester or niacinamide and salicylic acid for milder forms of acne and maintenance treatment.

There exist depending on regional availabilities a certain amount of topical formulations which are not proven for any evidence based use.

Systemic Treatment

Oral Antibiotics

Oral antibiotics mostly used in acne are doxycycline, lymecycline, and minocycline. Oral tetracycline hydrochloride is less used today. Other systemic antibiotics such as clindamycin or erythromycin are reserved for special situations. Quinolones, cotrimoxazole, and azithromycin are not well evidence based and should be used only with care and if specific resistances arise or mixed bacterial colonizations are detected on the skin (*Fig. 143.19*).

Tetracyclines, macrolides, and clindamycin inhibit the protein synthesis of bacteria in different ways; cotrimoxazole influences folate metabolism. The number of *P. acnes* is significantly reduced in a short time of 10–14 days.

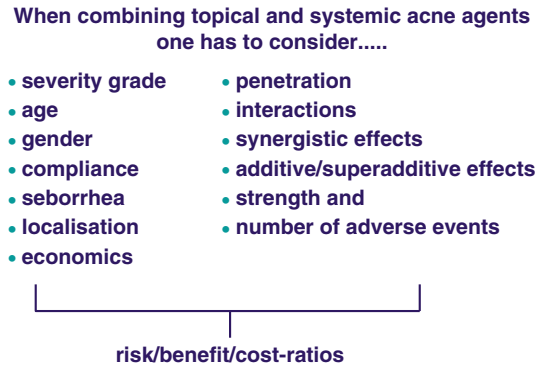

Figure 143.19
Considerations before selecting combination treatments

Today the focus is on the para-antibiotic mechanisms of actions of tetracycline, doxycycline, and minocycline. The inhibition of free fatty acids from the bacterial lipase of *P. acnes* is markedly reduced independent of killing *P. acnes*. In addition, increasing knowledge is being gained over the years in the dose-dependent and direct inhibition of lymphocyte mitosis, inhibition of chemotaxis which reduces pustular formation, and reduced phagocytosis. In particular, the reduced release of proinflammatory cytokines such as IL-1, IL-6, IL8-, and TNF alpha and increase of the anti-inflammatory IL-10 can be measured in vitro and in vivo as well. Furthermore the ROS release is significantly reduced.

Inflammatory moderate acne not responding to topical treatment and severe acne are good examples for evidence-based therapy for oral antibiotics.

A systematic review of all clinical studies between 1962 and 2008 with systemic tetracyclines confirms that no evidence of significant difference exists in terms of efficacy. A clear difference between dose and efficacy could not be figured out. In a double-blind randomized trial with minocycline and combination with and without tazarotene over 3 months and follow-up after another 3 months with oral placebo, minocycline, and tazarotene, a further increase of efficacy could not be found. Therefore, a 3-month oral antibiotic seems to be the appropriate length of application time.

Tetracyclines are usually given in a dosage of 2 × 250 mg/day, doxycycline 100 mg/day, and minocycline 100 mg/day. However, due to the changing view of the use of oral antibiotics as anti-inflammatory drugs, one is trying to apply lower doses. A slow-release minocycline formulation is going to be marketed for acne soon, and a doxycycline retarded formulation is already available on the market for rosacea.

Oral antibiotics can be combined preferentially on the topical route with retinoids and BPO and AzA as well. It significantly increases the efficacy and reduces the time to response >50% of inflammation and reduction of >50% total lesion count.

For the oral route, antibiotics can be combined with oral antiandrogens. In a comparative trial, the relapse rate was higher in the monotherapy arm with antibiotic alone.

The adverse drug profile of oral antibiotics is quite large and of different importance. Resistances of *P. acnes* occur with erythromycin and clindamycin, cross-resistances may come up, and transfer of resistances to other contact persons is possible. Concomitant use of topical BPO is preferable. Increased upper-respiratory infections have been reported.

Main contraindications are liver dysfunctions, hypersensitivity reactions, and renal insufficiency. These reactions are seen in adolescents less often than in patients with late type acne.

Gastrointestinal complaints, diarrhea, and candidiasis are mostly to be seen with tetracyclines. Minocycline can produce hyperpigmentations. Phototoxicity is dose dependent but less often observed with minocycline and doxycycline compared to oxytetracycline. All tetracyclines have the potency of increasing brain pressure.

Hypersensitivity syndrome with LE-like pattern and other autoimmune patterns have been, in particular, reported for minocycline. DRESS syndrome, even in children, exists as single reports with doxycycline and minocycline. Tetracyclines are not indicated in children before the end of dentation because of discoloration of teeth (Fig. 143.20).

Oral Isotretinoin

Oral isotretinoin was first reported as effective in 1971. Because of its teratogenicity it was not followed up longer by Stüttgen, but was then reported to be the most effective drug in conglobate acne by Peck in 1979.

Isotretinoin is the most potent antiacne drug available in particular for the most severe forms.

Isotretinoin is 13-cis retinoic acid, a naturally occurring product in the vitamin A metabolism. It is a monoaromatic retinoid which is chemically modified at the polar end group and the polyene side chain of the original vitamin A. It is related to the all-trans retinoic acid (tretinoin) to which it is under certain conditions converted.

Isotretinoin has multiple mechanisms of action, which are the suppression of the sebaceous gland hyperactivity by increased differentiation and reduced hyperproliferation of sebocytes, normalization of the disturbed keratinization, reduction of the inflammation at the humoral and cellular level, and indirect reduction of the amount of *P. acnes* in the follicle because of a change of the growth condition for the bacterium. In addition, matrix tissue metalloproteinases are normalized. Recent evidence from the lab shows that isotretinoin increases the skin surface levels of neutrophil gelatinase-associated lipocalin important in killing *P. acnes* and defense mechanisms as well as sebocyte apoptosis important in the action of this drug. Recently, a possible antiandrogenic action was discovered. It obviously inhibits the 3-alpha hydroxysteroid oxidation by retinol dehydrogenase which finally leads to reduced amounts of dihydrotestosterone and androstenedione. Both are involved in the activity of the sebocyte function

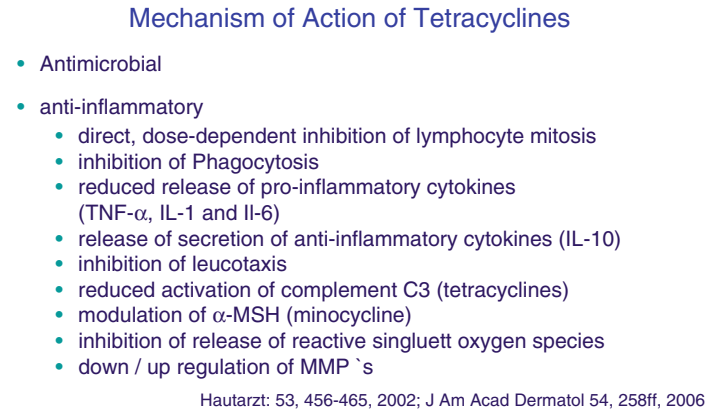

Figure 143.20
Mechanisms of actions of oral tetracyclines – the para-antibiotic anti-inflammatory efficacy

and therefore their reduction leads to a sebosuppressive effect (◉ *Figs. 143.4*, ◉ *143.6*, ◉ *143.7*, ◉ *143.9*, ◉ *143.17*).

Whereas in the past isotretinoin was the drug of first choice in severe recalcitrant nodular and conglobate acne, it was re-ranked by the FDA and the EMEA because of its adverse drug profile, in particular teratogenicity. This means that in those subtypes of acne, first a treatment with oral antibiotics combined with topical basic agents has to be given over 3 months; if this treatment approach is not successful it can be switched to oral isotretinoin. It should also not be given anymore to children under 12 years. The monitoring profile and time schedule of laboratory parameters have been intensified (◉ *Fig. 143.18*).

Isotretinoin is available in 10, 20, and 40-mg capsules. Several generic formulations are available on the market after Roche Comp. has discontinued the production of the original brand Roaccutane/Accutane. However, there is evidence from pharmacological reports that not all of them are of the same efficacy because of minor bioavailability. Eleven out of thirteen generics failed in several tests.

Today the range of doses given is 0.1–1.0 mg/kg bw/day. Usually one starts with 0.5 mg/kg, i.e., 20–40 mg/day, which can be increased to 40–80 mg/day according to the efficacy and side-effect profile, if necessary. There is evidence that a higher dose at the beginning and a cumulative dose of around 120 mg/kg given over a total of 12 months continuously have a lower relapse rate. Relapse rates in general are between 20% and 30% depending on the severity and the age of the patients. Patients respond without tachyphylaxia to a second course of the drug.

Isotretinoin compared to oral antibiotics is more cost effective having less long-term courses of the disease and less relapses.

The adverse drug profile is quite large and consists of mucocutaneous, systemic, and laboratory ones.

Dose-dependent cheilitis, xerosis, and skin fragility and dry nose are the most common skin symptoms. Systemically, myalgias, arthralgias, and headache are frequent and bone toxicity after long-term treatment is a complication; increased triglycerides and cholesterol are less common in adolescents but need to be monitored. The reader is referred to the special references and local regulations in his country.

The most important adverse effect is teratogenicity with craniofacial, cardiovascular, and CNS defects. Strong anticonceptive measurements (double method) and a clear indication in girls >12 years are demanded. Continuous negative pregnancy tests 1 month before treatment, monthly under treatment, and one menstrual cycle after cessation of the drug are necessary. Blood donation is prohibited during treatment and 1 year after.

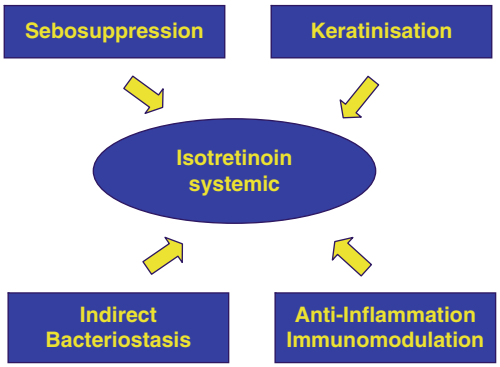

Figure 143.21
Effects of oral isotretinoin in acne

Psychiatric adverse events are critically evaluated over the last 10 years. Any psychiatric disorder, depression, or suicidal ideation is a strong contraindication for isotretinoin prescription. Two large retrospective cohort studies showed that the incidence of an increased risk of depressive mood or suicide attempts is not different in patients under isotretinoin compared to a group with the same severity grade of the disease under oral antibiotics (◉ *Fig. 143.21*).

Hormonal Antiandrogen Therapy

Antiandrogenic hormonal treatment was introduced in the early 1980s when cyproterone acetate and later chlormadinon acetate became available in combination with ethinylestradiol. These hormonal treatments are anticonceptive but in particular dedicated to the treatment of acne and seborrhea.

Acne often starts with adrenarche and the increased amount of circulating adrenal androgens producing hyperseborrhea from the sebaceous gland. Later, the effects from the ovaries and testes follow. Antiandrogenic therapy follows a reduction of circulating free testosterone. A classification of the mechanisms can be made as follows: blockade of the androgen receptor, suppression of ovarian-derived androgens, action on the hypophysis, suppression of the adrenal activity, and finally inhibition of the peripheral androgen metabolism.

The gestagens cyproterone acetate and chlormadinon acetate bind to the progesterone receptor and block the androgen receptor. Gonadotropin secretion is reduced

and consequently the production of androgens from the adrenals and the ovaries. Sexual hormone binding globulin is more available and free circulating testosterone is bound. Another antihormonal pill contains dienogest.

Drospirenone, a derivative of 17-alpha spironolactone, is antiandrogenic, and reduces antimineralocorticoidal efficacy in addition to causing premenstrual perifollicular edema.

Antiandrogenic treatment is foreseen for female patients only. It is indicated in young adolescents with sign of peripheral hyperandrogenism with and without hyperandrogenemia, early signs of the SAHA syndrome (seborrhea, acne, hirsutism, and alopecia), and in females with persisting acne as well as in females with acne and who wish for a hormonal anticonceptive.

Comparing these hormonal treatments the significant efficacy of cyproterone acetate and drospirenone are equivalent. Dienogest and chlormadinon acetate–containing pills are only slightly less effective. Different drugs are available in different countries and therefore all products cannot be mentioned here. Significant treatment effects can be seen on the comedo counts after 6 months, on the seborrhea after 6–9 months, and on hirsutism signs after a year. Monotherapy with antihormonal pills is not recommended. In general, depending on the type of acne, they have to be combined with topical drugs or oral antibiotics or isotretinoin.

Absolute and relative contraindications are, in particular, thrombophilia, chronic venous insufficiency, immobilization, severe obesity, migraine, and liver diseases; however, the individual risk and all other contraindications have to be evaluated with the first prescription by endocrinologic gynecologists.

Other Systemic Treatments

In children with acne and in adults, the use of diaminodisulphone (dapsone) does not have a very good evidence base. It can in certain situations be used as an adjunctive drug.

For oral zinc gluconate, some evidence exists. The use of flutamide is not recommended.

Maintenance Treatment

Acne is a chronic disease and therefore during the course of the disease over more than 5–10 years, long-term treatment is necessary (*Fig. 143.22*). In the center of relapse stands, the microcomedo from which either noninflammatory comedones or inflammatory papules and pustules develop. More than three evidence-based trials (level 2b) have been published in different types of acne in the last 5 years showing that after the interventional treatment phase using an additional course with

Acne as a chronic disease – comparison to atopic dermatitis

monotherapy of a retinoid (adapalene), a relapse could be prevented and even the outcome further improved. This has also been shown in one trial with tazarotene (*Fig. 143.23*).

Adjunctive Treatments

UV light should not be used for the treatment of acne, neither UVA which is comedogenic nor UVB which only produces a camouflage and, on the other hand, contributes to the lifelong cumulative dose of UV.

Visible light, in particular in the blue range (415 nm), can destroy *P. acnes* by activating porphyrins from the bacterium and production of ROS with consecutive destruction of the microbe. A comparative trial with BPO showed similar efficacy (EBM level 2b). Usually three to four applications per week are necessary and after 10 applications the treatment is successful.

Photodynamic therapy with visible light in the range of 550–770 nm plus topical 5-aminolevulinic ester showed, in a placebo-controlled study in mild to moderate acne, a significant improvement (EBM level 2b) and concomitant reduction of seborrhea and of *P. acnes*. Local pain during and shortly after irradiation followed by crusting and some pigmentation are the typical adverse events. It should be mentioned that significant destruction to the gland may harm the patient because the sebaceous gland today is seen as a small endocrinological adjacent organ of the skin which plays a role in the skin homeostasis.

Lasers are increasingly used in active acne with more or less good results depending on the type of laser. Mostly the trials are not well controlled and concomitant treatment is allowed or a conservative treatment arm is missing.

In mild comedonal acne, abrasives with aluminum particles can be used or manual comedo peeling by an experienced cosmetician can be done.

Chemical peeling as an intervention treatment is not established yet; however, it can be used in addition to topical treatments, oral antibiotics, or hormonal antiandrogens, but is contraindicated in parallel to oral isotretinoin. Peelings encompass salicylic acid, glycolic acid, and lactic acid.

Additional substances that can be considered in mild types of acne are retinaldehyde, genistein, and niacinamide.

Scarring

Acne scarring is the most prominent and unwanted outcome of acne. It starts in late puberty and progresses to late-type acne when acne does not cease naturally. It is quite common and because of its different types of scars and distribution it is difficult to treat. Acne scar types are

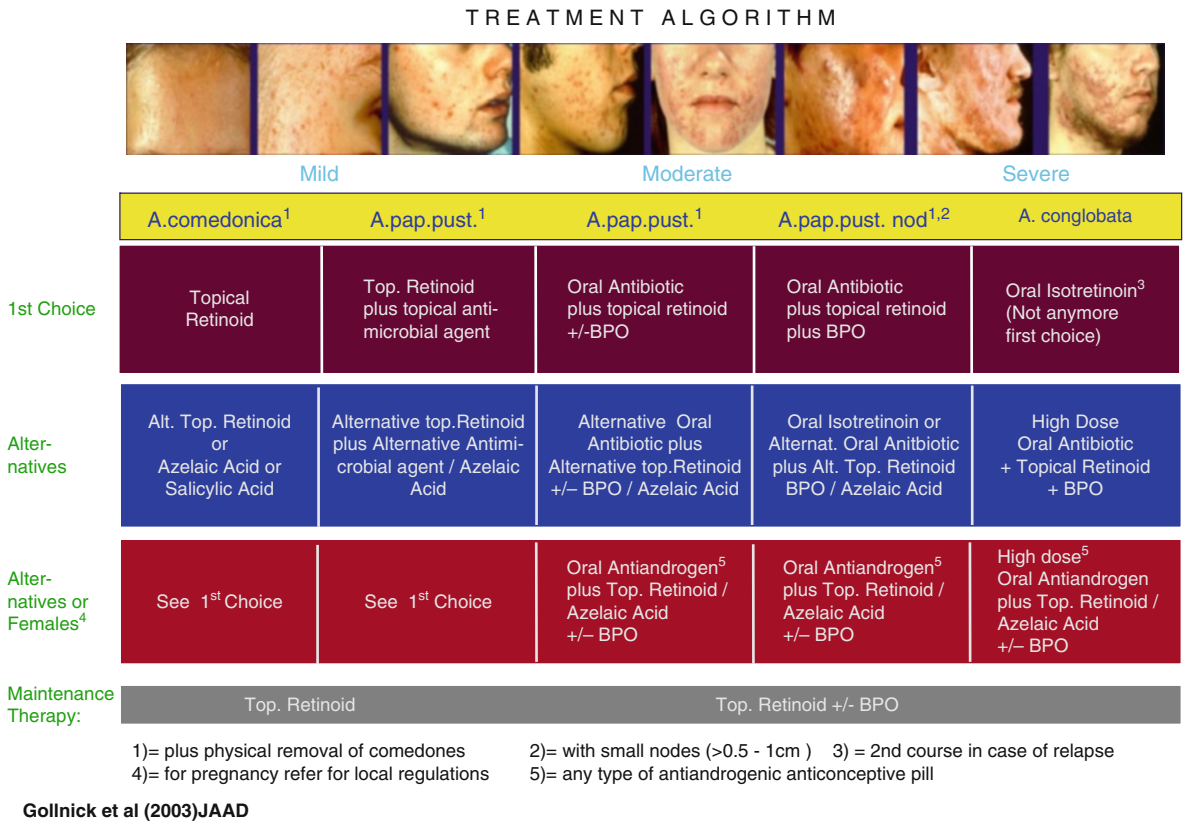

Figure 143.24
Acne treatment algorithm of the Global Alliance for Improvement of outcome in acne treatment

the following: hypertrophic and atrophic scars of which the latter consists of three types: icepick, boxcar, and rolling. All scar types can be mixed. Acne scars can be scored according to the ECCA (echelle d'evaluation clinique des cicatrices d'acne). In general, electrodesiccation, dermabrasion, punch elevation, small excisions or minitransplants, ablative and nonablative lasers, chemical peeling (CROSS technique), and dermafillers are used successfully in the hands of experienced dermatologists. Fractional lasers and microneedling are used in addition (*Fig. 143.24*).

Related Disorders

Hidradenitis Suppurativa

Hidradenitis suppurativa, formerly known as acne inversa, is an acne type of the elderly and therefore will not be discussed here. It is a disease of the terminal hair follicle. The apocrine gland is not the primary focus of the disease. A genetic background is increasingly being discussed. Radical dermatosurgical excisions of the involved areas at the axillas and groins or buttocks are essential. Reduction of smoking and obesity is essential. The use of biologics from the TNF alpha type may initially reduce the inflammatory process in preparation of the following surgery. Isotretinoin is less effective, only very early cases may respond. Acitretin affects positively the keratotic fistulas in the chronic stages.

Rosacea

Rosacea is rare in the second decade of life and a disease of the third and higher decades. However, some cases, in particular with strong family background, can be seen. Those are mostly of the telangiectatic type and have to be evaluated as differential diagnosis to cutaneous and systemic lupus erythematodes and dermatomyositis. Perniones or family related telangiectasia have to be considered.

Gram-negative Folliculitis

Gram-negative folliculitis of the minor or major type is a complication of long-standing oral and/or topical therapy. It is mostly located around the oral and perinasal area. Swabs from the pustules and inner nostrils reveal the pattern of a gram-negative microbial flora. The treatment is difficult and often frustrating. In general, a treatment with topical BPO and AzA alone or combined with oral co-trimoxazole should be used. Oral isotretinoin can be successful. Relapses with all treatments are quite common.

Perioral Dermatitis

Perioral dermatitis was in former times a disease of females in the third decade of life as a result of using excessive moisturizers and thereafter developing pustules around the mouth, which are consecutively treated by topical corticosteroids. Whenever the steroids were stopped a flare-up was observed and again corticosteroids were applied. This mostly led to a vicious cycle. Due to overprotection in skin care of the face with detergents and moisturizers and topical steroids, the disease was also seen around the periorbital area, not only in females but also in males and finally in younger adolescents and even in children in the first decade of life (❯ *Figs. 143.11*, ❯ *143.12*, ❯ *143.22–143.24*).

Most important is to cessation the usage of corticosteroids despite flare-ups. Short oral doxycycline can be used (caveat: not in children before end of dentation) with a local ketoconazole cream in combination with metronidazole (❯ *Figs. 143.10*, ❯ *143.13–143.15*). One crash type therapy is drying by lotio alba and oral doxcycline. Outcome is in general favorable.

144 Contact Dermatitis: Diagnosis and Therapy

Sharon E. Jacob · Elise M. Herro · James S. Taylor

Introduction

The term contact dermatitis refers to a group of exogenous dermatoses commonly affecting both children and adults, with irritant contact dermatitis (ICD) representing the vast majority of cases (~80%) and allergic contact dermatitis (ACD) accounting for the other large proportion (~20%). The current estimate is that ACD may actually account for as much as 20% of all childhood dermatitis. Patch testing is the gold standard for diagnosing ACD and a number of studies have demonstrated that appropriate epicutaneous patch testing improves quality of life measurements by directing the avoidance of inciting allergens.

In the last decade, multiple international tertiary care centers have reported clinically relevant positive patch test (PPT) reactions being identified in a relatively significant number of pediatric patients with prevalence rates ranging from 21% to 77%. These data sets, combined, serve as a useful guide in the selection of allergens used for patch testing, especially given that many of the same allergens appear across the lists globally. For example, Beattie et al. put forth the "allergens with a positive yield," Wöhrl et al. outlined the "allergen hit list," and Jacob et al. described a guide for screening allergens with the highest yield for patch testing children in particular locales.

Contact allergy (rates of positive responses to contact allergens) varies by referral patterns, regional and social variations in allergen exposure, selection criteria for patch testing, and the allergens tested. It is important to recognize the diagnostic clues, signs and symptoms which alert clinicians to the presence of ACD, especially in children where "eczema" and atopic dermatitis abound.

Pathophysiology

Contact dermatitis is a general term that encompasses adverse cutaneous reactions resulting from contact of the surface of the skin or mucous membrane with an exogenous agent. The type of reactions fall into several categories, namely ICD, ACD, as well as the less common IgE-mediated contact urticaria (CU).

Irritant Contact Dermatitis

Irritant contact dermatitis which accounts for approximately 80% of all contact dermatitis cases is a non-immunologic reaction which does not require prior sensitization or previous chemical exposure. The response is caused by contact with chemicals that directly injure the skin cells by abrasion or irritation**.** While damage to epidermal keratinocytes induces inflammation, it does not activate an immune cascade.

Onset of symptoms ranges from a few minutes to 48 h, appearing in any location on the skin or mucosa. The severity of the reaction is significantly affected by the concentration of the irritating substance and the duration of exposure**.** Patient history and clinical presentation are important clues to the diagnosis of ICD. Classically, acute ICD presents as a localized erythema, corresponding to the area of skin that was exposed to the offending agent; however, blistering and erosions may occur with strong or prolonged exposure. In addition, patients are more likely to complain of burning and pain rather than pruritus. Chronic cases can be more difficult to distinguish from ACD, especially when lichenification complicates the clinical and histopathologic picture. A common example of ICD in childhood is *liplicker dermatitis*, a perioral eruption caused by a series of events, such as irritation from cold, dry weather followed by subsequent lip licking to counteract the dryness leads to dermatitis, a secondary reaction from exposure to drying saliva.

Allergic Contact Dermatitis

It is important to differentiate sensitization (the ability to elicit a PPT, a contact allergy, in an asymptomatic person) from the clinical state of ACD, in which a sensitized person demonstrates a clinical dermatitis related to allergen exposure. Sensitization can occur very early in life. Bruckner et al.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_144,

tested a group of asymptomatic patients and found that 45% of those with PPT reactions were younger than 18 months. The top five allergens were nickel (12.9%), thimerosal (9.4%), methylchloroisothiazolinone/methylisothiazolinone (2.4%), neomycin (1.2%), cobalt (1.2%), and p-tert butylphenol (1.2%). Of note, 7 of the eleven reactions to nickel were in children less than 16.5 months of age, with exposure sources related to jewelry and clothing fasteners. Of note, sensitization does not always correlate with clinical-allergic disease, ACD. For example, in both adults and children PPT reactions to thimerosal and gold frequently have little direct clinical relevance to the contemporaneous dermatitis; the source of these PPTs may be from past exposure to vaccinations and piercings, respectively.

Allergic contact dermatitis refers to a T-cell mediated, type IV, delayed hypersensitivity reaction (clinical-allergic disease) that results when a person is sensitized to an environmental chemical. Small lipophilic chemicals (haptens) with a low molecular weight (<1,000 Da) penetrate the skin and bind with self-proteins forming hapten–protein complexes (complete antigens). Dendritic cells, antigen presenting cells (APC) of the skin, then uptake these hapten–protein complexes and express them on cell surface major histocompatibility complex (MHC) molecules. In the regional lymph nodes, the APC presents the antigen to naïve antigen-specific T-cells, which in turn differentiate into effector T-cells capable of acting on target cells presenting the antigen in the future. This induction phase of sensitization is usually asymptomatic and takes about 10–15 days.

Subsequent exposure to the antigen, which may occur transepidermally or systemically, e.g., intravenously, by inhalation, or by ingestion, leads to the second or elicitation phase. Elicitation corresponds to the clinical picture of ACD, typically characterized by pruritic, erythematous, and edematous patches and plaques in the distribution of the contactant. Further exposure to the allergen may increase the reactivity pattern to one which is more diffuse and disseminated.

Recent studies have reported relevant PPTs in children at a frequency equivalent to those of adult populations. It is vital to note that the majority of children with ACD are not patch tested and that true prevalence rates may be significantly underestimated.

Demographics and Prevalence of Allergic Contact Dermatitis in Children

In the past 5 years, there has been an influx of reports demonstrating a high prevalence of ACD in pediatric patients. The majority come from tertiary care centers, with patients referred by dermatologists and allergists, where rates of PPT reactions are significantly higher (41–83%) than in unselected asymptomatic patients from the general population (13.5–24.5%).

In US-based referral center studies a significant number of tested patients have been Caucasian and Hispanic, with Asians and African Americans making up the minority. This data is primarily indicative of the distribution of patients in referral populations, rather than the prevalence of ACD in specific ethnic groups. These same studies have also shown that with respect to race and gender, the demographics for subjects within analyzed age groups have been similar to one another and to the population of all enrolled subjects. Differences in the prevalence rates of a given allergen among different age groups likely reflect the frequency, type, and length of exposure required to induce sensitization to specific chemicals and the age at exposure.

The true prevalence of contact allergy in both adults and children is largely unknown, because a significant number of affected patients are never patch tested.

Diagnosis

The diagnosis of ACD depends on a careful medical and environmental history, a high index of suspicion for ACD, and confirmation by diagnostic patch testing. In general, ACD presents as eczematous plaques largely localized to the site of allergen exposure. Pruritus is a main feature, in contrast to ICD, where burning is more common. Classic presentations, such as geometric shapes or linear streaks on the extremities, may be associated with plant contact dermatitis especially *Toxicodendron* spp. (e.g., poison ivy, poison oak, and poison sumac). Allergic contact dermatitis may also present in focal skin areas, such as the earlobes, periumbilical area, or eyelids.

Pediatric Patch Testing

Patch testing is the "*gold standard*" for the diagnosis of ACD and should be performed when there is a clinical suspicion and a suggestive history. Currently, there is no approved commercially available patch test screening kit for use in children in the USA. Moreover, in both Europe and the USA, the majority of centers comprehensively screen children with specific allergens selected for individual patients based on the history and clinical distribution

of dermatitis. Comprehensive patch testing is cumbersome and not always available; therefore, a large number of cases of ACD in children do go undetected. Patch test protocols, allergen selection, and interpretation of results are vital to proper diagnosis of ACD and techniques for patch testing children have been discussed in detail.

Special Considerations in Pediatric Patch Testing

Current consensus recommends using the same patch test chemical concentrations as in children as those used in adults. In children older than 12 years (adolescents), testing can basically be performed in the same manner as in adults. While patients as young as 2 years of age have been tested, most clinicians reserve testing for children under the age of 6 to cases in which they have a high index of suspicion, and even then, only selectively test with suspected contact allergens. In addition, the German Contact Dermatitis Research Group (DKG) proposed that patch test allergens be removed after only 24 h in younger children to reduce frequency of irritant reactions, with readings then performed at 48 and 72 h.

One of the intrinsic challenges in pediatric patch testing is the limitation imposed by the anatomically smaller back size of the young child, which translates into a smaller number of allergens applied. The emotional and psychological impact and inherent activity of children means that special attention is required to properly secure the patches. Tools such as games and videos to distract a child during application of the tests are helpful.

Interpretation and the assignment of relevance to PPT results are critical, since there may be only partial concordance between a PPT and ACD. A PPT indicates that an individual has developed sensitization to a chemical allergen, which may or may not be the cause of the patient's contemporaneous dermatitis. Patient history and allergen exposure lists are reviewed to help determine current, past, or uncertain relevance of the test results. Positive patch tests may account for all, part of, or none of the patient's dermatitis. Additionally more than one diagnosis may explain the patient's dermatitis. Allergic contact dermatitis ICD, atopic dermatitis, and CU may co-exist in the same patient. In addition to allergen avoidance, repeat open application use test (ROAT) may be employed by patients to assess improvement after the avoidance of putative allergens. In the ROAT, the patient applies the suspected substance (i.e., lotions, diaper creams, lip balms, etc.) twice daily to the upper arm or posterior auricular area on the same area for a week or more to observe if the dermatitis is reproduced.

Patient counseling is a key component of the patch test protocol, including instruction on keeping patch tests dry by avoiding bathing and sweat-provoking activities, as well as discontinuing the use of potentially interfering medications. For 2 weeks prior to testing, topical corticosteroids or calcineurin inhibitors should not be used in areas where the patches will be applied. Before testing, parents should be educated about the nature and causes of contact dermatitis, realistic expectations for outcome after testing, including allergen avoidance, and the potential for negative patch test results.

Side Effects of Patch Testing

The most common *side effects* of patch testing are the expected local pruritus, burning, and inflammation at the site of application. Pustular and blistering reactions rarely occur, and there is the potential for hypo/hyperpigmentation and persistent reactions. Exacerbations of the patient's presenting dermatitis are to be expected, and while this is usually minimal and bearable, it can serve as an important diagnostic clue in assigning clinical relevance. Information extrapolated from adult studies indicates that the risk of active sensitization to one of the tested allergens is extremely low. Serious adverse effects, such as anaphylactoid reactions to neomycin or bacitracin, are reported to be very rare. Potential benefits of patch testing clearly outweigh the procedure's potential risks and side effects. Use of commercially available patch test chemicals in generally accepted and published concentrations are associated with the fewest side effects.

Important Contact Allergens in Childhood

Table 144.1 lists the predominating 20 pediatric allergens found ubiquitously among patch testing reports from the USA, Canada, Europe (Germany, Italy, UK, France, Spain, Belgium), and Brazil.

Metal Allergens

Nickel is the most prevalent allergen in patch-tested patients of all ages (*Fig. 144.1*).

Nickel contact dermatitis classically presents as an eruption on the earlobes, face, and periumbilical area, as a result of contact with items such as jewelry and clothing

Table 144.1
Important allergens in children (USA, Canada, Europe, Brazil)

Rank	Allergen	Description	Source	Frequent distribution
1.	Nickel	Metal	Jewelry, buckles, snaps, eyeglasses, orthodontics, studs on school chairs, musical instruments, cell phones, keys, coins	Face/eyelids, earlobes, neck, wrists
2.	Cobalt	Metal	Jewelry, buttons/snaps, ceramics, cement, vitamin B12	Earlobes, neckline, umbilical area, hands
3.	Potassium dichromate	Metal	Tanned leather, matches, cement, pigments (green felt), dental implants	Hands, generalized
4.	Gold	Metal	Jewelry and dentistry products	Eyelids, mouth/lips
5.	Neomycin sulfate	Topical antibiotic	Topical antibiotic preparations	Foot, eczema sites, wounds
6.	Bacitracin	Topical antibiotic	Topical antibiotic preparations	Foot, eczema sites, wounds
7.	Tixocortol pivalate	Corticosteroid, especially hydrocortisone	OTC and prescription creams, lotions, and ointments	Any location topical is applied
8.	Sorbitan sesquioleate	Emulsifier	Pharmaceuticals, cosmetics, ointments, creams, lotions	Iatrogenic – sites of dermatitis
9.	Propylene glycol	Solvent/moistening agent	Pharmaceuticals, foods, cosmetics, personal care products	Face, perioral, in sites of dermatitis
10.	Lanolin	Emollient	Emollients, rust-preventative waxes, soaps, lip balms	Hands, any body area with emollient use
11.	Fragrance mix 1	Mix of 8 fragrances	Perfumes, personal care products, household products, soaps, detergents, cleaners, medicaments	Eyelids/face, neck, mouth/lips
12.	*Myroxylon pereirae* (balsam of Peru)	Fragrance/flavorant – tree resin	Perfumes and cosmetics, toothpaste, lozenges, flavoring agent	Eyelids/face, neck, mouth/lips
13.	Colophony	Fragrance/adhesive – distillation product of conifers	Personal care products, adhesive bandages, pine extracts	First aid bandage application sites, eyelids/face
14.	Cocamidopropyl betaine	Detergent, surfactant	Shampoo, liquid soap, bath gel, toothpaste, contact lens solutions, make-up removers	Face, scalp, and neck
15.	p-tert butyl formaldehyde resin	Adhesive and neoprene cement allergen	Leather shoes, athletic shoes, protective sports gear, neoprene	Foot, sports gear distribution
16.	Carbamates	Rubber accelerant	Elastic waistbands, shoes, socks, gloves, swimsuits, tires	Waistline, feet, hands
17.	Thiuram	Rubber accelerant	Elastic waistbands, socks, swimsuits, shoes (soles or insoles), gloves, pesticides	Waistline, feet, hands
18.	Para-phenylene diamine	Hair dye chemical	Hair dye, ''black-henna'' (PPD-adulterated henna) tattoos	Hairline, ears, hands, henna tattoo sites
19.	Disperse dyes (blue 106/124)	Aniline dye	Textiles, diapers, glasses	Peri-axillary bands, diaper edge
20.	Quaternium-15	Preservative-formaldehyde releasing	Cosmetics and topical medications – non-prescription and prescription	Face and body

Figure 144.1
Nickel dermatitis

fasteners. With continued exposure and immune stimulation, involvement of distant sites, which are not in direct contact with the metal allergen, is seen in up to 50% of children. This is known as an *id*-reaction, where dermatitis affects sites such as the extremities and the upper trunk, is more diffuse, and may mimic follicular eczema.

Because nickel is so ubiquitous, allergic patients should purchase the commercially available dimethylglyoxime spot test kit to identify if nickel ions are released from metal objects. A few drops of 1% dimethylglyoxime-ammonia (DMG-A) are applied to a cotton tip applicator, which is rubbed against the object in question. If nickel is present at a concentration as low as 1:10,000 on a solid surface and 10 ppm in a liquid, the applicator will turn a pink color. Currently, in the U.S.A., there is an effort to encourage a limitation on the allowable release of nickel to be <0.2 mcg/cm^2/week in products with prolonged skin contact, as has been instituted in Europe since 2004.

Cobalt is also a metal that is naturally found in metal ore with nickel and is often used as an alloy with nickel. It can be used to increase the overall strength of other metals. Sensitizing exposures include jewelry, clothing snaps, buttons and metal objects, as well as cosmetics, joint replacements, ceramics, paints, cement, and multi-vitamins (vitamin B12/cyanocobalamine).

Another frequently sensitizing metal is *gold*, which is found in jewelry and dentistry. PPT reactions to gold do not always correlate with the area of suspected ACD. The most clinically relevant presentations usually include eyelid involvement and stomatitis.

Chromate (potassium dichromate), a metal salt derived from chromium, is the final metal to top the allergen chart. Tanned leather is a potential source of chromate exposure in the household and is found in couches, shoes, boots, belts, and gloves. Vegetable-tanned leather can be used as an alternative. Chromium is also used in dental implants and the metal wire used in orthodontia. Additional sources of chromium include orthopedic prostheses, suture materials (chromated catgut), vitamin supplements, green tattoo ink, some cosmetics with green tints, as well as dyes and pigments, paints, and ceramics.

Antibiotics and Medicament-Associated Allergens

Neomycin sulfate, a topical antibiotic, maintained second place on the list of most common sensitizing allergens for approximately 25 years. More recently, the prevalence has been on a decline, which may be a result of its replacement with other topical antibiotics, such as *bacitracin*. Neomycin, however, is still frequently found in many over-the-counter creams and ointments used for the treatment of superficial wounds or burns, as well as to treat skin, eye, and ear infections. Co-reactivity with other chemically unrelated substances has been noted, likely due to its use in formulations with other antibiotics, antifungals, or corticosteroids.

Corticosteroid allergy is becoming more widely recognized in children. In fact, 0.2–6% of patients have been found to display ACD to one of the five groups of *corticosteroids*. The sensitization potential of group A corticosteroids (e.g., Cortaid, Cortizone-10) is greater than that of the other structural classes [A (5.72%) > B (4.80%) > D1 (3.54%) > D2 (2.13%) > C (1.10%)], likely due to its over-the-counter usage. Tixocortol-21-pivalate is the screening substance for the group A corticosteroids (some investigators also screen with hydrocortisone 1% in alcohol), while budesonide and triamcinolone are the screening substances for class B, and hydrocortisone-17-butyrate for class D2. Cross-reactions between classes are possible, specifically between groups A and D2, as well as between certain corticosteroids in groups B and D2.

Personal Care Product and Vehicle Allergens

Another important and emerging allergen, especially in atopics, is *cocamidopropyl betaine (CAPB)*, a surfactant derived from coconut oil and commonly found in foaming

cleansers, shampoos (used in "no tear" formulations), and soaps. Thus, the distribution of dermatitis often involves the head and neck region. The true sensitizers in CAPB are thought to be the manufacturing contaminants, *amidoamine,* and *3-dimethylaminopropylamine* (DMAPA). Cosmetic manufacturers are being encouraged to remove these impurities, which may reduce sensitization rates from products containing CAPB.

Contact allergy to *fragrances* has also been associated with atopic individuals. One of the chemicals used to screen for fragrance allergy is *balsam of Peru (BOP),* a substance derived from the *Myroxylon pereirae* tree. Children (and adults) are commonly sensitized to this allergen. The distribution of dermatitis has a predilection for the face, neck, and axillae. BOP and/or cross-reacting chemicals can be found in cosmetic products, such as perfumes, lotions, diaper-area care products, and toothpastes and mouthwashes, which may cause contact stomatitis or cheilitis. Moreover, BOP may be found in pharmaceutical preparations, scents, and flavorings for foods, drinks, and liquid medicaments (i.e., tomato, soda, cinnamon, chocolate, and vanilla extract); it also may be associated with hand dermatitis.

Fragrance mix 1 (FM1) is a mixture of eight chemicals (geraniol, cinnamic aldehyde, hydroxycitronellal, cinnamic alcohol, eugenol, isoeugenol, oak moss absolute, and a-amylcinnamic alcohol) that is also used to screen for fragrance allergy. Since the products that incorporate these eight chemicals are similar to those that include BOP, the distribution of the dermatitis may be similar. In fact, some of the fragrances included in FM1 are constituents of BOP, which explains the cross-reactivity that may be seen between these allergens.

Colophony or rosin is a resin that is derived from the distillation products of pine and spruce trees. It is commonly used as an adhesive as well as in eyebrow wax, some cosmetics, and diapers (top-layer pad). There is cross-reactivity among colophony allergic patients with fragrance and BOP, as components of both colophony and BOP occur together in nature, and may be incorporated in fragrances.

Formaldehyde and formaldehyde-releasing preservatives (FRPs) are another group of allergens which may co-sensitize with fragrances due to similar product utilization patterns. Their widely effective antibacterial and antifungal properties have led to the FRPs use as disinfectants and preservatives in a number of products, such as lotions, shampoos, body washes, and even some medicaments (generic corticosteroid creams and permethrin cream). Many manufacturers have replaced formaldehyde with one of the FRPs in biocides and personal hygiene products. These FRPs include: *quaternium-15*, diazolidinyl urea (Germall II), DMDM hydantoin (Glydant), imidazolidinyl urea (Germall), 2-bromo-2-nitropropane-1,3-diol (Bronopol), and tris nitromethane (Tris Nitro). Systemic exposure to formaldehyde is possible through inhalation of cigarette smoke or ingestion of certain foods that metabolize into formic acid (i.e., aspartame-containing foods). These sources of exposure have been reported to stimulate allergic reactions, with some patients improving through dietary avoidance.

Sorbitan sesquioleate is an important emulsifier, specifically a fatty acid ester that is widely used in pharmaceuticals, such as topical corticosteroids, as well as in cosmetics, ointments, creams, and lotions; it has recently been shown to be a relevant contact allergen in the pediatric population. Its association with corticosteroids makes this allergen particularly relevant to those with atopic dermatitis, who often require topical corticosteroids for treatment.

Propylene glycol is a preservative and "wetting agent" found in a wide variety of products, including pharmaceuticals, foods (e.g., "moist" cakes), cosmetics, and personal care products, making allergen avoidance particularly challenging.

Lanolin (wool wax alcohol) is an emollient used for skin barrier protection and repair. It is made from the sebaceous excretions found on sheep's wool. Common sources are topical ointments, moisturizers, and lip balms. Lanolin allergy is difficult to diagnose clinically with "trial and error" product substitution; patch testing is essential.

Rubber Additives

The next category of allergens that commonly affect children is rubber accelerators, to which both *thiuram* and *carbamate* belong, in addition to mercaptobenzothiazole, mercapto mix, and diakylthioureas. These chemicals are major additives in most rubber products as they promote rubber's transformation from a liquid to a solid state. Sources of exposure include athletic shoes (insoles and soles), elastic waistbands, socks, swimwear, toys, pacifiers, cosmetic applicators, and adhesives.

Another allergen utilized with diakylthioureas in neoprene and athletic gear foam is *p-tert-butyl-formaldehyde resin.* The two are commonly referred to as the "neoprene cement" allergens. PTBFR is not a rubber accelerator, rather it is an adhesive that is used in the manufacture of shoes and cars, in addition to being an important component of neoprene and sports gear.

Dye and Textile Allergens

Para-phenylenediamine (PPDA) is a colorless aromatic amine commonly known for its use in permanent hair dye. Para-phenylendiamine acts as a primary intermediate in hair dyes, is oxidized by hydrogen peroxide, and then polymerized to a color within the hair by a coupler such as resorcinol. Although PPDA derivatives are used in screening chemicals for black rubber allergy (e.g., isopropyl-paraphenylenediamine and related chemicals), PPDA itself is a poor detector of sensitization for black rubber allergy and is usually patch test negative.

More recently PPDA is being used in temporary tattoos, where it is mixed with natural henna to make "black henna." Black henna tattoos may induce sensitization with severe bullous reactions and subsequent adverse reactions with hyper- and hypopigmentation and permanent scarring. While PPDA is the most commonly used "permanent hair dye" [limit permissible for hair dyes (<6%)], it has been detected in concentrations well above 15% in henna tattoo preparations. Due to this elevated concentration, adolescents that have become sensitized through "black-henna" tattoos at younger ages are at risk for unusually severe reactions to PPDA containing hair dyes. Potential for systemic reactions is also possible among PPDA-sensitized patients when exposed to cross-reactors, such as benzocaine, hydrochlorothiazide, and sulfonamide medications. Moreover, 25% of those allergic to PPDA can also be reactive to certain dark synthetic clothing, which may contain semi-permanent dyes.

Because of their sensitizing potential, *Disperse blue dyes 106 and 124* are often used to screen for textile dermatitis in pediatric patients. These partially water-soluble dyes easily leach out of fabrics onto the skin with normal wear and repeated washing. Allergic contact dermatitis in children has been reported from sensitization to aniline dyes found in clothes, undergarments, seatbelts, diapers, and eyeglass frames**.** In addition to patch testing with individual dyes, a swatch of the patient's suspect garment may also be directly applied, as many colors can make up a hue**.**

Another cause of textile dermatitis is *formaldehyde*, which may also cause hand and systemic contact dermatitis. In textiles, formaldehyde is used in resins to create "permanent press" or "wrinkle-resistant" clothing, and is associated with dermatitis in regions where clothing rubs against the skin, i.e., body folds. These chemicals are also used in rayon and corduroy, and patients that develop contact allergy to formaldehyde resins in textiles have also developed diffuse nummular eczema or erythroderma due to secondary sensitization from quaternium-15, a FRP.

Treating ACD

The basis of therapy for ACD is the avoidance of the causative agent(s). Once allergens are confirmed and identified through patch testing, patients are educated on allergen substitution, avoidance, and removal from their environment. With these interventions, it may be possible to "cure" dermatitis with a sustained remission.

At times, patch testing fails to identify the inciting agents, especially if multiple chemicals are involved; and in some instances, avoidance alone may not completely clear the ACD. In these cases, topical and/or systemic therapies will be necessary as an adjuvant. Cool, wet compresses are particularly useful in providing symptomatic relief to acutely inflamed skin. In cases of hand dermatitis and in "unavoidable exposures," such as toxicodendron exposure in a woodlands hiker on a trek or in the cases of aeroallergens, physical barrier creams can be utilized. With these, the patients apply the creams before and during the exposure in an effort to avoid absorption of the allergen.

First-line therapy is topical corticosteroids, which albeit effective, may have side effects with prolonged use. A word of caution is that corticosteroids themselves may be allergens or their vehicles may contain allergenic components. Thus, careful screening during patch testing and specific prescription of appropriate formulations is necessary. For atrophy-prone areas, such as the face and intertriginous areas, topical calcineurin inhibitors (TCIs) may need to be substituted. Also of note, ACD to the active ingredients pimecrolimus, and tacrolimus themselves, and to the benzyl alcohol component of pimecrolimus has been reported.

In particular cases, where dermatitis is severe or widespread, involves the mucous membranes, or continues to progress despite the use of topical agents, systemic therapies may be necessary. Oral corticosteroids, used at 1 mg/kg/day, can be effective for acute exacerbations or episodes of ACD. When dermatitis becomes severe and chronic, "steroid sparing" agents should be considered. These include ultraviolet light therapy, cyclosporine, mycophenolate mofetil, methotrexate, and azathioprine.

In conclusion, the most important first step in treating patients with patch test confirmed ACD is avoidance education. A number of resources are available to provide patients with easy-to-read facts on where their specific allergens are found and ways to avoid them. (http://www.contactderm.org/, http://www.truetest.com/, http://www.chemotechnique.se/). Furthermore, many physicians educate their patients on the substitution of safe alternatives by providing them detailed shopping list instructions formulated by software such as the new

Contact Allergen Management Program (CAMP), available to members of the American Contact Dermatitis Society at www.contactderm.org and the list of Alternatives for the 2007 NACDG Standard Screening Tray developed by the American Contact Alternative Group.

145 Papulosquamous and Related Disorders Including Psoriasis

Eckart Haneke

In this entry, various skin diseases characterized by papules that develop scales are summarized. They differ widely in their etiology.

Psoriasis

Epidemiology

Psoriasis is a frequent disease with about 2–3% prevalence among light-skinned Caucasians, but it is also observed in dark-skinned individuals. Type 1 psoriasis has its first manifestation peak in the second decade and is thus the form mainly found in children. Roughly one-seventh gets the first manifestation before age 10, and more than one quarter before age 15. HLA-Cw6-positive children have earlier manifestation.

Genetics

Family history is usually positive in type 1, and there is an association with HLA-Cw6, B13, B57, and DR7. Molecular genetic investigations have identified seven loci as psoriasis genes, so-called PSORS.

Pathogenesis

Both genetic as well as environmental factors are important for the outbreak of psoriasis. Bacterial infections of the respiratory tract, particularly streptococcal ones, and also various stress situations and drugs may precipitate psoriasis. Inflammation of the dermis and hyperproliferation of the epidermis are the main events. There is a whole lot of cytokines, particularly TNF-α, interleukins 8, 12, 17, and 23, involved in the inflammation, which is mediated by T lymphocytes, monocytes, and granulocytes. The proliferation of the epidermis that normally takes 28 days is accelerated and shortened to 4–7 days.

Clinical Features

Psoriasis is a chronic relapsing, noncontagious and noninfectious, inflammatory, oligogenic multifactorial disease. The latter explains its enormous clinical variability, both morphologically and concerning its unpredictable course and treatment response.

Psoriasis vulgaris, the most frequent type, begins with small red papules that rapidly enlarge to well-circumscribed red plaques often covered with a thick layer of silvery-white scales. The elbows, knees, scalp, os sacrum, and intergluteal cleft, and particularly typical for children is the face (*Fig. 145.1*) and retroauricular fold, are mainly involved. Scalp psoriasis is often characterized by hair ensheathed in a mixture of scales and crusts (tinea asbestina or amiantacea) (*Fig. 145.2*).

Psoriasis guttata is a particular form characterized by acute onset, usually after a streptococcal infection, and widespread, small, drop-sized red lesions with relatively little desquamation (*Fig. 145.3*).

Psoriasis inversa is characterized by lesions mainly in the flexural areas like armpits, inguinal regions, palms, and soles. It is not rare to see diaper dermatitis transform into psoriasis in the genetically susceptible (*Fig. 145.4*).

Erythrodermic psoriasis covers the entire body. Pain, itching, and relatively little desquamation are typical.

Psoriasis pustulosa is also observed in children though less frequently than in adults. In the primary generalized pustular form, innumerable small pustules develop in fiercely red skin and the general condition of the patient is severely impaired. Palmo-plantar pustular psoriasis is very rare in children as is Hallopeau's acrodermatitis continua suppurativa that involves the tips of the digits and nails. Pustular outbreaks may occur during corticosteroid treatment of *P. vulgaris*. Annular lesions with or without visible pustules are the hallmark of erythema annulare centrifugum-like psoriasis.

Psoriasis arthropathica is rare in childhood. When the axial skeleton is involved, HLA B27 is often positive, but rheumatoid serology is usually negative.

Diagnostic Measures

Psoriasis is diagnosed clinically. Typical clinical lesions and distribution allow the diagnosis to be made in more than 80% of cases. When a scale is scratched cautiously, first a red shiny moist surface appears as the parakeratosis is easily removed. One more scratch will remove the thinned epidermis over the elongated papillae, and capillary bleeding is seen as Auspitz' phenomenon. Often, nails show pitting, salmon spots, and subungual hyperkeratosis.

Radiographs may help to differentiate psoriatic arthritis from other types, and bone scans allow joint involvement to be detected much earlier.

Histopathology is diagnostic, particularly in pustular forms.

Differential Diagnosis

A variety of mainly exogenous factors may modify the clinical features. Itching and scratching irritate psoriasis and may lead to new lesions (Köbner's phenomenon). Eczematization makes it difficult to make the correct diagnosis, even histologically. Annular lesions resemble tinea corporis, and psoriasis guttata may be confused with pityriasis lichenoides (PL). Slightly erythematous lesions have to be differentiated from pityriasis rosea. Scalp lesions may look like seborrheic eczema, and in fact, they may be associated ("sebopsoriasis"). A diaper rash may be due to *Candida albicans*, but in psoriatic individuals may turn into diaper psoriasis.

Quality of Life in Psoriatic Children

Psoriatic children suffer from decreased self-esteem and often feel severely embarrassed by the skin lesions. This in turn negatively influences the disease.

Any trauma, including sunburns, has to be avoided. Some drugs may worsen psoriasis, e.g., chloroquine, aspirin, and beta blockers.

Treatment

While treating psoriasis, one has to consider that this is a chronic relapsing, often lifelong condition, a fact that has to be explained to the parent and patient. Even though trigger factors such as streptococcal infections play an important role, psoriasis is neither infectious nor contagious. Infant skin is more permeable for drugs, and thus topical treatment often has a systemic effect; this is true for the desired as well as undesired effects. Cytostatics are thus not indicated in childhood.

Topical Therapy

While treating the skin directly, the physician has to consider the age of the patient; the extent, the specific region, and acuity of the lesions; the patient's wishes; and the cost factors. Moisturizing creams and ointments, stress reduction, and light and climatotherapy are valuable adjuncts. Salicylic acid ointments are used to reduce the thick scales. Monotherapy or combinations as well as rotational treatments are helpful.

Topical steroids, usually class 2–3, are most widely prescribed and usually sufficiently efficient. Their drawbacks are skin atrophy, striae, systemic effects, and rebounds. The face and intertriginous areas are treated with milder steroids. Cyclical treatment is intended to reduce side effects.

Anthraline is not popular as it stains skin and clothes but is efficient and virtually without side effects even with decade-long application. Short-contact therapy with 0.1–1% anthraline ointment, with or without addition of salicylic acid, which is removed after 15–60 min, does not produce stains. Anthraline encapsulated in a matrix of semicrystalline monoglycerides (Micanol®) makes application even cleaner.

Coal tar is another staining and smelly, but very efficient, psoriasis drug for long-term use. It is particularly useful for the scalp and in itchy lesions. Refined tar extract (liquor carbonis detergens) is less active, but neither messy nor smelly.

Both anthraline and coal tar may be combined with ultraviolet radiation as the *Goeckerman* or *Ingram regimen*, respectively. The effects achieved with these regimens last much longer than those with topical steroids.

Vitamin D_3 analogs are indicated in mild-to-moderate psoriasis. Calcipotriol is as effective as potent steroids. It can be combined with steroids, usually betamethasone diproprionate or UV radiation. It may burn, particularly in the face of young children, but is otherwise well tolerated. A maximum dose of 50 mg/m^2/week should not be exceeded in order to prevent hypercalcemia.

Tazarotene is a topical retinoid for use in psoriasis. It is approved in adults, but has also shown efficacy in children.

Tacrolimus is a topical immunomodulator. In children above 2 years, 0.03% cream is applied twice daily to the lesions.

Phototherapy

Phototherapy with psoralens plus ultraviolet A or with narrow band UVB is seen critically in children because of its potential carcinogenicity. It is highly efficacious in plaque psoriasis.

Systemic Treatment

In children with guttate psoriasis, the use of penicillin over a week to 10 days for the treatment of streptococcal infection is often helpful.

Systemic treatments are only indicated for severe psoriasis not responding to topical treatments. They suppress

psoriasis; however, their potential side effects may be more serious than the disease.

Methotrexate is given 0.2–0.7 mg/kg/week PO/IM. The dose is elevated by 1.25–5 mg/week until the therapeutic effect is reached and then tapered to an effective maintenance dose.

Biologics have proven to be well tolerated and efficacious in treating psoriasis of adults and can also be applied in children. TNF-α inhibitors are particularly effective. Of the available biologics, etanercept is approved for use in children above 4 years and results in fewer and less severe side effects compared to infliximab in the juvenile rheumatoid arthritis population. Though biologics are generally safe and effective in the pediatric population, serious adverse effects, including infection, have been reported in the literature and have to be considered before beginning treatment with any biologic agent.

Reiter's Disease

Reiter's disease, also called reactive arthritis, is characterized by mucocutaneous, ocular, genitourinary, and joint lesions. There is a genetic background and most patients are HLA B27 positive. It is usually triggered by gastrointestinal infection and is very rare in children (mainly in boys). Conjunctivitis, asymmetric arthritis, dysuria, and psoriasiform skin lesions are the most common presenting symptoms. Mucosal lesions are seen as circinate balanitis or vulvitis. The arthritis is often self-limiting but may sometimes be debilitating. Enthesitis results in painful attachments of tendons and ligaments to the bones. Keratoderma blennorrhagicum is found in 10% of patients. Clear vesicles on an erythematous base develop to macules, papules, and nodules on the soles, toes, palms, scrotum, trunk, and scalp and progress to hyperkeratotic skin, resembling psoriatic lesions.

Treatment aims at removing triggering factors such as infections. Inflammation is controlled with aspirin or nonsteroidal anti-inflammatory agents, e.g., indomethacin 1–2 mg/kg/day PO, divided bid/qid. Acitretin may reduce the dose needed to control arthritic pain. Cutaneous lesions respond to topical steroids. Severe cases require systemic steroids. Alternatives are sulfasalazine, acitretin, cyclosporine, or methotrexate.

Pityriasis Rubra Pilaris Devergie

Pityriasis rubra pilaris is an uncommon condition in children. Familial cases are probably autosomal dominant. Five types were differentiated, of which three (approximately 40%) occur in children and adolescents. The skin is hyperkeratotic with a characteristic orange yellowish color and accentuation of the follicular openings resulting in a goose-skin appearance (◉ *Fig. 145.5*). The lesions gradually enlarge and typically spare some spots – nappes claires (clear spots or islands of sparing) or Leredde's sign. Palms and soles develop yellow hyperkeratoses with painful cracking on a red base (◉ *Fig. 145.6*). The nails may develop hyperkeratosis of the nail bed, become thickened, lose their shine, and shed. Oral mucosal involvement may lead to diffuse white appearance.

The classical infantile type III usually appears within the first 2 years of life. It is often associated with prior fever and involutes spontaneously in a year though protracted cases are known. Circumscribed juvenile PRP (type IV) rarely regresses (◉ *Fig. 145.7*). Atypical juvenile PRP (type V) runs a protracted course.

Basic treatment is application of emollients to reduce hard follicular hyperkeratoses and soften palmar plantar hyperkeratoses. Topical steroids may relieve itching but do not significantly improve the condition. Isotretinoin over several months is approved in adolescents over 12 years, and acitretin is also effective. Azathioprine and methotrexate are rarely indicated.

Figure 145.5
Pityriasis rubra pilaris type III showing red follicular papules and diffuse redness with scaling

Figure 145.6
Pityriasis rubra pilaris with typical papules on the arms and diffuse hyperkeratosis of the palms on a red base

Figure 145.7
Pityriasis rubra pilaris on the knees is clinically similar to plaque psoriasis; however, the scales are much smaller and adhere firmly to the skin

Pityriasis Rosea Gibert

Pityriasis rosea is common in children and young adults and characterized by light-red oval spots with fine scaling and a slightly elevated margin with a collarette. It often begins with prodromal symptoms and usually starts a week later with a single herald patch that remains the largest of the lesions. Typically, the trunk and most proximal parts of the extremities are involved. The long axis of the lesions is oriented along Langer's lines giving a fir tree pattern (*Fig. 145.8*). Atypical involvement of the face and peripheral extremities may be seen in children. Oral lesions include red plaques, dot-like hemorrhages, and shallow ulcers. Human herpes virus types 6 and 7 were recently identified as a cause. A variety of drugs may cause pityriasiform rashes. Pityriasis rosea is not contagious.

The condition is self-limited. Treatment is symptomatic with dry lotions not containing sulfur as this may considerably irritate and eczematize pityriasis rosea. When itching is a dominant feature, an antipuritic lotion or steroid is used.

Lichen Planus

The prevalence of lichen planus in children is not known. There appears to be a link with HLA A3, B8, B16, Bw53, DR1, and DQw1. Association with other autoimmune conditions and hepatitis C infection is not rare.

Lichen planus is characterized by the sporadic appearance of polygonal, purple, pruritic papules with a flat surface and a tiny central depression. The most characteristic localization is the flexural aspect of the wrist

Figure 145.8
Pityriasis rosea with light-red oval lesions, a slightly elevated scaling margin, and arrangement in a fir tree pattern

(Fig. 145.9). The papules tend to accumulate and give the appearance of coarse skin relief. Making the covering keratin layer transparent with a drop of oil often reveals a network of very fine white lines, the Wickham striae. Oral mucosal involvement is usually seen as a net of coarse white lines and is less common in children. Trauma may induce papules, called Köbnerization (Fig. 145.9). The incidence in children is not exactly known.

Morphological variants of lichen planus are atrophic, hypertrophic, erosive, annular, pigmented, follicular, linear, vesiculo-bullous, and actinic (Fig. 145.10).

The etiology of LP is not known. Lichenoid drug reactions are not exceptional.

Histopathology is usually diagnostic.

Figure 145.9
Lichen planus on the flexural aspect of the forearm showing flat red papules that are grouped or are in linear arrangement due to Köbnerization

Figure 145.10
Annular lichen planus showing a ring of lichen planus papules around a hyperpigmented center

Most cases are self-limited and resolve within a year. Topical medium-potency steroids relieve itching and reduce skin lesions. Calcineurin inhibitors such as tacrolimus ointment twice daily as well as narrowband ultraviolet B are also effective. Retinoids in low dose over several months were also shown to help in nail LP. Sulfasalazine was effective in a controlled study.

Lichen Nitidus

Lichen nitidus is a granulomatous disease of unknown etiology. Tiny skin-colored papules (Fig. 145.11) arise, usually in a diffuse distribution on areas of the trunk, flexor aspects of the extremities, and dorsal aspects of the hands as well as genitalia of children and adolescents. Nail involvement may lead to longitudinal ridging. Histopathology shows a granuloma with an occasional giant cell that fills and widens a connective tissue papilla.

The condition usually runs an asymptomatic course. No etiological treatment is known, though phototherapy may be effective. Topical and systemic steroids, topical tacrolimus, cetirizine, levamisole, etretinate, acitretin, itraconazole, cyclosporine, topical dinitrochlorobenzene, psoralen plus UV-A light, and narrowband UV-B light have all been tried.

Figure 145.11
Lichen nitidus showing crops of small flesh-colored papules

Lichen Striatus

Lichen striatus is a rare, self-limited disorder mainly affecting children. It is characterized by flat-to-slightly follicular papules arranged in a linear pattern, commonly along Blaschko's lines. The cause is unknown, but an epigenetic mosaicism may be present. Histopathology shows a deep lymphocytic infiltrate mainly around follicles, thus allowing this condition to be differentiated from linear lichen planus. The disease is self-limited. Vitamin D_3 analogs may shorten the course.

Lichen Aureus

This is predominantly a disease of children. Grouped asymptomatic papules, usually as a short line, on a brownish background are characteristic. The legs are most frequently involved and almost every region of the body may show lesions. Histopathologically, there is a lichenoid lymphocytic infiltrate in the upper dermis with epidermotropism and erythrocyte extravasation; the red blood cells are degraded by macrophages and leave hemosiderin, hence the brown color.

Whereas purpuric dermatoses in adults are often due to different drugs, this has not been proven for lichen aureus in children.

No specific therapy is known.

Pityriasis Lichenoides

Pityriasis lichenoides (PL) is usually divided into an acute and a chronic form. Their etiology is unknown though infections – predominantly EBV, Toxplasma gondii, and HIV – have repeatedly been thought to be triggers.

Pityriasis lichenoides et varioliformis acuta (PLEVA) makes up for approximately one-quarter of the PL cases. Crops of symmetrically distributed red papules with a tendency to central hemorrhage and superficial necrosis appear within a short period (◉ *Fig. 145.12*).

Histology shows a so-called lymphocytic vasculitis with hydropic degeneration of the basal keratinocytes, often necrosis of the epidermis and erythrocyte extravasation.

Pityriasis lichenoides chronica (PLC) is more common. Red, sometimes lichenoid, lesions appear often over a course of months to years. They develop a characteristic hourglass scale (◉ *Fig. 145.13*) that can often be removed as a whole confirming the clinical diagnosis. Older and fresh lesions are seen together

Figure 145.12
Pityriasis lichenoides et varioliformis acuta shows red papules of different sizes, the largest of which exhibits a hemorrhagic center

Figure 145.13
Pityriasis lichenoides chronica in a 2-year-old boy. The papules are covered with a single large transparent scale

(◉ *Fig. 145.14*). Histopathology demonstrates a band-like infiltrate and vacuolar degeneration of the basal cells.

There is no evidence-based treatment for PLC or PLEVA. Spontaneous resolution is the rule for PLEVA though waxing and waning is frequently seen in PLC. Narrowband ultraviolet B phototherapy and methotrexate may be tried in children. Tetracycline was effective in some cases; slow tapering maintained resolution and prevented recurrence.

Figure 145.14
Multiple red papules with variable scales are seen in pityriasis lichenoides chronica

Figure 145.15
Lymphomatoid papulosis of a 14-year-old girl. The papules waxed and waned over many years

Lymphomatoid Papulosis

Crops of small red papules appear mainly on the trunk and extremities (*Fig. 145.15*) that involute within a few weeks but may recur over a period of decades. Pruritus is usually mild. Ulceration may occur giving a clinical picture similar to pityriasis lichenoides (*Fig. 145.16*). The hallmark of lymphomatoid papulosis in histopathology is a large proportion of CD30+ cells.

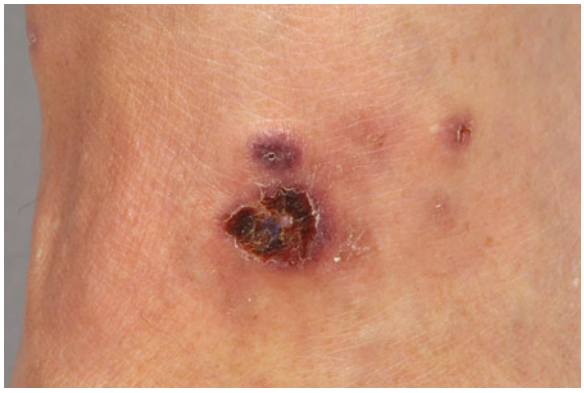

Figure 145.16
Lymphomatoid papulosis with central ulceration

Most cases remain benign, but in 10–20% the condition may be associated with, or progress to a malignant lymphoma.

Treatment is aimed at hastening of lesion resolution. Mid-potent steroids are used for itchy papules. The most consistent lesion suppression is achieved with low-dose methotrexate, but PUVA is also effective.

Parapsoriasis Group

Parapsoriasis is characterized by red scaly patches and plaques and a chronic course. The main localization is the trunk and upper extremities that are not chronically exposed to sunlight. Two types are commonly differentiated: small plaque and large plaque parapsoriasis. The former runs a protracted but benign course whereas the latter is thought to represent a cutaneous T cell lymphoma (mycosis fungoides). Both forms are rare in children. Small plaque parapsoriasis is often also referred to as digitate dermatitis as the lesions often show finger-like extensions, particularly those on the lateral aspects of the trunk. They are light red, finely scaly, smaller than 5 cm. Spontaneous resolution is common. Histopathology shows a mild superficial perivascular infiltrate in which CD4+ cells prevail.

Topical emollients and mild to medium-potency steroids as well as ultraviolet light are efficient.

Granuloma Anulare

Granuloma anulare (GA) is a benign condition of unknown etiology. Both the circumscribed (*Fig. 145.17*) as well as

Figure 145.17
Granuloma annulare of the foot and ankle with one deeper area looking like a nodule

Figure 145.18
Granuloma anulare of the palm and sole. Note the subcutaneous nodule of GA on the palmar aspect of the index finger

the subcutaneous variants (*Fig. 145.18*) are common in childhood, although generalized GA is also seen in children under 10 years of age. Small, relatively hard, red papules with mild scaling develop that often form ring-like lesions with violaceous skin in the center. The subcutaneous form develops deep dermal to subcutaneous nodules up to 10–15 mm in diameter, mainly on the dorsa of the feet, hands, and eyelids. Transepidermal elimination of necrobiotic collagen leads to perforating GA (*Fig. 145.19*). Generalized GA shows up to several hundreds of small skin colored to red nodules. The lesions are usually asymptomatic. Histopathology shows a palisading granuloma with necrobiosis and mucin deposition in the center.

Figure 145.19
Perforating granuloma annulare on the dorsum of the foot

Healing is mostly spontaneous and without sequelae, but generalized GA is often chronic. Potent topical steroids are rarely necessary. Traumatization, such as a biopsy, cryotherapy, or occlusive tape, may induce involution.

Perforating Dermatoses

Several perforating dermatoses are known. They have a perforation of the epidermis with transepidermal elimination of connective tissue in common.

Elastosis Perforans Serpiginosa

This rare condition usually appears in the second decade but may occur in early childhood. Three forms are differentiated: idiopathic, reactive in association with Down, Marfan, Ehlers–Danlos syndrome, osteogenesis imperfecta and pseudoxanthoma elasticum, and drug induced by D-penicillamine. Small papules in a serpiginous or circular arrangement develop, most commonly on the neck. In their center, a plug of degenerated connective tissue emerges. The area they surround slowly enlarges until apparently all pathological material has been extruded and the activity stops. Histology, particularly with elastic stains, is diagnostic showing clumped elastic fibers together with collagen and cellular debris being expulsed through a channel of the overlying epidermis.

Treatment is often not necessary. Spontaneous resolution with mild scarring after some years is the rule. Destructive methods are not indicated. Tazarotene was observed to be helpful and is approved in children older than 12 years.

Reactive Perforating Collagenosis (RPC)

Reactive perforating collagenosis (RPC) is a rare condition, of which an inherited form appearing in infancy or early childhood and an acquired form developing in old age are known. Nodules in frequently traumatized areas, precipitation or aggravation by cold, Köbner phenomenon, and pruritus suggest that superficial trauma plays a role in the pathogenesis.

Small red papules develop after minor trauma and steadily enlarge in the course of a few weeks. The center develops a scab, then a necrosis. Degenerated collagenous material is extruded and the lesion heals slowly with a small scar.

Histopathology shows basophilic collagen that has lost its birefringence. There are no laboratory tests for the inherited form. However, renal function tests should be performed in older children.

There is no established treatment for RPC. Anecdotal reports describe retinoids, allopurinol, doxycycline, and PUVA.

Perforating Folliculitis

Reddish, scaly folliculocentric papules, 2–8 mm in size, develop on hair-bearing surfaces of the arms, thighs, and buttocks, predominantly in youngsters and adults (*Fig. 145.20*). Expression yields keratotic debris, sometimes with a coiled hair. Most cases are idiopathic but diabetes mellitus is a common association. Its relation to Kyrle's disease is not entirely clear.

The diagnosis is confirmed by histopathology demonstrating focal disruption of the wall of the acroinfundibulum; however, serial sections may be necessary to find these changes.

Of all the different treatments tried, ultraviolet B therapy appears to give the most consistent beneficial effects. Reassurance and information about the nature of the disease are necessary.

Kyrle's Disease

This condition, originally called hyperkeratosis follicularis et parafollicularis in cutem penetrans by Kyrle, is characterized by the appearance of relatively large nodules with a central keratotic plug (*Fig. 145.21*). Keratinization probably occurs at the expense of proliferation until no basal layer is left, giving the impression of penetration of the keratin plug into the epidermis.

Kyrle's disease is often associated with chronic renal failure and diabetes mellitus. It is very rare in children. Its relation to perforating folliculitis and perforating reactive collagenosis is not entirely clear.

No specific treatment is known, though therapy of its associated disorders may be beneficial.

Pseudoxanthoma Elasticum (PXE)

Pseudoxanthoma elasticum (PXE) is a rare genetic disorder due to mutations in the ATP-binding cassette

Figure 145.20
Perforating folliculitis shows slowly enlarging nodules that eventually ulcerate centrally forming a crust and heal with a small scar

Figure 145.21
Hyperkeratosis follicularis et parafollicularis in cutem penetrans Kyrle in a 17-year-old adolescent showing nodules with massive circumscribed hyperkeratosis

Figure 145.22
Pseudoxanthoma elasticum has its name from the yellow color of the lesions as seen in this 16-year-old boy on the lateral neck

transporter C6 (*ABCC6*) (multidrug resistance-associated protein 6 (*MRP6*) gene), mapped to 16p13.1. It is characterized by fragmentation and calcification of elastic fibers of the skin, eye (Bruch's membrane), and cardiovascular system. Recessive and dominant forms are believed to exist with the latter exhibiting more severe alterations. Skin lesions begin in childhood, but are rarely diagnosed at this time, mainly between 10 and 15 years. In the flexural areas and the lateral neck, flat yellowish papules in linear or reticular arrangement develop (*Fig. 145.22*), and with time, the surrounding skin becomes flaccid looking like a plucked chicken. In the labial mucosa, yellowish spots are seen on stretching it. Systemic signs such as gastrointestinal bleeding, intermittent claudication, and retinal hemorrhage occur later in life though gastric bleeding may occur in the second decade. Elastosis perforans serpiginosa is a relatively common association. Histology shows fragmented and often whorled elastic fibers with calcification.

Regular monitoring is mandatory. Once the lesions have developed, they are irreversible. As high serum lipids aggravate the lesions, diet and exercise are recommended. Calcium intake is to be restricted. Smoking has a deleterious effect. Fundoscopy shows the characteristic angioid streaks representing ruptures of Bruch's membrane. Early laser treatment may prevent ocular complications. Intravitreal injections of antivascular endothelial growth factor have been proposed. Vitamins A, C, E, and zinc are beneficial. Antibiotics prior to surgical and dental interventions are proposed, e.g., amoxicillin 50 mg/kg in children 1 h before.

146 Hair Disorders and Alopecia

Zbigniew Ruszczak

Hair loss is a common problem in all ethnic groups. It may occur in all parts of the body; however, it more commonly affects the scalp, and the patient presents with major concerns about cosmetic effects, long-term outcome, and perspectives. Physiologically, hair is of minor benefit to humans. However, the psychological effect and disturbances of hair growth are a frequent source of concern to all age groups, including children and adolescents.

Hair is a protein product of follicles having periodic development phases, which assure physiologic regrowth. Hair is distributed everywhere on the body surface except palms, soles, vermilion part of the lips, glans penis and penile shaft, nail bed, and sides of the fingers and toes.

By week 22 of gestation, a developing fetus has all of its hair follicles formed. At this stage of life, there are about five million hair follicles on the body. There are a total of one million on the head, with 100,000 of those follicles residing on the scalp. This is the largest number of hair follicles a human will ever have, since no new hair follicles will be generated anytime during the course of one's life. The density of scalp hair reduces from childhood (1,135 hair per cm^2) to adulthood (615 hair per cm^2) since the scalp expands as we grow.

Each day the scalp hair grows approximately 0.35 mm (6 in. per year), while the scalp sheds approximately 100–150 hair per day, and more with shampooing. Because each follicle passes independently through three stages of growth, the normal process of hair loss is usually unnoticeable. At any one time, approximately 85–90% of scalp follicles are in the anagen phase of hair growth. Follicles remain in this phase for an average of 3 years (range, 2–6 years). The transitional, or catagen, phase of follicular regression follows, usually affecting 2–3% of hair follicles. Finally, the telogen phase occurs, during which 10–15% of hair follicles undergo a rest period of about 3 months. At the conclusion of this phase, the inactive or dead hair is ejected from the skin, leaving a solid, hard, white nodule at its proximal shaft. This cycle is then repeated.

Hair Growth Cycle

Unlike other mammals, human hair growth and shedding are random and not seasonal or cyclical. At any given time, a random number of hair will be in one of the three stages of growth and shedding: anagen, catagen, and telogen.

Anagen

Anagen is the active phase of the hair. The cells in the root of the hair divide rapidly. A new hair is formed and pushes the club hair (a hair that has stopped growing or is no longer in the anagen phase) up the follicle and eventually out.

During this phase, hair grows about 1 cm every 28 days. Scalp hair stays in this active phase of growth for 2–6 years.

Some individuals have difficulty growing their hair beyond a certain length because they have a short active phase of growth. On the other hand, individuals with very long hair have a long active phase of growth. The hair on the arms, legs, eyelashes, and eyebrows have a very short active growth phase of about 30–45 days, explaining why they are so much shorter than scalp hair.

Catagen

The catagen phase is a transitional stage and about 3% of all hair is in this phase at any time. This phase lasts for about 2–3 weeks. Growth stops and the outer root sheath shrinks and attaches to the root of the hair. This is the formation of what is known as club hair.

Telogen

Telogen is the resting phase and usually accounts for 6–8% of all the hair. This phase lasts for about 100 days for hair on the scalp, and longer for hair on the eyebrow, eyelash,

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_146,

arm, and leg. During this phase, the hair follicle is completely at rest and the club hair is completely formed. Pulling out a hair in this phase will reveal a solid, hard, dry, white material at the root. About 100–150 telogen hairs are shed normally each day.

A directed history and physical examination usually uncover the etiology of hair loss.

The history should focus on when the hair loss started; whether it was gradual or involved "handfuls" of hair; and if any physical, mental, or emotional stressors occurred within the previous 3–6 months. Determining whether the patient is complaining of hair thinning (i.e., gradually more scalp appears) or hair shedding (i.e., large quantities of hair falling out) may clarify the etiology of hair loss. The pattern of hair loss, especially whether it is focal or diffuse, also may be helpful. The hair-pull test gives a rough estimate of how much hair is being lost. It is done by grasping a small portion of hair and gently applying traction while sliding the fingers along the hair shafts. In the hair-pluck test, approximately 50 hairs are grasped with a hemostat and removed with one motion and prepared for microscopic examination. This test results in a trichogram that assesses the telogen/anagen ratio, but is rarely needed for clinical diagnosis of hair loss.

There is a necessity to distinguish age-related hair loss from hair loss that represents a true disease. There is also a need for patient education, especially when aggressive media is advertising full hair recovery in both medically promising and impossible situations.

The word "alopecia" is the medical term for hair loss. Alopecia does not refer to one specific hair-loss disease – any form of hair loss may be named an alopecia. The word alopecia is Latin, but can be traced to the Greek "alopekia," which itself comes from alopek, meaning "fox." Literally translated, the word alopecia (alopekia) is the term for mange in foxes.

Alopecia is usually categorized into nonscarring and scarring (critical, terminal) alopecia. Scarring alopecia may have either disease-related background or be genetically related and is much less predominant than the nonscarring one.

Hair loss on the scalp could then be classified as focal (areal) or diffuse, and may affect both sexes. This preliminary distinction is the first step in diagnosis and in determining further diagnostic and therapeutic procedures.

Some hair-loss conditions are named "effluvium," which means an outflow. Effluvia characteristically affect different phases of the hair growth cycle. Hair follicles on the scalp do not continuously produce hair. They cycle through a growth stage that can last 2 or more years, and then regress to a resting stage for up to 2 months before starting to grow a new hair fiber again. At any time on a healthy human scalp, about 80–90% of hair follicles grow hair. These active follicles are in what is called the anagen phase. That leaves up to 10–20% of scalp hair follicles in a resting state (telogen).

At birth, the hair is in the actively growing anagen phase, but within the first 2 days of life, there is a physiologic conversion to the telogen phase. Consequently, the majority of hair sheds within the first 4 months of life. This process, known as telogen effluvium of the newborn, usually occurs gradually. Sometimes, however, sudden hair loss is also possible. This physiologic hair loss may lead to either partial or total alopecia. At this stage, parents should be reassured that newborn hair loss is a normal process and that gradual replacement of the first terminal hair is generally completed before the first 6 months of life. This hair convert to vellus hair during the first year of life. At this time, scalp hair growth synchronously takes the typical adult pattern, which is usually achieved by the end of the first year. It is a gradual transition process of hair developing from an unmedullated, lightly pigmented hair having final length of less than 2 cm to terminal, pigmented, medullated, hair of thicker shaft with longer anagen phase and longer length. If light at birth, hair color usually tends to darken with age.

If born premature, newborns are covered with lanugo hair with main distribution over the face, limbs, and trunk. Lanugo hair may also be seen on the limbs and shoulders of full-term, normally developed newborns, but this hair should be shed within the first 2 months of age.

The examination of a child with hair loss should always be preceded by a profound medical history. Examination should include an entire skin inspection, and if indicated, also a microscopic examination of the hair bulb and shaft.

Basically, the scalp examination should distinguish whether the hair loss is diffuse, global, or focal. Diffuse hair loss may be either inherited, if hair development and/or hair follicle density is impaired, or acquired, in cases such as alopecia areata or telogen or anagen effluvium.

Examination of the scalp skin of patients with hair loss should determine if the hair follicles are still present (visible follicular openings), to rule out possible irreversible changes. This has not only diagnostic and therapeutic but also social implications.

It is important to distinguish if the hair loss depends on an abnormal growth rate or if abnormal hair shedding is occurring. The first can be simply evaluated by cutting a shaped hair window in an area that is difficult to manipulate by the patient (usually the back of the scalp) and

observing hair growth over few weeks. Even with underlying hair fragility problems, the hair should achieve a length of approximately 0.5 cm in 2–3 weeks.

If abnormal shedding occurs, hair-pull test mentioned earlier in the chapter and a subsequent microscopic examination is a simple and reproducible method to make correct diagnosis.

In some cases, the possibility of being confronted with a syndrome coexisting with hair loss should be ruled out. Multisystem abnormalities may include ectodermally derived organs (teeth, ears, eyes, central nervous system, and mammary glands), bone, cleft lips, or palate.

Hair-loss disorders are clinically and pathophysiologically divided into two main groups: congenital or acquired.

Acquired hair loss can be then divided into so-called nonscarring (noncicatricial) or scarring (cicatricial) alopecia.

Causes of nonscarring alopecia include alteration of hair growth cycle, structural abnormalities of hair, and inflammatory cutaneous diseases.

Traction alopecia or trichotillomania usually resolves without scarring as well.

Scarring alopecias tend to cause permanent hair loss and are part of disorders destroying hair follicles without regrowth and follow an irreversible course.

Congenital Hair Abnormalities

Congenital Hypotrichosis

Hypotrichosis is the term dermatologists use to describe a condition of reduced or no hair growth. Unlike alopecia, which describes hair loss where formerly there was hair growth, hypotrichosis describes a situation where there was no hair growth right from birth and which usually stays with the patient throughout its life.

The majority of hypotrichoses are due to genetic aberrations or defects of embryonic development. There are a multitude of types of genetic hypotrichoses. Often, affected individuals have other physical or mental problems beyond a lack of hair. Conditions such as Graham–Little syndrome, Ofuji syndrome, cartilage-hair hypoplasia, Jeanselme–Rime hypotrichosis, Marie–Unna hypotrichosis, and metaphyseal chondrodysplasia, among many others, can involve the symptom of hypotrichosis.

Despite a rapidly growing understanding of the human genome, the genetics and biochemistry behind hypotrichoses remain unknown and most conditions involving hypotrichosis have no known treatment.

The most common hypotrichosis will be discussed here also because they are interesting in terms of understanding hair follicle physiology.

Congenital Aplasia

Aplasia cutis congenita, or congenital aplasia, is a developmental defect where, for reasons not understood, the skin does not fully form as an embryo develops. A baby may be born with a patch of skin that is like an open wound or an ulcer. Often this defect occurs at the back of the scalp, at the center of the "whorl pattern" of hair growth. If the defect is small, the skin will grow over, closing the defect and the child is left with a hairless scar (*Fig. 146.1*).

Sometimes this healing process already occurs in utero, and all that can be seen at birth is a patch of scalp where there are no hair follicles. However, if a child is born with a large(er) surface congenital aplasia, it usually requires a surgical intervention and removal of the affected area to achieve the best cosmetic effect. This is especially necessary in cases when the open wound may be a site of potential hemorrhage and infection.

Triangular Alopecia

Triangular alopecia (alopecia triangularis) is a condition similar to congenital aplasia. It is usually apparent from

Figure 146.1
Aplasia cutis congenita. Aplasia cutis congenita in a 6-month-old girl. Typical, partially scarified, atrophic lesion of the scalp resulting in alopecia circumscripta

birth and tends to affect a triangular patch of skin and hair above the temples. For unknown reasons, the skin fails to grow hair follicles in this area. Even if children are not born with an open wound, as in the case of aplasia cutis congenita, the long-term result is the same – a bald patch where hair does not grow. To achieve better cosmetic result, the affected area can be surgically removed or implanted with hair follicles taken from elsewhere on the scalp.

Marie–Unna Hypotrichosis

Marie–Unna hypotrichosis is an autosomal-dominant genetic disorder in which scalp hair is sparse or absent at birth, but a coarse hair may grow in early childhood followed by a diffuse hair loss (especially over the vertex) at puberty. The hair morphology shows abnormal cuticula with longitudinal ridding and irregular twisting. Brows, lashes, and body hair are sparse or absent. Anodontia is common; nails are usually not affected. Increased tendency to atopy and early development of atopic dermatitis have been reported.

Congenital Atrichia

Congenital atrichia or papular atrichia is a unique condition in terms of hair-loss pattern. Inheritance (autosomal dominant versus recessive) is not fully clear even if hair-loss disease is postulated to be caused by a single gene defect. Although the condition is generally regarded as a hypotrichosis, it is not strictly so. Children with congenital atrichia can be born with normal, partial, or absent scalp hair. If not present at birth, hair will be successively lost within the first 2 years of life and never regrows. The only exception may be eyelashes, which can remain unchanged throughout the patients' lives.

Teeth and nails of patients with congenital atrichia are usually not affected; however, sweating may be impaired. Psychomotor retardation, ataxia, and hypogonadism have also been described to be associated.

Congenital atrichia has been studied as a model for understanding physiologic hair growth. Normal hair follicles rely on chemical communication between two basic cell types: bulb keratinocytes, which form both the hair papilla and the outer skin epithelium, and modified fibroblasts, the so-called dermal papilla cells. These two cell populations must permanently "talk" to each other through biochemical signals to ensure physiologic hair growth and cycling. The cells must keep close contact to each other to assure the continuation of this process. One cell population cannot exist and grow hair without receiving signals from the other cell population.

The mechanism of congenital atrichia is not fully understood yet. It is postulated that as the hair follicles enter their first resting (telogen) state in early childhood, the two cell types lose the ability to communicate with each other. It seems that when hair follicles go into the resting phase of the hair cycle, the dermal papilla cells lose their ability of reactivating them. Without this stimulation, a new anagen growth phase cannot occur and hair never grows again. While congenital atrichia is genetic, it is a gene defect that can spontaneously develop in some embryos born to parents who do not have such a condition.

Some patients diagnosed with alopecia universalis may, in fact, have congenital atrichia instead.

Some congenital hair shaft abnormalities may be associated with unruly hair.

Uncomable hair

Uncomable hair syndrome and woolly hair are the most prominent members of this group.

Uncomable Hair Syndrome

In uncomable hair syndrome, children have slowly growing silver-blond glossy hair that is disorderly and difficult to style or manage.

Potential explanation for this appearance is premature keratinization of the inner root sheath leading to triangular shape, longitudinal grooving, and expressing features of pili torti.

The condition can express an autosomal dominant pattern; however, in most cases it is sporadic and has no association with other abnormalities.

Uncomable hair syndrome usually improves with age; dietary supplementation has no effect. For better cosmetic effect, gentle hair styling and applying of hair conditioner may be beneficial.

Woolly Hair Syndrome

In woolly hair appearance, the hair is tightly coiled, but it has no typical shape of pili torti. The woolly hair is a styling or hair management problem since the hair becomes bushy or frizzy and the hair length is usually decreased.

Woolly hair is common in children of black African ancestry and usually does not have any specific associations or implications. An autosomal-dominant fashion has been postulated. In some cases, coexistence of woolly hair with enamel hypoplasia, ocular abnormalities, keratosis pilaris, or ichtiosis vulgaris has been reported.

In infants and children of non-African origin, the presence of woolly and curly hair may implicate the need to search for rare syndromes such as tricho-dento-osseous syndrome (small, sharp, widely spaced teeth, frontal bossing, and dolichocephaly) or CHAND syndrome (curly hair, ankyloblepharon, and nail dysplasia).

In general, woolly, curly, or difficult-to-style (comb) hair are common in black African, African-American, or Arabic population, expressing a normal phenomenon that should not be seen as a condition requiring medical intervention.

Hair Loss due to Increased Fragility

Variations in the structure of the hair may provide clues about possible pathologic abnormalities. Microscopic hair examination of snipped hair to find out possible hair shaft abnormalities (i.e., due to impaired keratinization or formation of hair shaft) may be helpful to verify if the hair loss depends on increased hair fragility.

There are multiple conditions where physical damage to the hair fiber results in hair loss. Sometimes this damage occurs to the hair which has been already improperly formed by the hair follicle, which increase the chance of hair loss. These conditions are usually determined by genetic defects. There are also conditions where physical damage of the hair fiber is caused by environmental influence, most often poor or inappropriate hair care.

Hair loss as a result of physical hair defects is very rare if compared to other causes of alopecia, but the most common ones are listed below.

Loose Anagen Hair Syndrome (LAS)

Loose anagen syndrome or loose hair syndrome describes hair that is "loose" and can be easily pulled out of the hair follicle. Loose anagen syndrome is most often first diagnosed in early childhood, more frequently in girls than in boys. Their scalp hair never seems to grow, they only rarely need a haircut, and the hair is usually thin, especially at the back of the scalp. The hair is easily pulled out by rubbing of the head on a pillow and explains why the back of the head is most affected. The remaining hair usually does not grow very long and it can be unruly and difficult to comb and style. Blond-haired children in the age of 2–5 years are most likely to be affected, but loose anagen syndrome can also appear later. The syndrome usually improves with age of its own, if symptoms first occurred in young children, but if symptoms develop in adolescents, the hair loss may be more persistent. The etiology of loose hair syndrome is not clear. It has been demonstrated that the root sheaths that normally surround and protect the hair shaft in the skin are not properly developed in children with loose anagen syndrome. Thus, there is a lack of adhesion between the hair shaft and the root sheath and the hair fiber is poorly anchored in the hair follicle.

The term "loose anagen hair syndrome" is also used for children with easily extracted hair having either patchy unruly hair (LAS type B) or otherwise normal hair with increased shedding in a subject of any age (LAS type A and C).

Genetic predisposition has been postulated, since the condition can occur in families; however, there are also many isolated case reports with no family history. Association with specific disorders has not been reported. There are no known effective treatments for loose anagen syndrome.

Trichorrhexis Nodosa

One of the most common hair shaft defects in children is trichorrhexis nodosa (also called trichonodosis). Trichorrhexis nodosa is a focal defect in the hair fiber. When observed under the microscope, isolated spots along the length of a fiber swelling and/or fracturing and splaying can be seen, giving broken hair a fan-like array. These focal defects develop where there is an absence of cuticle, which leads to exposed cortical fibers.

Causes of trichorrhexis nodosa can be congenital or acquired. Congenital trichorrhexis nodosa is very rare, but some patients have naturally weak hair where the cuticle is not properly produced. Congenital trichorrhexis nodosa is usually hereditary and it first develops in early childhood. Abnormal production of hair fiber that is irregular and brittle can also occur in metabolic disorders such as those involving abnormal urea synthesis, abnormal copper or zinc metabolism, or defective cysteine or sulfur incorporation into hair fiber (trichothiodystrophy). Acquired trichorrhexis nodosa is much more common and develops as a result of excessive hair manipulation and overprocessing. Extensive brushing, hairstyles that put constant stress on the hair, excessive washing, use of

chemicals for dying, and perming may disrupt the cuticle in focal areas along a hair shaft. Trichorrhexis nodosa is particularly seen in those patients whose parents overuse hot combs or permanent waves to style children's hair. Once the cuticle is removed from hair fiber, the hair cortex swiftly breaks down.

Trichorrhexis nodosa present in young children should trigger search for underlining metabolic disorders. One such association is argininosuccinic aciduria in which the absence of enzyme arginosuccinase leads to acidosis, hyperammonemia, low serum arginine, and increased serum and urine citrulline and argininosuccinic acid. In such children, psychomotor retardation, ataxia, and dull brittle hair with trichorrhexis nodosa occur usually at or after the age of 2 years.

Another disorder associated with trichorrhexis nodosa is citrullinemia with deficiency of the enzyme argininosuccinic acid synthetase. Children with this defect present scaly skin eruption and hair fragility. Microscopic hair examination shows trichorrhexis nodosa and pili torti.

Similarly, patients with trichopoliodystrophy (Menke's syndrome), an X-linked defect of MKN or ATP7A gene leading to disorder of copper transport, can have trichorrhexis nodosa and pili torti. In affected children, hair is normal at birth but is replaced by sparse, brittle, depigmented hair of steel wool-like appearance. This led to creation of a specific term for such a condition: a "steely hair syndrome." Associations with mental retardation, and degeneration of bone and connective tissue have been reported. A low serum ceruloplasmin is diagnostic. Copper supplementation is ineffective and most affected children die before the age of 3 years.

Trichorrhexis Invaginata

Trichorrhexis invaginata or "bamboo hair" is clinically present in infants with short, brittle, and sparse hair. Primary defect is an abnormal keratinization of the hair shaft allowing intussusceptions of the fully keratinized and hard distal shaft into incompletely keratinized and soft proximal portion of the shaft. In consequence, fraction of the hair in this particular area is very common. Usually, this hair anomaly is associated with the Netherton's syndrome, an autosomal recessive inherited disorder characterized by a triad of ichthyosis, atopic diathesis, and trichorrhexis invaginata. In Netherton's syndrome there is a mutation of the gene for serine protease inhibitor, SPINK5, localized on chromosome 5q32 has been postulated.

Pili Torti

Pili torti are characterized by short, brittle hair, which is flattered and twisted on its own axis, usually between 90° and 360°. Affected hairs usually fracture through the twist. To diagnose pili torti, there must be multiple twists at irregular intervals throughout the involved hair.

Pili torti can be present in association with or as a part of different hair shaft abnormalities and can be either inherited or acquired. The most prominent of such abnormalities are trichorrhexis nodosa and trichorrhexis invaginata (see above), but this phenomenon can also occur in monilethrix, pseudomonilethrix, or woolly hair. In the classic form of pili torti (so-called Ronchese type), the abnormality is autosomal dominant or can be found as a co-symptom of ectodermal dysplasia complex of findings.

Monilethrix and Pseudomonilethrix

The condition monilethrix makes hair fiber look like a string of beads. Along the length of a hair fiber, there are nodes and constrictions with regular, periodical appearance every 0.7–1.0 mm, making the edge of the fiber undulate. This hair beading weakens the fiber, and patients with monilethrix have diffuse hair loss. The back of the scalp and neck are most frequently affected, leaving the front of the head relatively unchanged. Monilethrix can also affect hair in other regions of the body. Microscopically, the hair fibers can be seen to have lost the cuticle covering over their nodes, while the constrictions keep their cuticle. The brittle hair easily breaks once it is exposed above the skin and, as a result, the fibers rarely grow very long. Monilethrix most often occurs in childhood but adolescents and young adults can also be affected. It is a genetically inherited disease, although different family members may be affected with different severities. This disorder has been linked to the mutations of keratin type-II gene cluster located on chromosome 12q13. The severity of monilethrix can also change with the seasons. It is often worse in winter and improves in summer. Monilethrix may spontaneously improve, although many patients have monilethrix for their entire lives.

Pseudomonilethrix is characterized by irregular beading along the hair shaft – opposite to the regular beading occurring in monilethrix. Current observations suggest that pseudomonilethrix is not a separate entity, but an artificial phenomenon.

Hair Damage due to Physical or Chemical Processes

Traction Alopecia and Trichotillomania

Based on the mechanical action, traction alopecia and trichotillomania are similar. Hair is plucked out of the skin, leaving clear bald patches or diffuse, thin hair. With traction alopecia, the cause may involve tight hat bands, pulling the hair into a tight pony tail, cornrow hair styles, and any other action that pulls on the roots of the hair. If traction alopecia continues for a long time and the same hair region is repeatedly pulled out, the hair follicles in this skin region become cumulatively damaged and they may stop growing hair permanently.

Trichotillomania is a psychiatric impulse control disorder. The mean age of onset is 8 years in boys and 12 years in girls, and it is the most common cause of childhood alopecia. Although any part of the body can be involved, the scalp is the most common. Patients also may eat their own hairs after plucking them (trichophagia), which may result in internal complications such as bowel obstruction. Hair loss often follows a bizarre pattern with incomplete areas of clearing. Often the hair on the scalp is plucked to leave bald patches, but the patient may also focus on the eyelashes, eyebrows, pubic hair, or any other hair-bearing region. There is a consensus that trichotillomania is not a habit like nail biting, but a real psychological problem.

The scalp may appear normal or have areas of erythema and pustule formation. A scalp biopsy may be necessary to rule out other etiologies, because patients may not acknowledge the habit. Because of its psychological nature, the mainstays of treatment are counseling, behavior modification techniques, and hypnosis. Treating trichotillomania is difficult; psychiatrists and psychotherapists can probably help more than dermatologists. Selective serotonin reuptake inhibitors or other antidepressants administered for other obsessive-compulsive disorders may be useful, although there are no specific FDA-approved medications for treatment of trichotillomania. If a more moth-eaten appearance of hair loss is present and no evidence of hair-pulling behavior can be elicited, syphilis should be suspected.

Traction Alopecia

In contrast to trichotillomania, traction alopecia involves unintentional hair loss secondary to grooming styles. It often occurs in patients who wear tight braids (especially "cornrows") that lead to high tension and breakage in the outermost hairs. Traction alopecia also occurs commonly in female athletes who pull their hair tightly in ponytails. It may also be connected with ethnic or religion-dependent way of hairdressing or hair cover. Hair loss usually occurs in the frontal and temporal areas but depends on the hairstyle used. Treatment involves a change in styling techniques. Other hair-growth promoters may be needed in end-stage disease, in which the hair loss can be permanent even if further trauma is avoided (*Fig. 146.2*).

Figure 146.2
Traction alopecia. Diffuse hair loss due to mechanical forces resulting in traction alopecia in a 7-year-old girl

Overprocessing, Cuticle Stripping, and Bubble Hair

Overprocessing the hair is the most common cause of physical hair damage. Perming, straightening, bleaching, and dyeing the hair all involve chemicals that can significantly affect the integrity of hair fiber. Using these approaches too frequently or inappropriately can lead to irreversible damage to the hair fiber. The more the hair fiber is damaged by these processes, the weaker it will be, and the more likely it will be for it to break off.

The hair cuticle is a very strong outer sleeve of highly keratinized cells that overlap each other like fish scales along the length of the hair fiber. The cuticle helps protect the softer inner cortex structure of the hair fiber from damage. The overlapping scales of the cuticle may become damaged and "flake up" if they are exposed to extensive processing. For perms, straighteners, bleaches, and dyes to

work, the cuticle has to be "opened up" so that chemicals can get into the hair cortex and rearrange the chemical bonds in the hair structure, as occurs with perms and straighteners, or to remove or add hair pigment, as occurs with bleaching and dyeing. If substances opening the cuticle are applied for too long, in an unsuitably high concentration, or too frequently, the cuticle may be irreversibly damaged or even completely stripped away. This leads to exposure of the softer cortex to the environment. The cortex with this rough surface is then directly visible, and the hair can look dull, "dry," and frizzy. Chemicals in shampoos, in the water, in air pollution, combined with UV light exposure can all contribute to further damage and weakening of the hair cortex. In consequence, the hair may become so weak that it splits or breaks off completely. More usually, this splitting and breakage occur to older part of the hair, toward the end of the hair fiber. However, if the chemical processing is very severe, it alone can damage the hair fiber, making the fiber at the root severely weakened. If this happens, the hair may break off at the skin surface.

In addition to chemical-induced damage, physical processes can also damage the hair. Aggressive brushing, backcombing, and other grooming techniques that put a lot of physical stress on the hair fiber can cause the cuticle to flake and strip away. Inappropriate use of the hair dryer can also cause hair damage. When patients wash the hair, water may penetrate under the cuticle and into the cortex. If the hair is then made to dry with a high heat, water gets heated up and expands inside the hair producing artificial spaces in the hair fiber. In severe cases, little bubbles develop within the hair shaft leading to so-called bubble hair. These bubbles make the hair much weaker and are likely to break off. Physical damage combined with damaging chemical processes aggravates all negative effects.

Physical and chemical damage to the hair through overprocessing are difficult to treat. The best is to avoid further processing, cut off as much damaged hair as possible, and wait for new, undamaged hair to grow. Some cosmetic treatments advertise to help "glue" damaged hair back together, but the end result is never as good as the original, undamaged hair.

Treatment of primarily defect hair depends on the considered cause of the focal defects. If the hair production is believed to be abnormal, then treatment will focus on the hair follicle and improving the strength of hair fiber. Where the defect is the result of excessive grooming, the obvious action is to reduce the amount of hair manipulation. Patients and parents should be encouraged to stop using brushes, avoid extensive hair styling involving chemical agents, and to use only very mild hair and scalp care products.

Infectious Condition Resulting in Hair Loss

Tinea Capitis (Ringworm)

The traditional term "ringworm" is used to describe a fungal infection (tinea) of the scalp and hair. Tinea is the most common infectious skin condition and can occur anywhere on the body, but if it develops on the scalp (tinea capitis) it may lead to patches of hair loss. It usually begins as a small, isolated area that progressively expands in size, leaving scaly patches of temporary baldness. Depending on the type, the fungus may penetrate into the hair fibers (exotrix or endotrix). In such cases, hair becomes brittle and breaks off easily on the skin surface. The affected areas are often itchy, red, inflamed, expressing scaly patches that may blister and ooze. The areas are usually more prominent (active) around the outside border of the lesions showing a more "normal" skin tone in the center. This phenomenon creates the appearance of a ring, leading to the common name, "ringworm."

The most common fungi causing tinea capitis in the North and South America and in Europe are *Microsporum audouini* and *Trichophyton tonsurans*. Other fungi that may cause tinea capitis include *Trichophyton schoenleinii*, *Trichophyton megninii* in Southern Europe and Africa, and *Trichophyton violaceum* in the Middle East. The fungus *Microsporum gypseum* can also cause tinea capitis in children. This fungus is common in soil and may be transferred to humans by contact with infected animals. A use of Wood's lamp may be helpful to confirm fungal infection, since several types of fungi fluorescents exist. However, the most common fungus in the United States (*Trichophyton tonsurans*) does not fluoresce, lessening the value of this test.

Children often get fungal infections from pets that carry the fungus, and cats in particular are the common carrier. Tinea capitis is a contagious disease. It can be passed from one child to the other by direct skin-to-skin contact and is often seen in siblings. Fungal skin and hair infections can also be transferred through contact with contaminated items such as combs, unwashed clothing, and shower or pool surfaces. The most severe form of tinea capitis is a kerion, a fluctuant, boggy lesion with overlying hair loss (*Figs. 146.3* and *146.4*).

Figure 146.3
Tinea capitis 1 (*Mycosporum canis*). Mycosporum canis infection resulting in focal hair loss in a 7-year-old boy

Figure 146.4
Tinea capitis 2. Pseudo-scaring alopecia areata due to deep tinea capitis in a 10-year-old boy. Hair regrowth completely after 12 weeks of terbinafine administration (125 mg per day)

Treatment for tinea capitis varies, depending on the particular fungus involved. Sometimes mild and localized fungal infection may resolve spontaneously. In general, however, tinea capitis needs specific antibiotic/antifungal treatment. In the United States, the most common agent is Griseofulvin. Griseofulvin is very effective due to keratine binding and gradual accumulation in both hair and skin, but it is not effective for treatment of yeast or bacterial infections. More recently, cases of tinea capitis have been showing signs of resistance to Griseofulvin necessitating higher doses and longer courses of treatment. This cheap and easily available drug remains, however, the first-line treatment of deep scalp tinea (kerion) in many regions of the world. As an alternative to Griseofulvin, other antifungal drugs such as Terbinafine, Itraconazole, and Fluconazole can be administrated. It is necessary to stress that systemic antifungal therapy in children, especially in cases of deep and prominent tinea capitis, requires often much longer and consequent administration than it is given by most standard protocols. By short course of treatment, relapses are preprogrammed and development of drug resistance may be the most negative outcome.

Folliculitis

Folliculitis describes a focal inflammation of hair follicles. In the early stages of a folliculitis, the hair fiber may still be present, but as the infection progresses, the hair often falls out. When folliculitis is severe, the inflammatory process can permanently destroy the hair follicles, leaving bald patches (*Figs. 146.5a, b*). There are rare forms of noninfectious hair follicle inflammation caused by oils and greases applied to the skin and clogging up the hair follicles. The most common infectious agent is *Staphylococcus aureus*. The so-called hot tub folliculitis is caused by *Pseudomonas aeruginosa* which grows in inadequately chlorinated water. In some cases, other infectious agents such as viruses, fungi, or yeast may contribute to pathogenesis of folliculitis involving *HSV-I*, *-II*, *and -III*, *Pityrosporum ovale*, and *Trichophyton rubrum*. For mild forms of bacterial or fungi folliculitis, over-the-counter topical antifungal agent or antibiotics such as bacitracin, mycitracin, or neomycin can be used. For more serious infections, oral antibiotics such as tertacyclines or antifungal agents such as griseofulvin or terbinafine are necessary.

Piedra

Piedra (*Trichomycosis nodularis*, piedra means stone in Spanish) is a condition where the hair fibers are infected by a fungus. The visible indicator of a piedra infection is development of hard perifollicular nodules (stone-like folliculitis). The nodules are a concretion of hyphae and

Figure 146.5
Chronic folliculitis (a and b). Chronic, scarifying folliculitis in a 14-year-old male patient with bush-like hire growth

fruiting bodies of the fungus, known as an ascostroma, from which the fungal spores are released. Two basic types of piedra have been described: black piedra and white piedra, referring to the color of the nodules formed around the hair fiber. The agent of black piedra is the fungus *Piedra iahortae* and is mostly found in tropical countries. The white piedra is due to *Trichosporon beigelii* and is common in Europe and North and Southern America.

The infection may affect hair of the scalp, body, and genital areas. Usually the infection is relatively benign. However, when the infection is severe, the fungus weakens the hair fiber, making it easy to break off, resulting in a patchy – diffuse hair loss. Treatment generally involves shaving off affected areas or a topical application of salicylic acid. White piedra is resistant to azole-based antifungals, but this category of treatments is effective for black piedra. Systemic therapy with terbinafine is usually very effective.

Seborrheic Dermatitis

Seborrheic dermatitis is not an infectious disease, but it can involve infection. Seborrheic dermatitis is, in many cases, one of the first of skin conditions seen in children and can involve temporary hair loss if the dermatitis is located on the scalp or other terminal-haired skin areas. The dermatitis presents as scaly, sometimes oily, inflamed skin that can be itchy or even painful to touch. In this inflammatory condition, the sebaceous glands produce a very rich form of sebum, which contains less free fatty acids and squalene, but increased amounts of triglycerides and cholesterol. Androgen steroids are considered to be a stimulating factor, and times of hormone fluctuation, such as during puberty, can activate the onset of seborrheic dermatitis. Seborrheic dermatitis can also be observed in some newborns, and maternal androgens that pass from the mother to the child across the placenta are considered to be involved.

Rich sebum production in seborrheic dermatitis can trigger the proliferation of skin flora. Yeast *Pityrosporon ovale* (also known as *Malassezia furfur*) has been shown to increase in numbers with the intensity of seborrheic dermatitis. Although this inflammation is not specifically directed at the hair follicle, hair growth can be adversely affected and seborrheic dermatitis may nonspecifically cause diffuse hair loss. This hair loss is reversible and hair fully regrows when inflammation dissolves. Although seborrheic dermatitis can involve a proliferation of years, it is important to stress that seborrheic dermatitis is not infectious (*Figs. 146.6a, b*).

There are several treatments for seborrheic dermatitis. The simplest treatment involves the use of medicated shampoos to suppress growth of involved microorganisms and control the skin proliferation and scaling. Shampoos for seborrheic dermatitis may contain sulfur, selenium sulfide, zinc pyrithione, tar, salicylic acid, or oil of Cade and have been available for many years. Azole-based shampoos (Ketoconazole) are very effective and have been recently made available over the counter in many countries. Other medicated shampoos may contain fluconazole. In some more severe cases, systemic antibiotics may be necessary to control the skin bacterial flora and reduce the inflammation.

Hair loss that may occur in severe cases of seborrheic dermatitis resolves and the hairs fully regrow as the inflammatory process is cured.

Noninfectious Hair Loss

Alopecia Areata

Alopecia areata (AA) is an autoimmune disease that presents as nonscarring hair loss and occurs in populations worldwide. The exact pathogenesis of the disease remains to be clarified. It is a common disease encountered by dermatologists, with a frequency ranging from 0.7% to 3.8%. In the United States, AA was estimated to occur in 0.1–0.2% of the general population, with a lifetime risk of 1.7%. AA can affect any hair-bearing area. It often presents as well-demarcated patches of nonscarring alopecia on skin of overtly normal appearance. The presence of AA is often associated with a higher frequency of other autoimmune diseases. Controversially, there may also be increased psychiatric morbidity in patients with AA.

Approximately 60% of patients with AA express their first patch before 20 years of age and pediatric cases constitute approximately 20% of all patients with AA. Although some AA features are known poor prognostic signs, the course of the disease is unpredictable and the response to treatment can be variable.

A history of allergy has been reported in 10–30% of cases with alopecia areata, but this association remains still unclear. In large studies, immunologic abnormalities, especially thyroid disorders, were found in approximately 10% of the patients with alopecia areata showing the main association with Hashimoto's autoimmune thyreoiditis. Recently, it has been postulated that all patients presenting with alopecia areata should obtain an ultrasensitive thyroid-stimulating hormone (TSH) assay and be tested for the presence of antithyroid antibodies.

Alopecia areata has been found to be present in 1.3–9% of the patients with Down's syndrome, but this association still remains unexplained.

Despite extensive studies and many interesting hypothesis, the pathogenesis of alopecia areata remains a puzzle. Without any doubt, several pathophysiological mechanisms and factors include autoimmune phenomena, and lymphocytotoxic phenomena triggering cytokine secretion may be involved. The role of specific cytokines has been recently discussed, but these phenomena are probably secondary and the initial factor still need to be discover.

In immunohistochemical and clinical studies, the role of viruses, especially CMV, activated T-lymphocytes attacking the hair follicle, keratinocytes and melanocytes, dysfunction of dermal papilla components, together with genetic predisposition (up to 47% of cases has been reported in identical twins) has been postulated.

Psychiatric studies suggest that the presence of alopecia areata may be associated with generalized anxiety disorders or depressions. The latter fact can be also explained by the great social impact of partial or total hair loss in any age groups, especially in children.

Lesions of alopecia areata can occur on any hair-bearing area of the body, but it affects the scalp in approximately 90% of cases. Typically, they appear suddenly overnight or within several days. The hair loss can present as single delimited patches (most common), multiple patches, or extensive, large-surface hair loss.

Based on the morphology of the lesion and involved skin area, the disease can be clinically classified as follows:

- Patchy AA, in which there is a partial, localized loss of scalp hair (*Fig. 146.7*)
- Alopecia totalis (AT), in which 100% of scalp hair is lost
- Alopecia universalis (AU), in which there is a 100% loss of all scalp and body hair. Approximately 5% of cases of patchy alopecia may progress to AT/AU.

The pattern of hair loss observed in alopecia areata can differ, showing reticular patches of hair loss, ophiasis type (band-like hair loss in parieto-temporo-occipital area), ophiasis inversus – a very rare band-like hair loss in the fronto-parieto-temporal region, and a diffuse thinning over part or all of the scalp.

The ophiasis pattern of alopecia areata begins as a hairless spot unilaterally or bilaterally located supraauricular at the posterior scalp and rarely on the anterior aspect of the scalp. This alopecia type occurs in approximately 5% of the children and is believed to have a poor prognosis.

Alopecia totalis is characterized by the loss of entire scalp hair and may develop in about 5% of patients with partial alopecia. Slow progress of partial alopecia into alopecia totalis is more common in children than in adults (*Fig. 146.8*).

Complete or almost complete hair loss of any localization (scalp, eyebrows, eyelashes, and genital area) occurs in alopecia universalis and may occur with or without prodromic appearance of alopecia areata.

Recently, another variant of acute diffuse and total alopecia has been described in larger series of patients showing similar characteristics. This new variant is characterized by its rapid progression of confluent alopecia patches and extensive skin involvement. Even if the onset and progression of the disease may be rapid, the prognosis is considered to be favorable.

In the classic form, alopecia areata lesions are well demarcated, round, or oval, complete bald patches with smooth and shiny surface. Hair follicle openings are present and are better visible under the dermatoscope. The skin within the patch appears normal, sometimes with a slightly peachy or reddened color. One of the common findings seen at the border of alopecia patches is "exclamation mark hair" – short hair tapered proximally and wider distally. In active disease, the hair-pull test may be positive if performed at the periphery of lesions.

Initial hair regrowth, whether spontaneous or induced by treatment, is typically non- or hypopigmented, but the color usually returns with time. The disease is frequently asymptomatic, although a few patients report pruritus, burning sensations, or pain before hair loss begins. The use of dermatoscopy or videodermoscopy with a magnification of 20–70 times may be a valuable, noninvasive tool in equivocal alopecia areata cases. Microscopic examination of the hair shafts of hair from the edge of lesions, particularly exclamation mark hairs, may reveal subtle defects in the structure and cuticle.

Figure 146.7
Alopecia areata. Alopecia areata in a 12-year-old boy

Figure 146.8
Alopecia totalis, hair loss all over the body

Nails changes are seen in 10–20% of children with alopecia areata. The most characteristic nail abnormality is a grid-like, fine stippling appearing in either vertical or horizontal rows, similar to changes seen in psoriasis. Other nail changes such as opacification, proximal shedding, and longitudinal ridging or more severe dystrophies seem to appear more common in patients with alopecia totalis and alopecia universalis.

The sudden hair loss and its unpredictable course seen in alopecia areata make this to be a challenge for both patients and their families and psychological support is usually required.

Only few therapies for alopecia areata have been comprehensively evaluated in randomized controlled trials. The lack of good evidence-based data for therapeutic approaches is a challenge to the dermatologist in choosing the most suitable treatment. Since there is no causal therapy of alopecia areata, the recommended regimens are designated to control the condition in the best possible manner.

It is important to stress that any therapeutic trial should be given for not less than 3–6 months since the scalp hair grows slow. Both patients and parents need to be educated about this issue.

In children, the most common therapy of alopecia areata is topical administration of potent steroids (class II steroids) without or with time-limited occlusion. Class I ultrapotent steroids can be used only in intermitted pulse regimens to avoid local skin atrophy and potential systemic effects of drug absorption.

Knowing that a high percentage of children with alopecia areata may demonstrate spontaneous hair regrowth, some physicians do not initiate any therapeutic action and instruct both patients and parents to wait for such spontaneous remission without initiating topical steroid administration as described above.

In general, however, patients with alopecia areata should be referred to a dermatologist for further evaluation and initiation of treatment.

For children less than 10 years of age, midpotent topical corticosteroid is the first line of therapy. Recently, a combination of 5% minoxidil solution twice daily and topical class II steroid has been recommended. If there is no response after 6 months, short-contact local sensitization (immunotherapy) with anthralin can be tried. For patients older than 10 years of age with less than 50% scalp involvement, intralesional injections of triamcinolone acetonide have been recently discussed by US authors to be the first option for therapy. However, if there is no improvement after 6 months, potent topical corticosteroid under occlusion at night and short-contact anthralin sensitization usually together with twice a day application of 5% topical minoxidil are also postulated.

For children and adolescents with more than 50% scalp involvement, topical immunotherapy with DPCP is the treatment of choice (*Fig. 146.9*).

Other therapy regimens include phototherapy and photochemotherapy, excimer laser application in limited patchy alopecia areata, infrared irradiation as monotherapy

Figure 146.9
Alopecia areata in an adolescent male patient. Progress of hair regrowth under short-contact local sensitization with DPCP

or adjunctive to conventional therapy have been demonstrated to have some success. Photodynamic therapy is considered to be ineffective.

Several reports of the use of modern biologics, including etanercept, efalizumab, adalimumab, and infliximab failed to show any improvement in patients with alopecia areata. Similarly, the use of topical calcineurin inhibitors was found to be unsuccessful.

It has to be stressed that in any of the therapy regimens discussed above, only adjuvant acting drug should be considered. Concomitant use of irritating or immunomodulatory agents such as anthralin and DPCP with drugs having anti-inflammatory properties such as corticosteroids leads to mutual neutralization of the biologic activity of both individual components, making such combinations ineffective.

In many cases of alopecia areata, the common-sense perception "more brings more" is not applicable.

Despite intensive clinical trials, there is still a need of developing treatment options for refractory cases and for specific hair-bearing sites (i.e., eyelashes) where treatment choices are almost nonexistent. Because of higher psychiatric morbidity in patients with alopecia areata, psychosocial support is a valuable tool and should be an integral part of any management plan.

Telogen Effluvium

Telogen effluvium occurs when the normal balance of hair in growth and rest phases is disrupted, and the telogen phase predominates. Disproportionate shedding leads to a decrease in the total number of hair. All anatomical localizations may be equally involved. The hair-pluck test usually shows up to 50% of hair being in a telogen phase (normally 10–15%). These results can, however, vary in persons with advanced disease. Majority of patients with telogen effluvium have had inciting events in the 3–4 months before starting hair loss (*Figs. 146.10a, b*).

In patients with telogen effluvium, the physician should always look for causes of severe metabolic derangements, toxic exposures, or underlying chemotherapy. No specific treatment for hair loss is required because normal hair regrowth usually occurs with time. Lack of significant historical events and a delay in regrowth should raise suspicion for syphilitic-derived alopecia.

Three basic pathways can be seen in patients with telogen effluvium:

1. An environmental insult that "shocks" the growing hair follicles, arresting hair in its telogen phase. This results in an increase in hair shedding and a diffuse thinning of hair on the scalp. This form of telogen alopecia can develop rapidly with the onset 1–4 months after the shock incident. If the trigger is short lived, the hair follicles may quickly return to their growing state. This form of telogen effluvium usually lasts less than 6 months and the affected individuals regain their normal scalp hair density again within a year.
2. The second form of telogen effluvium develops more slowly and persists longer, most likely as a response to a persisting trigger factor. The hair follicles may not all of a sudden shed their hair fibers and enter a resting

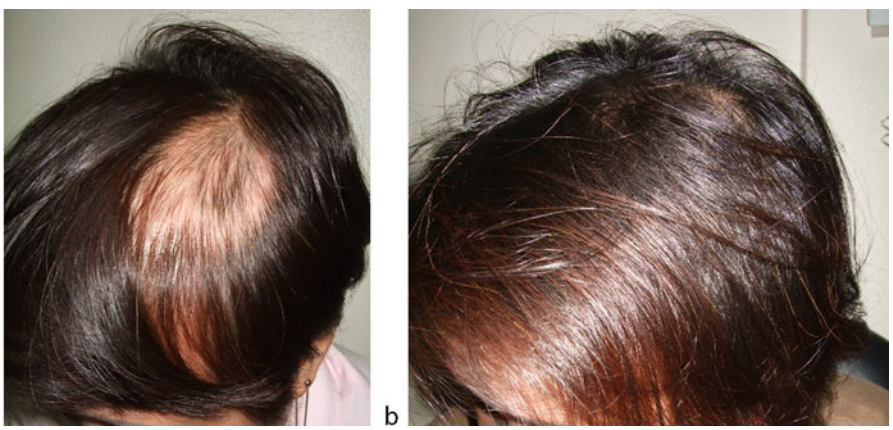

Figure 146.10
Telogen effluvium. (a) Telogen effluvium in a young girl to the stress resulting from surgery. (b) Full and quick hair regrowth without specific treatment after recovery from the surgery

telogen state. Instead, the follicles enter their resting phase but do not return to a new anagen hair-growing state and stay arrested in the telogen phase. This results in a gradual accumulation of telogen hair follicle state and progressive decrease of anagen hair follicles with growing hair. In this form of telogen effluvium, slow thinning of the scalp hair is more prominent than the noticeable hair shedding.

3. In a third type of telogen effluvium, the hair follicles do not stay in a resting state but rather cycle through truncated growth cycles. When this happens, the individual experiences thin scalp hair and persistent shedding of short, thin hair fibers.

Telogen effluvium can occur in many different conditions. In children, the most important causes of telogen hair loss include physiologic effluvium of the newborn, early stages of androgenic alopecia, injury or stress, high and prolonged fever (i.e., by malaria), severe infection, severe chronic illnesses or major surgeries, severe psychological stress, hypothyroidism and other endocrinopathies, and severe malnutrition. Telogen effluvium can also occur after treatment with specific antikeratinizing agents (i.e., etretinate), anticoagulants (especially heparin), antithyroid agents, or anticonvulsants and hormones.

There is no effective treatment for telogen effluvium. Educating both patients and parents about the pathophysiology of the disorder and its favorable prognosis can avoid unnecessary stress and desperate seeking for immediate solution.

However, adolescents predisposed to androgenic alopecia may show incomplete hair regrowth with the pattern typical for androgenic alopecia.

Anagen Effluvium

Anagen effluvium is a diffuse hair loss (similar to telogen effluvium), but it develops rapidly and affected individuals can lose all their hair. The main cause of anagen effluvium is the therapy with cytostatic drugs for cancer or those who have ingested toxic products. All these substances suppress cell proliferation. Cytostatic cancer drugs and various toxins and poisons arrest or inhibit the proliferation of cells in the hair follicles. The most common cytotoxic drugs causing telogen effluvium are cyclophosphamide, methotrexate, 6-mercaptopurine, doxorubicine, and vincristine. Anagen effluvium can be also associated with colchicine, toxic levels of boric acid, lead, thallium, arsenic, bismuth, and Coumadin. The result is a sudden stop of hair fiber generation and a very rapid onset of hair loss. Patients who start anticancer treatment can pull their hair out in clumps within the first 2 weeks of therapy, however the degree of hair loss varies from person to person. Some patients may have a mixture of anagen effluvium and telogen effluvium and have more limited hair loss. Some cancer treatment centers try to block the hair loss using a cold therapy. More popular in Europe than North America, cold therapy involves covering the scalp with ice packs or using a special hood filled with cold water while the anticancer drugs are given. The cold decreases the skin blood flow and sends the hair follicles into suspended animation prior to contact with the drug and prevent the hair follicle cells from accumulating the drug and being damaged by it.

The recovery from anagen effluvium is usually as rapid as its development. Because the follicles are just frozen in time, they are ready to grow once the factor causing the anagen effluvium has been removed. On completion of an anticancer drug treatment course, patients may notice new hair growth within a month. The hair follicles are not destroyed, so the hair growth speed and hair density remain normal. However, some patients may notice changes in the nature of the new hair finding them changed from straight to curly or vice versa, or changing hair color. Such changes are usually permanent.

Scarring (Cicatricial) Alopecia

Cicatricial alopecias cause permanent hair loss. These disorders destroy hair follicles without regrowth and follow an irreversible course. It is likely that they involve stem-cell failure at the base of the follicles, which inhibits follicular recovery from the telogen phase. Inflammatory processes, including repetitive trauma as in trichotillomania, also may lead to such stem-cell failure. Other processes may be caused by autoimmune, neoplastic, developmental, and hereditary disorders.

Among these disorders, discoid lupus, pseudopelade in Caucasian population, and follicular degeneration syndrome, especially in patients with African origin, are most common. Scarring alopecia may also be part of a severe condition such as systemic lupus erythematosus. Dissecting cellulitis, lichen planopilaris, and folliculitis decalvans also may cause scarring alopecia. In early stages of the disease, some lesions may respond to treatment with intralesional steroids or antimalarial agents. Patients suffering from scarring alopecia should, as early as possible, be referred to a physician who specializes in hair-loss disorders.

In all forms of scarring alopecia, the hair loss is potentially permanent, and irreversible destruction of the hair follicles is followed by their replacement with scar tissue. Most forms of scarring alopecia first occur as small patches of hair loss that may expand with time. In some cases, the hair loss is gradual, without noticeable symptoms, and may proceed unnoticed for a long period of time. In other cases, the hair loss is associated with severe itching, burning, and pain, and is rapidly progressive. The scarring alopecia patches usually look different from alopecia areata in that the edges of the bald patches are more "ragged." Affected areas may be smooth and clean, or may have redness, scaling, increased or decreased pigmentation, or may have raised blisters with fluids or pus coming from the affected area. These visual indicators may help with diagnosis, but it is difficult to diagnose a scarring alopecia just from the pattern of the hair loss and the nature of the scalp skin. If scarring alopecia is suspected, one or more skin biopsies need to be done to confirm the diagnosis and help identify the particular form of scarring alopecia. A small biopsy of 2–4 mm in diameter is enough for histological examination. Scarring alopecia usually burns out, hairless patches stop expanding, and inflammation, itching, burning, or pain successively reduces. Microscopically (dermatoscopy and videomicroscopy), no hair follicles can be detected. Rarely, a few hair follicles, at least at the periphery of a bald patch, may persist and the hairs can regrow in these areas.

Infection-Related Scarring Alopecias

Folliculitis Decalvans

Even if folliculitis decalvans is not a primary alopecia, it is an important part of diseases leading to focal hair loss. Folliculitis decalvans is a profound hair follicle infection showing crops of patchy lesions, which usually ends as postinflammatory scarring and permanent hair loss (*Fig. 146.11*).

This disorder is usually seen in adolescents and young male adults and is very rare in children. The scalp is most commonly affected, but the lesions may also appear on the trunk, axilla, and pubic region. In these localizations, folliculitis decalvans should be distinguished from acne inversa (hidradenitis suppurativa) demonstrating perifollicular nodules and cysts.

Typical lesions of folliculitis decalvans show painful follicular and perifollicular nodules, patches, and crusts, surrounding already atrophic and scarring areas. If the hair is coming out in tufts from enlarged follicular openings, this variant of folliculitis decalvans is known as "tufted folliculitis" and, if not sufficiently treated, always leads to irreversible hair loss and deep, painful scarring.

Figure 146.11
Folliculitis decalvans. Persistent, deep mixed fungal and bacterial infection of the scalp of a 15-year-old male

Therapy of folliculitis decalvans is difficult and usually frustrating for both patient and physician. From all available antibiotics, only those that sufficiently penetrate hair follicle such as tetracyclines, clindamycin, or erythromycin are recommended. Some authors recommend a combination therapy with one of these drugs and rifampicin. Treatment is, unfortunately, not curative but in most cases can suppress the disease and prevent spreading to surrounding scalp areas and prolong relapse intervals. Long-term administration of antibiotics is always needed to achieve satisfactory disease control.

Acne Keloidalis Nuchae

Acne keloidalis nuchae (also known as keloidal folliculitis) is clinically very similar to folliculitis decalvans showing deep folliculitis and perifolliculitis located in the upper neck and distal occipital scalp. In severe cases, deep abscess and interfollicular sinus formations are common. Lesions are often associated with pain and discomfort, especially if pressure is applied on affected areas (i.e., while sleeping).

Acne keloidalis nuchae affect mostly postpubertal males above the age of 12–14 years and is frequently seen in patients of African lineage, and is also common in Arabic patients, especially in warm and humid countries. In contrast to folliculitis decalvans, scars formed in acne

Figure 146.12
Acne keloidalis nuchae. Typical picture of acneiform lesions and deep keloidal scaring in a young male with acne keloidalis nuchae

keloidalis are often deep and nodular with polycyclic appearance. Lesions spread centrifugally and infection may be transmitted into other part of scalp by scratching. It is postulated that short haircut, especially in persons having thick and curly hair that can lead to development of ingrown hair, may promote the disease (*Fig. 146.12*).

Treatment is difficult and long-term systemic antibiotics that sufficiently penetrate into hair follicle (see above) are usually necessary. In many cases, combination with systemic or topical steroids may be helpful. In nonactive intervals, intralesional administration of steroid suspension may assist the treatment of persistent keloids. In some patients, surgical intervention and removal of deep, plaque-like keloids may be necessary.

Similar to folliculitis decalvans, the development of acne keloidalis nuchae may be promoted, and existing disease may often be accelerated by the use of hats, tight and occlusive-like caps or helmets, and stiff shirt collars, especially in hot and humid climate.

Dissecting cellulitis of the scalp (or perifolliculitis abscendens capitis) is a scalp skin disorder combining many clinical features of both folliculitis decalvans and acne keloidalis nuchae, even if the etiology may be different. In a typical situation, descending folliculitis begins on the occipital area of the vertex and spreads to the entire scalp showing follicular and perifollicular nodules often connected by deep sinuses and fistulae. Disintegration of the scalp skin and subcutaneous tissue may lead to the formation of pus reservoirs and dissection of skin from the underlining tissue – the phenomenon that, together with descending spreading of the lesion, gave the name to this pathological condition.

Descending cellulitis of the scalp usually leads to scarring and permanent hair loss. Treatment with systemic tetracyclines or erythromycin together with surgical intervention to drain deep debris collection is one of the possible options. Some studies, however, prefer the use of systemic isotretinoin as the first-line therapy.

Descending folliculitis occurs more frequently in adolescents and young adults having thick, curly hair and bushy hair growth with obstruction of sebum extraction. Upregulated inflammatory reaction to proprionibacterium acnes has been postulated as a possible causal factor, especially the association of descending folliculitis of the scalp with hydradenitis suppurativa and acne conglobata is not uncommon ("acne triad"). Since in many patients with acne triad pilonidal sinus is also present, all the disorders have now been grouped into a "follicular occlusion tetrad."

Disorders with Overgrowth of the Body Hair (Hypertrichoses)

Hypertrichosis – an abnormal or extensive hairiness – can be divided into congenital and acquired in terms of onset of the condition and localized or diffuse (generalized) in terms of affected body area. The term hypertrichosis is reserved to androgen-independent extensive hair growth in both female and male individuals. In females, hypertrichosis occurs without any evidences of abnormal menstrual cycles or masculinism. On the other hand, hirsutism refers to abnormally increased hair growth in girls and women showing typical, androgen-dependent hairiness in areas in which hair is usually not prominent. Hirsutism may also be seen as a "physiologic" variant of hair growth seen in different female members of the same family and does not need specific treatment. Affected girls and women are seeking medical intervention mostly because of individual or social pressure asking for removal of "overexposed" hair. In this respect, the frequent use of the terms "hypertrichosis" and "hirsutism" as synonyms is inappropriate from both an ethological and a clinical point of view. Hirsutism will not be discussed in this chapter.

One of the hereditary hypertrichoses is the general hypertrichosis lanuginosa, an autosomal-dominant disorder, in which the lanugo hair is confluent and generally cover the entire hair-bearing areas. In some cases, the hair may be then spontaneously lost during childhood; in most of the cases, however, the lanugo hair persist for life. Generalized hypertrichosis may create a real personal and social problem for children and their families.

General hypertrichosis has been described to be associated with different abnormalities, some of them have been connected with syndromes, for example, skeletal abnormalities, missing teeth, glaucoma, and many others. Over 25 different syndromes have been described as far. For more detailed information, we recommend consultation of genetic textbook or general monographs.

Localized inherited forms of hypertrichosis are usually divided into two groups – nevoid hypertrichosis and the so-called idiopathic hirsutism.

In the latter, extensive body hair of male pattern is present in girls without evidences of hormonal abnormalities or endocrine metabolic function. This may be understood as an overreacting response of the hair follicle to normal levels of androgenic hormones in genetically predisposed girls. Taking this into consideration, as per the definition above, the incorrect term "idiopathic hirsutism" should be replaced with "idiopathic inherited hypertrichosis."

Idiopathic inherited hypertrichosis (idiopathic "hirsutism") may often be seen in girls and women of particular ethnic origin, that is, in Mediterranean (Hispanic, Jewish, and Arabic) or Welsh girls. Physicians should, however, take into consideration that what is normal and acceptable in some regions may be seen as a handicap or disfiguration in others and that both children and their parents may force the doctor to treat this "wild disease."

Nevoid hypertrichosis describes an entity in which hair of abnormal length, diameter, or/and color may grow in different parts of the body often associated with other devoid abnormalities or localized developmental malformations.

Localized hypertrichosis is usually a part of large, congenital melanocytic nevi (i.e., Becker's nevus) or may be seen in plexiform neurofibroma, smooth muscle hamartoma, underlying kyphoscoliosis, duplication of the part of spinal cord, or tethered cord (as in faun-tail nevus). Localized hypertrichosis occurring in anterior cervical area is currently seen as a part of an autosomal recessive malformation connected with developmental delay and peripheral neuropathy.

In many cases, however, localized hypertrichosis is seen as a simple hair follicle hamartoma and does not have association with other defects.

Acquired Hypertrichosis

Several therapeutic agents may be related to the development of secondary or acquired hairiness. Newly stimulated hair is typically vellus-like.

One of the most prominent drugs causing diffuse hypertrichosis is minoxidil, a drug primarily developed and used to treat hypertension. Patients treated with this derivate of piperidinopyrimidine develop extensive new hair growing on the back, shoulders, extremities, and, especially on the face. This phenomenon occurs several weeks or even months after administration of the drug and slowly resolves after discontinuation of the drug. Young patient population is less affected by this drug when it is used systemically. However, similar development of localized hypertrichosis can be noticed in children and adolescents treated with topical minoxidil for diffuse scalp alopecia. This therapy is getting to be a standard adjuvant in older children, adolescents, and young adults (see treatment of alopecia areata section in this chapter). In such patients, hypertrichosis may develop on the lateral face, neck, and upper shoulder areas and resolves within months after discontinuation of the treatment.

Another prominent drug widely used in transplantology for prevention of organ rejection and causing diffuse hypertrichosis is cyclosporine. Children and adolescents obtaining the drug for treatment of graft versus host disease, develop gradual, sometimes extensive, hair growth within the first weeks after the drug has been introduced. Coexistence of insulin-dependent diabetes mellitus seems to aggravate the phenomenon. Discontinuation of cyclosporine leads to spontaneous decreasing of hypertrichosis. This process may, however, take months to resolve.

Children treated with phenytoin may also develop localized hypertrichosis. Extremities are the most common regions; face and trunk are usually less affected. Spontaneous regression occurs mostly within a year after discontinuation of the therapy.

Treatment of idiopathic hypoglycemia of the childhood with diazoxide may result in negative side effect in the form of localized forehead, neck, trunk, extremity, and eyebrow/eyelash hypertrichosis. It begins within the first few weeks of application of the drug and resolves usually during within a year after the drug has been stopped. Interestingly, increased hair growth similar to hypertrichosis lanuginosa of the newborns and neonates has been observed in cases when diabetic mother was treated with diazoxide during pregnancy.

Topical steroids are widely used in pediatric dermatology for treatment of inflammatory skin disorders and atopic dermatitis. One of the most prominent side effects of these drugs is extensive hypertrichosis localized to the places of prolonged application. Hair growing in this condition usually do not or only partially regress after discontinuation of the therapy (*Fig. 146.13*).

Figure 146.13
Acquired hypertrichosis. Acquired hypertrichosis on arms and legs due to long-term topical steroid application in an atopic dermatitis girl

Treatment of hypertrichosis is difficult. The most easy, but not always practicable, way is to shave the overgrowing hair. Even if there is an overall belief that this treatment may additionally stimulate the growth of the hair and result in thicker and faster hairiness, this has not been proved in clinical practice. In some regions of the world, depigmentation of hair using hydrogen peroxide is the most common to make the overgrowing hair less visible. Especially when after the use other bleaching agents in parson with dark(er) skin the contrast between the yellowish-white hair and the underlying skin becomes prominent. Applied in children, this technique may, however, lead to massive skin irritation and development of contact or irritative–toxic dermatitis. Chemical or mechanical depilation may be another option and, in large surface areas, is, however, less practicable and may also result in irritative–toxic dermatitis. Additionally, children with large-surface hypertrichosis should not be treated with chemical peels such as sulfides, or thioglycolates because of possible systemic absorption and toxic adverse reaction.

Recently, lasers or combination between laser and xenon pulse light has been successfully applied for treatment of hypertrichosis. It is necessary to stress that such techniques do not "remove" the hair, but primarily reduce their density. The principle of this therapy is a selective photo-chemo-destruction of melanin granules within the hair follicles, which together with thermal effect of laser light results in pigment and follicle destruction. If applied appropriately, this therapy is safe and effective. In less satisfactory outcome, extensive inflammation, postinflammatory patchy hyper- or hypopigmentation, or/and scarring due to thermal collateral damage of the tissue are the most common side effects. Repeated sessions are necessary to achieve satisfactory results.

Electric depilation (electrolysis) is an older, but still well-used, technique of hair removal. Based on thermal follicle destruction,this technique gives more permanent results but is very painful and almost not applicable in children. Side effects, if they occur, are similar to overdosed laser energy with inflammation, dyschromia, and focal perifollicular scarring. In individuals with African or Arabic origin having both ethnic and family predisposition to development of hypertrophic scars, this may lead to development of multiple small keloids in places of destructed hair follicles.

Supportive topical therapy decreasing hair growth through inhibition of ornithine decarboxylase (i.e., as 15% compound crème formulation) may be helpful.

Introduction of eventual systemic medication, however, needs profound endocrinological diagnosis and should always be done in close cooperation with an endocrinologist.

In case of hirsutism, all therapies listed above have only an ancillary value. The principle should be to refer the affected child to pediatric endocrinologist and/or gynecologist for appropriate diagnosis and treatment.

147 Nail Disorders

Eckart Haneke

The nail is the biggest cutaneous appendage. It is an integral part of the functional unit tip of the digit, supports its sensory functions, and is an important tool for manual dexterity, for scratching, and for defense.

The nail develops from fetal week 9 onward and requires an intact terminal phalanx as well as a series of signaling proteins for its correct shape and size. At week 13, the nail field is fully developed and at week 14, the nail plate starts growing to cover the nail field almost completely by week 17. From week 20 onward, the digit and the nail grow synchronously, and at birth the nail plate has normally reached the distal ridge of the finger. If the nail is still shorter, the infant may be born with a distally ingrowing nail. Koilonychia is also frequently seen at birth, but usually disappears spontaneously.

The nail is a plate of keratin containing both hard "hair" keratins and soft epidermal keratins. It is transparent allowing the distal matrix – the lunula – and the nail bed to be seen. The nail is both physically and chemically resistant. Antimicrobial peptides in the nail protect it against bacterial and fungal attack even though it does not have any vascular supply.

The nail is formed in its entirety by the matrix (*Fig. 147.1*), which continuously produces nail substances during the whole life. Most of the matrix is covered by the proximal nail fold, the ventral surface of which forms a horny layer, the eponychium, that is firmly attached to the dorsal surface of the nail. When the nail grows out, it pulls part of this keratin layer with it forming the cuticle, which seals the nail pocket. When this attachment is lost, usually as a result of inflammation, infection, or trauma, the cuticle disappears and foreign material may enter under the proximal nail fold. This further irritates the tissue giving rise to paronychia. In newborns, this may be due to *Candida albicans*, probably acquired during the birth process.

The nail bed is seen as a pink structure through the normal nail. What gives it this pink color is still not completely understood, although it is thought to be due to the particular parallel arrangement of the capillaries running longitudinally in several layers one above the other. The nail is a window to the bed permitting the vascular supply and blood oxygenation to be evaluated. Even subtle color changes can be seen through the thin newborn nail and give important hints at general health indicators. The nail plate is very firmly attached to the nail bed, which produces just a thin layer of keratin allowing the nail to slide over it without losing its attachment.

The distal margin of the nail divides from the nail bed at the hyponychium. This, again, is a specialized structure preventing foreign substances from entering under the nail. Detachment of the nail from the nail bed is called onycholysis, usually, as a result of infection or trauma, and is mostly seen in girls due to overzealous manicure.

The lateral nail folds, together with the proximal one, form a frame for the nail ensheathing it on three sides.

The Newborn Nail

In the newborn, the nail is soft, thin, and pliable. If the big toenail has not yet overgrown the hyponychium, it may grow distal-laterally or laterally. This is easily treated by the mother: a lubricating ointment is applied on the tip of the toe, and in a warm bath, the distal and/or lateral nail folds are gently massaged away from the nail. Within a few weeks, the nail will have reached the tip of the toe.

Koilonychia or spoon nails are frequent and harmless. This minor abnormality disappears by itself within months or the first 2 years of life.

Some weeks after birth, transverse grooves running parallel to the lunula border may be seen. These Beau's lines are thought to be due to the trauma of birth that may temporarily slow down the nail growth rate.

A large number of congenital hereditary diseases and intrauterine damages can affect the nails (*Tables 147.1* and *147.2*). Ectodermal dysplasias (ED) may also affect the nails, particularly the group of tricho-onychotic EDs. Small and hypoplastic nails or fluting are the most common nail changes. Pachyonychia congenita type 1 is a disease of keratins 6a/16 and type 2 of 6b/17.

Nail Changes in Infants

Some infants develop a hypertrophic medial nail wall, which may cover up to one-half of the nail. Debris is

Nail alterations in chromosomal anomalies (Adapted from Haneke E (2006) Nagelkrankheiten. In: Hamm H (ed) Pädiatrische Dermatologie, 2nd edn. Springer, Heidelberg, pp 677–698)

Condition	Nail changes	Other symptoms
Trisomy 3q	Hypoplasia, anonychia	Hirsutism, synophris, eye anomalies, short neck
Monosomy 4p	Overconvex	Fish mouth, cheilopalatoschisis, head asymmetry, preauricular pits, retardation
Trisomy 7q	Overconvex	Facial asymmetry, retardation
Trisomy 8p	Hypoplasia, anonychia	Facial asymmetry, retardation
Monosomy 9p	Wide convex	Hypoplasia of middle face, trigonocephaly, upward slanted eyes, abnormal dermatoglyphics, retardation
Trisomy 9p	Dystrophic, claw-like	Downward slanted eyes, microcephaly, short digits, retardation
Trisomy 13	Narrow, convex, hypoplastic	Cheilopalatoschisis, aplasia cutis, polydactyly, hemangiomas, microcephaly, vitium cordis, genital hypoplasia
Trisomy 18	Hypoplasia of fifth finger and fifth toe	Cramped hands with overlapping fingers, short sternum, abnormal dermatoglyphics
Trisomy 21 (Down's syndrome)	Clubbing and macronychia	Upward slanted eyes, hypoplasia, short broad fingers, four-finger-fold, vitium cordis, cutis marmorata
X0 (Turner syndrome)	Small, convex, deep lying	Pterygium colli, short neck, congenital lymphedema, ovarial dysgenesis, cubitus valgus, nevi
Ring chromosome group C	Pachyonychia	Facial anomaly, retardation

collected in the deep fold leading to subacute inflammation. Massaging from the nail to the plantar surface of the tip of the toe is usually effective. When it does not respond, it may simply be removed and the small wound left for second intention healing.

Congenital malalignment, originally described as congenital dystrophy of big toenails, is another abnormality of infant nails. Often, the distal phalanx of the big toe is deviated laterally and the nail even more. This may lead to oblique shearing trauma causing onycholysis and, as its consequence, the nail becomes oystershell-like distorted, triangular, discolored, thickened, and sharply bent medially. The condition may improve spontaneously up to the age of 2 years; however,

Table 147.2
Teratogens and their effects on nails (Adapted from Haneke E (2006) Nagelkrankheiten. In: Hamm H (ed) Pädiatrische Dermatologie, 2nd edn. Springer, Heidelberg, pp 677–698)

Teratogen	Nail changes	Other symptoms
Alcohol	Hypoplasia, anonychia of fifth finger, convex	Microcephaly, small lid opening, epicanthus, short nose, flat philtrum, retardation
Phenytoin	Hypoplasia, longitudinal pigmented streaks	Cheilopalatoschisis, deep-set ears, hirsutism, sunk-in nasal bridge, broad mouth, short neck, finger-like thumbs, short tapering fingers, wide distance between nipples
Trimethadione	Hypoplasia	Microcephaly, V-shaped merging eyebrows, ptosis, malformed ears, small flat nose, deafness
Warfarin	Hypoplasia	Hypertelorism, small nose, short neck, brachydactyly, spotted epiphyses

if this does not occur, the nail bed shrinks permanently, a distal nail wall develops, and the nail becomes more and more unsightly, sometimes painful. Unfortunately, there is no sign indicating spontaneous healing. Treatment is surgical by the age of 2 years with rotation of the entire nail organ into its correct axis.

Nail Changes in School Children

Ingrown nails are a common condition in children from around 12 years onward. There is a discrepancy between a relatively wide nail and a narrow nail bed distally. In most cases, the nails are markedly curved. Usually, the patient tends to cut the distal corner of the nail, leaving small spicules in the depth of the distal lateral nail groove, which pierce into the soft tissue when the nail grows out. Three stages of ingrown nails are distinguished: (1) Reddening and swelling of the lateral nail fold. (2) Secretion. (3) Granulation tissue. There may be fluctuations between stages 1 and 3 depending on foot care and hygienic measures. Treatment may be conservative in early stages with taping, packing, gutter treatment, artificial nails, or nail braces. This is a long-term treatment and requires good patient compliance. When conservative treatment is not successful or feasible, definitive surgical cure is achieved by selective lateral matrix horn resection or phenolization. Wedge excisions are obsolete.

Nail Signs

There are some nail changes that may be – to a certain degree – a marker of an internal or general condition.

Beau's lines are transverse, slightly curved furrows that run parallel to the lunula border. They indicate a temporary slow down in the nail growth that had occurred some weeks ago, most commonly a disease with high fever. Beau's lines are more marked in fast-growing fingernails than in slow-growing toenails. Single-digit Beau's lines are typical sequelae of a past surgical intervention.

Koilonychia, also called spoon nails, is typically seen in iron deficiency. It is a frequent finding in the big toenails of newborns and usually disappears spontaneously within a few weeks.

Leukonychia occurs as small dots, short transverse lines, or rarely as narrow longitudinal lines. Punctate and striate leukonychia is frequent in young girls, mostly due to overzealous manicure. Longitudinal leukonychia is caused by a narrow rim of keratin running from the lunula to the free nail edge; its cause is usually an onychopapilloma.

Melanonychia most commonly occurs as a longitudinal brown streak. In children, it is usually due to either a lentigo or a junctional melanocytic nevus of the matrix; nail melanomas are extremely rare in children. In warmer climate, some pathogenic fungi may produce a soluble melanin that may give rise to a grayish-to-blackish spike in the nail. In contrast to true melanonychia, subungual hematomas never reach the free nail margin and can easily be diagnosed dermatoscopically. Most hematomas have a history of a previous trauma.

Most other colorations are due to exogenous dyes or drugs.

Onycholysis is the distal separation of the nail from the nail bed. It has often a curved smooth border; this is called onycholysis semilunaris and is a result of manicuring the nail with sharp instruments.

Proximal onycholysis is called *onychomadesis*. It develops when the nail stops growing for a certain period. Single-digit onychomadesis typically develops after a

run-around or acute paronychia, whereas general diseases cause onychomadesis in a symmetrical fashion. It may be followed by nail shedding.

Characteristic Nail Conditions

Twenty nail dystrophy is characterized by the gradual development of rough nails of both the fingers and toes, a phenomenon called trachyonychia. The nails show fine depressions on their surface. One nail after the other may be affected, but very often one single nail remains spared. In the more common form, the nails lose their shine, but there is also a shiny variant. Skin lesions are not found. In most cases, histopathology exhibits a spongiotic dermatitis of the matrix; less frequently, a lichen planus, psoriasis, or eczema may be seen. Whether or not the spongiotic changes indicate an isolated alopecia areata of the nails remains to be clarified. The course is usually benign in children with spontaneous resolution around the age of 16. A combination of topical calcipotriol with a potent steroid accelerates healing.

Twenty nail dystrophy must be differentiated from nail lichen planus as this may cause permanent nail dystrophy even in children. The nails are rough, ridged longitudinally, and tend to break.

Nail Psoriasis

Nail involvement in children with psoriasis is not rare (see Papulosquamous and Related Disorders Including Psoriasis). Subungual hyperkeratosis, distal onycholysis, pits (*Fig. 147.2*), and so-called salmon or oil spots are the most frequent signs. Pits and small whitish spots develop from tiny psoriatic lesions of the most proximal part of the matrix. Salmon spots represent psoriatic plaques of the nail bed. Psoriatic leukonychia is due to a psoriatic affection of the middle of the matrix. Complete nail destruction indicates psoriatic involvement of the entire nail organ and is often seen in arthropathic psoriasis. In children, the nails may also become very thick and rough with huge subungual hyperkeratosis. Treatment of nail psoriasis is difficult as the nail wall and plate cover the diseased portions of the nail organ. Any systemic therapy resulting in clearance of the skin potentially also improves nail psoriasis.

Figure 147.2
Psoriasis of the nails in a 13-year-old boy

Lichen Planus

Roughly one-tenth of the patients with lichen planus develop nail changes. In about one-quarter, the nail changes come after diagnosis of skin and mucosal lesions. Most characteristically, this condition affects the proximal and dorsal matrix with subsequent ridging, roughness, and loss of shine of the nail. The problem with nail lichen planus is its propensity to permanently destroy the nail. Early treatment is therefore mandatory. Topical vitamin D_3 analogues, best in combination with a steroid, should be started first. When this is ineffective over a course of >3 months, low-dose etretinate may be given. An alternative is intramuscular triamcinolone acetonide crystal injections, about 0.5 mg/kg bodyweight every 4–6 weeks.

Alopecia Areata

Alopecia areata often affects the nail. The more severe it is, the more likely are the nail changes. The nails become rough, nontransparent, and lose their shine. Thickening and brittleness occur when the nail plate contains a lot of serum inclusions. Histologically, alopecia of the nail represents a spongiotic dermatitis and it may be difficult to differentiate it from eczema. No specific treatment is known, but it appears that ungual alopecia areata runs a benign course.

Eczema

The different forms of eczema may cause variable nail changes. Rubbing with the surface of the nail in chronic atopic eczema is the main cause for the characteristic shiny nails. In dyshidrotic eczema, the periungual skin may be involved with small itching vesicles. Allergic contact dermatitis may cause nail deformation, particularly when the

allergen gets under the proximal nail fold and induces an eczematous change in the matrix. In chronic eczema, a thickening of the proximal nail walls develops with rounding of its free margin and spontaneous loss of the cuticle. This leads to separation of the nail fold's undersurface with the nail, and more foreign substances, including allergens, microbes, and dirt, may enter the nail pocket. In girls, nail cosmetics may play a causative role.

Erythema Multiforme

Erythema multiforme is a skin disease characterized by round erythematosus lesions that develop a central blister, the roof of which often becomes necrotic and thus gray. The tricolor appearance make the lesions look like targets. When the nail organ itself is involved, onychomadesis, nail dystrophy, and later shedding may develop.

Infections and Infestations

Viral warts are common in periungual locations and are less frequent subungually. They are often rather oval than round, grayish hard lesions with a rough and sometimes clefted surface. The problem is not the diagnosis, but rather their treatment. A conservative approach with aggressive keratolysis and regular cautious curettage of the necrotized wart keratin has been adopted. Saturated monochloroacetic acid is applied sparingly on the wart and allowed to dry. It is then covered with 50% salicylic acid plaster and fixed with adhesive band. With all this on, the patient has to perform a hand or footbath as hot as tolerated twice a day for about 10 min. After a week, the adhesive tape and salicylic acid plaster is removed, showing a white soft surface of the wart. This is gently curetted and the procedure repeated until the wart is gone. The success rate is over 90%. However, after several debridements, the monochloroacetic acid tends to cause a nagging pulsating pain, and the treatment has to be interrupted. Whether duct tape is an alternative remains to be seen. Cryotherapy has about the same cure rate, but is very painful at the nail. Lasers are not more effective than other destructive methods. Limited evidence exists for the efficacy of topical 5-fluorouracil, intralesional interferons, photodynamic therapy, imiquimod, and a variety of vaccinations. Bleomycin, dinitrochlorobenzene, and other obligate topical sensitizers, 5-fluorouracil, interferons, and photodynamic therapy, are potentially hazardous or toxic treatments.

Digital herpes simplex is often underdiagnosed. It is commonly misdiagnosed as a recurrent paronychia or felon. It presents with painful blisters around the nail or on the pulp of the digit that are barely visible under the thick horny layer of this region. Very often, a red stripe indicating lymphangitis is seen, sometimes even before any visible vesicle. Within a few days, the blisters may become putrid. When the diagnosis is made early enough, acyclovir may be used. Antibiotics are of no use.

Although *mollusca contagiosa* are probably transmitted with the scratching finger nail, their localization at the nail is very rare.

Cow pox, milker's nodule, and orf are clinically almost identical lesions caused by similar viruses. The first are usually acquired from wild living cats, the second from an infected udder, and the last from sheep. One to two weeks after infection, a nodule develops with sanguinolent secretion. Healing takes a few weeks.

The most common bacterial infection is *bulla repens*, also called run-around. This is often derived from hangnails that are torn out and leave a small wound. It is mostly due to staphylococcus aureus, less frequently streptococci. In the beginning, a clear blister develops, which soon becomes cloudy, and yellow pus can be seen. Pain is moderate to severe. Treatment of choice is opening of the blister and disinfective baths twice daily as well as dressings with antimicrobial ointments. Systemic treatment is rarely necessary.

A *whitlow* is a deeper infection due to pyogenic micrococci. Reddening, swelling, and pulsating pain are characteristic. A subungual felon may cause irreversible matrix damage within 24–48 h in children and should therefore be treated as an emergency. A swab has to be taken for bacterial culture and systemic treatment with a staphylococcus-specific antibiotic begun until the result of sensitivity testing has arrived.

Blistering dactylitis is a streptococcal infection that often remains undiagnosed as it usually causes no symptoms. Blisters occur on the tip of the digits and the horny layer later sheds off. They may represent a chronic streptococcal focus and require treatment. The blister roof is cut and the finger disinfected. Systemic penicillin treatment is recommended.

Onychomycoses are fungal infections, most commonly of the nail bed. Dermatophytes are responsible for more than 80% of the cases. They are rare in infants and increase in prevalence with age.

Distal lateral subungual onychomycosis is the most frequent type. The fungus infects the tip of the digit and then the hyponychium and nail bed, where it slowly grows proximally toward the matrix. The nail plate itself is rather an obstacle for the fungus than the site of infection; thus the nail plate covers the infection and makes it difficult to treat. The nail bed develops a subungual hyperkeratosis that is

seen as a yellowish substance through the nail. Only in late advanced stages will the plate be destroyed (Fig. 147.3).

In *proximal subungual onychomycosis*, the fungus breaks the barrier of the cuticle and grows along the underside of the proximal nail fold toward the matrix. Once this is reached, the fungus is included into the growing soft nail and penetrates it in virtually all layers. The nail bed does not produce a subungual hyperkeratosis. The nail that is invaded by the fungus takes on a whitish color; hence, the term proximal subungual white onychomycosis is often used (Fig. 147.4).

Superficial white onychomycosis is a peculiar infection of the surface of the nail plate. Several molds may be the causative pathogen, particularly in warm climate, whereas *Trichophyton mentagrophytes* is the common pathogen in temperate climate zones.

Figure 147.3
Onychomycosis in a 12-year-old boy

Figure 147.4
Subungual exostosis of the big toe in an 11-year-old girl

Endonyx onychomycosis is mainly caused by *T. soudanense* and *T. violaceum*. The pathogen grows entirely in the nail plate.

Any of these onychomycosis types may progress to *total dystrophic onychomycosis*. This, however, is also a common finding in *chronic mucocutaneous candidosis*.

Treatment of childhood onychomycoses is hampered by the fact that the potent systemic antifungals are often not approved for use in children. As long as the infection has not yet reached the matrix, an antimycotic lacquer may be used, but the treatment has to be performed with consistent compliance over many months. When the matrix is reached, in proximal subungual and total dystrophic onychomycosis, systemic treatment is advised. Depending of the age and weight, terbinafine, fluconazole, or itraconazole are the most potent drugs. In some countries, griseofulvin is still available. Chemical nail avulsion supports treatment in total dystrophic onychomycosis.

Nail involvement is not uncommon though often overlooked in *crustous scabies*. There is subungual hyperkeratosis and some nail roughness. There may be hundreds of mites under the nails, and failure to treat subungual scabies usually results in recurrence and spread of the infection. Treatment is with topical scabicide drugs, which have to be brushed in twice daily over several days. Ivermectin is an alternative.

Tungiasis is common in endemic regions and often causes some sort of paronychia. Under the nail in the region of the hyponychium, the female *tunga penetrans* digs itself into the skin and causes an itching nodule growing to the size of a pea. A small black dot represents the opening through which the sand flea lays its eggs. Treatment of choice is curettage of the hole in which the flea lives in order to prevent infectious complications such as erysipelas, cellulitis, or gangrene.

Tumors of the Nail Organ

Benign nail tumors are not exceptional in childhood. They often differ in their clinical appearance from the same tumors in other locations.

Koenen Tumors

Koenen tumors are round to sausage-shaped lesions that develop in about one-half of the patients with tuberous sclerosis from the age of 12 years onward. They are flesh

colored and asymptomatic. Most grow under the proximal nail fold and thus cause a groove in the nail plate. They may be severed at their base, but new lesions tend to develop.

Recurrent Digital Fibromatosis of Reye

In early infancy, reddish dome-shaped lesions develop on the digits with the exception of the thumbs and big toes. When they grow in the periungual skin, they may distort the nail. Treatment is not necessary as they disappear spontaneously.

Keloids

Keloids in the nail region are rare, but may be monstrous. The most common cause is electrosurgery for periungual warts, which should therefore be abandoned. They may be painful and cosmetically embarrassing.

Angiomas

Pyogenic granuloma, an eruptive angioma, is sometimes seen around or even under the nail. It presents as a rapidly growing red nodule that tends to erode, superficially ulcerate, and bleed easily. It responds to potent topical steroids under occlusion, but may also be carefully removed at its base with cautery of the feeder vessel. The specimen has to be examined histopathologically in order to rule out other tumors.

Port-wine stains rarely affect the nail region. Whereas the periungual skin is deep violaceous red, the nail itself is usually white.

Glomus tumors are exceptional in children.

Exostosis

Subungual exostosis is a reactive lesion that may occur at any age. The most characteristic localization is the medial dorsal aspect of the distal phalanx of the big toe, but other digits may be involved as well. They present as a stone-hard round lesion covered with skin that is extended and shiny, usually without the typical ridges of plantar skin. A radiograph confirms the diagnosis. Treatment of choice is the generous surgical removal at the base.

Diagnostic Measures

In most cases, nail alterations do not require many sophisticated and expensive tests. Careful clinical inspection of the digits in relaxed position and with pressure to check potential vascular changes is important. Probing can localize circumscribed pain. Transillumination is useful to check for a cystic lesion or a foreign body. Bacterial and fungal cultures are indicated when an infection is suspected. Radiographs have to be very soft in order not to overexpose the distal phalanx. Computed tomography and magnetic resonance imaging are sometimes helpful as is variable high-frequency ultrasound. Direct microscopy of subungual keratin allows to find fungi. However, the gold standard for diagnosis is histopathology, which requires a biopsy.

Nail Biopsy

In case of onychomycosis, a nail clipping stained with PAS is twice as sensitive as a fungal culture.

For an incisional biopsy, a local anesthesia is applied. This may be a distal or proximal digital block or a transthecal block. The biopsy site within the nail organ is crucial: Changes involving the nail surface require proximal matrix tissue, best as a lateral longitudinal nail biopsy. A punch may be taken for nail bed lesions but should not have a diameter greater than 3 mm.

Nail Avulsion

This is very rarely helpful and must never be done as a substitute for a diagnosis. Many conditions are worsened by avulsing the nail.

Under local anesthesia, a blunt, slightly curved nail elevator is inserted under the proximal nail fold to separate it from the underlying nail by careful back-and-forth movements from one side to the other. The elevator is then pushed through the hyponychium till the matrix to detach the plate from the nail bed and matrix. The proximal avulsion approach detaches the nail from the matrix; this is technically more demanding but less traumatizing.

When the nail plate is lacking after avulsion, the pulp of the tip of the digit may be dislodged dorsally; this is often the case in the big toenails. A distal nail wall develops that prevents the nail from growing out. Instead, it becomes thicker, yellowish, and intransparent. With time, it loses its attachment with the nail bed.

Subungual Hematoma

Children often traumatize a finger; most commonly it is a car door crash. The result is a hematoma that causes

considerable pain. When it stretches over more than 50% of the nail field, a fracture is likely and requires adequate repair. In smaller hematomas, drilling a hole over it and releasing the blood immediately relieves the pain.

148 Pigmentary Disorders and Vitiligo

Arti Nanda

This chapter will review the common disorders of skin color including disorders of hyperpigmentation and hypopigmentation. People with colored skin including Asians, Mediterraneans, and Africans are more prone to pigmentary disorders. Parents of children with any deviation from normal pigmentation are concerned about the problem.

Pigment-producing cells called melanocytes are present in the bottom layer (basal cell layer) of skin's epidermis. They comprise 5–10% of cells in the basal layer of epidermis. Through the process called melanogenesis, these cells produce melanin, which is primarily responsible for the color of skin. Once made, melanin is moved along arm-like structures of melanocytes, called dendrites, in a special container called melanosomes and transferred to keratinocytes. The difference in skin color between different people is due not to the number (quantity) of melanocytes in their skin but to melanocytes level of activity of melanocytes.

Disorders of Hyperpigmentation

Hyperpigmentation is caused by the increase in melanin production. The disorders of skin hyperpigmentation will be discussed under the following sections:

1. Birth marks/Pigmented nevi
2. Benign hyperpigmented lesions
3. Postinflammatory hyperpigmentation
4. Hyperpigmentation related to systemic diseases/drugs

Birth Marks/Pigmented Nevi

Transient Pustular Melanosis of the Newborn

Transient pustular melanosis is characterized by pustules present at birth that evolve into macular pigmentation. The pigmented macules fade over 3–4 weeks' time. All areas of the body can be affected, including palms and soles. Gram or Giemsa staining of the pustule shows neutrophils and occasionally eosinophils. Clinical recognition of the condition can help physicians to avoid unnecessary diagnostic testing for infectious etiologies.

Mongolian Spots

Mongolian spots are the most frequently seen birthmarks in infants. These flat bluish grey or brown lesions occur on the back or buttocks. Their incidence varies among racial and ethnic groups and are more often seen in blacks, Native American, Asian, and Hispanic populations. The lesions may vary in size from a few millimeters to 10 cm. They tend to fade with advancing age. It is universally accepted that, in general, Mongolian spots are benign cutaneous manifestations that have no clinical significance. Their atypical or aberrant presentation (*Fig. 148.1*) may be associated with certain inborn errors of metabolism, including mucopolysaccharidosis, GMI ganglisidosis, and phacomatosis pigmentovascularis.

Café-Au-Lait Macules (CALMs)

CALMs present as uniform tan–brown, round or oval macules with distinct margins. They tend to enlarge in earlier years of life and then stabilize. They do not regress with advancing age. Their prevalence among children may vary from 0.3% to 36% depending upon the age of the pediatric population studied. Their prevalence increases during infancy and childhood.

Solitary CALMs usually have no clinical significance. The presence of multiple CALMs (*Fig. 148.2*) may indicate the presence of multiple systemic disorders, most important of which is neurofibromatosis type 1 (NF-1). It is generally assumed that the presence of six or more CALMs larger than 1.5 cm are pathognomic of NF-1.

Congenital Melanocytic Nevi

A congenital melanocytic nevus (CMN), also referred to as congenital nevocellular nevus, is considered to be nevomelanocytic proliferation with an estimated prevalence

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_148,

rate of 1–6%. The cause of CMN is not known. In normal human development *in utero*, melanocytes are derived from the neural crest as melanoblasts and migrate from a dorsal location in the embryo ventrally to the skin, the central nervous system, eyes, and adrenal glands between week 5 and 25 of gestation. Defects in migration or maturation are hypothesized.

The most commonly used classification for CMN is based on size, with small (<1.5 cm), medium (1.5–19 cm) (*Fig. 148.3*), and large (20 cm≥) (*Fig. 148.4*) CMN. The term giant CMN is used for nevi covering large segments of body. CMN can involve any location in the skin including mouth, palms, soles, and nails. One lesion is normally present, but multiple CMN can be present in the same patient, numbering hundreds. "Satellite nevi" describes the presence of multiple small congenital nevi in association with a large CMN.

Figure 148.1
Multiple, widespread Mongolian spots on the back of an infant

Figure 148.2
Multiple café-au-lait macules on the back of an infant

Figure 148.3
Medium sized congenital melanocytic nevus on the forearm of a child

Figure 148.4
Giant congenital melanocytic nevus on the face of an infant

The lesions usually are round to oval in shape and may be associated with the long axis along lines of skin development. The color is usually brown to dark brown or black plaque with rugose or black mamillated topography. The lesions can develop hypertrichosis. The clinical appearance is important for assessment of malignant potential with and without regard to size. A homogeneous uniform color and symmetric CMN with uniform topography (e.g., no distinct papules) is less concerning than a multicolored CMN with an uneven surface with irregular borders (◉ *Fig. 148.5*).

A CMN can have medical, cosmetic, and psychological implications. The most significant medical concern is risk associated with transformation to malignant melanoma. Estimates for risk transformation vary and lifetime risk ranges from 4% to 10%. Smaller lesions are thought to have lower risk for transformation than larger CMN relative to the nevus burden. The other medical concern is the association of CMN with neurocutaneous melanocytosis (NCM). NCM refers to increased melanocytes in the central nervous system in the presence of CMN. NCM is usually associated with large CMN. The exact incidence of NCM is unknown. It can be symptomatic or asymptomatic. Symptomatic NCM with features including seizures, developmental delay, motor delay, hydrocephalus, etc., is associated with grave prognosis. Patients who have a large CMN at the posterior head, neck, spine, or paravertical location have higher risk of NCM, especially those with multiple satellite lesions. Diagnosis of NCM is made by magnetic resonance imaging.

Treatment of CMN needs to be tailored according to the patient. Treatment options include surgical excision, lasers, or a combined approach. A multidisciplinary approach with plastic surgery, dermatology, pathology, radiology, and psychology is important.

Nevus of Ota

Nevus of Ota, also referred as oculodermal melanocytosis, arises from dermal melanocytes. The lesion appears as a blue-to-purple, mottled discoloration of the skin in the distribution of the ophthalmic and maxillary divisions of the trigeminal nerve (◉ *Fig. 148.6*). It is usually congenital and unilateral and frequently is associated with ipsilateral ocular melanocytosis involving the conjunctiva, sclera, and uveal tract. Diagnosis is based on the typical clinical appearance. Important associated disorders include ipsilateral glaucoma and intracranial melanocytosis. Malignant degeneration may occur, particularly in white, with choroid the most common site of involvement. Thus periodic dilated fundus examination is recommended. Treatment is indicated due to cosmetic concern. Treatment options include laser treatment with Q-switched Ruby laser and Q-Switched Nd:YAG laser.

Figure 148.5
Giant congenital melanocytic nevus with a multicolored, uneven surface

Figure 148.6
Nevus of Ota in the distribution of maxillary division of an infant

Becker's Nevus

Becker's nevus (Fig. 148.7) is a unilateral, solitary, acquired, localized, macular, light brown to hyperpigmented lesion of the skin. It is considered to be a cutaneous hamartoma and is covered more or less by terminal hair. Male-to-female ratio of occurrence is 2:1. It usually occurs in adolescence, but a congenital onset is also recorded. These lesions are usually localized on the shoulder, anterior chest, or upper arms, but lesions in other areas have been reported. Lesional tissue in Becker's nevus has been found to have an increased level of androgen receptors. Becker's nevus may occur in association with other conditions including breast hypoplasia, smooth muscle hamartoma, lipoatrophy, and acanthosis nigricans. "Becker's Nevus syndrome" refers to the occurrence of Becker's nevus with unilateral breast hypoplasia or other cutaneous, muscular, or skeletal defects. All of these anomalies tend to show a regional correspondence to the nevus and are mostly ipsilateral. No effective treatment for Becker's nevus is known. Er-YAG and Nd-YAG lasers have been used to improve cosmetic results.

Benign Hyperpigmented Lesions

Lentigines

Lentigines are small, tan, brown, or black, oval, or circular macules that may occur on any cutaneous surface and on mucous membrane. They do not darken on exposure to sunlight and do not disappear spontaneously. Histology of a lentigin shows elongation of epidermal rete ridges and increased activity of basal melanocytes without nesting of melanocytes, but melanocytes may be increased in number. Presence of multiple lentigines may be a sign of LEOPARD syndrome. The acronym LEOPARD stands for: *L*entigines; *E*lectrocardiographic abnormalities; *O*cular hypertelorism; *P*ulmonary stenosis; *A*bnormal genetalia; *R*etarded growth; and *D*eafness (sensory). Another multisystem disease associated with lentigines is Peutz-Jeghers syndrome, an autosomal dominant disorder that consists of multiple lentigines in the perioral area and elsewhere and gastrointestinal hamartomas situated most densely in the jejunum. No definite treatment of lentigines exists. Laser may be helpful in some cases.

Ephelides (Freckles)

Freckles are common in light skin, red-haired people and seem to be inherited as an autosomal dominant trait. The histology of ephelides shows increased melanin in epidermis without an increase in melanocytes and elongation of rete ridges. They are mainly present on sun-exposed areas, darken in summer and fade during winter months. They tend to fade in adults. Excessive, progressive freckling (Fig. 148.8) may be a feature of xeroderma

Figure 148.7
Becker's nevus on the lower back of a child

Figure 148.8
A child with xeroderma pigmentosum having multiple freckles

pigmentosum where it is associated with photosensitivity and photophobia. Patients with freckles should be advised about photoprotection. Treatment is for cosmetic reasons. Laser therapy may be useful in some cases.

Postinflammatory Hyperpigmentation

Postinflammatory hyperpigmentation refers to hyperpigmentation following skin inflammation or skin rashes, e.g., following sun damage, acne vulgaris, urticaria pigmentosa, etc. People with darker skin tones including Asians, Mediterraneans, or Africans are more prone to postinflammatory hyperpigmentation especially if they have excess sun exposure. Postinflammatory hyperpigmentation tends to fade with time.

Hyperpigmentation Related to Systemic Diseases/Drugs

Many endocrinological disorders including Addison's disease, Cushing's disease, and acanthosis nigricans are associated with different patterns of hyperpigmentation. Hyperpigmentation can also be induced by certain drugs including salicylic acid, bleomycin, psoralens, and cisplatin. A careful review of medical history, drug history, and relevant investigations are important in such cases.

Disorders of Hypopigmentation

Disorders of hypopigmentation are characterized by reduced melanin content in the skin that results in lightening of the skin. They can be congenital or acquired and may have hypopigmented or depigmented skin lesions.

Congenital Disorders of Hypopigmentation

Nevus Depigmentosus

Nevus depigmentosus (ND) is most frequently observed as a hypopigmented macule or patch in infants. Up to 1 in 130 otherwise healthy infants may have at least one ND. Most of the lesions appear during infancy and remain static throughout life. They are most commonly found on the trunk and can vary in size from 2–3 to 10 cm in diameter. The lesions are well circumscribed with irregular serrated borders, non-progressive, hypopigmented, lighter than the surrounding skin, seldom white, and without associated pathology. Occasionally, lesions may be segmental (◉ *Fig. 148.9*), linear with or without whorls, or block-like following Blashko's lines but without any other associated pathology; differential diagnosis includes hypomelanosis of Ito (HI). Histopathology and immunohistochemistry show that the melanin content is decreased in the affected skin, but there is no change in the number of melanocytes.

Nevus Anemicus

Nevus anemicus is a congenital lesion, 1–3 cm in diameter, round, slightly hypopchromatic with a ragged outline. Clinically, it may look like nevus depigmentosus. If pressure is applied with a convex glass, the nevus disappears, and if stroked, no flare is elicited. It is a congenital vascular anomaly and the lesional pallor is due to localized hypersensitivity to catecholamines with resultant vasoconstriction.

Ash-Leaf Macules

Ash-leaf macules are 1- to 3-cm hypopigmented macules that are ash-leaf in shape, i.e., oval at one end and pointed at the opposite. Lesions are most often found on the trunk, rarely on other sites, and are usually present at birth. Doubtful lesions should be visualized by Wood's light (ultraviolet light with 365-mm wavelength). They often

Figure 148.9
Nevus depigmentosus in a segmental distribution in an infant

are the first cutaneous sign of tuberous sclerosis complex (TSC). The diagnosis of TSC should be strongly suspected in patients having three or more ash-leaf macules (Fig. 148.10).

Hypomelanosis of Ito

The skin lesions in the HI include white, linear, extensive lesions usually affecting more than one body segment, unilateral or bilateral, whorls or whirl shaped (Fig. 148.11). They are not present at birth and have a tendency to disappear with age. Associated neurological and bone abnormalities may be present in 60% of the patients. HI is considered to be a heterogeneous disorder and its genetic nature is still not characterized. Chromosomal abnormalities (mosaicism and chimerism) are often detected in HI.

Piebaldism

Piebaldism is an autosomal dominant disorder caused by a defect in migration and maturation of melanoblasts from the neural crest. Clinically, it is characterized by congenital, extensive, and symmetrically distributed white patches on the forehead, anterior thorax, and limbs (Fig. 148.12), and a tuft of white hair on the forehead (white forelock). Small pigmented macules may be characteristically observed within the white patches with advancing age. The disorder is the result of the KIT gene mutation that encodes a tyrosine kinase receptor responsible for development of pigment cells and is located in chromosome 4q12.

Figure 148.10
Ash-leaf macules in a patient with tuberous sclerosis complex

Waardenburg Syndrome

Waardenburg syndrome (WS) is a group of auditory-pigmentary syndromes that are caused by physical absence of melanocytes from skin, hair, eyes, and stria vascularis of

Figure 148.11
An infant with hypomelanosis of Ito having unilateral linear whorled hypopigmentation

Figure 148.12
An infant with piebaldism having classic distribution of white patches

the cochlea. It is characterized by varying degree of sensorineural deafness, minor defects in the structures arising from the neural crest, and pigmentary abnormalities. Various clinical features include very pale or brilliantly blue eyes, eyes of two different colors (heterochromia) or eyes with one iris having two colors, a forelock of white hair (poliosis), premature graying of the hair, dystopia canthorum, moderate to profound hair loss, presence of white patches on the skin, and neurological abnormalities. At least four types of WS are described. *Table 148.1* summarizes the distinguishing clinical and molecular features of all the four types. A great inter- and intrafamilial variability among cases exist.

Others

Oculocutaneous albinism (OCA) is a heterogeneous group of disorders characterized by generalized reduction in pigmentation of skin, hair, and eyes. The clinical spectrum of OCA ranges, with OCA1A being the most severe type with complete lack of melanin production throughout life, while the milder forms of OCA1B, OCA2, OCA3, and OCA4 show some pigment accumulation over time. Clinical manifestations include various degrees of congenital nystagmus, iris hypopigmentation and translucency, reduced pigmentation of the retinal pigment epithelium, foveal hypoplasia, reduced visual acquity, refractory errors, color vision impairment, and prominent photophobia. The degree of skin and hair hypopigmentation varies the type of OCA. The incidence of skin cancer may be increased. All four types of OCA are inherited as autosomal recessive disorders. At least four genes are responsible for the different types of the disease (TYR, OCA2, TYRP1, and MATP). Persons with OCA have normal life span, development, intelligence, and fertility.

There are several syndromes of albinism associated with systemic pathology. These include Chediak-Higashi syndrome, Hermansky-Pudlack syndrome, Griscelli syndrome, and Elejalde syndrome. The genetic basis of some of these has been characterized.

Table 148.1
The four types of Waardenburg syndrome

Type	Inheritance	Distinguishing clinical features	Mutation
I	AD	Dystopia canthorum	Nearly all have PAX3 mutations
II	AD	No dystopia	Heterogeneous, MITF; SNAI2; SOX10 mutations
III	AD (most cases sporadic)	Hypoplasia of limb muscles, contractures of elbows, fingers	PAX3 heterozygotes; some may be homozygotes
IV	Mostly AR	Hircshsprung's disease	Heterogeneous; includes homozygotes for EDN3 or EDNRB mutations

AD autosomal dominant, *AR* autosomal recessive

Acquired Disorders of Hypopigmentation

Pityriasis Alba

Pityriasis alba is a common benign dermatosis usually seen in preadolescent children. It is characterized by the presence of hypopigmented, irregular, slightly scaly macules with well-defined borders that vary from 0.5 to 6 cm in diameter. The lesions are most commonly seen on the face and limbs. The trunk may also be affected. Males are thought to be affected more frequently, as are patients with darker skin color. The etiopathogenesis of pityriasis alba is still poorly understood. Excessive and unprotected sun exposure, frequent bathing, dry skin conditions, and atopic background are strongly linked to the development of pityriasis alba. The treatment should include sun protection, use of moisturizers, and mild potency topical steroid creams in resistant cases.

Pityriasis Versicolor

Pityriasis versicolor (PV) is a common benign recurrent superficial fungal disease that is caused by *Malassezia furfur* species. These yeasts are part of normal human skin flora and occur predominantly in seborrheic areas because of their lipid dependency. The prevalence is higher in hot and humid climates. Some host factors including use of anticoagulants, systemic corticosteroids, and immunosuppressive state are also noted to influence the development of disease. PV is most commonly seen in adolescents and young adults but has been reported in children as well. The disorder manifests as hypopigmented scaly macules on seborrheic areas. The lesions are usually oval or scalloped and tend to be asymptomatic. Diagnosis is made on clinical suspicion and can be confirmed by

examination of scales under a microscope using 10–20% potassium hydroxide alone or in combination with Parker ink in equal parts. This examination reveals a typical "spaghetti and meatballs" pattern that reflects the presence of hyphae and blastospores. Treatment includes various topical modalities including selenium sulfide 2.5% shampoo, ketoconazole shampoo, topical clotrimazole, miconazole creams, or lotions. Patients with recurrent or resistant disease may need systemic treatment with itraconazole or fluconazole.

Halo Nevus

A halo nevus is a pigmented nevus surrounded by a ring of depigmentation (◉ *Fig. 148.13*). The nevus usually undergoes progressive regression over a period of several months. The lesions usually develop in children and young adults and are preferentially located on the back. The pathophysiology of halo nevus is not well known. A cytotoxic cell-mediated immune response is suspected to be involved in the destruction of nevomelanocytes. Halo nevus and vitiligo seem to have different pathognomic mechanisms. Some patients with vitiligo after the appearance of halo nevus have been reported. Treatment options may include laser and noncultured epidermal cellular grafting.

Vitiligo

Vitiligo is an acquired disorder of depigmentation characterized by progressive loss of melanocytes from the epidermis and epidermal appendages that results in well-circumscribed milky white macules. It affects 1–2% of the world population. Approximately half the affected individuals develop the disease during childhood and adolescence. It affects all racial types but is a disease of major concern among those with dark skin. According to the distribution of the lesions, several types of vitiligo have been distinguished. Focal vitiligo refers to the presence of one or more macules in distant areas (◉ *Fig. 148.14*). Segmental vitiligo refers to the presence of one or more vitiligo lesions in segmental distribution (◉ *Fig. 148.15*). Acral vitiligo refers to that with predominant acral distribution including the hands, feet, and face (◉ *Fig. 148.16*). Most often the lesions are precipitated by trauma. Stress and infections may act as other precipitating factors. The etiopathogenesis of the disease is still not completely elucidated. Various theories including genetic, autoimmune, neural, and hormonal have been proposed. Its association with various autoimmune disorders including thyroid disease, pernicious anemia, etc., and the presence of

Figure 148.13
Halo nevus

Figure 148.14
An infant with perianal vitiligo

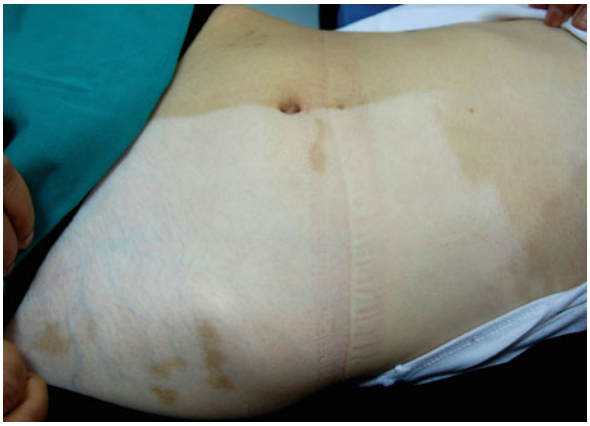

Figure 148.15
A child with segmental vitiligo

Figure 148.16
A child with periorbital vitiligo

Figure 148.17
Lichen striatus on the arm of a child

organ specific autoantibodies in vitiligo patients favors an autoimmune etiology. The treatment of vitiligo is based on finding ways to stimulate melanocytes, stopping the destruction of melanocytes, and providing ways to allow for melanocyte migration. The choice of treatment depends upon the extent of the disease, sites affected, and age of the patient. For localized disease, topical modalities are preferred that include topical steroid creams, calcineurin inhibitors (pimecrolimus and tacrolimus), calcipotriene, pseudocatalase, and topical meladinine. Narrow band ultraviolet B (NB-UVB) phototherapy and photochemotherapy (PUVA) are indicated for extensive disease. PUVA is relatively contraindicated in young children. Excimer laser is indicated for localized, stable vitiligo that does not respond to conventional topical preparations. Surgical options include autologous punch grafting, suction blister grafting, split-thickness skin grafting, cultured-melanocyte transplantation, and noncultured-melanocyte transplantation. Surgical options are indicated for stable disease or segmental vitiligo where other treatments have failed and choice of surgical therapy depends upon availability and the experience of the treating physician. Combination therapies or a cyclic approach between various treatments is useful in several cases.

Lichen Striatus

Lichen striatus is usually characterized by a linear, finely popular, hypochromic asymptomatic skin eruption most frequently located on the extremities following lines of Blashko (*Fig. 148.17*). It spontaneously disappears in 1–2 years leaving behind hypopigmentation that slowly regresses. It is relatively common in children and adolescents and rare in infants. Lichen striatus has been histologically related to a virus.

Lichen Sclerosus et Atrophicus

Lichen sclerosus et atrophicus (LSA) is rare in children. The lesions are chalk white and are associated with pruritus. Lesions can happen anywhere but perivulval and perianal locations are more common (*Fig. 148.18*). Female children are more often affected than males. The etiopathogenesis is still not clear but several mechanisms including genetic, autoimmune, and hormonal are suspected to play a role. Typical lesions of LSA are milky white atrophic papules that coalesce to form plaques and may also show follicular plugging. The main differential diagnosis is vitiligo. Child abuse is also considered in some cases. Treatment possibilities are mid- to high-potency topical steroids, calcineurin inhibitors, and pimecrolimus. In female children the lesions tend to show spontaneous remission with the onset of menarche.

Hypopigmented Mycosis Fungoides

Mycosis fungoides (MF) is a variant of cutaneous T-cell lymphoma with an indolent course. It is rare in children and adolescents. Hypopigmented MF is a variant of patch stage MF that has been reported in races (*Fig. 148.19*) and is more often seen in younger patients including children and adolescents. The lesions may manifest as hypopigmented to depigmented macules with or without

Figure 148.18
Lichen sclerosus et atrophicus on the perigenital distribution in a female child

Figure 148.19
A child with multiple hypopigmented mycosis fungoides lesions on the forearms

scales present anywhere on the skin. Differential diagnosis includes vitiligo, pityriasis alba, and postinflammatory hypopigmentation. If suspected clinically diagnosis needs to be confirmed by histopathology. Phototherapy (NB-UVB) and photochemotherapy (PUVA) are the treatments of choice.

Postinflammatory Hypopigmentation

In colored races, skin inflammation and rashes may sometimes heal leaving behind postinflammatory hypopigmentation.

149 Infectious Diseases of the Childhood, Including Fungal and Viral Infections

Sara A. Lohser · Camille Sabella · Kenneth J. Tomecki

Bacterial Infections

Bacterial infections are a common cause for medical appointments, emergency room visits, and hospital admissions among children. Such infections occur in both immunocompetent and immunocompromised children, the latter group being more susceptible to more serious and potentially resistant infections due to frequent use of antibiotics. The most common causes of infections are *Staphylococcus aureus* and group A beta hemolytic (GABHS), which is also known as *Streptococcus pyogenes*. In some instances, there can be overlap with multiple bacterial pathogens involved, e.g., *Corynebacterium, Pseudomonas* species, and *Neisseria meningitidis*.

MRSA

Folliculitis, Furuncles, and Carbuncles

Folliculitis is an infection of the hair follicle most commonly caused by *S. aureus*, less often, occlusion without bacteria, or *Pseudomonas* secondary to hot-tub exposure (see ❯ *Pseudomonas* Infections).

Patients have perifollicular erythematous papules with overlying pustules on the buttocks, axillae, chest, back, within areas of occlusion/friction/irritation (e.g., shaving), but may occur anywhere on the body. Folliculitis is often seen in immunocompetent patients, but obese, diabetic, and/or immunocompromised patients are at increased risk for this infection. A furuncle is a deeper infection of the follicular unit with spread into the surrounding tissue. A carbuncle is the fusion of several furuncles. Furuncles and carbuncles are generally painful, and purulent drainage is common (❯ *Figs. 149.1* and ❯ *149.2*).

The differential diagnosis includes molluscum contagiosum, keratosis pilaris, *Pseudomonas* folliculitis, ruptured epidermal inclusion cyst (which can look identical to a furuncle), hidradenitis suppurativa and acne conglobata (distinguished by negative cultures), *Pityrosporum* folliculitis, candidiasis, scabies, acne, miliaria rubra, and tinea corporis.

Evaluation should include KOH prep and culture with sensitivity, specifically for *S. aureus*, including methicillin-resistant *S. aureus* (MRSA). Treatment is directed at good hygiene, including bleach baths and antibacterial soaps, such as chlorhexidine or benzoyl peroxide. If the area of involvement is small, topical mupirocin is worthwhile. Widespread infections require oral antibiotics, such as first-generation cephalosporins or amoxicillin/clavulanic acid for methicillin-susceptible pathogens, clindmaycin, or trimthroprim sulfamethoxasole for MRSA infections.

Impetigo

The most common cause of impetigo in the USA and Europe is *S. aureus*, while in developing countries, *S. pyogenes* is the more prevalent causative agent. However, overlapping infections are becoming more common. MRSA has also been implicated and is seen more commonly in the nonbullous form of impetigo.

S. pyogenes typically colonizes the skin after trauma secondary to excoriations, bites, or dermatitis, and precedes the clinical appearance of erosions and resulting infection by approximately 2 weeks. Infection is superficial, contagious, and, most often, occurs in the summer months in children under age 6 years. Systemic signs and symptoms are common. Children develop oozing erosions, often on the face, specifically around the nose and mouth that form typical "honey-colored crusts" (❯ *Fig. 149.3*).

Bullous impetigo is a variant with bullae, often in the groin or intertriginous areas. Bullae are initially clear and become turbid and occasionally pustular. Ruptured bullae leave a raw, eroded base with a peripheral collarette of scale. Both nonbullous and bullous forms of impetigo heal without scarring.

The differential diagnosis of impetigo includes herpes simplex, diagnosed via Tzanck smear, PCR, or DFA; tinea infections, diagnosed via KOH; and contact or nummular dermatitis. Biopsy may be required to confirm the diagnosis.

Secondary glomerulonephritis may occur, but is rare. Treatment includes gentle debridement, cleansing with

Impetigo

antibacterial soap or wash (chlorhexidine), and topical antibiotics (mupirocin or retapamulin). Retapamulin has better bacterial coverage than mupirocin, with less likelihood (thus far) of resistance. Fusidic acid is a useful alternative for treatment, but is not available in the USA. For patients with widespread involvement, oral antibiotics are necessary, e.g., first-generation cephalosporins (cephalexin), or beta lactam/beta lactamase inhibitors; for MRSA infection, tetracycline, trimethoprim/sulfamethoxazole, clindamycin, or linezolid may be required. Recurrence may be secondary to Staphylococcal carriage in the nares, axillae, groin, or umbilicus. Treatment with mupirocin ointment twice daily for 5 days may help eliminate colonization, but periodic retreatment is often required, and the long-term efficacy of decolonization is not clear.

Staphylococcal Scalded Skin Syndrome (SSSS)

SSSS is caused most commonly by a phage group 2 of *S. aureus*, which produces exfoliative toxins, ETA and ETB. The toxins are serine proteases targeting desmoglein 1 which produces a split within the epidermis at the granular cell layer. The toxins spread hematogenously from a localized source of epidermal damage, but the source of infection is often unknown; possible sites include wounds, nasopharynx, urinary tract, anus, umbilicus, conjunctiva, surgical site, or pneumonia.

SSSS typically affects children under age 2 (62%) and almost all affected patients are children under age 6 years (98%), due to decreased renal ability to excrete the ETA and ETB toxins. Clinically, children have severe irritability, skin tenderness, malaise, and +/− fever. Skin disease erupts rapidly with crusting and scaling occurring around the mouth or intertriginous areas, progressing until the entire body is covered with tender erythroderma. Patients may develop fragile bullae (with Nikolsky sign) that rupture easily yielding skin peeling in sheets. Healing typically begins in approximately 10 days without scarring, and mucosal surfaces are not involved.

Evaluation should include cultures obtained from the eye, nose, throat, axillae, groin, blood, or other suspected sites of infection. Cultures obtained from desquamative areas are negative since denuded skin is toxin-medicated. Frozen section of peeling skin may help differentiate toxic epidermal necrolysis.

Differential diagnosis includes toxic shock syndrome, pemphigus foliaceus, graft-versus-host disease, epidermolysis bullosa, thermal burn, Kawaski disease, nutritional deficiency, keratolysis exfoliativa, drug eruption, and viral exanthem.

Most patients require hospital admission unless there is very minimal involvement. Treatment includes rehydration, temperature control, topical wound care (often with burn unit treatment depending on level of severity), avoidance of handling infant/child as much as possible due to sensitivity of skin, analgesia, and parenteral antibiotics (e.g., nafcillin, oxacillin, or vancomycin). Most cases are resistant to penicillin.

Methicillin-Resistant *Staphylococcus aureus*

Historically MRSA infections occur in institutionalized and hospitalized populations. However, over the past few years these have become more common throughout the community. The clinical presentation is typically an abscess (often in the diaper area of infants) due to the Panton–Valentine leukocidin (PVL) toxin, which is lethal to neutrophils. MRSA infections can affect children of all ages, but those with increased risk factors include atopic patients and some athletes, e.g., wrestlers and football players.

Abscesses develop and may resolve without treatment especially when drained either manually or spontaneously. Hyperpigmentation persists after resolution and scarring is common. Though uncommon, MRSA can be potentially fatal if it progresses to sepsis, pneumonia, or osteomyelitis.

Evaluation includes bacterial culture with sensitivity of abscess and culture for potential colonization. The mainstay of therapy is incision and drainage of the abscess. With that simple approach, the vast majority of patients do well. Antibiotics are necessary for those patients with cellulitis, comorbidities, large lesions, and/or fever. Tetracycline, clindamycin, and trimethoprim-sulfamethoxazole generally provide good outpatient coverage, while intravenous vancomycin or linezolid are often required for hospitalized patients.

Streptococcal Infections

Perianal Streptococcal Dermatitis

Perianal streptococcal dermatitis is caused by group A ß-hemolytic *Streptococcus* (GABHS) and affects children aged 7 months to 10 years (mean age 4–5 years), more commonly males. Thirteen percent of patients have symptomatic pharyngitis, but 60% have a positive throat culture. Affected patients have tender, raw, well-demarcated, beefy red perianal erythema. As disease progresses, scaling develops, resembling inverse psoriasis. Other possible diagnoses include irritant dermatitis, candidiasis, and inflammatory bowel disease with cutaneous involvement. Dermatitis typically involves the perianal area, but buttocks and vagina or penis (balanitis) may also be affected. Associated signs/symptoms include painful defecation, fecal avoidance or incontinence, blood streaked stool, and anal fissures.

Bacterial culture should be obtained: standard treatment is penicillin for 14–21 days, and alternatives include amoxicillin or clarithromycin. A second course of antibiotics is sometimes required and recurrence is common. Bland emollients will help soothe the affected areas. Treatment is important to offset progression to post streptococcal glomerulonephritis, followed by posttreatment urinalysis and culture to confirm clearance. Guttate psoriasis may follow perianal streptococcal dermatitis in the same manner that it follows streptococcal pharyngitis.

Scarlatina

Scarlatina occurs in children aged 2–10 years after streptococcal pharyngitis or soft tissue infection. Children present with fever, sore throat, adenopathy, and strawberry tongue, and within 2–3 days, they develop a fine, sandpaper erythema on the face, posterior neck, and upper back that spreads downward over the body. Erythema is most notable in skin folds and fades in a week, followed by desquamation that may persist for days to weeks.

Erysipelas and Cellulitis

Erysipelas is a superficial cellulitis typically caused by group A ß-hemolytic *Streptococcus* (GABHS) with a recent shift toward non-group A *Streptococci*. Patients have a well-defined, erythematous, indurated, tender, warm, shiny plaque with a rapidly advancing border that develops as the bacteria spreads through lymphatic vessels. Infection is associated with fever (+/−), chills, and malaise. The legs are the most commonly affected areas, but infection may occur on the face and less often on other areas of the body.

Cellulitis is caused by GABHS, *S. aureus*, *Haemophilus* (incidence markedly decreased with advent of Hib vaccine), *Pasturella multocida* secondary to animal bites, *Klebsiella pneumoniae*, and *Yersinia enterocolitica*. Patients develop deep dermal or subcutaneous erythema with poorly defined borders at the site of a previous wound. As with erysipelas, a leading edge of erythema is often present, but cellulitis has no sharp demarcation from surrounding skin. Cellulitis has attendant warmth, edema, and pain often with fever, chills, and malaise. Bullae and petechiae may occur (*Fig. 149.4*).

The cause of both erysipelas and cellulitis is bacterial inoculation of the skin (skin trauma). Potential portals of entry include the nasopharynx (streptococcal pharyngitis in one-third of cases of facial erysipelas), abrasions, and
