Other associated features of the primary liver or gastrointestinal disorders such as muscle wasting, jaundice, clubbing, or hepatosplemegaly should be looked for in the overall evaluation of the child with ascites. Edema is precipitated by hypoproteinemia or venous obstruction. Examination should also include the chest to rule out associated pleural effusion or pneumonia. It should also

Figure 212.5
A young infant with neonatal hepatitis syndrome showing tense ascites, flat or everted umbilicus, and left inguinal hernia

ensure exclusion of other conditions associated with abdominal distention such as bladder distention, obesity, fecal distention, tumor masses, or gaseous distention of the gut.

Diagnosis

Ascites is a clinical condition, the diagnosis of which requires only a few diagnostic measures beyond a thorough clinical examination. Usually, the clinical features stated above are sufficient to diagnose the patient as having ascites. Ultrasound examination performed as part of the investigation of affected patients with liver disorder may reveal the presence of ascites at its early stage. Computed tomography is not performed routinely in the diagnosis of ascites. Its application or that of magnetic resonance imaging is mainly confined to identifying the cause or assessing the progress of the disease.

Diagnostic tapping of ascites is indicated in progressive liver disease, where there is a recognized risk of developing spontaneous bacterial peritonitis and to decide appropriately on therapy. The fluid is examined for cytology, protein content, leukocyte count, amylase, and culture as well as being examined for its color and consistency. Sterile ascitic fluid is usually clear and straw-colored but may sometimes be bile-stained with a protein content of less than 2.0 g/dL. Concentrations higher than 2.0 g/dL are consistent with infection or obstruction of hepatic vein (Budd–Chiari syndrome).

Spontaneous bacterial peritonitis may develop in the absence of localized intra-abdominal sepsis. It is associated with abdominal pain, tenderness, and fever. Abdominal ultrasound is indicated in the course of management to assess progress of the disease and rule out the development of abscess formation.

Management

Management of ascites should be part of the overall management of the primary liver or gastrointestinal disease. Management of ascites due to other causes is covered in the appropriate chapter. The outcome of the management is very much influenced by the status of the primary disease to the extent that occasionally treatment of the underlying cause may result in resolution of ascites, as in the case of ascites due to peritonitis. Evaluation of serum electrolytes, albumin, total protein, urea nitrogen, creatinine, and urine volume should be performed quite regularly, maybe daily in some cases.

Sodium intake is limited to 1–2 mEq/kg/day. In practice, a very low sodium intake is not always acceptable by the affected child as compared to the adult. Moreover, water restriction is only enforced in cases of hyponatremia.

In end-stage liver disease with ascites, the optimum therapy is liver transplantation, short of which the management is mainly to relieve the patient's distress and minimize the risk of associated complications. In spite of the above, the physician while managing a patient with ascites and severe abdominal distention is obliged to try and alleviate the symptoms by applying certain therapeutic modalities as follows:

Diuretics

Aldosterone antagonists, thiazides, and loop diuretics are the most commonly used diuretics in children with ascites to achieve a negative fluid balance. An aldosterone antagonist (spironolactone) is usually prescribed for patients with ascites and liver disorders. It has the advantage of a potassium-sparing effect, which is useful for such patients known already to be prone to potassium depletion. The required dose varies with the severity of the condition and the associated side effects of therapy, especially hyponatremia. The average dose is about 3 mg/kg/day in two to three divided doses. The physician should allow a few days for the drug to show its effect on ascites before resorting to increasing the dose if the patient's condition permits. However, the dose may still have to be increased to achieve negative fluid balance.

In cases of severe ascites where spironolactone administration is not effective, addition of thiazide diuretics or loop diuretics (furosemide) is advisable, provided the patient is receiving satisfactory evaluation, especially for any potential electrolytes disturbances such as hypokalemia, which is known to aggravate hepatic coma. Potassium supplement may be necessary in some cases.

Moreover, it has been recognized that furosemide increases ammonia production, which could contribute to the development of hepatic encephalopathy. The starting dose of furosemide in infants and young children is 1 mg/kg/day increased gradually up to 5 mg/kg/day.

Thiazide diuretics have also been used with spironolactone in children with ascites. The usual starting dose of hydrochlorothiazide in children is 2 mg/kg/day. Triamterene may be prescribed to enhance potassium retention. In case of associated renal failure, diuretic therapy ought to be stopped.

If the above measures are inadequate in alleviating the child's symptoms, salt-free albumin transfusion in a dose up to 1 g/kg is required to be infused over a few hours with simultaneous furosemide infusion.

Abdominal Paracentesis

Abdominal paracentesis to drain a large volume of the ascitic fluid is occasionally required in the treatment of tense ascites refractory to the above-mentioned therapeutic measures. Studies have demonstrated that large-volume paracentesis when combined with intravenous infusion of albumin can be safely performed on children with massive ascites and respiratory distress. However, because of the availability of fairly effective drug therapies in most cases of childhood ascites with early recognition and management, the need for total paracentesis or even large volume is rarely necessary nowadays except perhaps in those with respiratory compromise.

Surgery

In refractory ascites, peritoneovenous shunt (LeVeen shunt) is performed. The excess fluid is drained extraperitoneally into the internal jugular vein, resulting in rapid resolution of ascites. The use of this device is not without major complications such as coagulopathy and infections. Long-term prognosis after such an operation remains very much determined by the underlying disease contributing to ascites formation.

Chylous Ascites

This is a congenital or acquired condition with accumulation of chylomicron-rich lymphatic fluid within the peritoneal cavity, resulting from obstruction or disruption of abdominal lymphatic channels.

Chylous ascites may he precipitated by trauma, neoplasms, or obstruction to the abdominal portion of the thoracic duct. The condition may also be associated with accumulation of the chyle in the thorax (chylothorax). Diagnostic aspiration of the fluid is needed to establish the milky appearance of the ascitic fluid with an increase in its fat content.

The incidence of spontaneous chylous ascites in patients with chronic liver disease is estimated to be 0.5–1%, and results from rupture of the serosal lymphatic channels secondary to portal hypertension. It is generally believed that the incidence has increased due to the longer survival of patients with cancer and more aggressive abdominal and cardiothoracic interventions.

The most common causes of chylous ascites in developed world are abdominal malignancy and cirrhosis, in contrast to infectious etiologies in the developing world.

Other causes include congenital, inflammatory, traumatic, postoperative, and miscellaneous disorders. Peritoneal tuberculosis and filariasis are the common infectious causes of chylous ascites.

Congenital lymphatic abnormalities are more common in the pediatric age group.

Chylous ascites can occur early after abdominal surgery due to disruption of the lymphatic vessels or late due to adhesions or extrinsic compression of the lymphatic vessels.

Chylous ascites is a rare complication following liver transplantation.

The diagnosis of chylous ascites is made by paracentesis, which shows a milky ascetic fluid with a specific gravity of 1.010–1.054 and total fat content of 4–40 g/l. Triglyceride level is greater than 110 mg/dl, and the cholesterol level is usually low. Lymphangiography is the gold standard in defining cases of obstruction and to identify leak sites, but it is associated with several complications such as tissue necrosis, fat embolism and hypersensitivity related to the volume and type of contrast used. Palmitic acid, a long-chain fatty acid which enters directly into the intestinal lymph trunk after absorption, has been used labeled with 13C, to detect chyle leaking from the intestinal lymphatic system, to help determine the site of leakage and the degree of obstruction. It can be used in patients who had negative results with isotope examination and lymphangiography.

Management is primarily medical with a high-protein diet and medium-chain triglyceride-based low-fat diet to ensure its absorption through the portal circulation and not the systemic circulation. Treatment with high-protein diet and low fat diet with mCT reduces the production and flow of chyle. Dietary restriction of long-chain triglycerides (LCT) avoid their conversion into monoglycerides and free fatty acids (FFA), which are transported as chylomicrons to the intestinal lymph ducts. As with other forms of ascites, the indication for paracentesis is basically limited to those patients with massive ascites and respiratory distress.

Somatostatin and total parenteral nutrition are an effective option for the treatment of chylous ascites after living donor liver transplantation.

In patient with cirrhosis and chylous ascites refractory to medical therapy insertion of transjugular intraheptic portosystemic shunt (TIPS) may be effective in reducing ascites significantly by decreasing portal pressure.

Fibrin glue application on absorbable mesh after dissection of the leakage zone is easy, safe, and effective. It is recommended that surgery with glue application to be repeated until control of ascites is achieved. Furthermore, fibrin glue application has been recommended as a preventive measure against postoperative chylous ascites. Laparoscopic surgery, instead of open surgery, has been recommended as a treatment of choice for intractable chylous ascites. Intractable chylous ascites may also respond better to combination of octreotide and total parenteral nutrition.

213 Budd–Chiari Syndrome

Hisham M. Nazer

Definition

Budd–Chiari Syndrome (BCS) is a rare disorder characterized by venous outflow obstruction either at hepatic veins or inferior vena cava associated with blood clots that completely or partially block the hepatic vein anywhere between the efferent hepatic vein and the entry of the inferior vena cava to the right atrium. BCS is rarely associated with portal vein thrombosis.

Etiology

Hepatic vein occlusion may result from various clinical conditions such as polycythemia, leukemia, neoplasms (e.g., hepatoma and hypernephroma), systemic lupus erythematosus, infections, membranous obstruction of the inferior vena cava, and trauma. However, no definite cause can be found even at autopsy in a majority of cases. The obstruction to the hepatic vein may also be caused either by compression from outside or by invasion by tumor or thrombi.

Other recognized causes of BCS include thrombophilic conditions, chronic inflammatory disease like Behcets syndrome, inflammatory bowel disease, antiphospholipid syndrome, paroxysmal nocturnal hemoglobinemia, veno-occlusive disease, and hypereosinophilic syndrome. Other inherited and hypercoagulable states may also predispose to thrombosis (protein C or S deficiency, antithrombin III deficiency, etc.). A similar picture of BCS has been observed in association with primary pulmonary hypertension, constrictive pericarditis, and right atrial myxoma.

Hepatic vein thrombosis has also been reported in neonates with gastroschisis or large omphalocele after surgical repair and in older children following some herbal ingestion. Enlargement of the caudate lobe is a recognized potential cause of obstruction to the inferior vena cava or hepatic veins.

Pathology

The histopathologic changes of the liver in BCS are affected by the time interval between the onset of symptoms and the time of the biopsy. Early in the disease, the changes are usually those of severe central venous congestion, centrilobular hemorrhage, and necrosis. Later on, the hepatic cells in the central zones may resemble ghost cells, and thrombi may be found in some of the larger hepatic veins. The thrombus may contain malignant cells or inflammatory cells.

The primary lesion shows intimal thickening and fibrous obliteration of the ostium of the major hepatic veins or intrahepatic portion of the inferior vena cava.

The liver is enlarged and smooth. BCS is associated with progressive liver disease leading to cirrhosis. There is a marked central venous congestion with hepatocellular necrosis with endothelial thickening and fibroblastic proliferation.

Clinical Manifestations

The clinical presentation is highly variable and may be categorized as acute, and perhaps fulminant hepatic failure, as subacute without evidence of cirrhosis, or as chronic with evidence of portal hypertension and cirrhosis.

The most common features in BCS include abdominal distention with pain, marked hepatomegaly, and ascites. Other recognized features of BCS include nausea, vomiting, diarrhea, edema of the legs and those of portal hypertension as esophageal varices, massive hemorrhage, splenomegaly, mild jaundice, and distended abdominal veins. In progressive condition, hepatic failure may develop with a fatal outcome.

Diagnosis

BCS is characterized by venous outflow obstruction either at hepatic veins or inferior vena cava. The diagnosis of BCS is highly suspected in the presence of the above-mentioned clinical manifestations. The goal of the initial evaluation of a patient with suspected BCS is to determine the cause and level of obstruction.

Liver function tests reveal mild elevations of serum bilirubin, alkaline phosphatase, aspartate transaminase, low albumin, and prolongation of the prothrombin time.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_213,

Computed tomography or magnetic resonance imaging with contrast demonstrates no visualization of the hepatic veins. Liver scintigraphy reveals diminished uptake in the right and left lobe and increased uptakes in the caudate lobe since it drains directly into the inferior vena cava.

Hepatic vein catheterization with pressure measurement and hepatic venography contribute further to the diagnosis. Wedged hepatic vein pressures and venograms from the wedged position are helpful. These are not possible if the obstruction is in the hepatic portion of the inferior vena cava. Saphenous or femoral vein studies may show complete obstruction of the vena cava.

Occasionally, obstruction of the infra diaphragmatic portion of the inferior vena cava may result from massive ascites precipitating increased intra-abdominal pressure.

Open liver biopsy is recommended to confirm the diagnosis. There has been some concern about the percutaneous liver biopsy because of potential increased risk of bleeding due to elevated intrahepatic venous pressure and liver engorgement. Histologic findings include sinusoidal dilatation with centrilobular congestion and minimal inflammation.

Management

Management of BCS depends on the underlying cause, anatomic location, the extent of the thrombotic process, and the functional capacity of the liver. It can be divided into medical, radiological, and surgical.

Medical treatment, including anticoagulation and thrombolysis, starts at the time of diagnosis initially with low-molecular heparin and switching to oral agents after an average period of 2 weeks.

The use of warfarin for anticoagulation proved to be simple, safe, and feasible for BCS with chronic IVC thrombosis.

Spontaneous fibrinolysis of IVC thrombus occurs within 1 year in the majority of the patients treated with warfarin.

Major bleeding is common in BCS patients receiving anticoagulant therapy. Invasive procedures and portal hypertension are major factors while excess anticoagulation plays a contributory role.

Radiological therapeutic intervention is feasible and safe in children with BCS. Radiological intervention in the form of balloon angioplasty or transjugular intrahepatic portosystemic shunt (TIPS) gives good results in a subgroup of BCS patients. Complete disappearance of the thrombosis may be successfully achieved with balloon dilatation.

Pulmonary embolism is one of the major complications after percutaneous balloon angioplasty for BCS. Pretreatment with warfarin may prevent such complication.

Transjugular intrahepatic portosystemic shunt (TIPS) is a minimally invasive vascular and interventional radiological procedure. TIPS could be regarded as a definitive treatment option in BCS.

TIPS seems to have replaced surgical shunting as the most common invasive therapeutic procedure. The overall results of stenting/TIPS are better than angioplasty and surgical intervention including orthotopic liver transplantation.

Surgical: Various surgical procedures have been suggested and implemented in cases of BCS with variable degrees of success. Failure to relieve the obstruction through various surgical modalities may result in hepatic failure and death.

Portacaval shunt (side-to-side anastomosis) is the operation of choice in most cases; however, mesocaval shunt provides good results in selected cases. Orthotopic liver transplantation (OLT) should be limited to patients who cannot be managed by TIPS.

The prognosis in some cases of BCS with progressive liver disease has been very much improved with liver transplantation. Liver transplantation can be an effective treatment, particularly for people with severe liver failure and those with deteriorating liver function and complications.

214 Portal Hypertension and Esophageal Varices

Mohamed A. El Guindi · Hisham M. Nazer

Over the past several years, there has been a noticeable progress in the field of portal hypertension especially in its management. Such progress has also benefitted the overall management of esophageal varices especially during its episodes of hemorrhage. The implementation of beta-blockers in the overall management of esophageal varices variceal and the establishment of endoscopic variceal band ligation in the management of acute variceal bleeding have become the mainstays of clinical management of children with portal hypertension.

Embryologically, the portal system in also unique, as it develops from the extra-embryonic vitelline and umbilical veins draining from the yolk sac and the placenta, in contrast to the systemic which develop from the intraembryonic anterior and posterior cardinal veins. Thus, any umbilical infection or intervention could affect the portal venous system. The portal vein is formed by the uniting of the splenic vein with the superior mesenteric vein which occurs mostly in the retroperitoneal area of the pancreas. It is the main transporter of blood from the gastrointestinal tract and the spleen to the liver.

The liver has a unique blood supply consisted of two afferent vessels, a portal vein and a hepatic artery, and an efferent vessel the hepatic vein. Then portal vein represents the main blood supply to the liver around 70% leaving the other 30% to the hepatic artery. Thus, any burden on the portal vein would have its impact on the liver blood supply and any burden on the liver would have its impact on the portal pressure. Another unique feature is that the portal venous system is the only venous system in our body, which begins with capillaries and ends with capillaries. The intrahepatic branches of the portal vein terminate in small vessels forming the hepatic sinusoids.

Definition

Portal hypertension (PH) or, more strictly, portal venous hypertension, is defined as an increase in the intravascular pressure within the portal vein of over 11–12 mm of mercury as measured directly or a splenic pulp pressure of over 16 mm of mercury. The rise in portal pressure is not simply a consequence of an increase in systemic venous pressure, but it is intrinsically part of an increase in the pressure gradient between the portal venous inflow to the liver and its hepatic venous outflow.

A rise in the portal pressure leads to splenomegaly and the development of natural portosystemic shunts at the following sites:

- Gastresophageal varices at the lower end of the oeophagus and cardia through the gastroesophageal veins
- Fundal varices at the fundal area of the stomach below the cardia and to a lesser extent the body of the stomach and the duodenum through the gastric veins
- Anal hemorrhoids at the anal canal via the hemorrhoidal veins
- In the falciform ligament via the umbilical veins
- In the abdominal wall and retroperitoneum

In pediatric age group, esophageal varices are the most likely cause for large gastrointestinal bleeding. Variceal bleeding is associated with a mortality rate of around 7% in children with portal vein obstruction due to the massive bleeding and most probably the presence of fundal varices.

Portal hypertension is usually due to an extrahepatic or intrahepatic portal venous obstruction. Umbilical vein catheterization especially when it is associated with complications as obstruction or infection has been recognized as predisposing cause. Other associated causes include hepatic vein thrombosis (Budd–Chiari syndrome), portal vein thrombosis, schistosomiasis pancreatitis, hepatoveno-occlusive disease, tumors, and cirrhosis. Other well-recognized progressive liver disorders associated with portal hypertension include tyrosinemia, biliary atresia, α1-antitrypsin deficiency, cystic fibrosis, Wilson's disease, congenital hepatic fibrosis, and chronic active hepatitis. Those liver disorders have been covered in details elsewhere in this section.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_214,

Classification

The causes of portal hypertension are classified into (1) posthepatic, (2) prehepatic, and (3) intrahepatic causes.

The intrahepatic causes can be further subdivided into presinusoidal, parasinusoidal, and postsinusoidal causes.

The major causes of posthepatic causes of PH are right-sided heart failure, constrictive pericarditis, and Budd–Chiari syndrome (BCS).

The prehepatic causes of PH include portal vein thrombosis (PVT) and portal compression or occlusion by biliary and pancreatic neoplasms and metastases.

PH may be caused by an increase in flow secondary to arterioportal fistula, pancreatic arteriovenous malformations, and massive splenomegaly. The most common intrahepatic cause is cirrhosis. The common feature of all the causes is an increase in resistance to portal venous flow, although in a few cases, increased inflow into the portal venous system is present.

The basis of PH in patients with cirrhosis is an increase in resistance to portal venous flow at the level of the sinusoids as a result of the perisinusoidal deposition of collagen leading to fibrosis and narrowing and compression of the central veins. Augmentation of such compression is due to the excessive regenerative nodule. Arteriovenous anastomosis in a fibrous scar would further increase the portal venous pressure.

The commonest cause of cirrhosis in neonates is biliary atresia. Besides this cause alpha-1- antitrypsin deficiency and metabolic liver diseases are the commonest medical conditions leading up to cirrhosis of the liver. Many of these patients have the stigmata of their underlying disease and the diagnosis of portal hypertension is not difficult.

The diagnosis may not be as clear in children with prehepatic PH. Portal vein thrombosis (pre-hepatic PH) may present within the first 5 years of life as a major hematemesis with only splenomegaly and a reduced platelet count as clues to the diagnosis. Many affected patients have no documented cause for their portal hypertension. However, at times, a history of umbilical vein canulation, abdominal infection, trauma, or pancreatitis may be responsible for the portal thrombosis. The liver size and function tests in such patients are essentially normal. A confirmation of portal vein occlusion will rely on Doppler and ultrasound demonstration of collateral venous channels in the porta hepatis replacing the occluded portal vein. Half of these patients have a history of umbilical vein catheterization or abdominal sepsis in the neonatal period, while the other half appears to be congenital in origin.

Congenital hepatic fibrosis may also present with the same picture of acute hematemesis and normal liver function tests but the difference would be in the clinical features which will include hepatomegaly. A liver biopsy shows bands of fibrous tissue joining the portal tracts and this condition may be associated with polycystic disease and other renal disorders.

Several studies have shown an idiopathic non-cirrhotic subendothelial thickening of intrahepatic branches of the portal vein causing presinusoidal obstruction to portal blood flow within the liver leading to the formation of collateral venous channels in the porta hepatis thus being named hepatoportal sclerosis.

Several studies in the Middle East and Asia have discussed a post-sinusoidal PH named veno-occlusive disease. This disease is claimed to be due to bush tea and herbs but no definite etiology has been definitely outlined. This can be of acute, subacute, or chronic onset of the disease leading to congestive hepatomegaly with ascites.

Suprahepatic obstruction caused by either an occlusion or a web in the inferior vena cava above the entrance of the hepatic veins or thrombotic occlusion of the hepatic veins (Budd-Chiari syndrome) is extremely rare in childhood. The clinical features may be mimicked by constrictive pericarditis but echocardiography and venography should make the diagnosis clear.

Clinical Features

The clinical features of PH depend, in general, on the etiology.

In portal venous occlusion: The presentation is usually in younger children (5 years) with acute episode of upper or lower gastrointestinal bleeding. This may or may not be accompanied by splenic enlargement depending on the blood loss due to the hematemesis or malena and the site of occlusion. The accompanying anorectal varices and hemorrhoids are present in more than half of patients with portal venous occlusion.

In older children suffering from chronic liver disease, *the intrahepatic PH* is presented mainly with abdominal distension due to hepatomegaly, splenomegaly, and/or ascites. Once hematemesis is present in those patients, encephalopathy together with the abdominal distension due to ascites may complicate the condition. Growth retardation is a well-recognized complication of cirrhosis and portal hypertension. In patients with post-sinusoidal and post-hepatic PH Budd–Chiari syndrome, intractable ascites with hepatomegaly is the usual initial presentation.

Investigations

Blood Investigations

Anemia and reduced WBC and platelet count are signs of hypersplenism. A bone marrow hyperactivity will differentiate hypersplenism from bone marrow depression. Plasma concentrations of procoagulant and anticoagulant proteins may be reduced in portal venous thrombosis or Budd–Chiari syndrome. Biochemical liver function tests are abnormal in cirrhosis, but are rarely deranged in portal venous occlusion. Serum albumin levels are depleted in acute variceal bleeding as well as in cirrhosis.

Ultrasound and Doppler Scan of Abdomen

Abdominal ultrasonography is used to identify hepatomegaly, cirrhosis, fibrosis (recently by fibroscan), large collateral veins, portal cavernoma, and splenomegaly. Ascites can be definitely identified and quantified by ultrasonography. Doppler studies provide the information about the direction, velocity, and waveform characteristics of vessels including portal blood flow.

In cirrhosis of liver, the maximum velocity of the blood flow in the main portal trunk is correlated to the portal pressure and inversely correlated with the severity of the liver disease. Budd–Chiari syndrome is diagnosed conclusively with Doppler sonography of the hepatic veins and the inferior vena cava.

Upper and Lower Gastrointestinal Endoscopy

This procedure is the cornerstone in the diagnosis and treatment of varices of the esophagus, stomach, the proximal duodenum, and the ano-rectal area. Several trials has been undergone to use noninvasive parameters for diagnosis of large esophageal varices of chronic liver diaseases, but all were not as accurate as endoscopy. In children, for safer and easier endoscopic procedure, the use of anesthesia or sedation is recommended.

Various grading systems are used in the assessment of esophageal varices in adults and adopted in children (*Fig. 214.1*).

Grade I: small varices which are bluish with a relatively thick mucosal covering

Grade II: larger ones may have signs of recent or impending bleed like "cherry red spots" leading next to

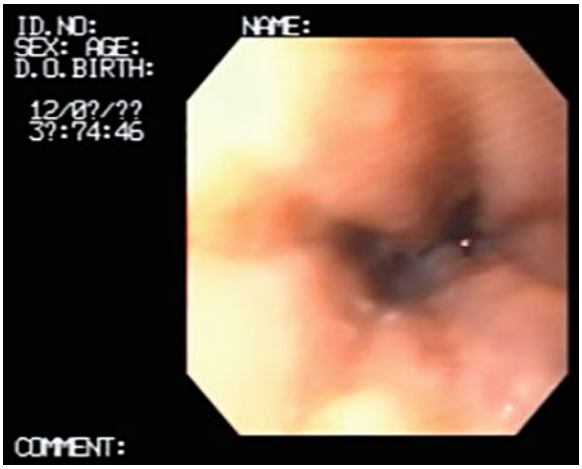

Figure 214.1
Esophageal varices grade II (Mohamed El Guindi 2010)

Grade III: confluent varices covering the whole circumference of the esophagus

Portal congestive gastropathy is characterized by mucosal hyperaemia with dilated submucosal veins.

Fundal varices are present just below the cardia and are isolated and should be differentiated from esophageal varices extended into the stomach due to difference in treatment.

Recently, capsule endoscopy is a useful diagnostic tool for all forms of varices especially the duodenal varices out of reach of upper endoscopy or in cases after devascularization and formation of intestinal varices.

CT Angiography and MRI Scan

The evolutionary modalities of multislice CT and MRI have replaced many of the conventional procedures. The above modalities are increasingly used in the diagnosis of Budd–Chiari syndrome and to identify liver lesions associated with portal hypertension like focal nodular regenerative hyperplasia. MR angiography is recently used as a noninvasive alternative to conventional angiography to delineate porto-mesenteric venous anatomy.

Inferior vena cavography with pressure measurements is valuable in patients with Budd–Chiari syndrome in whom hepatic venography can be used to assess hepatic venous patency. Balloon dilatation can be undertaken of inferior vena caval membrane or short segment narrowing of the hepatic veins, which can prove therapeutic.

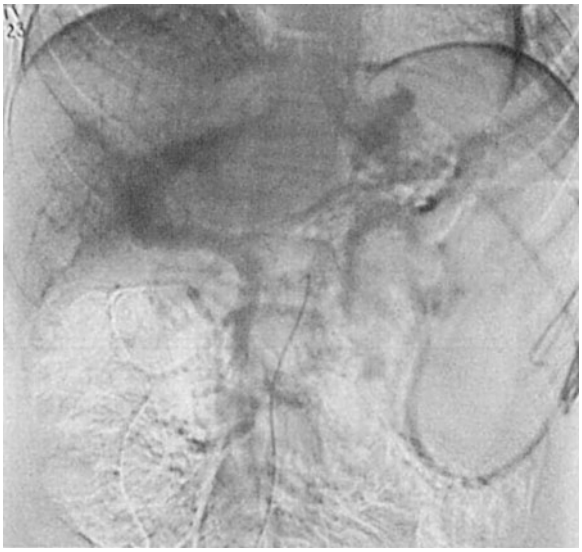

Figure 214.2
Superior mesenteric angiogram in a 13-year-old girl with hematemesis. There is patency of the mesenteric-portal varices. Retrograde flow to the splenic Collaterals and esophageal varices with irregular intrahepatic branches (Nazer)

Superior mesenteric angiogram is also performed to assess the size and patency of the superior mesenteric, splenic, and portal veins and to identify bleeding site (*Fig. 214.2*).

Treatment

As previously stated, the main aim of therapy is to promptly treat the serious complication of hematemesis and massive blood loss. Recent reports indicate that esophageal varices in childhood are well controlled with either injection sclerotherapy or banding and if this fails, portosystemic shunting would be the answer. Patients with portal vein obstruction and normal liver histology can be expected to live normal lives providing the esophageal varices are under control.

Medical Treatment of Variceal Bleeding

The cornerstone in treatment of acute variceal bleeding is endoscopic sclerotherapy or banding, therefore in areas where PH are prevalent, skilled and well-equipped endoscopic centers should be within accessible distances to improve morbidity and mortality outcomes. A delay in immediate management could prove fatal for a child.

Immediate medical measures include blood transfusion and the intravenous infusion of vasopressin (0.2–0.4 units/1.73 m/min) which may arrest the bleeding. Vasopressin has been used for decades in controlling gastrointestinal hemorrhage through its effect on blood flow and pressure through the portal circulation. It lowers the portal blood pressure by about 25–50% through splanchnic arteriolar vasoconstriction Vasopressin is a peptide produced by the posterior pituitary gland. It regulates the permeability of the collecting tubules of the kidney to water.

Vasopressin or its precursor, glyopressin may be used to reduce the portal venous pressure. These agents have tolerable side effects related to systemic vasoconstriction like headache, nausea, and abdominal cramps.

Somatostatin reduces splanchnic blood flow and portal pressure with minimal side effects, but it has a short half-life of less than 3 min. Octreotide, a long-acting analog of somatostatin, has a plasma half-life of more than 1 h and proved its safety and low side-effect profile thus encouraging its use in cases of acute variceal bleeding.

The use of Sengstaken-Blakemore (S-B tube) compression balloon has been minimized after the experience with endoscopes; however, it may still prove to be life-saving when there is a failure of visualization of the varices due to overwhelming hemorrhage.The risks involved in the usage of such instrument cannot be overemphasized. Correct placement of the gastric balloon must be checked with X-ray control in order to avoid the inflation within the lumen of the esophagus.

After stabilizing the child, continued bleeding should be controlled with injection sclerotherapy or by band ligation using the pediatric video endoscopes. General anesthesia should be advocated in all cases.

Endoscopic Intervention of Variceal Bleeding

Injection Sclerotherapy

Injection sclerotherapy was suggested for the treatment of esophageal varices in children because of failures and complications of primary surgery. Portosystemic shunt thrombosis and rebleeding, the hazards of splenectomy in children and long-term risks of encephalopathy all encouraged an alternative therapy.

Controlled trials in adult patients confirmed that early endoscopic sclerotherapy after the onset of bleeding significantly reduced the risk of rebleeding and may prolong survival in the cirrhotic. Injections are performed through

a flexible upper GI endoscope under general anesthesia. Intravenous sedation has been used occasionally in older children. A variety of sclerosants are available for esophageal varices including ethanolamine oleate, sodium tetradecyl sulpfate, sodium morrhuate, phenol in almond oil, and polidocanol (Fig. 214.3).

For gastric varices, intravariceal injection of *histoacryl and lipiodol* is the standard measure (Fig. 214.4). The recent results showed well-tolerated histoacryl with minimal complications. It is a life-saving procedure as the hemorrhage due the fundal varices is always life-threatening.

For esophageal varices, the injections are given either intra or para-variceal and are mostly given into the cardia and lower 3 cm of the esophagus. A maximum of 3 mL is injected into each varix to a maximum of 5–20 mL per session depending on the age and the size of the patient. A nasogastric tube is inserted in small infants to control the degree of gastric distension. The initial three injections are given at weekly intervals and subsequent treatments on a monthly basis until the varices are obliterated.

Mild symptoms of retrosternal discomfort and a transient fever are common after endoscopic sclerotherapy. The variceal hemorrhage may recur, particularly between the first two or three treatments, and esophageal ulceration may be followed by stricture formation and dysphagia. Rare serious complications have included broncho-esophageal fistula, chylothorax, and pericarditis. One case of paraplegia has been reported from injection of segmental spinal vessels.

An analysis of seven reports published since 1984 of the results of sclerotherapy in 248 children shows a mortality rate of 3% and a rebleed rate of 12%. The rebleed rate in a series of seven reports of surgery for portal hypertension (1980–1986) was 14%.

Figure 214.4
Gastric fundal varices with histoacryl injection (Mohamed El Guindi 2010)

Variceal Banding

The application of an elastic band to an esophageal varix is done through upper gastrointestinal endoscopes (*Fig. 214.5*). A device is loaded with multiple bands and then applied to the endoscope tip. The varix is sucked into the device and a band is fired to ligate the varix. Several bands can be are applied to a single varix and to all varices in each session. Multiband devices allow the application of several bands without the need for reloading. The strangulated ligated varix will be thrombosed and sloughed. Treatment is performed initially at 1–2 weekly intervals, extending to monthly intervals once the larger varices are treated. The incidence of esophageal stricture and systemic side effects is lower with this treatment modality. All reports showed superior results of banding versus injection regarding the numbers of sessions needed for obliteration and complications.

Partial Splenic Embolization (PSE)

Hypersplenism is one of the major complications of portal hypertension. Splenectomy had been the treatment of choice for severe hypersplenism owing to portal hypertension, but because of the risk of overwhelming sepsis after splenectomy, partial splenic embolization (PSE) has been used widely in patients with severe hypersplenism especially in small children. PSE proved to be a safe and effective procedure. Hematologic indices improve in all patients after PSE, and its long-term efficacy is shown in 70% of the survivors.

Transjugular Intrahepatic Portosystemic Shunt (TIPS)

Transjugular intrahepatic portosystemic shunt (TIPS) is considered a valid therapeutic option for the treatment of portal hypertension and its complications. This intervention includes the insertion of an expandable metallic stent connecting the hepatic to the portal vein through the percutaneous tranjugular route. Under fluoroscopic imaging, the procedure involves needle advancement over a guide wire into the hepatic vein and thence to the portal vein. A balloon catheter is subsequently inflated to dilate the intrahepatic tract and the stent is deployed.

The indications of TIPS in children include uncontrolled variceal bleeding especially the ones awaiting liver transplantation, thus working as a bridge procedure. Some patients of Budd–Chiari syndrome or intractable ascites may also benefit by this procedure. Portal vein thrombosis, bacterial sepsis, and coagulopathy are contraindications to TIPS.

TIPS, if correctly placed, has no adverse effect on the transplant operation. Close communication with the interventional radiologists who place TIPS is important in the overall management strategy. The concept that TIPS placed prior to transplant to relieve the portal hypertension would make transplant technically easier has not been well supported by data. TIPS is a nonsurgical means of diverting blood from the portal circulation through the hepatic parenchyma to the systemic circulation, thereby creating a portosystemic shunt. Where successful, this results in immediate decompression of the portal circulation and elimination of portal hypertension.

Surgery – Portosystemic Shunts

Endoscopic sclerotherapy with banding is an effective treatment modality of bleeding esophageal varices in most of children with reasonable liver function. However, a further step to TIPS, surgical intervention is indicated for the following cases:

- Uncontrolled bleeding from the not responding esophageal varices
- Bleeding gastric or ectopic varices not responding to endoscopic treatment
- Hypersplenism or massive symptomatic splenomegaly
- Lack of access to endoscopic treatment
- Symptomatic biliary obstruction due to choledochal varices
- Selected patients with Budd–Chiari syndrome

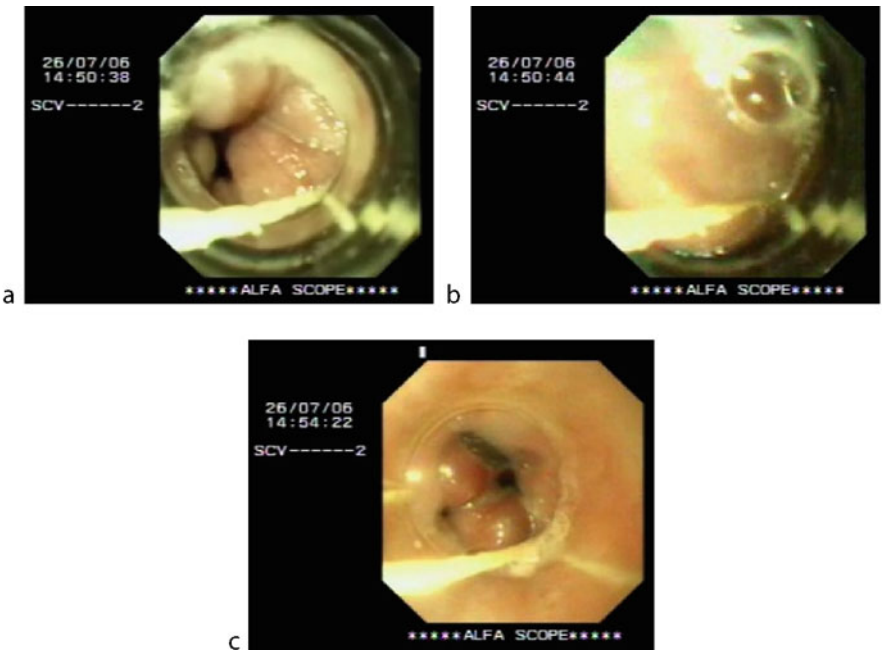

Figure 214.5
Band ligation of gastric varices as seen through a banding device before and after sucking of the varix and then the band applied (Mohamed El Guindi 2010)

The great variety of surgical procedures advocated for the management of portal hypertension was reflected in several studies due to the wide range of the pathology of the portal venous system and the preferences and experience of individual surgeons. Thirty different operations have been mentioned, which included a range of portosystemic shunts and various devascularization techniques.

The construction of a shunt between the superior mesenteric vein and the inferior vena cava using a segment of the internal jugular vein bypassing the liver seems to offer the best combination of long-term patency and the lowest incidence of rebleeding.

The complications of portosystemic shunting are not only concerned with rebleeding, which is minimal, but to more serious ones including deterioration of liver function and hepatic encephalopathy particularly in children with advanced cirrhosis.

Portosystemic shunt surgery should be regarded as a complementary therapy to endoscopic treatment. Porto-mesenteric venous anatomy does not permit successful shunt surgery in every child, and shunt thrombosis has been recorded with all types of shunts especially in smaller children.

The introduction of the mesoportal bypass or mesenterico-left portal (Rex) shunt is likely to broaden the indications once more for shunt surgery as the primary treatment for children with portal venous occlusion. This shunt utilizes an interposition graft between the superior mesenteric vein and the intrahepatic portion of the left portal vein, which is identified in the Rex recessus adjacent to the falciform ligament thus bypassing the thrombosed portal vein. By restoring hepatic portal blood flow and correcting portal hypertension, this technique is more physiological and obviates the potential disadvantages of the portosystemic shunts with close to cure after 5 years follow-up.

A percentage of these patients are not suitable for any form of shunt surgery due to advanced thrombosis and massive collaterals thus leading to some type of devascularization specially the esophageo-gastric devascularization. Most of the cases showed low incidence of rebleeding.

Liver Transplantation (LT)

Liver transplantation is the procedure of choice for patients with complications of portal hypertension associated with end-stage liver disease. This procedure is done using living related LT or cadaveric LT. Most countries are

using both procedures but in some countries living related LT is the only one used where segments of the liver are donated from a relative. The 5 years survival is relatively high reaching 70–80%.

Differential Diagnosis

The major differential diagnosis would be mainly related to those of hematemesis and melena.

In the esophagus the most common differential diagnosis to varices are reflux esophagitis, the Mallory–Weiss syndrome, and corrosive esophagitis should not be forgotten together with foreign bodies or irritants such as lye especially in children. Barrett esophagitis and ulcers caused by ectopic gastric mucosa are rare causes of hematemesis. Aortic aneurysms, mediastinal tumors, and carcinomas of the lung may ulcerate through the esophagus and bleed although these causes are very rare in children.

In the stomach, inflammation, especially gastritis and ulcers, is a prominent cause. Aspirin or NSAID, however, is often the cause and should be differentiated from varices of the cardia of the stomach. Carcinomas and hereditary telangiectasis are less common causes.

Duodenal ulcers are usually the cause of bleeding from the duodenum, but occasionally regional ileitis may be involved. Ulceration of gallstones through the gallbladder and duodenal wall is another rare cause of bleeding from this site. The pancreas can occasionally cause gross hematemesis during acute hemorrhagic pancreatitis into the duct and the duodenum.

Trauma is an important cause of bleeding from all the aforementioned sites, especially following intubation or surgery.

Blood dyscrasias associated with coagulation disorders should always be considered immediately whenever a focal cause of hematemesis cannot be found, especially if bleeding is massive.

Prevention

The best way to prevent portal hypertension and esophageal varices is to reduce the risk of cirrhosis. It is not always possible to prevent esophageal varices in children with liver disease or portal hypertension. Treating the underlying problem such as chronic hepatitis, iron overload, or exposure to toxic chemicals and drugs is of primary importance. Equally important is the use of beta-blockers and other medications to prevent increased blood pressure in the portal vein and eventually ruptured varices.

Prevention of rebleeding of varices should be achieved through scheduling repeated endoscopic sessions for variceal injections and/or band ligation until the varices is obliterated. Other surgical interventions mentioned earlier such as TIPS and devascularization should be resorted to prevent uncontrolled bleeding.

Diuretics may be necessary to suppress ascites. Salt restriction is often necessary, as cirrhosis leads to accumulation of salt (sodium retention).

Growth failure in cases of liver diseases in children is prevented through healthy nutrition and close follow-up.

Prognosis

This depends on the prognosis of the underlying disease, and on the outcome of any complications such as variceal bleeding. The Pediatric End-Stage Liver Disease [PELD] model is the best overall model for prioritization of pediatric patients for liver transplantation.

The Child–Pugh classification system indicates prognosis of cirrhosis in adults and can be extrapolated in children. It includes five parameters (serum albumin, total serum bilirubin, international normalized ratio (INR), ascites, and encephalopathy). Serum albumin is given a score of 1 if >35 g/l, 2 if 28–35 g/l, and 3 if <28 g/l. Total serum albumin is given a score of 1 if <34 μmol/l (<2 mg/dl), 2 if 34–50 μmol/l (2–3 mg/dl), and 3 if >50 μmol/l (>3 mg/dl). INR is given a score of 1 if <1.7, 2 if 1.7–2.2, and 3 if >2.2. Ascite is given a score of 1 if absent, 2 if it controlled medically, and 3 if poorly controlled. As for encephalopathy, it is given a score of 1 if absent, 2 if it controlled medically, and 3 if poorly controlled.

A score of 5–6 is class A predicts life expectancy of 15–20 years; a score of 7–9 is class B predicts life expectancy of 4–14 years; and a score of 10–15 is class C predicts life expectancy of 1–3 years. This aligns with a perioperative mortality for abdominal surgery of 10%, 30%, and 80% respectively.

Survival rates according to Child–Pugh class are 1 year survival in class A is 100%; class B 81%; class C 45%.

As mentioned earlier, almost 90% of patients with cirrhosis develop varices, but only 30% of varices bleed. The first episode of variceal hemorrhage is estimated to carry a mortality rate of 30–50%. At least 50% of people who survive bleeding esophageal varices are at risk of more bleeding during the next 1–2 years. The risk can be reduced by endoscopic and drug treatments.

TIPS does not necessarily improve survival. A TIPS risk score has been devised to help predict prognosis after the procedure.

215 Chronic Hepatitis in Childhood

H. Hesham A-Kader · Fayez K. Ghishan

Chronic hepatitis refers to an ongoing inflammatory process within the liver. This inflammation is reflected by clinical signs and symptoms of hepatitis, abnormally high serum levels of liver enzymes, or by a spectrum of pathological and histological changes. The evolution of these inflammatory changes is variable, whereby the inflammation may subside, may persist unchanged, or may progress to more severe disease and possibly cirrhosis.

The definition of chronicity with respect to hepatitis in childhood does not follow the same criteria used in adults. International criteria used to define chronic hepatitis in adults demand evidence of continued hepatic inflammatory activity for a period exceeding 6 months. Most pediatric hepatologists, however, consider 3 months of persistent inflammation as an adequate time frame to exclude an acute hepatic inflammatory insult. At that point, the diagnosis is confirmed by obtaining a liver biopsy. This more aggressive approach enables early diagnosis of treatable conditions such as autoimmune hepatitis in a timely fashion. If the patient initially presents with signs and symptoms suggestive of chronicity then a liver biopsy should be obtained without further delay.

Etiology

There are various conditions that lead to chronic hepatitis including infections, metabolic, autoimmune and toxic causes (*Table 215.1*).

With the discovery of specific markers for hepatitis viruses B and C it has become apparent that approximately 70% of all cases of chronic hepatitis in adults have a viral origin. Although definitive data from children are not available, it is reasonable to expect that genetic and autoimmune causes also play a significant role in younger patients.

Evaluation

Evaluation of a child suspected to have chronic hepatitis may represent a challenge as the condition may result from a long list of possible etiologies and can present with a wide variety of symptoms and signs. The evaluation includes clinical assessment, serologic testing in addition to imaging, and histopathologic examination. The goals of evaluation should include confirming the diagnosis, grading and staging the disease, and the detection of the associated conditions and complications.

Clinical Presentation

Some patients with hepatitis are asymptomatic and the condition can be accidentally discovered following routine laboratory testing, during the evaluation of unrelated illness, or as a result of screening individuals at risk such as family members of patients with chronic hepatitis B and C, transfusion recipients, patients with inflammatory bowel disease, and those receiving drugs known to cause hepatotoxicity such as methotrexate.

On the other hand some children will present with the typical clinical features of hepatitis such as right upper quadrant pain, jaundice, and malaise. Patients with end-stage liver disease may present with symptoms and signs of cirrhosis, portal hypertension, and liver failure including ascites, gastrointestinal bleeding, and cachexia.

Patients suspected to have chronic hepatitis should undergo a detailed history intake including medication use, drug abuse, family history of congenital and acquired liver disease as well as history of prior surgery and blood or blood products transfusion. A thorough physical examination is mandatory looking for icterus, petechiae, ecchymosis, popular erythema, acanthosis nigricans, spider angiomas, clubbing, muscle wasting, ascites, hepatosplenomegaly, edema in addition to the assessment of mental status.

Laboratory Testing and Imaging

Following history intake and physical examination, the physician should be able to *formulate* an idea about which laboratory tests are needed in the evaluation process. Several imaging modalities are now available and can be helpful in the evaluation of children with chronic

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_215,

hepatitis. The role of different imaging techniques will be discussed separately during the review of common causes of chronic hepatitis in children.

Histology

Although liver biopsy is not usually indicated in patients with acute hepatitis, it can provide critical information in the evaluation of children with chronic hepatitis, including confirming the diagnosis in addition to the grading and staging of hepatic inflammation and fibrosis. The role of an experienced hepatic pathologist familiar with pediatric liver disease cannot be over stressed.

Chronic Hepatitis B

Etiology

Hepatitis B virus (HBV) is a member of Hepadnaviridae family of DNA viruses. The intact virion is double-shelled, with an outer component designated as the HBV surface Ag (HBsAg) and the inner component designated as the HBV core antigen (HBcAg). The HBV core Ag or nucleocapsid houses the genome of HBV in the form of partially double stranded DNA, along with DNA polymerase and the HBeAg. The genomic DNA of HBV consists of four open reading frames corresponding to four gene products: The S gene and the pre-S gene encode for the HBsAg, the C gene encodes for the viral nucleocapsid HBeAg as well as for the HBcAg, the P gene encodes for DNA polymerase, and the X gene encodes for a protein (HBxAg). The HBxAg contains an enhancer/promoter complex with transcriptional transactivity function that is thought to play a role in the promotion of hepatocellular carcinoma.

HBV exhibits trophism for liver cells and replicates freely within hepatocytes producing an excess of HBsAg found in the serum of acutely or chronically infected patients. Immunity to HBV is mediated through virus-neutralizing antibodies directed against the HBsAg (anti-HBs). The appearance of these antibodies signifies recovery from Hepatitis B and subsequent immunity to HBV infection. During acute infections, IgM antibody to the core antigen appears during the onset of clinical symptoms indicating persistent viral replication. IgG antibody to the core Ag appears at the onset of symptoms and may persist for years if viral replication continues. The presence of HBeAg or HBV-DNA in serum correlates with ongoing viral replication and the complete viral particles in the circulation and thus, reflects HBV infectivity or the potential for transmission of HBV. The presence of antibodies directed against HBeAg (anti-HBe) usually correlates with the clearance of HBeAg from the circulation. However, some HBsAg- and anti-HBe-positive patients exhibit ongoing viral infection as evidenced by HBV DNA seropositivity and HBeAg in liver.

Pathogenesis

HBV is not itself directly cytopathic to hepatocytes. The evidence for this comes from the observation that during the long latency period between infection and hepatic disease, active viral replication occurs without liver damage. Injury is mediated through the patient's immune system. In the majority of patients, all infected hepatocytes are destroyed by primed cytotoxic lymphocytes. An overly aggressive immune response can result in fulminant hepatitis. In the chronic state, the immune system destroys only a portion of infected liver cells. The HBV virus, therefore, may survive to replicate and infect other hepatocytes. The mechanism behind this variable immune response has not been completely elucidated.

One proposed theory explaining how the immune system attacks infected hepatocytes may also explain the reason behind the effectiveness of alpha interferon therapy in some patients. In patients with HBV in active replication as evidenced by the presence of HBeAg in the circulation, a component of the replicating virus, either the core antigen or the e antigen, migrates to the cell surface

where it presents a target for primed cytotoxic lymphocytes. In a successful immune response, the hepatocyte is stimulated by intracellular interferon to produce an HLA class I surface antigen that serves as a second target for the lymphocyte. T-cell release of lymphotoxin and subsequent cell lysis is possible only when both antigens are present. Patients with chronic Hepatitis B may have diminished production of HLA Class I surface antigens as a result of inadequate interferon production. This theory explains why some patients with chronic active hepatitis respond to interferon therapy.

Epidemiology and Risk Factors for Chronicity

Transmission of HBV typically occurs through the parenteral route, primarily through the exchange of blood or other body fluids (excluding stool).

HBV infection incidence and prevalence vary with geographic areas. In North America and Europe the prevalence is less than 1%. On the other hand, HBV infection is highly endemic in Southeast Asia and parts of Africa (up to 15–20% of the general population).

In the Middle East and the Arab world, the prevalence of Hepatitis B in children varies with different countries, and within different regions of the same country. In 1990, 6.7% of Saudi Arabian children were HBsAg positive, a rate similar to adults, with the highest prevalence being among urban dwellers. The peak prevalence (9.7%) was among the 1 year age group. Significantly the degree of infectivity as reflected by a positive HBeAg was 17.9%. In Jordan, a study conducted in 1985 demonstrated that Hepatitis B was highly endemic, with a prevalence of HBsAg of approximately 10% among children. A WHO collaborative study published in 1980 demonstrated HBsAg age specific prevalence of 23% in Egyptian children aged less than four, with the prevalence decreasing to 3.7% by late adolescence.

Perinatal Transmission

In some areas of hyperendemicity such as the Far East, perinatally acquired disease is the major vehicle for transmitting the disease and perpetuating the chronic carrier state. The offspring of all HBsAg positive mothers are at risk but infection is most frequently noted when the mother is a chronic HBV carrier, has acute disease in the third trimester, or is HBeAg or HBV DNA polymerase positive. If the mother is HBeAg seropositive, the risk of transmission without treatment of the neonate is 90%. If the mother is seronegative for HBeAg, the risk of transmission is around 20%.

While there is some evidence to indicate that Hepatitis B is endemic in the Arab world, horizontal transmission plays a more significant role than vertical transmission in propagating the disease. In Egypt vertical transmission occurred in only 1.7% of births to HBsAg positive mothers, while 17.2% of children born to Hepatitis BsAg negative mothers acquired Hepatitis B in childhood. Similar trends demonstrating a low contribution by vertical transmission to the pool of HBV carriers has been demonstrated in Jordan, Egypt, Saudi Arabia, Kuwait, and Yemen. This has been partly attributed to a low level of HBsAg and HBeAg seropositivity in the child-bearing age group of females.

Infants who acquire HBV infections through vertical transmission from HBsAg positive mothers usually do not exhibit serologic evidence of infection until they are 1–3 months old. This implicates ingestion of maternal blood during birth as the route of transmission. Rarely, transmission occurs in utero via a maternal-fetal transplacental leak.

The significance of acquiring Hepatitis B perinatally or early in life lies in the significantly higher risk of developing a chronic infection. More than 90% of infants infected in the perinatal period will develop chronic HB infection, as will 25–50% of children infected before the age of 5 years. This is in contrast to patients who acquire the infection in adulthood, where only 6–10% will continue to be chronically infected. The frequent development of the chronic carrier state after acquiring HBV infection perinatally has been attributed to the immaturity of the newborns' immune system.

Chronic disease is unusual in patients with acute icteric hepatitis B, and the majority of cases of chronic hepatitis will not experience an episode of clinically apparent icterus, thus suggesting that clearance of HBV infection requires a hepatitis illness.

Chronic disease is also more common in immunocompromised patients, especially those patients with T-cell dysfunction. Children with Down's syndrome, leukemia, or leprosy are also at greater risk for chronicity. As mentioned previously, the age at the time of initial infection seems to be essential. Eighty percent of those infected prior to 1 year of age develop chronic infection. This figure decreases to 40% between 1 and 10 years of age, and is less than 10% in adults.

It is also believed that administering corticosteroids during the acute state increases the risk of persistent infection.

Diagnosis of Chronic Hepatitis B and Laboratory Data

The diagnosis of chronic hepatitis B is suspected in patients who are HBsAg seropositive in the absence of anti-HBs, particularly if this picture persists for more than 6 months. Infection is confirmed with the evidence of ongoing viral replication through the presence of either HBeAg or HBV-DNA in serum or HBcAg in liver tissue. HBeAg may be absent in patients with mutant HBV that does not synthesize HBeAg.

Serum aminotransferase levels and bilirubin are moderately elevated. Prolonged prothrombin time and low albumin may be seen in advanced cases.

There are eight different HBV genotypes with geographic propensity. Types B and C are common in Asia, types A and D in Europe, type E in west Africa, types F and H in South America, and type G in France. Compared to type A, type D is associated with a more severe disease. Similarly type C is more aggressive than type B leading to cirrhosis and hepatocellular carcinoma.

Natural History

HBV infection in children is characterized by high rate of chronicity especially in newborns with approximately 90% of perinatally infected babies developing chronic disease compared to 25% in children between 1 and 4 years and 1–5% in adolescents. The high rate of chronicity at early age may be explained by immaturity of the immune system.

Long-term studies have shown that 50% of children have seroconversion of HBeAg to HBeAb within 5 years and 70% cleared the infection in 10 years with spontaneous clearance of HBsAg at 0.5% per year. Patients with high ALT and later acquisition of the infection seem to have the best seroconversion rate.

Children usually develop a less severe liver disease compared to adults. Cirrhosis is rarely seen during childhood and is more commonly found in patients with perinatal or early postnatal infection. On the other hand, hepatocellular carcinoma, though rare, have been reported in children under the age of 10 years

Prevention and Immunization

Prevention remains the cornerstone of the management of this disease. The first HBV vaccine was a plasma-derived HBsAg subunit vaccine, prepared from plasma of chronic HBsAg carriers. Extensive studies and worldwide use of this vaccine proved its safety and efficacy. Immune response occurred in up to 90% of the healthy individuals and in 50% of immunocompromised patients.

The nucleotide sequence of HBV genome that codes for HBsAg has been isolated and inserted into yeast, thus producing large amounts of HBsAg using recombinant DNA technology. These recombinant vaccines have proven to be as safe and effective as the plasma vaccine.

Based on the epidemiology of the disease, different immunization programs have been tried in different parts of the world. In Taiwan, where perinatal exposure is the main vehicle for infection, immunization starts in early infancy and childhood. In the USA, where the disease is acquired later in life, immunization was recommended for high-risk groups only, which includes homosexuals, IV drug abusers, health care workers, and infants of HBsAg positive mothers. However, failure of this strategy in reducing the incidence of the disease has led to the recent recommendation of universal immunization of all infants and children by the age of 11 years regardless of their maternal HBsAg status. Immunization of adolescents and adults in high-risk groups is also recommended.

Pre-Exposure Prophylaxis

For high-risk groups and partners of infected people, testing for anti-HBs before immunization is recommended. If the level of anti-HBs is more than 10 RU by RIA or positive by ELISA, this would indicate previous exposure and immunity. If anti-HBs is less than 10 RU or negative by ELISA, anti-HBc needs to be checked. If positive, the patient is immune to the disease or has the disease. If negative, the person needs to be immunized.

Post-exposure Prophylaxis

This approach is recommended for (1) newborns with perinatal exposure to a known HBsAg carrier mother; (2) accidental exposure to HBsAg positive contaminated blood, whether mucosal, ocular, or percutaneous; and (3) sexual exposure to a chronic HBsAg carrier.

Hepatitis B immunoglobulin (HBIG) 0.5 ml IM should be given within 12 h after exposure followed by HB vaccine given at a different site. Two more HB vaccine doses should be given at 1 month and at 6 months after the first dose.

When used as a sole agent, HBIG has a protective effect on newborns of 75%. Combined with HB vaccine, the protection approaches 95%. Since 5% of perinatal infections are thought to be acquired in utero, further reduction of perinatal transmission may not be possible.

Protective levels of HBsAg develop in 90% of healthy adults given the Hepatitis B vaccine, and the efficacy in healthy children and newborns appears to be even higher. Several investigators, however, have reported the detection of antibody escape mutants in children vaccinated against hepatitis B. These mutations are usually found in the S gene or associated with alteration in the antigenicity of a component of HBsAg resulting in the inability to raise protective antibodies to the vaccine.

Clinical Manifestations

As mentioned before, the presentation of chronic hepatitis B can be extremely variable. Prolonged jaundice after an acute hepatitis, neonatal cholestasis, liver cirrhosis with portal hypertension or mild fatigue are a few of the wide spectrum of clinical manifestations.

Hepatocellular carcinoma is well documented in adults, but is extremely rare during childhood. However, children who are suffering from chronic hepatitis B are at a high risk to develop hepatocellular carcinoma in their adult years.

Histology

Liver tissue may show inflammatory cell infiltrates of the portal triad, mainly by plasma cells and lymphocytes, piecemeal necrosis, and bridging necrosis in more severe cases. HB particles can be occasionally identified in liver cell by the ground glass appearance of the cytoplasm and confirmed by Shikata's orcein staining.

Complications of HBV – Chronic Hepatitis

Cirrhosis

Adult studies have shown that the risk of cirrhosis is significant, especially in the presence of bridging necrosis. Cirrhosis in HBsAg positive infants and children was thought to be a rare occurrence. However, it has been frequently reported in Taiwanese children and is particularly common among infants and children who acquired the disease perinatally.

Hepatocellular Carcinoma

Hepatocellular carcinoma is one of the ten most common cancers worldwide, and is one of the most common cancers in some parts of Southeast Asia where the hepatitis BsAg carrier rate is approximately 20% of the population. The molecular mechanism behind carcinoma induction in HBsAg positive patients is not completely clear. However, it is thought that integration of HBV into the genome of the host precedes hepatic oncogenesis. Recent evidence points to a possible role for the HBV-X gene as a promoter in those patients who develop cancer.

Polyarteritis Nodosa

Glomerulonephritis and papular acrodermatitis have been reported in adult patients.

Management of Chronic Hepatitis B

The optimum goals of treating patients with chronic hepatitis B are to decrease viral replication in addition to normalization of liver enzymes and histology. Unfortunately these goals are not easily attainable in all patients with currently available medications. There are currently seven approved medications for the treatment of hepatitis B in adults in the USA including IFN-α, Lamivudine, Adefovir Diprovoxil (ADV), Entecavir, Telbivudine, and Tenofovir. However, only three medications are approved for treating children, which are IFN-α, Lamivudine, and Adefovir.

Children should be considered for treatment if they are in the immuno-reactive phase with ALT levels at least twice the normal levels and have serologic evidence of chronicity as shown by positive HBeAg and/or HBV DNA on two samples 6 months apart.

Liver biopsy is usually recommended prior to initiating therapy in order to grade inflammation and stage fibrosis.

IFN-α is the only approved therapy for hepatitis B in Europe. Typical dosing is 6 MU/m^2 with maximum dose of 10 MU/m^2 per dose thrice weekly subcutaneous injection for 16–24 weeks. Children with high ALT and later acquisition of the virus are more likely to respond to therapy. Side effects of IFN-α are similar to those in adults including flu-like symptoms, bone marrow suppression, irritability, alopecia, nausea, vomiting, diarrhea, hypothyroidism, exacerbation of depression, and suicide ideation.

In general, seroconversion of HbeAg and DNA ranges between 26% and 60% as shown in multiple studies. Studies of pretreatment with prednisone have shown conflicting

results and currently, therefore, pretreatment with prednisone is not a standard therapy. On the other hand patients with genotypes A and B appear to respond better to therapy compared to those with genotypes C and D.

In general although spontaneous HbeAg seroconversion can happen in many patients, treatment with IFN-α accelerates the seroconversion especially in children with high ALT. Whether or not the acceleration of seroconversion by 12–36 months can help prevent long-term damage to the liver has yet to be studied.

Lamivudine is a nucleoside analogue that can be taken orally. Children who received lamivudine (3 mg/Kg) for 52 weeks had a higher virologic response compared to those who received placebo (23% vs. 13%). The response was associated with the normalization of ALT and suppression of HBV DNA. Lamivudine is usually well-tolerated without adverse effects. However, the long-term use of lamivudine can be associated with the development of viral resistance. The most common HBV mutation that leads to resistance is a codon change at site 552 in the C domain of the YMDD motif of the HBV polymerase gene (methionine to valine or isoleucine) and therefore, called the YMDD mutation. The duration of lamivudine therapy is yet to be determined but has to continue for 12 months and at least 6 months following HBVeAg seroconversion.

Lamivudine may be also helpful in patients with fulminant hepatic failure due to exacerbation of chronic hepatitis B infection. Twenty-four patients with chronic hepatitis B and fulminant hepatic failure responded to lamivudine therapy without the need for transplantation.

Adefovir dipivoxil has been used successfully in adults with chronic HBV infection for years both as first-line therapy as well as in patients with lamivudine resistance. Studies in adults have shown twice the HBeAg seroconversion rate in patients treated with adefovir compared to those who received placebo (12% vs. 6%) in addition to normalization of ALT and decreased HBV DNA. The usual adult dose is 10 mg per day as higher doses were associated with nephrotoxicity and failed to demonstrate better efficacy.

A multi-center study by Jonas et al. in children with chronic hepatitis B in various age groups found that the use of adefovir is safe and that 48 weeks of therapy was superior to placebo in HBeAg positive adolescents. However, the study did not demonstrate efficacy in children under the age of 12 years.

The disappointing results of monotherapy in patients with chronic HBV infection have led to multiple trials examining the effects of combining medications either simultaneously or sequentially with mixed results.

In a promising study, 23 children with perinatal-acquired HBV infection were treated for 8 weeks with lamivudine followed by IFN-α combined with lamivudine for 10 months. HbeAg seroconversion was seen in 22% of the patients. In addition 78% became HBV DNA negative and 17% lost HBsAg and became HBsAb positive. None of the patients developed YMDD mutation and all maintained their seroconversion when followed up for at least 3 years.

In summary, chronic HBV infection is a major cause of liver disease in children worldwide. Children are more likely to develop chronic HBV infection as they demonstrate greater immunotolerance to the virus, and response to therapy in children remains disappointing. Only three medications have been approved for treatment of children with chronic HBV infection. IFN-α has been shown to be the most effective so far with approximately 30% HBeAg seroconversion and 10% HBsAg seroconversion. IFN-α is more effective in patients with ALT at least twice the upper normal limit and in children with later-acquired infection. However, IFN-α is associated with a long list of side effects. Moreover, long-term follow studies have suggested that IFN-α simply accelerates a spontaneous event. Lamivudine's virologic response is not much different from IFN-α in terms of HbeAg seroconversion, however, it has a lower HBsAg seroconversion (2–3%). Advantages of lamivudine include easy administration and better safety profile but it has high rates of drug resistance. Although adefovir has been shown to be safe in children, its efficacy is limited to children above the age of 12 years. Adefovir's efficacy is also lower than lamivudine (16% HBeAg seroconversion; <1% HBsAg seroconversion).

In the future, therapies approved in adults such as entecavir and tenofovir may prove to be effective in children, and combination therapy may be another available option in the pediatric age group. The search for a perfect therapy for children with chronic HBV infection continues and careful observation for these patients while awaiting such therapy is not unreasonable.

Chronic Hepatitis C

A third form of infectious hepatitis not caused by hepatitis A or B has been termed as non-A, non-B hepatitis (NANB). The long-suspected virus is currently known as the hepatitis C virus (HCV), an RNA virus cloned in 1989. The virus is composed of 9,400 nucleotides encoding a 3,010–3,033 amino acid sequence, which is further cleaved into distinct polypeptides during or after translation to yield different viral proteins. The envelope and nucleocapsid proteins are encoded at the 5′ end of the open reading

frame, while nonstructural proteins are downstream. Because of nucleotide sequence diversity, six major genotypes of Hepatitis C with different component subtypes based on nucleotide homology have been identified. Genotype information can provide useful information regarding prognosis and response to therapy. For example, type I has been shown to be resistant to anti-viral therapy. Geographical differences in the prevalence of these types have been reported. For example, while types 1 (a and b) and 2 are more prevalent in North America, genotype 4 appears to predominate in patients from the Middle East.

The E_1, E_2 regions of the open reading frame have hypervariable regions. Their variability is postulated to play a role in the persistence of infection.

Epidemiology and Transmission

The distribution of HCV is worldwide similar to HAV and HBV. Twenty-eight thousand new cases of HCV happen in the USA each year. However the proportion of pediatric cases is not known. The prevalence of HCV infection in the USA is approximately 1.8%, which represents approximately 3.9 million people. The seroprevalence is 0.2% among children below the age of 12 years and 0.4% in children between 12 and 19 years.

Studies in children without identifiable risks have shown seroprevalence rates ranging from 0% in Japan and Taiwan, 0.4% in Italy, 0.9% in Saudi, and 14% in Cameroon. On the other hand, the prevalence of HCV in patients with NANB is much higher in patients with identifiable risk factors such as thalessemia (60–65%), hemophilia (59–95%), and leukemia (52–72%).

Although HCV infection is much less common than HAV and HBV, the propensity of HCV infection to chronicity has resulted in HCV responsible for 63% of chronic hepatitis and 35% of all cases of chronic liver disease and cirrhosis.

The typical mode of transmission of HCV is parenteral. Transmission may be divided to percutaneous (Blood transfusion, intravenous drug abuse) and non-percutaneous (intrafamilial and sexual).

Traditionally the transmission of HCV has been attributed to the transfusion of infected blood as well as blood products. However, this route of transmission has declined tremendously following the advent of screening for HCV antibodies after 1991. Similarly blood products are now much safer thanks to the improvement of inactivation procedures.

On the other hand there has been a progressive increase in the number of cases attributable to intravenous drug abuse, which may be as high as 60% of new cases. This may be explained by the declining risk of transmission with blood and blood products and the increased frequency of drug abuse.

Other percutaneous transmission modes include accidental needle stick that carries a risk of 10% and usually results in a symptomatic disease. Tattooing has become very popular among adolescents and has been associated with the transmission of HCV.

The risk of transmitting HCV by sexual contact is not well defined. Although accumulated epidemiologic evidence indicates that HCV can by transmitted by sexual contact, this mode of transmission is much less efficient than other sexually transmitted viruses such as HBV and HIV. Individuals engaged in long-term monogamous relationship carry a low risk for transmission of HCV (0 – 0.6% per year), and there is no need to change their regular practice. On the other hand those involved in short-term relationship with multiple partners may experience a higher risk, and barrier or abstinence methods are advised. In general, couples should refrain from sharing tooth brushes, razors, and nail-grooming equipments.

Maternal-infant transmission of HCV infection is comparatively uncommon. The mother to infant transmission is estimated to be 4 – 7% per pregnancy. However, co-infection with Human Immunodeficiency Virus (HIV) will increase such risk by fourfold to fivefold. Transmission happens when HCV RNA is detectable and possibly related to high levels (above 10^6 copies/ml). The time and mode of transmission are not known and therefore, cesarean section should not be recommended in order to prevent the transmission of HCV.

HCV can be detected in breast milk. Nevertheless, breast feeding is not considered a risk factor for the transmission of HCV in the absence of traumatized, cracked, or bleeding nipples. As a matter of fact, several studies have shown that the rate of transmission of HCV is similar in breast-fed and bottle-fed infants. However, breast feeding may pose risk for transmitting HCV during periods of postpartum hepatitis flare up.

Some cases of HCV infection can be attributed to intrafamilial and occupational spread. However, in 35–50% of the cases no source can be identified creating uncertainty regarding the existence of other modes of transmission.

Pathogenesis

The pathogenic mechanisms of HCV are not well understood. The virus is presumed to be directly cytopathic, but

there is some evidence that immune reaction to HCV may also lead to liver damage.

Frequent episodes of hepatitis are observed which may represent re-activation or reinfection. These episodes are postulated to be due to the emergence of mutants of HCV not neutralized by circulating antibodies.

Immune cross-reaction of P450 epitopes and hepatitis C proteins may explain the occurrence of anti-LKM antibodies in some patients.

Clinical Presentation

Hepatitis C causes both *acute* and *chronic* infection, although the rate of chronicity is alarmingly higher than Hepatitis B infection.

In *acute* transfusion-related transmission, the disease is usually mild and often asymptomatic and subclinical. The mean incubation period of hepatitis C is 6–12 weeks, the average time from transfusion to anti-HCV positivity is 8 weeks, and HCV RNA has been detected within 1–3 weeks of transfusion. The acute course of HCV is clinically mild with only 25% of cases having an icteric phase. The peak aminotransferase levels are less than those encountered in acute Hepatitis B. During the early phase, serum aminotransferase levels may fluctuate (multiphasic), may become normal (monophasic), or may plateau. Patients with the single monophasic rise are at the least risk for developing chronic infection.

Chronic HCV infection occurs in 50–75% of patients with HCV post-transfusion or sporadic hepatitis. Aminotransferase levels decline from the peak values of the acute phase to remain two to eight folds above normal. These levels may fluctuate over time, and may even be intermittently normal. Unlike the acute disease, chronic HCV may lead to grave consequences. Persistent HCV infection leads to chronic hepatitis, and cirrhosis develops in 20% of patients within 10 years of acquiring the infection, although the cirrhosis remains indolent and progresses slowly. The disease has also been linked to the development of hepatocellular carcinoma.

Diagnosis

The diagnosis of HCV infection rests on the detection of anti-HCV antibody in the serum of infected individuals, or the detection of HCV RNA in the serum or liver. HCV antigens cannot be detected in the serum due to the low concentration of the virus in the blood.

The detection of antibodies to HCV is an indicator of past or present infection. The methodology used in assaying for HCV antibodies has undergone rapid evolution. The first generation ELISA assay detected antibodies to c100-3, a polypeptide representing part of the HCV genome. This assay, however, lacked sensitivity and specificity. Subsequently, second generation ELISA assays (versus c100-3, c200, c33c) and third generation ELISA assays (versus epitopes from the NS5 region) have greatly improved sensitivity. Although the mean interval from the onset of hepatitis to seroconversion is 8 weeks, some individuals may not seroconvert for up to 1 year. Thus, when using ELISA tests it may be necessary to test sequential samples over a 1 year period to exclude the diagnosis. Moreover, in acute phases that fully recover, there may be considerable delay in the clearance of anti-HCV.

Recombinant immunoblot assay (RIBA) detects recombinant antibodies to structural and nonstructural proteins of HCV coated on nitrocellulose strips. This test has decreased the incidence of false positive results seen with ELISA tests. A positive test for HCV using RIBA 4 not only confirms infection but is an indicator of viremia and infectivity.

A negative anti-HCV does not exclude infection in the early stage or past infection as it may disappear with disease resolution.

Detection of serum HCV RNA using polymerase chain reaction techniques is now the "gold standard" for detection of the disease. This method allows the detection of HCV RNA in almost all of anti-HCV positive patients and also in a proportion of those who are antibody negative, particularly neonates born to anti-HCV-positive mothers. RNA is detected in the serum during the incubation period and can detect as low as 1 – 10 molecules of nucleic acids. The persistence of RNA in the circulation for 6 months indicates chronic infection. Quantification of HCV RNA can help determining response to therapy. Rarely, HCV RNA is absent from the circulation but present in hepatic tissue.

Serum aminotransferase levels rise with the development of symptoms and the appearance of jaundice. The enzymes decline in a rapid monophasic fashion or a multiphasic pattern with fluctuations and more protracted course.

Histological features of HCV infection are similar to those in adults. Mild inflammation and necrosis is usually seen. However, patients may develop fibrosis which progresses with increase in age and infection duration.

Treatment

Studies of treatment for HCV infection in children have used the same drugs and measures of efficacy as in adults

(see section "Evaluation"), but have been limited to relatively small numbers of children.

A meta-analysis of 19 trials of IFN[alpha] for children with HCV infection examined the effect of treatment in 366 children compared with 105 untreated controls. Response to treatment occurred in a mean of 54% (range 0–91%) of patients, with a sustained response in 36% (0–73%). HCV genotype 1 adversely affected the likelihood of response, with a sustained response in 27% of children compared with 70% in those with other genotypes. A small study of pegylated IFN[alpha] as monotherapy for 48 weeks in 14 children achieved an SVR in 43% of children with HCV genotype 1.

Children may benefit from the treatment of HCV infection. Meta-analysis of studies of monotherapy with interferon has shown sustained virologic response (SVR) in 33–45% of chronically infected children, which is significantly higher than adults. The SVR was considerably less in patients with genotype I (26%) compared to other genotypes (70%). The spontaneous clearance rate in untreated children was 5%. Treatment duration ranged from 6 to 18 months. Most studies used a dosage of 3 MU/m^2 via subcutaneous injection three times weekly. The better success rate in children may be explained by the shorter duration of infection and the absence of co-morbd conditions and aggravating factors. The spontaneous clearance rate in untreated children was 5%. Treatment duration ranged from 6 to 18 months. Most studies used a dosage of 3 MU/m^2 via subcutaneous injection three times weekly.

Studies of the use of combination therapy using interferon and ribavirin have shown SVR of 38%. Recently, combination therapy with pegylated interferon and ribavirin has been approved by the FDA in the USA in children 3 years of age and older.

Children seem to tolerate IFNα well. Although interferon therapy can affect weight gain and linear growth, these effects disappear following cessation of therapy. Possible complications following interferon therapy in young children include serious hemangiomas, spastic diplegia, and seizure. On the other hand, ribavirin is usually well tolerated in children. Although dose-dependent hemolytic anemia may be seen, this usually does not result in discontinuation of treatment.

HCV infection is a common indication for transplantation in adult patients. Reinfection following transplant is universal. Although liver transplantation is a rare indication for HCV infection in children, the outcome after transplant is not different with 31% of the patients requiring retransplantation mainly for HCV recurrence. Immunosuppressive therapy decreases the efficacy of HCV treatment and potentiates ribavirin-induced hemolysis. On the other hand, HCV treatment induces acute and chromic rejection in 10–25% of transplanted patients. Pre-emptive treatment of HCV early after transplant is associated with adverse effects in 50% of the patients and results in an SVR of only 10–20% compared to SVR of 25–40% in patients treated after recurrence of HCV following transplantation.

Future Directions

Future therapy may include the use of ribavirin analogues that are liver-specific, minimizing the risk of hemolytic anemia. Fusing albumin with recombinant IFNα-2b is currently under evaluation with the potential of a monthly rather than weekly administration injection which will be much more convenient for patients especially those in the pediatric age group. Other future options may also include protease and polymerase inhibitors and Toll-like receptor agonists which can prevent the activation of inflammatory response initiated by microbe gene and cytokine induction. Gene therapy strategies aiming at rendering hepatocytes resistant to HCV are currently under evaluation in animal models including transfer of IFNα gene and also the integration of antisense DNA/RNA molecule into the host genome. Finally, clinical trials of human monoclonal antibody against HCV are underway.

The development of HCV culture model that is infectious in chimpanzees has raised hopes for an effective vaccine. Data in chimpanzees indicates that the vaccine may prevent the progression to chronic disease. Clinical trials in humans are going through phase I and II presently.

Autoimmune Liver Disease

Autoimmune liver disease encompasses a group of disorders characterized by the presence of circulating antibodies and inflammatory process directed toward the hepatocytes causing autoimmune hepatitis or directed against the biliary tree resulting in sclerosing cholangitis or both (overlap syndrome).

Autoimmune Hepatitis

Autoimmune chronic hepatitis is characterized by features of chronic hepatitis, hypergammaglobulinemia, and the

presence of non-organ–specific autoantibodies as well as liver-specific autoantibodies, in the absence of a known cause of liver disease.

Etiology

The pathogenesis of autoimmune chronic hepatitis has not been completely elucidated. It is postulated that liver damage in patients with autoimmune hepatitis stems from the interaction of helper/inducer T-cell lymphocytes with a self-antigen, the asialoglycoprotein receptor (ASPGR) that is mistakenly recognized as foreign. This initiates a cascade of events leading to the production of cytokines, activation of cytotoxic T-cells, and induction of autoantibody production by B lymphocytes. A genetic background has been suggested due to the high frequency of HLA haplotypes HLA B*/DR3 and allotypes DR3 in addition to the presence of other autoimmune disorders.

Several triggers have been proposed such as viral infection–inducing autoimmune hepatitis. A long list of viruses including Hepatitis A and C, Epstein Barr, and human herpes virus 6 have been suggested as triggering factors for autoimmune hepatitis. It is known that the molecular structure of the HCV polyprotein bears resemblance to a component of cytochrome P450 and therefore, it may trigger the production of liver kidney microsomal (LKM) antibodies. Similarly, an epitope of P450 displays homology with a herpes simplex virus type I (HSV-I) protein, and in adults, increased frequency of HSV-I has been reported.

On the other hand several drugs have been associated with the development of autoantibodies. ANA, SMA, LKM, and anti-liver microsomal antibody have been reported secondary to the use of α-methyldopa, nitrofurantoin, and tienilic acid dihydralazine, respectively. Although the mechanism of drug-induced autoimmune hepatitis is still poorly understood, a possible mechanism might be the production of unstable drug metabolite, which can induce an antibody response followed by combining with cellular component.

Diagnosis

Diagnosis of autoimmune hepatitis rests on clinical picture, histological changes, and the detection of autoantibodies. Liver biopsy of patients with autoimmune hepatitis shows necroinflammatry changes with portal triad dense infiltration with mononuclear inflammatory cells including plasma cells and parenchymal collapse.

Transaminase levels are elevated 2–30-fold. Alkaline phosphatase and gamma-glutamyl transferase are normal or modestly elevated up to twice the normal level. Hyperbilirubinemia is usually present except in those patients presenting insidiously. At presentation, the prothrombin time is usually prolonged 4 s or more. Serum albumin concentrations are usually low. Hypergammaglobulinemia is a characteristic abnormality with levels greater than 2.0 gm/dL. Serum IgG levels are always high, while serum IgM levels are occasionally high, and serum IgA levels are occasionally low. C_3 and C_4 levels may be low.

IgG autoantibodies to internal components of cells are present in almost all patients. However, antibodies may occasionally disappear on immunosuppressive therapy, or infrequently, may appear only after the initiation of immunosuppression. Some clinicians divide autoimmune hepatitis into *different subgroups* based on the type of non-organ–specific autoantibodies detected.

Type I is that associated with smooth muscle antibody (SMA) with or without antinuclear antibody (ANA).

Type II is that associated with anti-liver/kidney (LKM) antibody, which is also designated as endoplasmic reticulum antibody because it is directed against P-450 antigens and other antigens of the monooxygenase system. This type of autoimmune hepatitis has a more severe course with rapid progression to cirrhosis, despite immunosuppressive treatment. Of note is that antibodies to the P-450 component of LKM are commonly found in adult patients with hepatitis C.

Type III characterized by the presence of anti-soluble-liver-antigen antibody (SLA) has been proposed but has not gained universal acceptance as many believe that it is a subset of type I.

These forms of autoimmune hepatitis may be associated with a Coomb's-positive hemolytic anemia, thyroid antibodies, and rheumatoid factor (RF), or parietal cell antibodies. In addition, autoantibodies to liver-specific lipoprotein (LSP) antigen or to one of its components and the asialoglycoprotein receptor (ASGPR) found on hepatocyte membranes may be present. The titers of LSP and ASPGR antibodies frequently correlate with the extent of liver damage and disease activity, respectively.

Clinical Manifestations

Autoimmune hepatitis affects both children and adults with two peaks at 10–20 and 45–70 years of age. Eighty percent of adult patients have type I, while type II is mainly a disease of younger patients especially females.

Patients with autoimmune hepatitis may present acutely with anorexia, malaise, nausea and vomiting, and features suggestive of ongoing hepatitis. Occasionally, the presentation is insidious with nonspecific symptoms. Rarely, the picture may be that of acute liver failure. A group of patients may initially present with manifestations of end-stage liver disease such as jaundice, ascites, and gastrointestinal bleeding. Extrahepatic manifestations such as amenorrhea, acne, arthritis, dermatitis, thyroiditis, or hemolytic anemia may accompany the hepatitis. Some patients may be diagnosed following an incidental finding of elevated serum aminotransferases during routine laboratory testing.

Autoimmune hepatitis may be seen in association with a long list of autoimmune disorders such as celiac disease, inflammatory bowel disease, glomerulonephritis, hemolytic anemia, idiopathic thrombocytopenia, Sjogren syndrome, Grave's disease, and thyroiditis. Manifestations of autoimmune hepatic may precede; accompany, or follow the presentation of these autoimmune disorders. Autoimmune hepatitis may also be seen in 20% of patients with polyglandular syndrome type I (APECED) which is a monogenic disorder with a variable phenotype. About 20% of the cases develop autoimmune hepatitis (AIH) that resembles AIH type 2. This disorder is an autosomal recessive disorder caused by homozygous mutations in the ***AIRE1*** gene and characterized by a variety of organ-specific autoimmune diseases, the most common of which are hypoparathyroidism and primary adrenocortical failure, accompanied by chronic mucocutaneous candidiasis.

Treatment of Autoimmune Hepatitis

Patients with autoimmune hepatitis usually respond to corticosteroids which is the mainstay therapy and should be tried even in patients with fulminant hepatic failure or with cirrhosis.

Predinosolone at a dose of 2 mg/kg/day (maximum 60 mg/day) is usually recommended with gradual tapering after normalization of serum aminotransferases which is usually seen in 80% of the patients within few months. Clinical improvement usually precedes biochemical normalization of liver enzymes. On the other hand histologic resolution may take 3–6 months. A low dose of steroids is usually needed to maintain remission. If maintenance therapy with steroids is associated with side effects the addition of another immunosuppressive agent may allow discontinuation of steroids.

Azathioprine acts by inhibiting maturation of lymphocytes and therefore, may take up to 3 months to be effective. Azathioprine is usually used as a steroid sparing agent in patients requiring long-term steroid therapy or with the appearance of unacceptable steroids side effects. An initial dose of 0.5 mg/kg/day is usually recommended and can be increased to 2 mg/kg/day while monitoring carefully for side effects. Azathioprine may also be used at the start of treatment if relapse is considered likely.

A related Purine analogue, 6 *Mercaptopurine*, can be substituted for Azathioprine in lower doses in patients who fail to respond to Azathioprine. Remission of autoimmune hepatitis can be maintained by Azathioprine alone or in combination with low-dose steroids.

Cyclosporine has been shown to be effective in patients with autoimmune hepatitis who failed therapy with steroids/azathioprine. Cyclosporine has been also tried as monotherapy. In a study that involved 32 patients, treatment of cyclosporine for 6 months was followed successfully by the introduction of low-dose steroids and Azathioprine with withdrawal of cyclosporine. The significant side effects of cyclosporine such as renal toxicity, gingival hyperplasia, and hirsutism have limited its use as a first-line therapeutic agent.

There is little evidence supporting the use of *tacrolimus* in children with autoimmune hepatitis. As in the case of cyclosporine the significant side effects associated with tacrolimus including renal impairment have been reported.

Recently *mycophenolate mofetil (MMF)* has been shown to be a promising therapeutic agent but this needs to be further studied.

There is no consensus regarding the duration of therapy in children with autoimmune hepatitis. In general, treatment is continued for 1–2 years and then discontinued in the absence of biochemical hepatic dysfunction or activity in liver biopsy.

Unfortunately in many patients, the only remaining consideration is orthotopic liver transplantation such as in patients with fulminant hepatic failure, end-stage liver disease, and failed medical therapy and with the appearance of unacceptable side effects. Autoimmune hepatitis recurs in 25% of the patients following liver transplantation, despite aggressive immunosuppressive therapy.

Prognosis

Spontaneous remission is rare. In adults not treated, clinical deterioration is rapid, ultimately leading to cirrhosis and death within 5 years of onset in 50% of cases. With the advent of immunosuppressive therapy, the prognosis has improved; up to 85% of adults respond to treatment with

a subsequent 93% 5-year survival in patients in remission. However, relapse rates after histological cure and discontinuation of therapy remain high, in some series exceeding 85%.

Forty percent of children will have at least one episode of relapse while on therapy for autoimmune hepatitis and many will progress toward cirrhosis. Bad prognostic signs include cirrhosis on initial biopsy, young age on presentation, and HLA B* or DR3 phenotypes. Patients with type I are more likely to maintain remission compared to those with type II.

Autoimmune Sclerosing Cholangitis (ASC)

ASC has the same prevalence as AIH type 1 in childhood. Susceptibility to ASC in children is conferred by the presence of HLA DRB1*1301.

In a prospective study conducted over 16 years, approximately 50% of patients with serological and histological features of autoimmune liver disease presentation had alterations of the bile ducts characteristic of sclerosing cholangitis on cholangiogram. Despite the presence of abnormal cholangiogram, a quarter of children with ASC have no histological features suggesting bile duct involvement. Inflammatory bowel disease was present in about 45% of children with ASC compared to about 20% of those with AIH. At the time of presentation, standard liver function tests did not help in discriminating between AIH and ASC, though the alkaline phosphatase/aspartate aminotransferase ratio was significantly higher in ASC. pANNA were present in 74% of patients with ASC compared to 45% of patients with AIH type 1 and 11% of those with AIH type 2.

ASC in children usually responds to the same immunosuppressive regimens used in patients with AIH. Although steroids and azathioprine are helpful in reducing the parenchymal inflammatory changes, they do not seem to be as effective in controlling the bile duct disease. Based on data from adult studies *ursodeoxycholic acid* is usually added at a dose of 20–30 mg/kg/day, although there is no evidence that it has an effect on the progression of the disorder. Following patients with ASC for 7 years has shown survival in 100% patients, despite the fact that orthotopic liver transplantation was needed in 15% of the patients.

A prospective study done at King's college Hospital has shown that ASC is more common than sclerosing cholangitis lacking autoimmune features as it has been observed in only few children referred over the 16-year-study period. In order to prove that, a prospective study examining bile duct at the time of the initial presentation of AIH is needed.

De Novo AIH Following Liver Transplantation

De novo AIH is characterized by a histological picture of interface hepatitis and multilobular collapse associated with increased IgG levels and positive autoantibodies including ANA, SMA, and classical anti-LKM-1as well as atypical anti-LKM-1, staining the renal tubules but not the liver. Importantly, treatment with prednisolone and azathioprine in parallel to reduction of the calcineurin inhibitor dose is usually effective in de novo AIH as these patients do not usually respond to standard anti-rejection treatment.

Many physicians believe that AIH following transplant is a form of rejection. Another possible theory is an "autoimmune" injury, possibly triggered by drugs. The administration of cyclosporin A or tacrolimus to rodents who received bone marrow may interfere with maturation of T lymphocytes favoring the emergence of autoaggressive T-cell clones. This experience in animals may explain, in part, the development of this disorder in immunosuppressed children after liver transplantation.

Nonalcoholic Fatty Liver Disease in Children

Childhood obesity has grown considerably in the past 2 decades. The percentage of overweight children and adolescents has more than doubled since the early 1970s. According to the Centers for Disease Control, about 15% of children and adolescents are considered overweight. Unfortunately, despite the fact that obesity is an easy medical condition to recognize, it is very difficult to treat.

Chronic liver disease associated with obesity was first reported in the 1970s in obese pregnant women. The histological features were similar to those seen in patients who are heavy alcohol drinkers and hence the disorder was initially called nonalcoholic steatohepatitis (NASH). Currently, a new term "Nonalcoholic Fatty Liver Disease (NAFLD)" is more widely used as it encompasses a spectrum of hepatic pathological changes ranging from fatty liver (steatosis) to cirrhosis. Nonalcoholic steatohepatitis (NASH) is an intermediate form of liver damage that may progress to fibrosis and cirrhosis.

The first report of steatohepatitis in obese children was published in the early 1980s. The authors reported three

American children with steatosis and steatohepatitis. Although NAFLD was considered to be a disease of adults, it has been realized recently that NAFLD can also affect children and is currently the most common hepatic disorder in pediatric hepatology practice.

Pathogenesis

There is lack of complete understanding of the pathogenesis of NAFLD as well as the mechanisms involved in the progression from steatosis to NASH and cirrhosis. The most accepted theory involves a "two hit" process. Disorders of the hepatic uptake, synthesis, degradation, and secretion of free fatty acids will lead to accumulation of lipids in the hepatocytes resulting in macrovesicular steatosis which will prime the liver for a second hit resulting in inflammatory changes and disease progression.

Fat-derived factors such as fatty acids, adiponectin, and tumor necrosis factor (TNF) alpha regulate the inflammatory response and promote NAFLD in patients with metabolic syndrome by modulating the hepatic inflammatory response. *Adiponectin* inhibits fatty acid uptake, stimulates fatty acid oxidation and lipids export, and enhances hepatic insulin sensitivity. On the other hand, TNF recruits inflammatory cells to injured tissues and promotes insulin resistance. Therefore, adiponectin and *TNF alpha* are mutually antagonistic. Patients with metabolic syndrome have cytokine imbalance with increased production of TNF and reduced activity of adiponectin, which may result in increased insulin resistance with fat accumulation, inflammation, and cell necrosis.

Epidemiology

The exact incidence and prevalence of NAFLD are not known due to the lack of accurate noninvasive diagnostic methods. Noninvasive imaging techniques such as ultrasonography can detect fatty changes but they lack sensitivity in patients with mild steatosis and cannot differentiate steatohepatitis from simple steatosis.

The prevalence of NAFLD ranges from 9% to 36.9% worldwide in patients with no known risk factors. In the USA, the percentage of subjects presumed to have NAFLD due to unexplained high liver enzymes has been estimated to be 23% of the population. The prevalence of NAFLD is much higher in subjects with known risk factors such as those with metabolic syndrome. The prevalence of NAFLD in morbidly obese patients undergoing bariatric surgery was reported to be as high as 96%, while the prevalence of NASH in the same group ranges from 12% to 25%.

Although NAFLD has been reported in patients as young as 2 years of age, the majority of pediatric patients are diagnosed during the second decade of life. In the largest pediatric report published so far, 77% of NAFLD patients were males. NAFLD seems to be more common in Hispanics with higher prevalence in non-Hispanic whites compared to non-Hispanic blacks.

Clinical Picture

Most patients with NAFLD are asymptomatic. Common symptoms include mild right upper quadrant abdominal pain, fatigue, and malaise. Patients usually come to medical attention due to abnormal serum aminotransferase level detected during a routine lab or abnormal hepatic imaging performed for different reasons such as abdominal pain or suspected gall stones. The most common physical finding is *Acanthosis Nigricans*, which may be seen at the nape of the neck, axilla, and groins or over the knuckles. Hepatomegaly can be difficult to detect in obese children.

Patients with advanced liver disease may have manifestations of end-stage liver disease such as jaundice, pruritus, ascites, spider angiomatas, splenomegaly, sharp liver border, palmar erythema, or asterixis. Manifestations of metabolic syndrome are seen in most patients including obesity, diabetes, hypertension, and dyslipidemia.

Diagnosis

Liver Biopsy

Liver biopsy is the gold standard for diagnosing NAFLD and the only method that can differentiate steatohepatitis and fibrosis from simple steatosis. Liver biopsy will establish the diagnosis, provide prognostic information, assess severity, and motivate the patient and the family to seek treatment. Although trial of weight loss while monitoring liver enzymes has been suggested, normalization of liver enzymes is not necessarily associated with histological improvement. A reasonable approach for patients suspected to have NAFLD is to measure ALT level and perform liver ultrasound. If one or both tests are abnormal liver biopsy is needed, but if both are normal, risk factors should be corrected if present.

Histological features include macro- and microvesicular steatosis, acute and chronic inflammation, cytologic ballooning, and glycogen nuclei of hepatocytes, perisinusoidal fibrosis and Mallory hyaline bodies (*Figs. 215.1* and *215.2*). The use of serum markers of fibrosis, though promising, needs further validation. The lack of availability of these tests in most labs limits its use in routine clinical practice.

In patients with suspected NAFLD, lab testing should include levels of AST, ALT, total and direct bilirubin, and fasting serum glucose, as well as a lipid panel. Viral, autoimmune hepatitis and metabolic liver diseases, including Wilson's disease, hypothyroidism, and α-antitrypsin deficiency need to be excluded. Patients usually have mild to moderate elevation of serum aminotransferases (mean range, 100–200 IU/L). AST to ALT ratio is usually less than one, but may reverse with development of fibrosis. Liver enzymes may be normal in children with NAFLD, despite the presence of advanced disease. Serum alkaline phosphatase and gamma-glutamyl transpeptidase may also be mildly abnormal. Albumin, bilirubin, and platelet levels are usually normal unless in the presence of cirrhosis. Autoimmune antibodies (antinuclear and anti-smooth-muscle antibody), ferritin, and transferrin may be elevated in some patients with NAFLD. The reason of such elevation is still unknown.

Liver biopsy in a patient with nonalcoholic fatty liver disease showing steatosis and lobulitis (*arrow*)

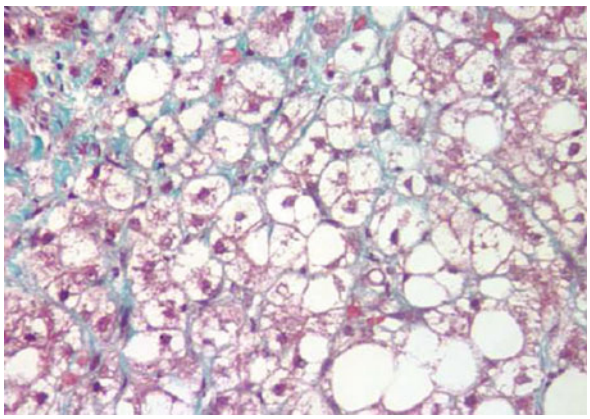

Figure 215.2
Liver biopsy with trichrome stain in a patient with nonalcoholic fatty liver disease showing fibrosis

Radiology

Ultrasonography is the most commonly used radiologic modality in patients suspected to have NAFLD. Ultrasonic examination of fatty liver usually reveals the characteristic picture of "Bright Liver" due to increased echogenicity of the liver. Other features include hepatomegaly, hypoechoic kidney, and decreased visualization of hepatic and portal veins secondary to compression of swollen hepatocytes on their walls. Accumulation of fat may also result in abnormal hepatic vein. Doppler waveform pattern may either be monophasic or biphasic.

Several studies have looked into the sensitivity of ultrasound in detecting steatosis and fibrosis with a wide range of results. The sensitivity of ultrasonography seems to improve with increased hepatic fatty infiltration with a range of 60– 90% in patients with moderate hepatic steatosis. The major limitation of ultrasonography is subjectivity as it is an operator-dependent procedure.

Computed tomography (CT) has been commonly utilized in the evaluation of patients with fatty liver. Disadvantages of CT include limitation of use in patients with hepatic iron overload and radiation exposure.

Different magnetic resonance imaging (MRI) techniques have been used in the evaluation of NAFLD patients. Disadvantages of MRI include limitation of use in patients with hepatic iron overload, and it is contraindicated in patients with implantable devices and pace makers and also in claustrophobics.

In the future, other diagnostic modalities may prove to provide diagnostic information in patients with NAFLD such as contrast-enhanced ultrasonography, localized proton magnetic resonance spectroscopy (MRS), and measuring liver stiffness by fibroscan.

Natural History

It is difficult to determine the natural history of NAFLD in children in the absence of long-term prospective studies. In a recently published report, 18 children were reported to have a follow-up biopsy over an average period of 28 months. No change was seen in eight patients, while seven patients had progression of fibrosis, three patients had regression or disappearance of fibrosis followed by loss of weight. The only patient who progressed from stage I fibrosis to cirrhosis had a significant weight gain over a short period of time.

Hepatocellular carcinoma (HCC) is a known complication of liver cirrhosis and can be seen in patients with NAFLD-associated cirrhosis. Therefore, it is recommended to screen patients with NAFLD who develop cirrhosis for HCC periodically by ultrasound and serum alpha fetoprotein.

Orthotopic liver transplantation has been successfully performed in patients with NAFLD and end-stage liver disease with survival rates not different from results following transplant due to other forms of liver disease. Unfortunately, NAFLD commonly recurs following transplant and can be severe enough to cause failure of the allograft.

Treatment

Weight Loss

Weight reduction leads to loss of adipose tissue and decreases insulin resistance. Exercise improves muscular insulin sensitivity and leads to weight loss. Reduction of body weight through dieting with or without exercise has been shown to improve liver enzymes in children and adults with NAFLD (Some reports have shown histological improvement). It is recommended that weight loss not to exceed 1.6 kg/week as more rapid weight loss may result in portal inflammation and fibrosis.

Antiobesity medications have also been tried with promising results including orlistat (an enteric lipase inhibitor), and sibutramine (a serotonin and norepinephrine reuptake inhibitor). However, the long-term effects of these medications remain to be determined.

Insulin Sensitizers

Insulin sensitizers have been the subject of intensive research efforts.

Thiazolidinediones is a group of drugs known to decrease insulin resistance mainly in adipose tissue by activating the nuclear transcription factor, peroxisome proliferators–activated receptor-γ (PRAPγ) by binding selective ligands. The first drug, troglitazone showed promising therapeutic effects in patients with NAFLD. However, it was withdrawn from the market due to severe idiosyncratic hepatotoxicity. The second generation drugs rosiglitazone and pioglitazone have been shown to improve histological features, liver enzymes, and insulin sensitivity in adult NAFLD patients.

Metformin is an insulin sensitizer that has been studied in children and adults with NAFLD. The use of metformin has been associated with improved insulin sensitivity, liver enzymes, and histological features. Metformin has been also shown to decrease the incidence of diabetes by 31% compared to placebo in a large trial of the Diabetes Prevention Program involving nondiabetics and prediabetics. Taking into consideration that the majority of patients with NAFLD are either diabetics or prediabetics, the use of metformin seems to be a reasonable choice in these patients.

Antioxidants

Antioxidants have been proposed as a possible therapeutic option as oxidative stress has been implicated in the pathogenesis of NAFLD. Therefore, *vitamin E* alone or in combination with other medications or life style modification has been evaluated for the treatment of NAFLD. In a small open-label trial, vitamin E was found to improve liver enzymes in ten children with NAFLD. The enzymes, however, increased following cessation of therapy. In another randomized trial, vitamin E was superior to placebo in a study involving 28 children. Although vitamin E has many advantages including low cost and tolerability, the lack of proved efficacy and the concern about long-term safety do not support its use in patients with NAFLD.

Antihyperlipidemics

Dyslipidemia is common in patients with NAFLD and may promote the progression of steatosis to steatohepatitis. Therefore, treatment with antihyperlipidemics seems like a reasonable option. Several agents have been looked at including statins, gemfibrozil, probucol, and omega3 fatty acids. However, the efficacy of these medications remains uncertain. Antihyperlipidemic agents may have a role in patients with significant dyslipidemia and increased risk for cardiovascular disorders.

Ursodeoxycholic Acid

Ursodeoxycholic acid is a known chloretic, immunomodulator, and cytoprotective agent. An initial report showed promising results in adult patients with NAFLD. However, a large randomized placebo-controlled trial that involved 166 patients with NASH for duration of 2 years could not reproduce similar findings.

The search for an effective therapy for NAFLD continues. Ideally such therapy should be safe, effective, well-tolerated, and of limited duration, and the effects should be sustained following cessation of treatment. For the time being several agents are being evaluated including angiotensin converting enzyme inhibitors (ACEI), angiotensin receptor blockers (ARB), probiotics, antibiotics, lactulose, and nateglinide (insulin secretagogue). In the absence of a proved effective pharmacologic therapy in children, diet and exercise remain to be the safest approaches.

Surgery

Surgical treatment of obesity should be considered in patients with BMI greater than 40 or in patients with obesity-associated health disorders. However, the safety and effects of this approach has not been examined in children.

Several obesity surgical procedures have been tried including jejunoileal bypass, biliopancreatic diversion, gastroplasty with stapling, and gastric banding. However, the most effective and safest antiobesity surgical procedure is gastric bypass. In the procedure, gastroenterostomy is created dividing the stomach into a small proximal pouch excluding the fundus and the antrum. Gastric bypass is a very effective procedure and 49% of the patients can maintain loss of 50% of their excess weight. The procedure has been successfully performed in patients with cirrhosis and following liver transplant due to recurrent NASH. Marked improvement in steatosis, inflammation, ballooning degeneration, and perisinusoidal fibrosis have been reported following gastric bypass. However, there was little improvement in periportal fibrosis.

However, the anti-obesity procedures can be associated with significant morbidity including pulmonary embolism, sepsis, wound infection, volvulus, nutrient deficiencies, stomal stenosis, dilatation, ulceration, and bleeding. Approximately, one third of the patients develop gall stones within 6 months of the procedure and 10% develop symptoms requiring cholecystectomy. However, the use of UDCA can dramatically decrease the incidence of gall stones development.

Finally the rising incidence of NAFLD, NASH, and cirrhosis emphasizes the need for the development of effective therapeutic modalities. However, our efforts are limited by the lack of complete understanding of the pathogenesis of NAFLD. Increased awareness, prevention, early recognition, and management of obesity in the pediatric age group may prevent the development of NAFLD and its progression to advanced liver disease.

216 Fulminant Hepatic Failure

Tamir Miloh · Fredrick J. Suchy

Definition

Fulminant hepatic failure in children is a clinical syndrome that evolves over a period of 8 weeks from the onset of signs and symptoms of liver disease. The clinical manifestations result from massive necrosis or severe functional impairment of hepatocytes. The synthetic, excretory, and detoxifying functions of the liver are all severely impaired, presenting in coagulopathy, jaundice, and hepatic encephalopathy. In children, recognition of hepatic encephalopathy is difficult and subtle and may only be apparent at the terminal stages.

The multinational Pediatric Acute Liver Failure (PALF) Study Group, formed in 2000, defined entry criteria of the study:

1. No evidence of a known chronic liver disease.
2. Hepatic-based coagulopathy not corrected by parenteral administration of vitamin K.
3. Hepatic encephalopathy must be present if the international normalized ratio (INR) is between 1.5 and 1.9.
4. Hepatic encephalopathy not required if INR is greater than or equal to 2.0.

There are a number of limitations to this narrow definition of fulminant hepatic failure, which are particularly highlighted in pediatric patients. For example, infants may present with hepatic failure in the perinatal period associated with the prenatal onset of liver disease, which may even evolve to cirrhosis before birth. This pattern may be observed in neonates with several inborn errors of metabolism including tyrosinemia, neonatal hemochromatosis, and inborn errors of bile acid synthesis. Congenital viral infection may also become manifest as hepatic failure. In some cases of non-A-E hepatitis, the onset of encephalopathy may occur later, often from 8 to 28 weeks after the onset jaundice and have a subfulminant course. In older children, fulminant Wilson disease may also present in children who were previously asymptomatic but have a prior significant preexisting liver disease and have an acute or chronic presentation. The time frame over which loss of hepatic function occurs may also present problems.

Etiology

In developed countries, the etiology of pediatric ALF significantly differs from adults. In adults, drug-induced liver failure (especially acetaminophen overdose) is the leading cause. In children, it accounts for less than 20% of cases. A diagnosis is not established in up to 50% of children. Etiologies are presented in ❯ *Table 216.1*.

Viral hepatitis types A, B, D, or E are a common cause of identifiable fulminant hepatic failure worldwide; however in only 5% of children in North America and the United Kingdom, infections are identified more frequently in infants and immunodeficient patients. The viruses include Herpes simplex, human herpesvirus-6, Parvovirus B19, cytomegalovirus, adenovirus, varicella zoster, enterovirus, and paramyxovirus, while Epstein–Barr virus (EBV) occurred more frequently in older patients. The viral hepatitis often presents as part of a more generalized, severe, systemic illness. The routine immunizations of children for hepatitis A and B may be responsible for the decline in these infections. Hepatitis A virus is a common cause in endemic areas but not in developed countries in the absence of an outbreak. Children with underlying chronic liver disease are more susceptible to develop ALF with HAV infection. Hepatitis B as a cause of ALF is less common in children than in adults and risk factors include older age, genotype D, and infants born to mothers with hepatitis B e antigen negative chronic hepatitis. Hepatitis C virus is a very rare primary cause of ALF. Hepatitis E occurs in endemic areas such as India, Africa, and Mexico. Non-A-E hepatitis (seronegative hepatitis) is the most common cause of ALF in the Western world and accounts for 45% of cases. The diagnosis is one of exclusion in which other causes of ALF are eliminated with appropriate laboratory investigations and clinical examination.

Fulminant hepatic failure may result from some hepatotoxic drugs and chemicals. Risk factors for drug-induced hepatotoxicity are age (very young children or adolescents), abnormal renal function, concurrent use of other hepatotoxic agents, drug interactions, and preexisting liver diseases. Drug-induced hepatotoxicity can be dose-dependent, idiosyncratic, or a synergistic

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_216,

Table 216.1
Causes of fulminant liver failure

Infection	
Viral; Hepatitis A, B, C, D, and E	
Non-A-E hepatitis	Herpes simplex, Adenovirus, Varicella, EBV, and CMV
Enterovirus	Septicemia
Drugs	
Dose-dependent; Acetaminophen, Halothane	
Idiosyncratic reaction; Isoniazid, NSAID, Phenytoin, valproate	
Antibiotics (Penicillin, Amoxycillin + Clavulanic acid Erythromycin, Tetracyclines, Sulfonamides, and Quinolones)	
Toxins	
Amanita, herbal medicines, CCl4	
Metabolic	
Wilson's disease	Galactosemia
Tyrosinemia	Hereditary fructose intolerance
Neonatal hemochromatosis	Niemann–Pick disease type C
Mitochondrial cytopathies	Inborn error of fatty acid oxidation
Hereditary fructose intolerance	Congenital disorder of glycosylation
Autoimmune hepatitis	
Vascular/ischemic	
Budd–Chiari syndrome	Acute circulatory or cardiac failure
Cardiomyopathies	Heat stroke
Infiltrative	
Leukemia, lymphoma	Hemophagocytic lymphohistiocytosis

reaction. Acetaminophen-induced liver injury is dose-dependent and may be intentional or a result of "therapeutic misadventure." Recent studies have identified APAP-cysteine protein adducts, which are detected in the plasma of patients with liver injury due to APAP long after the parent compound has been metabolized. Among children with indeterminate ALF, 12.5% had positive APAP-cysteine protein adducts, despite a lack of acetaminophen history. Fasting associated with an extended illness (depleted glutathione stores) and underlying susceptibility (e.g., fatty acid oxidation defect, altered cytochrome P-450 enzymes) are risk factors for APAP ALF. Common drugs that induce an idiosyncratic toxicity include isoniazid, sodium valproate, carbamazepine, penicillin, erythromycin, tetracyclines, sulfonamides, quinolones, amiodarone, and pemoline among others. Toxins that induce ALF include amanita phalloides (mushroom poisoning), herbal medicines, and Carbon tetrachloride (CCl4).

Metabolic causes of ALF are more common in children less than 1 year of age, but may be observed in all age groups. Galactosemia, hereditary tyrosinemia type 1, mitochondrial disorders, fatty acid oxidation disorders, hereditary fructose intolerance, neonatal hemochromatosis, inborn errors of bile acid metabolism, congenital disorder of glycosylation, and other inherited metabolic disorders may all result in hepatic failure. Wilson's disease is currently the most common metabolic disease presenting with ALF in older children and adolescents.

Autoimmune hepatitis can present as ALF, most of these patients being liver/kidney microsome antibody–positive. Nonspecific elevation of autoimmune antibody titers can occur in children with ALF, making the diagnosis difficult.

Fulminant hepatic failure may also be associated with severe birth asphyxia, sepsis, vascular occlusion (Budd–Chiari syndrome and veno-occlusive disease), congestive heart failure, cyanotic congenital heart disease, obstructive lesions of the aorta, circulatory shock, heat stroke, and hemophagocytic lymphohistiocytosis. Celiac disease and sclerosing cholangitis are rare causes of ALF.

Pathogenesis

The pathogenesis of hepatic encephalopathy remains an area of controversy and continued investigation. Increased serum levels of ammonia do not entirely explain altered cerebral function, as ammonia may be normal or only slightly elevated even when patients are deeply comatose. False neurotransmitters, amines, increased γ-aminobutryic acid receptor activity, or increased circulating levels of endogenous benzodiazepine-like substances have all been proposed. Increased absorption of these potential neurotoxins and decreased hepatic clearance may be involved in producing encephalopathy. Impaired regeneration of the liver following massive destruction of liver cells is likely to be a critical determinant. The mechanisms that underlie the poor regenerative response in these cases are not well defined.

Massive destruction of hepatocytes may represent a direct cytotoxic effect of a viral agent or hyperimmune response to viral antigens. Indeed, in over a third patients with hepatitis B-induced hepatic failure, serum may be negative for hepatitis B surface antigen within a few days

of presentation and there is often no detectable hepatitis B DNA in serum. In inborn errors of metabolism, the accumulation of potentially hepatotoxic metabolites may be involved in cellular injury. Oxidative damage may be of importance in disorders such as Wilson disease or neonatal hemochromatosis. Formation of hepatotoxic metabolites that bind to cellular macromolecules is involved in the injury produced by acetaminophen and isoniazid. Depletion of intracellular glutathione, which is essential for detoxification of reactive metabolites, is involved in the pathogenesis of hepatic injury.

Table 216.2
Clinical grades of hepatic encephalopathy

Grade 1	Confused; altered mood or behavior, psychometric defects[a]
Grade 2	Drowsy; inappropriate behavior[a]
Grade 3	Stuporous but speaking and obeying simple commands; inarticulate speech; marked confusion
Grade 4	Coma

[a]In infants, irritability, poor feeding, disturbance of sleep cycle

Pathology

Fulminant hepatic failure is associated with little or no regeneration of hepatocytes. Patchy or confluent, massive necrosis of hepatocytes is commonly found on liver biopsy or explant. Collapse of the reticulin frame work of the liver may occur as a result of multilobular or bridging necrosis. Centrilobular necrosis may be characteristic of certain forms of liver injury, particularly with acetaminophen intoxication or with circulatory shock. Microvascular fatty change of hepatocytes may be the predominant lesion rather than liver cell necrosis. This occurs in defects of the B-oxidation of fatty acids, Reye syndrome, and valproate hepatotoxicity. The absence of cell necrosis in these disorders implies a failure of organelle function. In inborn errors of metabolism such as galactosemia and hereditary fructose intolerance, there may be spotty hepatocyte necrosis combined with microvascular fat accumulation within the hepatocytes. Hepatocyte death may occur predominantly by apoptosis rather than by necrosis in some metabolic disorders. *Liver biopsy* is rarely helpful in ALF and is usually contraindicated because of the presence of coagulopathy.

Clinical Manifestations

The child with fulminant hepatic failure usually has been previously healthy. Progressive jaundice, fetor hepaticus, fever, anorexia, vomiting, and abdominal pain are commonly observed. In patients with severe acute liver there should be careful observation for features of hepatic encephalopathy, which initially may be characterized by minor disturbances of consciousness or motor function (*Table 216.2*). Early stages of encephalopathy may be particularly difficult to detect in infants. Irritability, poor feeding, and a change in sleep rhythm may be the only finding in infants. In older children asterixis may be demonstrated. The patient may become somnolent and confused or combative on arousal and eventually may become responsive only to painful stimuli. Progression can occur over the course of a few days or even weeks to deeper stages of coma in which extensor responses and decorticate posturing appear. The neurologic dysfunction associated with higher grades of coma is thought to be related to the development of cerebral edema, which is related to both cytotoxic and vasogenic factors.

Respiratory rate may be increased early, but respiratory failure may occur in evolution to stage IV coma. A rapid decrease in liver size without clinical improvement is an ominous sign. Bleeding from the gastrointestinal tract and easy bruising, as a result of severe coagulopathy is a common finding. Pruritus, ascites, growth failure, digital clubbing, palmar erythema, cutaneous xanthoma, and prominent abdominal vessels suggest a chronic liver condition.

Laboratory Findings

Serum aminotransferase levels are often markedly elevated. Serum direct and indirect bilirubin levels are variably increased. Although extremely high levels of serum aminotransferase activity are often found, the peak level does not correlate well with the severity of illness. In metabolic disorders, liver failure may be present with only modest elevation in their activity. Serum aminotransferase activities may actually decrease as the patient deteriorates, as the process of liver necrosis has released most of the available sources for the enzymes. A coagulopathy is always present with prolongation of the prothrombin time, which does not improve after the parenteral administration of vitamin K. Hypoglycemia can occur, particularly in infants. A functional form of renal failure – so-called hepatorenal syndrome – can occur in patients with liver failure and correlates with a

very poor outcome. A number of electrolyte disturbances are common, including hypokalemia, hyponatremia, hypophosphatemia, hyperammonemia, metabolic acidosis, and respiratory alkalosis. Renal function may be impaired as a result of tubular injury or hypovolemia. Serum acetaminophen levels after 4 h of ingestion are useful in identifying high-risk patients but are not informative in patients in whom toxicity is secondary to chronic administration. Myelosuppression is associated with non-A-E ALF and nonimmune hemolytic anemia with Wilson's disease. Alpha fetoprotein and selective clotting factors may serve as a marker of liver regeneration.

Treatment

There is no proven therapy that is known to reverse hepatocyte injury or to promote regeneration of hepatocytes. The treatment of fulminant hepatic failure involves primarily supportive care. Patients with fulminant hepatic failure with higher stages of coma should be treated in the setting of an intensive care unit, where monitoring of vital functions is possible. A quiet environment is necessary to avoid increase in intracranial pressure. Caregivers must carefully examine the child multiple times to assess evidence of changing mental status, increased respiratory effort, changing heart rate, or changes in blood pressure that might be signs of infection, increased cerebral edema, bleeding, or electrolyte imbalance. Numerous complications can also be identified and promptly treated (*Table 216.3*). In patients who are significantly disoriented or in coma, endotracheal intubation may be required to prevent aspiration, to reduce cerebral edema by hyperventilation, and to facilitate aspiration of secretions. Cerebral edema is an extremely serious complication that responds poorly to measures usually used to treat this complication in other disorders. Initial treatment would include minimizing excess stimulation, reduction of protein intake, treating suspected sepsis, and removing sedative medications that would affect mental status. The role of hypothermia in clinical practice remains unclear. Hyperventilation may actually worsen oxygen availability to the brain, but osmotic diuresis may be useful in maintaining cerebral perfusion pressure. The placement of an intracranial pressure monitor may be useful in guiding treatment. The gut should be purged with lactulose, a nonabsorbable disaccharide, thought to lower blood ammonia by decreasing microbial ammonia synthesis and trapping ammonia in acid colonic contents. Lactulose is administered in a dose sufficient to produce several acidic loose bowel movements daily. Nonabsorbable antibiotics, as neomycin, may be given to decrease enteric bacteria that produce ammonia. A variety of approaches have been used to assist the liver in removing toxins that may cause encephalopathy. Plasmapheresis or perfusion of the patient's plasma through an ion-exchange resin or a column of charcoal has been used in several studies. In uncontrollable studies, the patients may experience some clinical improvement, but no impact on neurological outcome or ability of the liver to recover spontaneously. Albumin dialysis is suggested in selective patients. Gastrointestinal hemorrhage, infection, sedatives, electrolyte balance, and hypovolemia may precipitate or exacerbate hepatic encephalopathy and should be prevented and aggressively treated.

Mechanical ventilation and the administration of oxygen are often required in more severely affected patients. Input and output should be strictly monitored. Renal dysfunction commonly occurs from dehydration, from acute tubular necrosis, from the initial toxic insult, and from hepatorenal syndrome. Renal replacement therapy with continuous veno-venous hemofiltration or dialysis may be necessary in some cases, but only liver transplantation can reverse HRS. Intravenous fluids should be restricted to between 85% and 90% of maintenance fluids to avoid over hydration. Electrolyte- and glucose-containing solutions should be administered intravenously to maintain urine output, correct electrolyte abnormalities, and prevent hypoglycemia. Hyponatremia is usually dilutional and not a reflection of sodium depletion. Parenteral infusion of calcium, phosphorous, and magnesium is often required.

Table 216.3
Extrahepatic complications of fulminant hepatic failure

Failure (in order of relative frequency)
Hepatic encephalopathy
Complex coagulopathy
Cerebral edema
Cardiovascular abnormalities
Acid–base disturbances
Gastrointestinal bleeding
Electrolyte imbalances
Renal failure
Sepsis
Pulmonary problems
Hypoglycemia
Pancreatitis

Intravenous/subcutaneous or intramuscular vitamin K should be given in an attempt to correct coagulopathy. Disseminated intravascular coagulation may be present in these patients as a result of liver failure as well as from infection. Infusion of FFP, factor concentrates (recombinant factor VII), or platelets may be necessary in the setting of active bleeding or in anticipation of an invasive surgical procedure, rather than treating laboratory abnormalities. Patients can rapidly become fluid overloaded with infusions of large amounts of fresh frozen plasma. Bone marrow suppression may be treated with immunomodulatory medications, steroids, cyclosporine A, antilymphocyte or antithymocyte globulin, as well as hematopoietic stem-cell transplant.

Infection commonly occurs and is often responsible for the demise of these patients. At least 50% of patients experience serious infections, including septicemia, pneumonia, peritonitis, and urinary tract infections. Gram-positive and gram-negative organisms as well as fungal infections can occur. Infection may present subtly, with tachycardia, intestinal bleeding, reduced renal output, or changes in mental status. Fever may not be present. Blood cultures should be obtained daily or with any evidence of clinical deterioration and antibiotics initiated with a clinical concern for sepsis. Prophylactic administration of H2-receptor blockers is usually advised because of the high risk of developing gastrointestinal bleeding. Ascites may be managed by fluid restriction and diuretics, but should be reserved for those patients who experience respiratory compromise or discomfort due to the fluid accumulation. Spironolactone is the drug of choice to initiate therapy, but furosemide may also be required. Overly aggressive diuresis may precipitate hepatorenal syndrome.

Specific therapies for unique causes of ALF are few: NAC for acetaminophen overdose, removal of galactose-containing formula in children with galactosemia, intravenous glucose and avoidance of fasting for children with inherited defects in fatty acid oxidation, and prompt administration of 2-(2-nitro-4-3 trifluoromethylbenzoyl)- 1,3-cyclohexanedione (NTBC) in children with hereditary tyrosinemia type 1. Other therapies in use include activated charcoal and high-dose intravenous penicillin for mushroom poisoning; corticosteroids for autoimmune hepatitis; copper chelation, plasmapheresis, and antioxidant therapy for Wilson disease; lamivudine or entecavir for acute hepatitis B; acyclovir for herpes simplex virus infection; hemodynamic support for shock or ischemic liver injury; decompressive surgery or transjugular intrahepatic portosystemic shunts (TIPS) for acute Budd–Chiari syndrome, corticosteroids, and chemotherapy for hemophagocytic syndrome; and antioxidant cocktail IVIG and double volume exchange transfusion for neonatal hemochromatosis. Currently, the only effective therapy of ALF is liver transplantation.

There are a number of liver assist devices under evaluation: non-cell-based (molecular absorbents recycling system, MARS), cell-based bioartificial liver systems, hepatocyte bioreactor, and stem-cell transplantations. These devices are being used to support patients until regeneration of the patient's liver occurs or to serve as a bridge until a suitable organ donor can be found.

Prognosis

Survival depends on the ability of the liver to recover from the ensuing insult, but it is very difficult to predict the potential for recovery. There is no single criterion that can predict the outcome with absolute certainty and be universally applicable to all patients with ALF with different etiologies. The prognosis varies and depends on the etiology of the hepatic injury, age, and stage of encephalopathy. Survival without liver transplant was highest in the APAP group (94%), while children with non-APAP drug-induced ALF (41%), metabolic disease (44%), or indeterminate ALF (43%) fared less well. In contrast, children with a non-A-E hepatitis or acute Wilson's disease rarely recover without liver transplantation.

Twenty percent of children in the PALF study who never developed encephalopathy either died or underwent liver transplant and those who presented with grade 4 encephalopathy fared better than those who progressed to grade 4. Complications of liver failure including sepsis, hemorrhage, or renal failure increase mortality. An INR <4 was associated with 73% survival versus 16.6% in those with an INR >4. Jaundice for more than 7 days prior to the onset of encephalopathy, alanine aminotransferase $<2{,}384$ IU/L on admission, factor V concentration of $<25\%$ of normal are other predictors of poor outcome. A liver injury unit score based upon total bilirubin, INR, and ammonia at presentation and with "peak" values appears to effectively predict survival without liver transplant; further prospective analysis will be necessary to confirm these findings.

217 Mitochondrial Hepatopathies and Reye's Syndrome

Roshni Vara · Giorgina Mieli-Vergani

Definition

- *any symptom in any organ or tissue at any age with any mode of inheritance*

Mitochondria are ubiquitous organelles and the main source of the high energy adenosine triphosphate (ATP) required for intracellular processes. ATP is synthesised from oxidative phosphorylation, which takes place via the respiratory chain enzyme complex. The liver is highly dependent upon ATP for its many metabolic functions and, consequently, disorders of mitochondrial function can cause liver disease. Clinical manifestations of mitochondrial hepatopathies vary from mild liver dysfunction, chronic liver disease, fulminant hepatic failure, and end-stage liver disease, which can occur at any age, with or without other organ involvement.

Liver involvement in mitochondrial disorders rarely presents in adulthood but is a common feature of childhood disease, especially in the neonatal period. Mitochondrial hepatopathies can be classified as either primary (or genetic) or secondary when mitochondrial dysfunction occurs as a consequence of an exogenous insult, e.g., highly active anti-retroviral therapy (HAART), non-alcoholic steatohepatitis (NASH), and viral hepatitis (*Table 217.1*).

Mitochondria are unique in possessing two genomes; nuclear and mitochondrial DNA and therefore, mutations in either can lead to phenotypic expression. Whichever organ is affected, the clinical manifestations are heterogeneous despite identical genotype. This chapter will address the clinicopathological features of primary disease and secondary mitochondrial hepatopathy in Reye syndrome.

Epidemiology

Disorders of mitochondrial respiratory chain are thought to affect approximately 1 in 20,000 children. Around 10% of these have liver involvement, half of whom present in the neonatal period. It is likely that this is an underestimate in view of under recognition and difficulties in establishing the diagnosis. Mitochondrial disorders are pan-ethnic and those resulting from autosomal recessive inheritance, i.e., nuclear DNA mutations tend to be more common within consanguineous families.

Pathogenesis and Genetics

Mitochondria are multifunctional, double membrane subcellular organelles; the respiratory chain enzyme complex is embedded in the inner membrane (*Figs. 217.1* and *217.2*). The outer layer is a freely permeable phospholipid bilayer, which allows molecules to pass with ease. The inner membrane structure is complex and includes transport proteins whilst the cristae allow a greater surface area for the inner membrane.

Many oxidative pathways exist within the mitochondria, including β-oxidation for fatty acids, the pyruvate dehydrogenase complex, and the tricarboxylic acid cycle. These reactions generate reduced cofactors (e.g., $FADH_2$, NADH) and coupled with reoxidation via the respiratory chain produces ATP. This process is known as oxidative phosphorylation and is the final stage in aerobic respiration.

The respiratory or electron transport chain is a series of five coupled reactions. Each complex is made up of separate polypeptide subunits. There are also two independent electron carriers, ubiquinone or coenzyme Q and cytochrome c. The reduced cofactors allow electrons to pass into the respiratory chain; complex IV (cytochrome oxidase c) is the last carrier, which reduces oxygen to water. The energy produced by these reactions is sufficient to drive protons across the mitochondrial membrane and, by creating a gradient, powers the linked ATP synthase (complex V) in its phosphorylation of ADP to ATP and net production of energy. For this process to take place, it requires not only the functional integrity of the enzyme complexes but also the presence of other components such as substrate transport proteins.

Table 217.1
Classification of mitochondrial hepatopathies

Primary	Molecular defect
Respiratory chain defects	
– Single	Complex I deficiency
	Complex III deficiency (*BCSL1*)
– Multiple	Complex IV deficiency (*SCO1*)
	Complex V (*ATP12*)
mtDNA depletion syndrome	*POLG, DGUOK, MPV17*
Aplers–Huttenlocher syndrome	*POLG*
Pearson syndrome	*mtDNA depletion*
Mitochondrial neurogastrointestinal encephalomyopathy (MNGIE)	*TP mutation*
Villous atrophy with hepatic involvement	Complex III deficiency
Navajo neurohepatopathy	*MPV17*
Fatty acid oxidation defects	
Urea cycle disorders	
Secondary	
Reye syndrome	
Hepatic copper overload (Wilson disease)	
Hepatic iron overload	
Drugs/toxins – HAART, valproate, ethanol	
Viral hepatitis	
Cholestasis	
Cirrhosis	

Source: Modified from Treem WR, Sokol RJ (1998) Disorders of the mitochondria. Semin Liver Dis 18:237–253

In disorders of the respiratory chain, liver injury is thought to occur through a variety of pathogenic mechanisms:

1. Generation of reactive oxygen species (ROS) – their accumulation may contribute to liver pathology and the initiation of apoptosis.
2. Failure of ATP production and an energy-deficient state leads to cell death and subsequent fibrosis.
3. Secondary inhibition of pathways, such as β-oxidation of fatty acids, contributes to steatosis in liver and muscle.

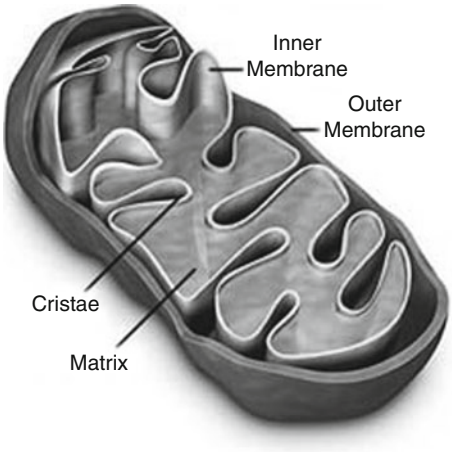

Figure 217.1
Schematic appearance of a mitochondrion (From www.cartage.org.lb)

Mitochondria are unique in possessing their own mitochondrial DNA (mtDNA); this is a circular double stranded molecule, 16,569 base pairs long. It codes for 37 genes, including the 13 polypeptides of complex I, III, and IV, the two ribosomal RNAs, and 22 transfer RNAs of mitochondrial protein synthesis. The proteins responsible for its transcription, translation, and replication are nuclear encoded.

Nuclear genes enocode more than 70 respiratory chain subunits and an array of enzymes and cofactors involved in mtDNA maintenance. These include DNA polymerase γ (POLG), thymidine kinase 2 (TK2), and deoxyguanosine kinase (DGUOK).

Unique to mtDNA is to be exclusively maternally inherited. The genome contains few introns, no protective histones, nor an efficient repair system. These factors, coupled with the increased number of reactive oxygen species mtDNA, increase greatly the potential of the mitochondrion for mutations when compared to nuclear DNA (nDNA).

Each mitochondrion contains two to ten copies of mtDNA; a typical hepatocyte contains approximately 1,000 copies of mtDNA. Normally, all copies of mtDNA in a cell are identical, a phenomenon known as "homoplasmy." A state of heteroplasmy exists when a cell harbours both normal (wild-type) and mutant mtDNA in various amounts as a consequence of random partitioning during cell division. This phenomenon accounts for the wide variation in severity and phenotypic expression of disease. Clinical manifestation of disease is determined by the percentage of mutant mtDNA in a given cell or tissue.

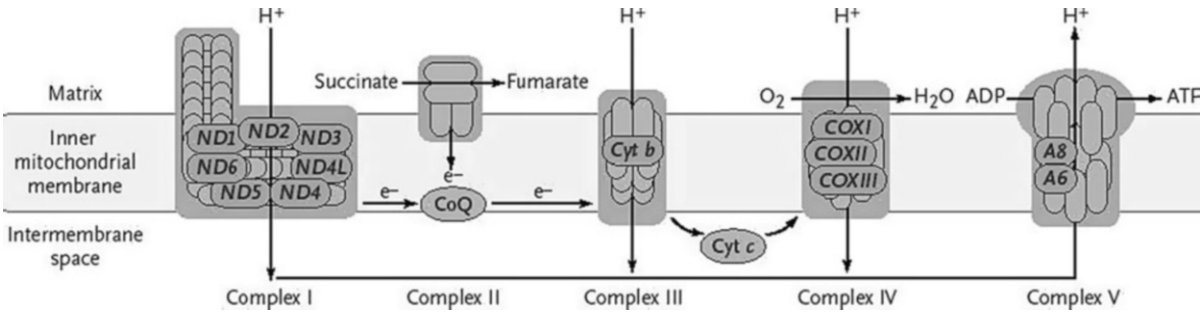

Figure 217.2
The respiratory chain enzyme complex (From DiMauro S, Davidzon G (2005) Mitochondrial DNA and disease. Ann Med 37:222–232)

Children with a defect in oxidative phosphorylation affecting a single respiratory chain complex may have a mutation in a gene encoding a subunit of that complex or in a gene encoding an assembly factor for that complex and therefore a defect in mtDNA or nDNA. Multiple complex deficiencies in children with liver involvement can be due to primary pathogenic point mutations or single deletions of mtDNA, but are more often associated with mitochondrial depletion syndromes (see below).

Mutations in mtDNA explain only about 20% of mitochondrial disorders in children and probably an even smaller percentage of those with liver involvement, despite there being over 200 pathogenic point mutations, deletions, insertions, and rearrangements identified since 1988. Most disorders involving primarily the liver are caused by nDNA mutations and the number of nuclear gene mutations identified is increasing continuously with improved molecular diagnostic techniques. Only mutations associated with liver disease in children are discussed in this chapter (◉ *Table 217.1*).

Single Respiratory Chain Defects

Complex I is the largest subunit with seven of its 43 subunits encoded by mtDNA. Nuclear mutations are probably involved in 95% of all children with complex I deficiency, the first mutations were identified in 1998 in the NDUFS4 and NDUFS8 genes by the group in Nijmegen. Isolated complex I deficiency is relatively frequent in mitochondrial hepatopathies and is associated with Alpers syndrome and a Leigh-like presentation with encephalopathy, hepatomegaly, growth retardation, and anemia.

Complex III is encoded by nDNA, except for one subunit. BCSL1 is an assembly factor for complex III: mutations in this gene have been identified in children with complex III deficiency and features of tubulopathy, encephalopathy, and liver failure and in GRACILE (growth retardation, aminoaciduria, cholestasis, iron overload, lactic acidosis, and early death) syndrome.

Complex IV or cytochrome oxidase (COX) is the terminal enzyme and has 3 out of 13 subunits encoded by mtDNA. Mutations in the nDNA encoded subunits have not yet been identified. SCO1 and SCO2 are proteins thought to be involved in copper delivery for the copper centers of COX. To date, mutations in the *SCO1* gene have been reported in two siblings with COX deficiency, neonatal-onset hepatic failure, and encephalopathy.

Complex V or *ATP synthase*, site of the final step in oxidative phosphorylation, uses the proton gradient across the inner mitochondrial membrane for the production of ATP. nDNA encodes all the subunits. Pathogenic mutations on one gene, *ATP12*, have been reported in two unrelated cases with isolated complex V deficiency, one with a cerebral malformation syndrome and the other with lethal neonatal lactic acidosis.

Multiple Respiratory Chain Defects

Mitochondrial depletion syndromes (*MDS*) are autosomal recessive diseases characterized by a dramatic decrease in mtDNA content leading to disease in the affected organ. These disorders, like all mitochondrial diseases, are extremely heterogeneous and are classified as myopathic, encephalomyopathic, and hepatocerebral. The latter group is associated with mutations in *Twinkle (PEO1), POLG1, DGUOK, and MPV17* genes and, in general, present with neonatal progressive liver failure and neurologic abnormalities.

POLG1 encodes the catalytic subunit of mitochondrial DNA polymerase and is probably the most frequently

involved nuclear gene with three commonly screened mutations. The clinical spectrum ranges from neonatal to adulthood onset, failure to thrive, hypoglycaemia, hypotonia, liver dysfunction (ranging from persistent jaundice to fulminant hepatic failure), and progressive neurological symptoms. A particular form is *Alpers–Huttenlocher syndrome* characterized by infantile onset, variable liver involvement, and intractable seizures.

DGUOK encodes the mitochondrial deoxyguanosine kinase (dGK) which is involved in the initial steps of the mitochondrial nucleoside salvage pathway. More than 80 affected patients from about 50 families have been reported. Characteristic presentation is with neonatal liver failure and variable neurological involvement. The condition is often fatal before 1 year of age.

TRMU nuclear gene encodes for a long protein that participates in the modification of mitochondrial tRNAs and is important for mitochondrial translation. Mutations in this gene have been found in infants presenting with acute liver failure with no evidence of mtDNA depletion and in one case with liver cirrhosis.

MPV17 is an inner mitochondrial protein of unknown role in mitochondrial maintenance. Mutations in the gene were initially identified in patients with neonatal liver failure, hypoglycaemia, failure to thrive, and neurological symptoms. A particular homozygous mutation is associated with *Navajo neurohepatopathy*, prevalent in the Native American Navajo population and manifesting as liver disease and motor neuropathy. Novel mutations are being identified in association with hepatocerebral forms with a variable clinical phenotype.

TYMP encodes thymidine phosphorylase, a multifunctional enzyme playing a role in the nucleoside salvage pathway by catalysing the breakdown of thymidine to be reutilized for mtDNA synthesis. Impaired thymidine metabolism has been demonstrated in patients with *MNGIE*, this progressive neurodegenerative syndrome was first described in 1983 and involves skeletal muscle, peripheral and central nervous systems, the intestinal tract, and liver. It is an autosomal recessive disease with multiple mtDNA deletions and depletion in muscle.

Mitochondrial deletion syndromes are due to large-scale mtDNA rearrangements and defects in nDNA. They are usually sporadic, heteroplasmic, and probably arise de novo during oogenesis or in early development. Pearson, or marrow-pancreas, syndrome is included in this group and is characterized by sideroblastic anaemia in infancy, often associated with pancytopenia, and variable exocrine pancreatic insufficiency, enteropathy, renal tubulopathy and hepatomegaly, or abnormal liver function tests.

Diagnostic Classification

There are as yet no definitive diagnostic criteria for mitochondrial hepatopathies in children, while diagnostic criteria have been proposed for adults with encephalomyopathies in 1996 by Walker et al.

Modified Walker criteria have been proposed for children with neurological disease. In children, the diagnosis of a mitochondrial hepatopathy with or without other organ involvement should be defined as:

1. Clinical, biochemical, and/or histological evidence of liver disease
2. Tissue respiratory chain enzyme deficiency (liver or muscle)
3. And/or identification of a nDNA or mtDNA mutation

The interpretation of respiratory chain enzyme deficiency, however, is sometimes difficult because of inadequacy of the tissue sample size, only moderately reduced activity and the theoretical effect of hepatic failure on enzyme activity. Therefore, diagnosis remains a challenge in clinical practice, with an urgent need for rapid and accurate diagnostic tests. In those cases where genetic mutation analysis can be directed by clinical manifestations and/or specific complex deficiency, recently developed sequencing techniques are proving beneficial. It is now possible to sequence the whole mitochondrial genome, though this is time-consuming and expensive. Oligonucleotide microarray sequencing (Mitochip) is a novel method to identify rapidly targeted gene mutations and a focus of great interest.

Clinical Manifestations

Mitochondrial hepatopathies can manifest at any age:

- Antenatally, e.g., with ascites, polyhydramnios
- Neonatal period with liver failure, often associated with poor feeding, vomiting, lethargy, hypotonia, seizures
- From the neonatal period to adulthood, with liver dysfunction, jaundice, hepatomegaly, chronic liver disease, end-stage liver disease

Initial symptoms of hepatic involvement can be masked by other organ involvement. Elevated transaminase levels, but rarely above 10 times the normal limit, can be the first indication of hepatopathy. In some patients, the liver dysfunction spontaneously resolves or remains stable, but in others there can be rapid progression with cholestasis, coagulopathy, and ascites.

Extrahepatic involvement, in particular of the central nervous system, is common, though infrequently, the liver can be involved in isolation. Liver disease can precede neurological involvement. This is a serious problem for children presenting with acute liver failure, in whom life-saving emergency liver transplantation might be followed by seizures, progressive neurological impairment, and early death. Other organs involved include kidneys (Fanconi-type tubulopathy), bone marrow (pancytopenia), intestine (enteropathy, villous atrophy), and heart (cardiomyopathy, arythmias).

The biochemical parameters listed below can suggest general mitochondrial dysfunction in the presence of liver dysfunction, but they are difficult to interpret/assess in the presence of severe liver failure:

- Hypoglycaemia
- Raised serum lactate
- Serum lactate/pyruvate ratio (>20)
- Raised cerebrospinal fluid lactate
- Raised ketone body ratio (β-hydroxybutyrate: acetoacetate >2.0)
- Raised plasma amino acids (alanine, glutamine)
- Organic acid profile; Kreb cycle intermediates, 3-methylglutaconic acid
- Aminoaciduria
- Raised tubulopathy markers (RBPs, NAGs)

Investigation of a Child with Suspected Mitochondrial Hepatopathy

Clinical history: Clinical suspicion guides formal tests. Physicians should maintain a high index of suspicion when liver disease presents in a consanguineous family, with other organ involvement without a known cause. Documentation of an extensive family history including minor signs in relatives is of paramount importance.

Laboratory tests include those listed above and the following precautions in taking samples should be observed:

- Sampling for lactic acidaemia, which may be present or absent, should be optimal and other conditions causing it, i.e., hypoxia, hypoperfusion, shock, sepsis and cardiac failure, should be excluded.
- Reduced respiratory chain complex activity should be measured in snap frozen tissue (muscle, liver, or skin fibroblasts).
- Leukocyte or tissue sample should be analyzed for mtDNA and nDNA mutations (this can be directed toward specific mutations in light of clinical features and respiratory chain complex(es) deficiency).

Histological features are often variable and nonspecific. Red ragged fibers in muscle biopsies, a common finding in affected adults, is extremely rare in children. Where liver biopsy is not contraindicated by coagulopathy, it may provide additional information with the presence of steatosis (micro- or macrovesicular) as a consequence of defective β-oxidation (Fig. 217.3a). However histological features can range from giant cell hepatitis, cholestasis with bile duct proliferation, to cirrhosis with nodular formation. Electron microscopy depicting megamitochondriae (Fig. 217.3b) are seen but are not as common as previously reported.

Neuroimaging can be useful in identifying features compatible with mitochondrial disease usually with symmetrical basal ganglia and/or brain stem changes. However, it can be normal and in the acute presentation, it may show generalized nonspecific changes.

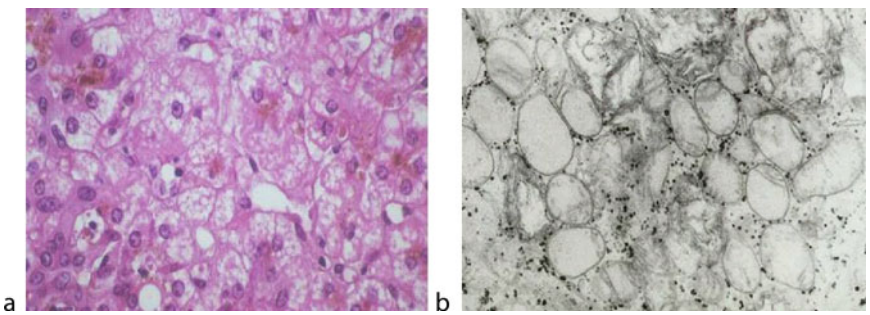

Figure 217.3
Light microscopy and electron microscopy appearance of liver disease in mitochondrial disorders. (a) shows microvesicular steatosis (light microscopy, haematoxylin and eosin); (b) shows abnormal mitochondrial architecture and megamitochondria (electron microscopy) (Pictures courtesy of Professor Bernard Portmann)

Table 217.2
Summary of mitochondrial hepatopathies

Clinical signs/ syndrome	Age at onset	Extrahepatic involvement	Complex deficiency	Molecular defect	Outcome
Neonatal liver failure	First weeks of life	Hypotonia, seizures, lactic acidaemia, hypoglycaemia	Single or multiple	*POLG1, DGUOK, SCO1, MPV17*	Mostly fatal
Acute liver failure	Postnatal–adolescence	Central nervous system or any other organ	Single or multiple; can be isolated to liver	*POLG1, DGUOK TRMU*	Variable
Alpers–Huttenlocher	Infancy–adolescence	Developmental delay, intractable seizures	Usually multiple	*POLG1*	Variable
Pearson	Infancy	Bone marrow, pancreas, gut, kidney	Normal or any	mtDNA rearrangement	Variable
Navajo neurohepatopathy	Infantile, childhood	CNS	All	*MPV17*	Usually fatal in first decade
Other chronic liver disease	Any	Any	Normal or single or all; can be isolated to liver	Not clearly defined	Variable; some survivors after liver transplant

If a mitochondrial hepatopathy is diagnosed, extensive investigation to search for extrahepatic involvement is of paramount importance to guide appropriate management. A summary of characteristics is presented in *Table 217.2*.

Treatment

Presently, there is no satisfactory treatment for mitochondrial disorders. Management remains symptomatic and in the case of mitochondrial hepatopathies is directed by the presence of acute or chronic disease. Medical treatments include the use of various vitamins, cofactors, respiratory substrates, and antioxidant compounds, e.g., thiamine, riboflavin, ubiquinone, though none of them has universally proven effectiveness. Ubiquinone, or coenzyme Q, may be effective in myopathic patients, but there is no reported benefit for cases with liver disease.

Supportive measures include bicarbonate infusions or oral supplementation where acidosis requires correction, carnitine supplementation in patients with secondary carnitine deficiency and fat-soluble vitamins in cases with cholestasis and features of chronic liver disease.

Sodium valproate can induce liver failure in mitochondrial disorders. *Valproate-induced hepatotoxicity* is well described and has been ascribed to alteration of several metabolic pathways including mitochondrial dysfunction. It is advised to avoid sodium valproate in children with cryptogenic liver disease and neurological involvement due to the small but significant risk of inducing acute liver failure.

Liver Transplantation

The decision to perform a liver transplantation involves two main scenarios:

(a) Children presenting with *fulminant hepatic failure* in whom an immediate diagnosis is not possible. Symptoms of mitochondrial disorders or severe liver failure due to different causes are often identical. Enzymatic studies are time-consuming and initial brain imaging may be normal or nonspecific. There are reports of patients transplanted in this situation, with diagnosis of mitochondrial disorder made retrospectively: those with neurological involvement have a poor prognosis.

(b) Children with a *chronic presentation* in whom liver disease progresses to require transplantation. In these cases, extensive investigation to exclude extrahepatic involvement is essential, there are few cases where the defect is isolated to the liver and liver transplantation can be an option. In cases where neurological involvement is thought to be stable and liver disease is progressive, again liver transplantation could be considered, but this needs to be decided in the setting of a multidisciplinary and tertiary referral center.

In conclusion, liver transplantation remains an option for selected cases, but the risk of progressive neurological deterioration and early death highlights the need for extensive investigation and caution when assessing patients.

Longer-term, posttransplant follow up of patients with isolated liver involvement and those with extrahepatic involvement presenting with liver disease is essential.

Prognosis

The prognosis of mitochondrial hepatopathies is variable, but those with an acute and early presentation tend to be fatal, neurological deterioration being often the cause of death. Children with a more chronic presentation can have stable liver and neurological disease and should be monitored with regular outpatient follow up, liver function tests, ultrasound scan, and neurological assessments. A small proportion of these children have progressive liver disease, developing cirrhosis, end-stage liver disease, and even hepatocellular carcinoma.

With the possibility of defining more accurate genotype/phenotype correlations and with more medium- to long-term follow up studies being published, our ability to provide an accurate prognosis is improving.

Genetic Counselling and Future Directions

Genetic counselling of affected families is important however complicated by the involvement of two genomes. Certain clinical phenotypes allow prediction of their mode of inheritance. nDNA mutations identified in the proband provide the possibility of prenatal testing of amniocytes or chorionic villi. In cases of maternal inheritance, the risk is absent for the progeny of an affected male but is high for that of an affected female. Mitochondrial inheritance is hampered by the incomplete knowledge of the exact proportion of mutant mtDNA required to produce a clinical phenotype, making recurrence risk difficult to predict. Available techniques to reduce the risk of recurrence are respiratory chain enzyme-based prenatal testing (if identified in fibroblasts), donor oocytes, preimplantation genetic diagnosis, nuclear and cytoplasmic transfer. It is important to consider each family individually and assess ethical issues appropriately within a multidisciplinary team of specialists.

Reye Syndrome

Reye syndrome is a rare and severe secondary mitochondrial hepatopathy with often, fatal consequences. There is typically a preceding viral illness and/or salycilate use (this is still a debatable association) and an intermediate recovery phase of about 3–5 days with subsequent development of encephalopathy and liver dysfunction. The syndrome was first described by the Australian pathologist R. D. Reye in 1963. The exact cause of 'classical' Reye syndrome is unknown, but most cases occur in the winter months with a peak age of occurrence between 5 and 15 years. Symptoms develop several days following an influenza or varicella infection. The child appears to be recovering but then develops sudden onset intractable vomiting followed by a noninflammatory encephalopathy and liver dysfunction (elevated transaminases rather than bilirubin), hyperammonaemia, mild to moderate coagulopathy, and variable hypoglycaemia. Progression of encephalopathy would lead to cerebral oedema and brainstem herniation. Urgent intervention with metabolic support and control of raised intracranial pressure are the mainstays of treatment until spontaneous recovery occurs or irreversible brain injury develops. The liver makes a full recovery. Mortality is high (40%) and higher in males than females. Abnormal mitochondrial architecture characterizes this disorder with involvement of brain, liver, muscle, and kidney. Liver biopsies are characterized by microvesicular steatosis in the absence of inflammation or necrosis.

Nowadays, many children thought to have had Reye syndrome are subsequently diagnosed with an inherited metabolic disorder, namely fatty acid oxidation effects. The incidence of Reye syndrome has dramatically declined since 1986 in Western countries following restriction of salycilate use in children, though not all agree that this is the only explanation. Some believe that improvement in diagnostic tests for fatty acid oxidation defects and other metabolic diseases also accounts for the decline in its incidence. It is, therefore, imperative to exclude fatty acid oxidation defects and other known metabolic causes in a child with an unexplained encephalopathy and liver dysfunction.

218 Pyogenic Liver Abscess

Mortada El-Shabrawi · Fetouh Hassanin

History

Liver abscesses have been recognized since the age of Hippocrates. In 1883, Koch described the amoebae as a cause of liver abscess. In 1938, Ochsner and Debakey published the largest series of pyogenic and amebic liver abscesses in the literature. The complications of liver abscess were not uncommon in that series and reported to result from rupture of the abscess into adjacent organs or body cavities resulting in pleuropulmonary and intra-abdominal complications. Pleuropulmonary complications are the most common and have been reported in 15–20% of early series including pleurisy, pleural effusion, empyema, and broncho-hepatic fistula. Intra-abdominal complications included subphrenic abscess and rupture into the peritoneal cavity, stomach, colon, vena cava, or kidney. A large abscess compressing the inferior vena cava and the hepatic veins may result in Budd-Chiari syndrome. Rupture into the pericardium or brain abscess from hematogenous spread is rare.

Types of Liver Abscesses

There are three major forms of liver abscesses, classified by etiology:

1. Pyogenic abscess, which is most often polymicrobial, and accounts for 80% of hepatic abscess cases in the United States
2. Amebic abscess, due to *Entamoeba histolytica*, accounts for 10% of cases
3. Fungal abscess, most often due to *Candida* species, accounts for less than 10% of cases

Pyogenic liver abscess (PLA) is a potentially life-threatening condition, complicating diverse abdominal pathologies. The global reported incidence for PLA is variable, ranging from 3 to 25 per 100,000 pediatric hospital admissions. PLA is a problem in developing countries. Children with liver abscesses constitute more than 79 per 100,000 pediatric admissions (<12 years old) in tertiary care centers in India. In larger series from developing nations, as Brazil, its frequency is approximately 1 out of 140 admissions. However, in developed countries, it is rare with an incidence of 25 per 100,000 admissions in United States to 11 out of 100,000 admissions in Denmark. It is a cause of significant morbidity and mortality. For unknown reasons, boys are affected by liver abscesses more than girls.

The frequency of individual infective agents as causes of liver abscesses is intimately linked to the demographics of the affected population. In developing countries, parasitic abscesses are most common, including amoebae, *Echinococcus granulosus* (hydatid disease of the liver), as well as protozoa and helminthes. In developed countries, liver abscesses are rare in healthy individuals, with imported infections from overseas visits accounting for the majority of cases. In developing countries, bacterial liver abscesses are more common and are usually seen in the setting of abdominal sepsis, especially the immunocompromised children, such as in diabetes mellitus, human immunodeficiency virus (HIV) infection, chemotherapy/transplant recipients, and in malignancy. Also, it may occur due to trauma or use of endoscopic retrograde cholangio-pancreatography (ERCP) and occasionally cryptogenic in about 15% of cases. Trauma may predispose to liver abscesses both by direct injury to the liver or by providing habitat for proliferation of organisms elsewhere. Child abuse can sometimes be the cause of sepsis and liver abscesses. Most of the liver abscesses in children are pyogenic in nature with amoebic liver abscesses constituting from 21–30% up to 50% of cases.

The most common microorganisms isolated from blood and abscess cultures are as follows: *Escherichia coli* (33%), *Klebsiella pneumoniae* in (18%), *Bacteroides* species (24%), streptococcal species (37%), and microaerophilic streptococci (12%).

Biliary disease accounts for 21–30% of reported cases. Extrahepatic biliary obstruction leading to ascending cholangitis and abscess formation is the most common cause. The infectious process originates within the abdomen and reaches the liver by embolization or seedling of the portal vein. With the liberal use of antibiotics for intra-abdominal infections, portal pyemia is now a less frequent cause of PLA but still accounts for 20% of cases.

Hematogenous infection via the hepatic artery results from seedling of bacteria into the liver in cases of systemic

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_218,

bacteremia from bacterial endocarditis, urinary sepsis, or following intravenous drug abuse. Blunt or penetrating trauma and liver necrosis from inadvertent vascular injury during laparoscopic cholecystectomy are recognized causes of PLA. In addition, transarterial embolization and cryoablation of liver masses are now recognized as etiologies of PLA.

Diagnosis

The clinical presentation of liver abscess is insidious. Many patients have symptoms for weeks prior to presentation. Fever and right upper quadrant pain are the most common complaints. Pain is reported in as many as 89–100% of patients and may be associated with pleuritic chest pain or right shoulder pain. Symptoms are often misdiagnosed as acute cholecystitis. Fever occurs in 87–100% of patients and is usually associated with chills and malaise.The most common symptoms and signs of PLA are shown in *Table 218.1*.

Ultrasound examination is the investigation of first choice (*Fig. 218.1*). It is rapid, safe, relatively inexpensive, and accurate in picking a liver lesion. Appearances of an abscess may be a rounded or an oval lesion which is usually hypoechoic, but may have heterogenous echotexture. A solid or heterogenous lesion often evolves into a hypoechoic lesion on subsequent examination. Real-time ultrasonography findings are 80–100% sensitive.

Computed tomography (CT), as in *Figs. 218.2* and *218.3*, is more sensitive in detecting even small abscesses anywhere in the liver; yet it is inconvenient and expensive with risk of contrast reactions being always there. A hypodense lesion with low attenuation areas and an enhancing rim is a classical contrast-enhanced CT image. Small hypoechoic lesions in clusters may suggest the beginning of later process of coalescence into a single large abscess.

CT scanning has become the imaging study of choice for detecting liver lesions. If ambiguity arises in the diagnosis of an occasional patient with conventional imaging, scintigraphy may help. Diagnostic aspiration should

Table 218.1
Symptoms and signs of pyogenic liver abscess

Symptoms	Percentage	Signs	Percentage
Abdominal pain	89–100	Normal findings	38
Fever	87–100	Right upper quadrant tenderness	41–72
Chills	33–88	Hepatomegaly	51–92
Anorexia	38–80	Mass	17–18
Weight loss	25–68	Jaundice	23–43
Cough	11–28	Chest findings	11–48

(a) Markedly hypoechoic nature of the lesions suggesting further breakdown of the solid liver tissue (liquifactive necrosis). On aspiration, the fluid was typically anchovy sauce-like in appearance. This suggests hepatic amebic abscess at a more advanced stage. The gallbladder shows wall thickening suggesting edema of the wall. (b) This figure shows a small pleural effusion just above the right lobe abscess (reactionary fluid collection due to pleurisy) (Ultrasound images were taken using a Toshiba Xario ultrasound system, courtesy of Gunjan Puri, MD, India)

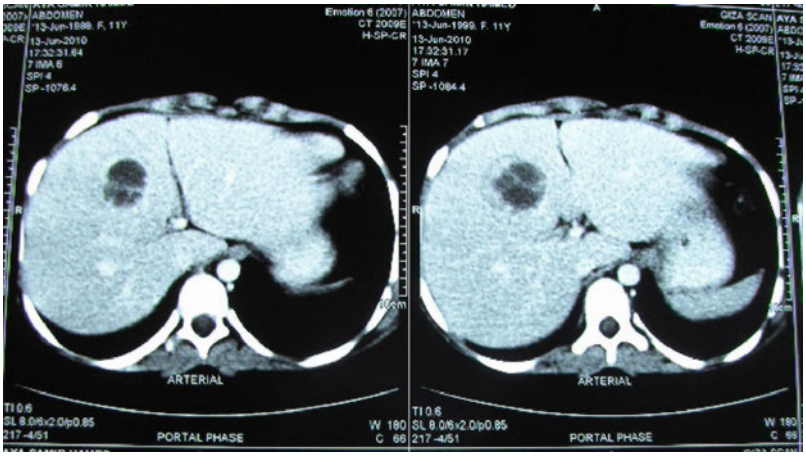

Figure 218.2
CT scan of a 9-year-old girl with pyogenic liver abscess

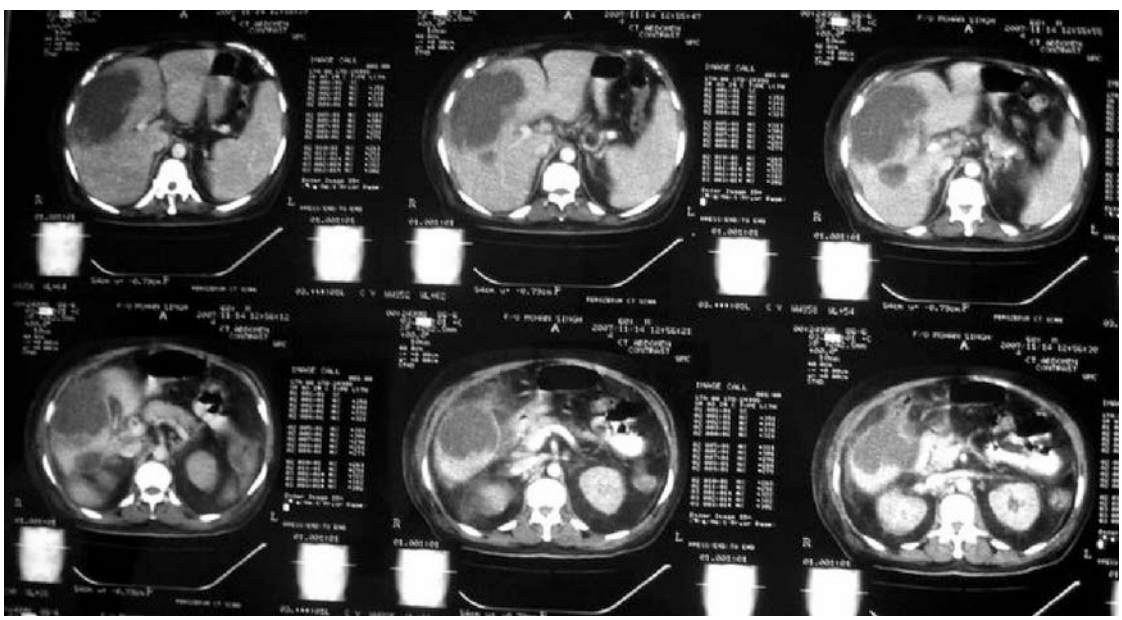

Figure 218.3
CT scan of an amebic liver abscesses involving the right lobe of liver (Courtesy of Vikas Arora, MD, India)

be performed as soon as the diagnosis is made. It can be performed under ultrasonographic (if small or superficial) or CT guidance and is usually followed by placement of a drainage catheter. Multiple abscesses necessitate CT-guided drainage. Once positioned, the catheter should be irrigated with isotonic sodium chloride solution and placed to allow gravity drainage. The drain is removed when the abscess cavity collapses, as confirmed on CT scan images. Presence of ascites and proximity to vital structures are contraindications to percutaneous drainage. Coagulopathy can be corrected with transfusion of fresh frozen plasma prior to drainage.

Treatment

The most dramatic change in the treatment of PLA has been the emergence of CT-guided drainage. Prior to this modality, open surgical drainage was the treatment most often employed, with mortality rates as high as 70%. If the abscess is multiloculated, multiple catheters might be needed to achieve adequate drainage. The current accepted approach includes three steps: initiation of antibiotic therapy, diagnostic aspiration and drainage of the abscess, and, finally, surgical drainage in selected patients.

Antimicrobial agents adminstered should provide adequate coverage against aerobic gram-negative bacilli, microaerophilic streptococci, and anaerobic organisms, including *Bacteroides fragilis*. Usually, a combination of two or more antibiotics is used. Metronidazole and clindamycin have wide anaerobic coverage and provide excellent penetration into the abscess cavity. A third-generation cephalosporin or an aminoglycoside provides excellent coverage against most gram-negative organisms. Fluoroquinolones are an acceptable alternative in patients who are allergic to β-lactams. This modality has been shown to be effective in patients with unilocular abscesses that are less than 3 cm in size.

The success rate of *percutaneous drainage* ranges from 80% to 87%. Percutaneous drainage is considered failed if no improvement occurs, if the condition worsens within 72 h of drainage, or if the abscess recurs despite adequate initial drainage. Percutaneous drainage failure can be treated by either inserting a second catheter or performing open surgical drainage. Surgical drainage is indicated in the following:

- Abscesses larger than 5 cm
- Abscess not amenable to percutaneous drainage secondary to location
- Coexistence of intra-abdominal disease that requires operative management
- Concominant biliary tract disease
- Failure of antibiotic therapy
- Failure of percutaneous aspiration
- Failure of percutaneous drainage

Untreated, PLA is associated with 100% mortality. Early series reported a mortality rate of greater than 80%. With early diagnosis, appropriate drainage, and long-term antibiotic therapy, the prognosis has improved dramatically. Poor prognostic factors are multiplicity of the abscesses, polymicrobial infection, presence of associated malignancy or immunosuppressive disease such as HIV infection, and evidence of systemic sepsis.

219 Drug-Induced Liver Injury

Lama H. Nazer · Hisham M. Nazer

Drug-induced liver injury (DILI) is an important cause of liver disease in adults and pediatrics. Although most patients develop mild hepatotoxicity such as hepatitis, cholestasis, or asymptomatic enzyme elevation, some patients may progress to fulminant hepatic failure, which may lead to liver transplantation or death.

Etiology

Hepatotoxicity has been reported with numerous drugs and the number is expected to increase with the development and approval of new medications (*Table 219.1*). Acetaminophen is considered as one of the main drugs causing liver injury. In a study of 348 pediatric patients with acute liver injury, 14% of the cases were due to acetaminophen, while 5% were due to non-acetaminophen drugs, such as antituberculous and antiepileptic drugs. Acetaminophen-induced liver injury usually results from acute or chronic ingestion of high doses, but hepatotoxicity resulting from therapeutic doses has also been reported. Initially, patients develop nonspecific symptoms such as nausea, vomiting, and anorexia. However, if not managed early, patients develop histological and biochemical liver toxicities and other non-hepatic complications such as cerebral edema and multiorgan failure. Overall, patients presenting with acetaminophen-induced liver injury have a better prognosis, compared to patients presenting with liver injury due to non-acetaminophen drugs, especially when the acetaminophen hepatotoxicity is recognized and managed early.

Aspirin-induced liver injury is uncommon, but has been described in children receiving chronic aspirin therapy for juvenile rheumatoid arthritis. Aspirin was associated with an increase in liver transaminases and alkaline phosphatase, and in some patients prolongation of prothrombin time and epistaxis.

Most antimicrobial drugs may cause hepatotoxicity, although the incidence is relatively low. Penicillins and cephalosporins may cause an increase in the liver transaminases, which is usually subclinical and reversible. Drug-induced liver injury has been described with amoxicillin and the incidence increases when amoxicillin is combined with clavulanic acid. Liver injury associated with amoxicillin-clavulanic acid is usually delayed in its onset, with a cholestatic or mixed hepatocellular cholestatic pattern. In most cases, the patient's condition resolves within a few weeks of discontinuing treatment, but progressive hepatotoxicity due to amoxicillin-clavulanic acid therapy has been reported.

All forms of erythromycin are potentially hepatotoxic. The onset of hepatotoxicity is usually delayed. Patients may present with anorexia, nausea, jaundice, abdominal pain, and a mixed hepatocellular cholestatic injury pattern. Complete recovery is typically seen after discontinuation of erythromycin therapy, although cases of severe liver failure have been reported. Azithromycin and clarithromycin are generally associated with fewer side effects, compared to erythromycin. However, cases of abnormal liver function, including hepatitis and cholestatic liver disease have been reported.

Tetracycline antibiotics are associated with a dose-related hepatotoxicity. Liver injury usually appears 4–6 days after initiating therapy and is characterized by nausea, vomiting, abdominal pain, mild jaundice, and increased serum aminotransferases up to 10 times the upper limit of normal.

Trimethoprim-sulfamethoxazole may induce hepatotoxicity. Symptoms are usually apparent within days to 1 month of initiating therapy. Most cases of liver injury involve cholestasis, although cases of hepatocellular hepatitis have also been described with trimethoprim-sulfamethoxazole. Patients may also present with extrahepatic manifestations such as fever, rash, peripheral eosinophilia, and other organ involvement.

Hepatotoxicity has been reported with all antifungal agents, though the incidence varies between the individual drugs. Amphotericin rarely causes severe liver injury, but may result in asymptomatic self-limited hepatitis. Azole antifungal drugs (i.e., ketoconazole, itraconazole, fluconazole, voriconazole, posaconazole) may cause hepatotoxicity, with the highest reported incidence with ketoconazole. Asymptomatic elevations of serum aminotransferases, with or without elevations in bilirubin, have been reported within a few days to a few weeks after initiating azole antifungal therapy. Hepatitis, cholestasis, and fulminant

Table 219.1
Drugs associated with liver injury

Antipyretics/analgesics	*Antiepileptic drugs*
Acetaminophen	Phenytoin
Aspirin	Phenobarbital
Nonsteroidal antiinflammatory drugs (ibuprofen, naproxen)	Carbamazepine
Antimicrobial drugs	*Chemotherapy medications*
Penicillins and Cephalosporins	6-Mercaptopurine
Macrolides (erythromycin, azithromycin, clarithromycin)	Cisplatin
Sulfa (trimethoprim-sulfamethoxazole)	Decarbazine
Antifungals (azoles, echinocandin)	Cyclophosphamide
Antituberculous (isoniazide, rifampicin, pyrazinamide)	

The table lists commonly used drugs that are associated with liver injury. It does not provide a comprehensive list of drugs that may induce liver injury

hepatic failure have also been described in patients receiving azole therapy. Laboratory abnormalities have been seen in patients treated with the echinocandin antifungal drugs, caspofungin, anidulafungin, and micafungin, and cases of clinically significant hepatic dysfunction, hepatitis, and hepatic failure have been reported.

Hepatotoxicity associated with antituberculous drugs varies depending on the specific drug, presence of other hepatotoxic drugs, and the age of the patient. In one study, the incidence of severe hepatotoxicity, defined as serum tansaminases five times above the upper limit of normal, in pediatric patients was 8%. Age younger than 5 years and the coadministration of pyrazinamide were significant contributions to the development of severe hepatotoxicity. The clinical presentation ranges from asymptomatic elevations of liver enzymes to severe hepatitis or acute liver failure, resulting in death or the need for liver transplantation in some patients.

Subclinical and significant hepatotoxicities have been reported with most antiepileptic drugs, though progression to severe hepatic failure is not common. Elevated transaminases with phenytoin are common, but mostly reversible after discontinuation of therapy. Hepatotoxicity due to phenobarbital and carbamazepine is rare. Cases were associated with a multisystemic drug hypersensitivity syndrome, with the liver involvement predominating. Valproic acid is associated with two types of liver injury: one that is dose-dependent, which develops shortly after starting therapy and liver enzymes improve after reducing the dose. The second type of hepatotoxicity is delayed and is not influenced by the dose.

Various antimetabolites used in the therapy of leukemia and other neoplastic conditions may result in hepatic injury with jaundice, hepatomegaly, dark urine, and elevated liver enzymes. Antineoplastic drugs such as 6-mercaptopurine, cisplatin, decarbazine, and cyclophosphamide are associated with hepatotoxicity. Patients usually present acutely with an enlarged tender liver, ascites, jaundice, and elevated liver enzymes. Liver disease may continue to progress to cirrhosis with hepatic venular sclerosis and sinusoidal fibrosis.

The drugs discussed above are those that are commonly used, which may cause drug-induced liver injury. However, single cases have been reported with many other drugs

Epidemiology

The true incidence of DILI in pediatric patients is unknown. In one study, DILI was reported in about 20% of cases of acute liver failure in children. However, the actual incidence of DILI is thought to be higher than the reported incidence in the literature. In a French prospective study, the incidence of hepatic drug reactions was 16 times more than the number reported in the French Pharmacovigilance system.

Pathogenesis

The exact pathogenesis of drug-related hepatocellular injury is not always identified. Childhood drug hepatotoxicity is generally uncommon compared to that of adult. This may be partly due to the fact that children are usually free of many of the factors like smoking and cardiovascular disorders as hypertension, compared to adults.

The pathogenesis of DILI occurs through direct intrinsic hepatotoxicity or idiosyncratic reactions. Intrinsic hepatotoxins are associated with a dose-dependent predictable liver injury and the latent period between exposure and onset of symptoms is typically short (i.e., hours to days). Serum aminotransferases are typically 8–500 times normal and serum alkaline phosphatase is one to two times the upper limit of normal. The classic example of an intrinsic hepatotoxin is acetaminophen.

Acetaminophen is metabolized by cytochrome P-450 to a reactive metabolite, *N*-acetyl-benzoquinone imine (NAPQI). The NAPQI metabolite is detoxified by

glutathione to form an acetaminophen-glutathione conjugate. At therapeutic doses, there is sufficient glutathione to conjugate acetaminophen. However, toxic doses of acetaminophen deplete the glutathione stores, and the acetaminophen covalently binds to cysteine groups on protein, forming acetaminophen-protein adducts, which are responsible for acetaminophen-induced hepatotoxicity. Several other mechanisms such as superoxide formation and mitochondrial dysfunction may play a role in the pathogenesis of acetaminophen toxicity, but the concept of the reactive metabolite NAPQI is still considered as the primary mechanism. Salicylate-induced hepatic injury is also thought to be dose-dependent, since most cases of liver injury were reported in children receiving chronic therapy for arthritic disorders.

The pathogenesis for most drug-related hepatotoxicity is considered an idiosyncratic reaction. In this type of reaction, the liver injury is unpredictable, is not dose-dependent, and the latent period between exposure to the drug and the sensitivity reaction is variable. The idiosyncratic reaction may be either immunologic/allergic or nonallergic/metabolic. In the immunologic reaction, it is thought to depend upon a complex interaction of the drug and its metabolites with the immune system, which results in hepatocyte necrosis and apoptosis and the release of cytokines that can lead to secondary cell damage or have immune modulating effects.

Clinical Manifestations

The clinical presentation of DILI ranges from asymptomatic enzyme elevations to fulminant hepatic failure, which may be fatal. Symptoms resembling acute viral hepatitis with jaundice, malaise, anorexia, nausea, and abdominal pain are commonly reported in patients with DILI. However, several other clinical presentations have been reported, such as hepatic veno-occlusive disease, cirrhosis, and steatohepatitis.

Based on the laboratory findings, patients may present with hepatocellular, cholestatic, or mixed liver injury. Acute hepatocellular liver injury is defined as an increase in ALT $>$ 2 folds the upper limit of normal (ULN) or an ALT/AP ratio $>$ 5. Patients with hepatocellular liver injury have nonspecific clinical features, and jaundice is not always present. In some patients, findings suggestive of a drug allergy may be present, such as fever, rash, or peripheral eosinophilia. Acute cholestatic injury is defined as an increase in serum AP $>$2-fold the ULN or by an ALT/AP $<$2. Patients with acute cholestasis usually present with jaundice and itching. As for mixed liver injury, the clinical and laboratory findings are intermediate between a hepatocellular and cholestatic pattern. The ALT/AP ratio is between 2 and 5 and drug allergy manifestations are usually present. In the event of mixed liver injury, a drug etiology should be considered, as the mixed liver failure findings are not characteristic of viral hepatitis.

The clinical presentation of patients may also be classified based on the onset of symptoms. The time between the initiation of the drug and the onset of symptoms may be short (i.e., hours to days) as with acetaminophen, intermediate (i.e., within the first 8 weeks) as with phenytoin, or long (i.e., within 1–12 months) as with isoniazid. With some antibiotics, such as amoxicillin/clavulonate and ciprofloxacin, patients may present with symptoms of liver toxicity several weeks after discontinuation of therapy.

Diagnosis

The diagnosis of DILI can be difficult, especially in the presence of other medications and underlying disease states. The patient's initial assessment may include liver function tests, serologies for viral and autoimmune hepatitis, and an abdominal ultrasonography. The diagnosis involves ruling out other potential causes of liver failure and evaluating the clinical features associated with the liver injury. The clinical features of DILI include the patient's clinical presentation, laboratory findings, the time from drug intake/withdrawal and onset of symptoms, and time for symptoms to resolve after removal of the suspected drug. Although variations exist among patients for each drug and the clinical features commonly associated with specific drugs are not consistently seen in all patients, evaluating the clinical presentation of the patient still helps in identifying the most likely culprit, especially when multiple hepatotoxic drugs are present. The findings of the liver biopsy may also aid in the diagnosis of DILI, but in most cases, a liver biopsy is not done.

Rechallenging the patient with the suspected drug may help in confirming the diagnosis of DILI. However, one should weigh the risks and benefits of a rechallenge, especially with drugs that are known to cause hepatocellular damage, as in these cases patients may rapidly progress to fulminant hepatic failure. In addition, failure to demonstrate hepatic injury following a rechallenge may not completely exclude DILI. With certain medications, several weeks of therapy is required before liver damage is detected and in some patients a recurrence of hepatic injury may not occur after one rechallenge dose is given.

Several scales and scoring systems have been developed in an attempt to provide an objective tool for the diagnosis

of DILI and to establish a causal relationship between the offending drug and liver damage. The most common scales are the Rouse Uclaf Causality Assessment Method of the Council of International Organization of Medical Sciences (RUCAM/CIOMS), the Naranjo Probability scale, and the Maria and Victorino (M&V) scale. Compared to the Naranjo and the M&V Scales, the RUCAM/CIOMS scale demonstrated better validity and reproducibility in the assessment of DILI. However, the RUCAM/CIOMS has risk factors (e.g., pregnancy, alcohol consumption, and age >55 years) that are not applicable to pediatric patients, and therefore its use is limited in this patient population.

Treatment

The key to the management of DILI is early recognition and discontinuation of the suspected drug. In most cases, once the culprit drug is discontinued, liver disease improves, although the rate of recovery varies. Cholestatic and mixed liver injuries tend to resolve slower than the hepatocellular reactions and may last for more than a year in some cases. Liver transplantation is considered in patients who progress to fulminant hepatic failure, despite removal of the culprit drug. However, liver transplantation is associated with complications and a risk of death that should be weighed into the clinical decision. In an analysis of the United Network for Organ Sharing database, which included 22 patients less than 18 years old with acute liver failure due to antiepileptics, 73% died within the first year of transplantation.

The use of ursodeoxycholic acid has been suggested for patients with drug-induced cholestatic liver failure. The drug has not been evaluated in this setting, but case reports of patients with drug-induced cholestasis in which ursodeoxycholic acid was administered reported improvement in the clinical and laboratory findings. Therefore, given the relatively safe adverse event profile and the concerns of prolonged cholestasis, it is recommended to consider ursodeoxycholic acid in patients with severe or prolonged drug-induced cholestasis.

The role of corticosteroids in the management of DILI has not been well established. The available evidence is limited to case reports that described improved symptoms after the administration of corticosteroids. Two studies that evaluated the use of corticosteroids in patients with acute liver failure, regardless of the etiology, did not show improved outcomes with steroid therapy. In one of the studies, the subset of patients with DILI that received steroids had a trend toward worse prognosis. The studies had several limitations and did not include pediatric patients, which makes the role of steroids for the management of DILI in pediatric patients unclear. Despite the lack of strong evidence, steroids are generally recommended in patients who develop severe hepatitis associated with jaundice and coagulopathy, along with a clinical picture suggestive of drug allergy (i.e., fever, rash, eosinophilia), and who do not improve following the discontinuation of the suspected medication.

It is unclear if a patient who develops hepatotoxicity due to a specific drug can be safely switched to another drug within the same class, without experiencing a similar adverse reaction. Cross hepatotoxicity has been reported between chemically related drugs. However, there are also cases in which cross hepatotoxicity was not seen when switching from one drug to another within the same class. Due to the lack of sufficient data regarding cross hepatotoxicity, it is advisable to be cautious in patients who develop severe DILI when switching to a drug within the same chemical class.

220 Pediatric Liver Transplantation

Michael B. Ishitani

Pediatric liver transplantation is a widely accepted therapy for children with end-stage liver disease or liver-based inborn errors of metabolism. This chapter is intended to briefly review the development of this technique and to highlight the indications and contraindications for liver transplantation in children. It also examines some of the new technical advances that have been made over the last decade and resulted in an increase in the pool of available donor organs. The chapter also discusses some of the complications and management issues that occur after liver transplantation, especially those problems unique to children.

History

Liver transplantation in humans was first attempted in 1963 when Thomas Starzl performed a liver transplant in a 3-year-old child. Initial efforts at other centers also failed and it was not until 1967 that Starzl was able to obtain long-term survival of a patient. Mortality in these patients was high due to technical problems with the operation itself and complications of the relatively crude immunosuppressive agents.

The introduction of cyclosporin into clinical use in the late 1970s coupled with advancements in surgical technique led to major improvements in patient survival. By 1983, a National Institutes of Health consensus statement declared that liver transplantation was no longer experimental and was now an accepted form of therapy for end-stage liver disease. Over the last decade, survival rates for children undergoing liver transplantation have improved, with current 1-year survival rates of 89%, 3-year survival rates of 83%, and with many centers reporting greater than 90–95% 1-year survival rates.

In the past, a major problem in pediatric liver transplantation has been obtaining an adequate supply of size-matched cadaveric donors. The majority of children who require liver transplantation weigh less than 20 kg and the potential pool of donor organs is therefore small. Initial reports indicated that mortality rates ranged from 25% to 40% among children who were awaiting a suitable size-matched cadaveric liver. In the mid-1980s, Bismuth and Houssin in France and Broelsch in the United States pioneered the use of reduced size cadaveric grafts for children. Using this technique, an adult cadaveric donor liver could be utilized in a child with nearly equivalent results to a size-matched pediatric cadaveric donor graft. In the 1990s, new technical advances led to the successful use of split-liver grafts, whereby a single liver was divided into two pieces and given to two recipients, and living-related liver transplants, whereby a segment of liver from an adult living donor was removed and transplanted into a child. Some centers are now utilizing donor organs from non-heart-beating donors with some success.

Indications

Children who are referred to a transplant center for evaluation generally have some form of acute or chronic liver failure or a correctable inborn error of metabolism. Clinical presentation is variable, but usually consists of some combination of signs and symptoms, noted in (*Table 220.1*). For children in the United States, the most common etiology of chronic liver failure is cholestatic liver disease due to biliary atresia (*Table 220.2*). Other common etiologies for chronic liver failure in children include neonatal hepatitis, autoimmune hepatitis, and viral hepatitis. Secondary causes of liver failure include cystic fibrosis with minimal pulmonary involvement and Langerhans histiocytosis.

Acute fulminant hepatic failure presents with the sudden onset of encephalopathy, coagulopathy, and jaundice in children with no previous history of liver disease. The most common causes are viral hepatitis (usually non-A, non-B or hepatitis B) or drug-induced liver failure (acetaminophen, valproic acid). Mortality can be very high and early referral is mandatory to maximize the chance for survival.

Certain disorders of metabolism are also successfully treated by liver transplantation. These include common disorders where the liver is injured by the underlying disease process (Wilson's disease, a_1-antitrypsin disease) and uncommon disorders (ornithine transcarbamylase deficiency, tyrosinemia type 1) where the new liver provides a missing enzyme and allows phenotypic normal function.

Experience with liver transplantation in children with unresectable neoplasms is limited, although there is

Table 220.1
Clinical presentations indicative for liver transplantation

Decreased hepatic synthetic function (hypoalbuminemia, coagulopathy)
Encephalopathy
Intractable pruritus
Complications of portal hypertension (ascites, variceal bleeding, subacute bacterial peritonitis)
Episodes of cholangitis
Bone complications of liver disease (hepatic osteodystrophy)
Pulmonary complications of liver disease (hepatopulmonary syndrome)

Table 220.2
Clinical conditions requiring liver transplantation in children

Primary end-stage progressive liver disease (e.g., biliary atresia, Alagille syndrome)
Secondary progressive liver disease (e.g., a_1-antitrypsin deficiency, Wilson disease)
Acute fulminant hepatic failure (e.g., acetaminophen overdose, non-A, non-B viral hepatitis)
Inborn errors of metabolism that are correctable by liver transplantation for which there are no acceptable alternatives (e.g., ornithine transcarbamylase deficiency)
Neoplasms in which a reasonable chance for cure is present with transplantation (e.g., hepatoblastoma)

a definite improved survival in children with unresectable hepatoblastoma, who have undergone transplantation followed by adjuvant chemotherapy.

Referral to a transplant center should be done as soon as the child has been identified as having a progressive condition that will eventually require transplantation. An early referral allows the greatest flexibility possible for the transplant center to assist in the management of the patient and provide the parents with the best choice of alternatives for treatment that could allow the transplant center the best opportunity to find a suitable donor. In addition, results with liver transplantation are significantly better in patients who undergo early elective procedures as opposed to those who are transplanted in a state of acute hepatic decompensation.

Contraindications

The current contraindications for liver transplantation are those children who have an untreated systemic infection, are infected with the human immunodeficiency virus, have an untreated malignancy outside the confines of the liver, or have a condition with an acceptable alternative therapy. Relative contraindications to liver transplantation include children with poor neurologic, psychosocial, or physical condition prior to transplantation with no expectation for improvement (e.g., cerebral palsy), impairment of other organ systems at the time of transplant that would preclude successful transplantation, or disease that would be expected to recur following transplantation (e.g., hepatocellular carcinoma). These relative contraindications may change over time as either medical progress is made or the condition of the patient improves.

Technical Advances in Pediatric Liver Transplantation

A significant problem facing pediatric liver transplantation in the early 1980s was the scarcity of suitable size-matched cadaveric donors. Biliary atresia is the most common cause of chronic liver failure in children. Unfortunately, these children frequently present during the first or second year of life following a failed Kasai portoenterostomy and almost invariably weigh less than 10 kg. Because of their small size, relatively few size-matched cadaveric donors are available for these patients.

Recent advances in surgical technique with cadaveric reduced-size, split-liver, and living-related segmental liver grafts have allowed the use of small adult livers in small children. As a result, the mortality of children awaiting transplant is now less than 5%.

Reduced-Size Liver Transplantation

The technique of reduced-size liver transplantation was initially suggested and performed by Bismuth and Houssin in 1984. Broelsch popularized the technique in the United States, and it has gained widespread acceptance as a means to increase the number of donor organs available for children. In most cases, an adult donor liver is obtained using standard techniques of multiorgan procurement. An anatomic dissection is then performed on the back-table with the appropriate segment determined by the relative sizes of the donor and recipient.

In general, a left lateral segment graft (segments 2 and 3) is used in a recipient up to eight times smaller than the donor, a left lobe graft (segments 2, 3, and 4) is used in

recipients up to four times smaller than the donor, and a right lobe graft used in recipients up to two times smaller. However, these are estimates, not rigid size determinations, since the anatomy of the donor liver (e.g., long slender left lateral segment) and recipient abdominal cavity can vary significantly (e.g., ascites, hepatomegaly). After preparation of the donor liver, the recipient hepatectomy is done in standard fashion and the reduced-size graft placed in orthotopic position. Care must be taken to place the graft so as not to have it twist upon itself and cause kinking of any vascular or biliary structures.

Overall success with the technique of reduced-size cadaveric grafts approaches that of size-matched cadaveric grafts. However, there does appear to be an increased risk of complications due to bile leakage from the surface of the liver.

A logical extension of this technique is to split the liver into two separate portions and to use the pieces in two different recipients. Results suggest an increase in morbidity with this approach, but recent experience indicates that this approach may be more successful as technical improvements have been made. In many centers, split liver transplantation is now the preferred approach.

Living-Related Liver Grafts

Recently, another approach to increase the availability of donor grafts for children has been to utilize living-related adults to undergo a segmental liver resection to provide a graft for the child. In most cases, consenting adult volunteers undergo a full medical and surgical evaluation. If he/she is deemed a suitable candidate, a left lateral segmentectomy or a left or right lobectomy is performed in the donor. The donor graft is then transplanted into the recipient using standard techniques.

Results with this technique appear good. However, there is a small but real risk for donor morbidity and mortality associated with the living-related donor procedure. At least five donors have died since this technique has been developed and popularized for use in adults and children.

Long-Term Management Issues and Complications after Liver Transplantation

The care of children immediately following liver transplantation is often complex and difficult. However, the overall success rates are high and these children will usually return to relatively normal lives. This portion of the chapter examines some of the many long-term management issues and complications that have to be dealt with as these children grow and develop. The transplant center is designed to address these problems in a timely fashion through a multidisciplinary approach.

Rejection

Rejection of the liver occurs in 40–70% of patients. Rejection usually occurs after the first week following the transplant. The clinical presentation is highly variable but may include fever, chills, tachypnea, abdominal pain, ascites, or a picture resembling sepsis. Hepatic biochemical abnormalities are usually seen, with elevation of alkaline phosphatase, bilirubin, and aminotransferases.

A liver biopsy is generally performed to confirm the diagnosis and an ultrasound done to exclude hepatic artery thrombosis or bile duct stricture as a cause for the abnormalities. Treatment is generally begun with a short course of high-dose corticosteroids and an increase in baseline immunosuppression. If the response is not satisfactory, treatment with OKT3 or thymoglobulin is indicated. These measures are able to reverse rejection in the vast majority of cases.

Growth and Development

Children with end-stage liver disease are often delayed in both growth and development. Following successful liver transplantation, growth and development recover to some degree, though recipient growth rates often do not completely return to normal. Since it is known that corticosteroids retard growth, efforts have been made to wean corticosteroid doses as rapidly as possible. Indeed, with the use of immunosuppressants such as tacrolimus and mycophenolate mofetil, it may be possible to discontinue corticosteroids within the first year after transplantation; nevertheless, the immunosuppressant regimen that best optimizes growth in children has still not been clearly defined.

Hypertension

Hypertension develops in most children following liver transplantation. This is usually a complication of the immunosuppressant regimen. Cyclosporine, tacrolimus, and corticosteroids are all known to predispose to hypertension. As the risk of rejection decreases over time, the dosages of immunosuppression drugs can be decreased

and the antihypertensive regimen can often be modified or discontinued.

Immunizations

The immunization history should be obtained early in the pre-transplant evaluation and a plan developed to ensure that appropriate vaccines are given. In general, response to vaccination is better prior to transplantation and immunosuppression. After transplant, live virus vaccines as a rule should be avoided.

Infection

Infections are common following liver transplantation. While bacteria are still the most common cause of infection, viral and fungal infections are frequent. Cytomegalovirus (CMV) infections characteristically occur 4–8 weeks following transplantation and present with fever, interstitial pneumonia, gastrointestinal bleeding, and graft hepatitis.

Treatment with prophylactic antiviral agents is still controversial; however, once CMV disease has been diagnosed, a course of intravenous ganciclovir is warranted. Infection with the herpes viruses can lead to localized or generalized herpes type 1 infection. Varicella infections can lead to systemic infection or viral reactivation and shingles. Epstein–Barr virus infections can lead to systemic symptoms and have been linked to posttransplant lymphoproliferative disorders and lymphomas. *Pneumocystis carinii* infections are seen in immunosuppressed patients, and most centers employ prophylaxis with trimethoprim–sulfamethoxazole. Prophylaxis for *Candida albicans* fungal infections is also routinely employed with oral nystatin.

Quality of Life

Children with successful liver transplants can achieve an excellent quality of life. With improvements in survival come questions as to the limitations in life they have as they grow and develop.

As children go through adolescence, they ideally develop a sense of self-confidence, independence, and responsibility. Unfortunately, adolescence may also lead to rebellious behavior influenced by a desire to conform with peer behavior and appearance. It is clear that immunosuppressive medications can lead to significant alterations in physical appearance, ranging from hirsutism to cushingoid complications of corticosteroids.

Compliance with medications in adolescent renal transplant patients is recognized to be poor, but information is lacking in adolescent liver transplant patients. Compliance is probably somewhat better, since most patients realize that there is no life-sustaining counterpart to dialysis for patients with liver failure. Nevertheless, noncompliance should be suspected in previously stable adolescents who present with low blood levels of cyclosporine or tacrolimus and liver function abnormalities. A low threshold for investigation must be maintained in order to prevent graft injury and life-threatening rejection.

Respiratory Disorders

Gabriel G. Haddad

221 Development of the Lung and Respiratory System

Gabriel G. Haddad

Introduction

By reviewing the development of the respiratory system, this introductory chapter paves the way to the understanding of diseases of the chest in children. It is important to realize that the chest, the lungs, the ribcage, and the respiratory muscles in the newborn are very different from those of the child and from those of the adolescent and young adult. This is the case for both the structural and functional aspects of the development of the respiratory system.

In animals living on land, the gas-exchanging apparatus develops in alveolar (reptiles, amphibian, mammals) or parabronchial (birds) lungs. Gas-exchanging surfaces in lungs depend on two important factors, one is related to a surface-active material, the pulmonary surfactant, which prevents collapse and the other depends on a pump operated by muscles. The function of these respiratory muscles is regulated by a feedback system inclusive of a network of sensors, which relay information from the blood (e.g., gases), the airways (e.g., stretch), and the pump itself to a control center in the brain. The pump can in this manner generate lung ventilation that keeps pace with the metabolic pace of warm-blooded animals and humans.

Early Development: Lung Morphogenesis

In humans, the morphological development of the respiratory system is divided into five periods. The first, or *embryonic period,* begins at approximately 4 weeks of gestation, when the primitive airways appear as an outpouching of the foregut and which divides almost immediately into two main stem bronchial buds. The bronchial buds start to branch, first by monopodal outgrowth (secondary branches grow out of a main branch) and then by asymmetric dichotomy (two secondary branches originate from one main branch). The peribronchial mesenchyme plays an essential role in shaping the lungs during the embryonic period. Close contact between this mesenchyme and the epithelium of the bronchial buds is essential for the continued branching of the airways. The factors that promote bronchial division are not fully identified but steroid-induced secretion of growth factors by the mesenchymal fibroblasts and direct molecular communications between fibroblasts and endodermal cells have been proposed as signaling mechanisms.

Soon after their appearance, the bronchial buds are surrounded by a vascular plexus, which stems from the aorta and drains into the major somatic veins. This vascular plexus connects with the pulmonary artery and veins to complete pulmonary circulation at about the seventh week of gestation but retains some aortic connections that form the bronchial arteries.

Toward the sixth week of gestation, at the beginning of the second or *pseudoglandular period*, the lungs resemble an exocrine gland with a thick stroma with narrow ducts lined by tall epithelial cells. Even at that early stage, the major airways are already in close association with pulmonary arteries and veins. The trachea and the foregut are now separated after the progressive fusion of epithelial ridges growing from the primitive airway. During the pseudoglandular period, the airways continue to branch until the entire conducting airway system is formed, including the primitive bronchioles that eventually give rise to the air-exchanging portions of the lungs. Simultaneously, the pluripotential cells that line the airways differentiate, starting from the trachea and main bronchi, in a process that appears to be under some degree of mesenchymal control. They will form a thinner, pseudostratified epithelium containing ciliated, secretory (Clara), globular, and neuroendocrine cells of neuroectodermal origin. Mucous glands, cartilage, and smooth muscle can be easily distinguished by the 16th week of gestation.

The diaphragm is formed during this period. Its central tendon originates from the transverse septum, a plate of mesodermal tissue located between the pericardium and the stalk of the yolk sac. Its lateral portions are formed by the pleuroperitoneal folds, which grow from the body

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_221,

wall until they fuse with the esophageal mesentery and the transverse septum. The fusion eliminates the communication between thorax and abdomen and establishes a barrier to the caudal growth of the lungs. Its failure, usually on the left side, causes the *congenital diaphragmatic hernia of Bochdalek*. This defect, which is the most frequent type of diaphragmatic hernia, allows the abdominal organs to enter the primitive pleural cavity and interferes with airway and pulmonary vascular branching. The result is severe hypoplasia of the lung, particularly on the side of the hernia. Initially membranous, the normal diaphragm is eventually invaded by striated muscle derived from cervical myotomes.

During the third or *canalicular period*, between the 16th and 26–28th week of gestation, epithelial growth predominates. As a result, the bronchial tree develops a more tubular appearance, whereas its distal regions subdivide further to lay the structural foundations of the pulmonary acinus. The epithelial cells in these regions become more cuboidal and start to express some of the antigen markers that characterize cells as *type II pneumocytes*. Some cells become flatter and can be identified as potential type I pneumocytes by the presence of a sparse endoplasmic reticulum and cytoplasmic glycogen. The capillaries contained in the distal bronchial mesenchyme form a denser network and grow closer to the potential air spaces, making a very limited gas exchange possibly by the 22nd week of gestation. This is precisely why a premature at about 24-week gestation has a limited gas-exchange capacity.

Between the 26th and 28th week of gestation, lung morphogenesis enters its *saccular period*, during which the terminal airways continue to widen and form cylindrical structures known as saccules. Initially smooth, the internal surface of the saccules soon develops ridges, which originate as folds of the epithelium and contain a double capillary layer. The distance between the capillaries and the potential air spaces narrows further until eventually only a thin basal membrane separates them. Exactly when the saccular period ends and the alveolar period begins depends on the definition of what constitutes an alveolus. Formation of alveoli before birth is not a requisite for survival, as demonstrated by the observation that in altricial species, such as the rat or the rabbit, alveoli are not present until several days after birth. In the human fetus, the saccular septation initiated with the appearance of the secondary crests continues at a rapid rate so that multifaceted structures analogous to the alveoli of the mature lung can be seen at 32-week gestation. Furthermore, there is substantial evidence that the timing and progression of alveolar septation is under endocrine regulation. Thyroid hormones stimulate septation, whereas glucocorticoids impair it in a fashion that – at least in the rat – can be irrevocable (even though they accelerate the thinning of the alveolar capillary membranes). Alveolarization is also influenced by physical stimuli. Both the stretch by the liquid contained in the fetal lung and the periodic distention provided by the action of the respiratory muscles during fetal breathing, for instance, appear to be necessary for the development of acini. Their absence when the lungs or chest are compressed (as in the case of a diaphragmatic hernia or oligohydramnios) or when fetal breathing is abolished (e.g., by spinal cord lesions) results in pulmonary hypoplasia with reduced numbers of alveoli.

A number of gene families have been identified as being essential for development. The homeo-domain or homeo-box (hox) gene family was discovered first in *Drosophila* and was later shown to be well preserved in mammals and critical mammalian organ development, including that of respiratory system. Hoxa-1,2,3,4,5 and Hoxb-3,4,6,7,8 mRNA transcripts have been identified using molecular biologic techniques in branching regions of the developing mouse lung. These Hox genes were differentially expressed in time and space in early lung development, indicating that they play a role in the differentiation, maturation, and proliferation of various lung cells throughout the various phases of lung development. Furthermore, some of these genes seem to be important in distal versus proximal branching and differentiation. Hoxa-2 seems to be tied to a proximal role, whereas Hoxb-6 is involved in distal airway branching.

A number of other gene families have also been implicated in fetal lung development. For example, GATA-6 is a member of a family of six zinc finger transcription factors and its expression is restricted to the bronchial epithelium. Its importance is demonstrated by the fact that GATA-6 knockout mice die at day ~7. *Foxa2*, which is a downstream target of GATA-6, is a transcription factor which is expressed in the lung epithelium throughout embryonic and into adult life. Null mutations in Foxa2 are also lethal by a couple of days later than for GATA-6. Vitamin A (retinoic acid) is essential for growth, vision, reproduction, and survival. Retinoic acid acts through two groups of receptors: the RAR and the RXR families. Depriving pregnant rats of vitamin A in early fetal life results in animals with lung agenesis. Mutations in both α and β_2 RAR genes produced animals with left lung agenesis or hypoplasia of the lungs. Similar defects are seen in vitamin A-deficient infants. These defects can be are prevented by administration of vitamin A. Fibroblast growth factors and receptors (fgfs and fgfrs), which are

transmembrane receptor tyrosine kinases are expressed in the developing lungs. These are critically important for early branching morphogenesis. Mutations in these receptors lead to trachea with no branching, a striking similarity between mice and Drosophila (mutation in branchless, an FGF ortholog).

Gas Exchange and Adaptation to Air Breathing

The transition from fetal to postnatal gas exchange requires adaptive changes in the lungs. These changes include the (a) production of *surfactant* in the alveoli, (b) the transformation of the lung from a secretory to a *gas-exchanging* organ, and the establishment or parallel *pulmonary and systemic* circulation.

As soon as the newborn takes the first breath, an air–liquid interface is established in the lungs. Unless the surface tension generated at this interface is reduced, the walls of the air spaces would collapse, threatening the stability of lung units. The pulmonary surfactant makes such a reduction in surface tension possible by forming a lipid monolayer at the very surface of the liquid film that lines the air spaces. This surfactant is a heterogeneous mixture of phospholipids and proteins secreted into the saccular or alveolar spaces by the type II pneumocytes. Its presence is first recognized in secretory organelles known as *lamellar bodies* as early as the 24th-week gestation. However, surfactant lipids, of which the most abundant is phosphatidylcholine, are not detectable in the amniotic fluid until the 30th week of gestation, suggesting that there is a chronologic gap between surfactant synthesis and secretion. Labor probably shortens this gap because phospholipids are consistently found in the air spaces of infants born before the 30th week of gestation. Four apoproteins (SP-A, SP-B, SP-C, SP-D) identified in the lung promote the effective reduction of surface tension. Apoproteins also appear to be important for the reuptake and recycling of surfactant products and for the formation of tubular myelin (the structures in which surfactant is stored in the liquid subphase).

Surfactant apoproteins and phospholipids share some, but not all, of their regulatory influences. Glucocorticoids, for instance, increase the synthesis of both apoproteins and lipids; accordingly, their prenatal administration has been used to prevent the respiratory distress syndrome associated with prematurity. Because many actions of the steroids involve direct stimulation of response elements in apoproteins and phospholipid enzyme genes and therefore require messenger RNA production, sufficient time must elapse between steroid administration and birth. Thyroid hormones also enhance the synthesis of phospholipids by a receptor-mediated mechanism, but, unlike the glucocorticoids, have little or no effect on surfactant apoproteins synthesis. Conversely, β-adrenergic agonists and other agents that raise cellular cyclic adenosine monophosphate content increase apoprotein synthesis and phosphadylcholine secretion into the air spaces but have ketosis, and androgens may have negative effects on the production of surfactant proteins and phospholipid, thus explaining the high incidence of respiratory distress syndrome in infants of diabetic mothers and the slight maturational delay of the lungs of male fetuses compared with female fetuses.

Surfactant proteins and lipids also may play an important role in lung immunity, although the molecular details are not known. Surfactant proteins A and D are lectins (bind to carbohydrates) and belong to the collectins family of genes. These proteins, present in the serum and lungs, stimulate phagocytosis and chemotaxis, produce reactive oxygen species, and regulate the production and release of cytokines by immue cells. Alternatively, surfactant lipids can suppress immunity. It is possible that the ratio between surfactant lipids and proteins is important in regulating the immune status of the lungs. This may be critical in premature infants and in newborns who lack surfactant proteins; knockout mice with SP-A deficiency have major problems with infections.

The fetal lung is a secretory organ. Throughout gestation, a Cl^--, K^+-, and H^+-enriched fluid is produced in its peripheral air spaces with the help of a Cl^- pump and channels. The presence of this fluid appears to be important for the development of the acinus because chronic drainage of the trachea in experimental animals results in lung hypoplasia. Fluid secretion, however, is incompatible with air breathing. Therefore, in preparation for birth, lung fluid production decreases slowly at the end of gestation. This decrease, which is accelerated by the beginning of labor, denotes a transformation in the ion transfer activities of the pulmonary epithelium *from Cl^- (and water) secretion to Na^+ (and water) absorption.* In experimental animals, such a transformation can be precipitated by the administration of β-adrenergic agonists at doses that result in serum levels comparable to those found during labor. After birth, the still substantial amount of fluid left in the lungs is absorbed over several hours into the circulation either directly through pulmonary vessels or indirectly through an already very effective lymphatic system. The cellular elements responsible for fluid secretion and absorption in the lungs are not fully identified. It is obvious that a mature alveolar epithelium

is not essential for fluid secretion, which is already taking place before alveoli or even saccules exist.

A number of transporters and channels that have importance on water and solute transport in early life have been cloned and identified in the past decade. Most prominent has been the epithelial sodium channel or ENaC. It is the amiloride-sensitive apical channel that is responsible for sodium and water absorption in the luminal surface of the airways and renal tubular cells. This channel is made up of three types of subunits, α, β, and γ. This channel seems to be critical in early life; knockout mice for this channel develop pulmonary edema and die soon after birth.

At birth, the pulmonary circulation changes from a high resistance to low-resistance system and, as a consequence, pulmonary blood flow become capable of accommodating systemic venous return. The change in resistance is brought about by the combined effects of the mechanical forces applied on the pulmonary vascular walls by the expanding lung tissue and the relaxation of the pulmonary arterial smooth muscle caused by the increased alveolar concentrations of oxygen and probably by endogenous release of vasodilators. The subsequent closure of the foramen ovale and the ductus arteriosus completely separates the pulmonary from the systemic circulation. Arterial oxygen tension then rises sharply and becomes homogeneous throughout the body. Pulmonary vascular resistance continues to decrease gradually during the first few weeks after birth through structural remodeling of the pulmonary vessels.

Postnatal Alveolar and Capillary Development

The postnatal development of the lungs is divided into two phases. During the first phase, which extends to the first 18 months after birth, there is a disproportionate increase in the surface and volume of the compartments involved in gas exchange. Capillary volume increases more rapidly than air space volume, which in turn, increases more rapidly than solid tissue volume. This process is particularly active during early infancy and may reach completion within the first 2 years of life. The configuration of the air spaces becomes progressively more complex, not only because of the development of new septae but also because of the lengthening and folding of the existing alveolar structures. Soon after birth, the double capillary system contained in the alveolar septa of the fetus fuses into one single one. At the same time, new arterial and venous branches develop within the circulatory system of the acinus and muscle starts to appear in the medial layer of the intra-acinar arteries.

During the second phase, all compartments grow more proportionately to each other. Although there new alveoli can still be formed, the majority of the growth occurs through an increase in the volume of existing alveoli. Alveolar and capillary surfaces expand in parallel with somatic growth. As a result, taller individuals tend to have larger lungs. However, the final size of the lungs and, ultimately, the dimensions of the individual constituents of the acinus are also influenced by factors such as the subject's level of activity and prevailing state of oxygenation (altitude), which allow for a better adaptation of lung structure and function. The same factors are probably operative in the compensatory responses to pulmonary disease and injury.

222 History and Physical Examination

Anthony E. Magit

The initial assessment of the airway begins with a focused history. Information obtained from the history influences decisions regarding the extent of the examination, the need for diagnostic tests, and the urgency of interventions. The history addresses the onset of the airway problem, whether congenital or acquired, as well as the presence of signs or symptoms of an infectious process. A history of airway manipulation, including intubation, can be key factor in the development of an airway problem.

Assessment of a child's airway may start before birth. Critical information regarding the airway may be available prior to a birth as a result of prenatal ultrasound or other imaging modalities. Ultrasound findings suggesting airway obstruction include masses of the head or neck, anatomic abnormalities including micrognathia or retrognathia, as well as a distended pulmonary system suggesting high airway obstruction due to laryngeal or tracheal obstruction. The prenatal evaluation may include ultrasound findings predicting airway obstruction at delivery. Ultrasound abnormalities may influence the decision to obtain other imaging studies, particularly a magnetic resonance imaging (MRI) study.

The degree of airway obstruction predicted to be present at delivery may necessitate creating a specific plan for managing the child's airway at the time of delivery. A means of maintaining fetal circulation while assessing a newborn's airway is the ex utero intrapartum treatment (EXIT) procedure.

The type of airway intervention required to stabilize the airway provides valuable information regarding the level of obstruction. Airway compromise present at birth can result from obstruction from the level of the nose to the lower airway. Bilateral nasal obstruction will cause respiratory distress as a result of newborns being obligate nasal breathers. Relief of airway obstruction with ventilation through a facemask is consistent with obstruction from the nose to the oral cavity. Resolution of airway obstruction following laryngeal intubation with an appropriately sized endotracheal tube suggests that the etiology of the obstruction is from the level of the glottis or superior to the glottis. Airway obstruction resolved with the placement of a smaller than expected endotracheal tube implies glottic or subglottic stenosis.

The timing and quality of airway noises correlates with the site of the airway abnormality. Stertor, the sound associated with disrupted nasal airflow, indicates partial nasal obstruction. Stridor is the term used to describe the high-pitched sound associated with partial airway obstruction below the level of the oropharynx. Stridor is typically tied to a phase of respiration, whether present on inspiration or expiration. Stridor present on inspiration, referred to as inspiratory stridor, is associated with lesions above the vocal folds. Stridor present on expiration, referred to as expiratory stridor, is associated with lesions below the level of the subglottis. Stridor present on inspiration and expiration, referred to as biphasic stridor, typically results from lesions at the level of the glottis or subglottis.

Airway problems developing subsequent to delivery may be anatomic or functional. A non-obstructing mass at birth may increase in size and lead to a compromised airway.

A history of airway manipulation can provide valuable information. Previous intubation, including a brief period of time for a procedure or short-term respiratory management, can be associated with the development of subglottic lesions, including cysts and stenosis. A hoarse or raspy cry may result from vocal fold inflammation as a result of silent or clinically apparent gastroesophageal reflux (GER). Signs and symptoms of GER include agitation during or after feeding as well as arching of the neck during or after feeding.

Coughing while feeding may be an indication of laryngeal penetration or aspiration. Underlying conditions predisposing to laryngeal penetration or aspiration include vocal cord paralysis, vocal cord paresis, laryngeal clefts, and tracheoesophageal fistulae.

Examination of the airway is influenced by the age of the patient and the urgency of the clinical situation. The initial evaluation of the airway consists of assessing for impending airway obstruction and determining the need for acute intervention. Signs of upper airway compromise include suprasternal retractions, abdominal breathing, and worsening stridor. Clinical deterioration of the airway is suggested by hypoxia, tachypnea, and diaphoresis. The clinician must recognize the urgency of the clinical situation and transition from a diagnostic algorithm to an interventional mode to improve the airway.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_222,

Airway assessment involves a systematic review of anatomic sites. The basic elements of an airway assessment are typically a component of any comprehensive physical examination. A detailed evaluation of specific anatomic sites is driven by the patient's condition.

Newborn

The nasal examination begins with a visual inspection of the external nose. A newborn's nose is assessed for symmetry of the dorsum. Significant deformity resulting from intrauterine positioning may result in deviation of the nasal tip and distortion of one or both nares. Anterior rhinoscopy using a handheld otoscope allows for inspection of the anterior nasal cavities posteriorly to the anterior aspect of the middle turbinate. Patency of the nose has traditionally been established by passing catheters through each side of the nose into the nasopharynx. This procedure can be traumatic and falsely indicate that the nose is patent if the catheters curl in the nasopharynx when posterior nasal obstruction exists. A nontraumatic means to determine nasal patency is to place a mirror in front of the nares and observing condensation on the surface of the mirror. This method does not provide information regarding the caliber of the nasal opening; however, it does prove that airflow is present. The addition of a dilute nasal decongestant can facilitate the intranasal examination.

Examination of the oral airway includes the mandible, tongue, oral cavity, and oropharynx. Mandibular position and size directly relates to adequacy of the airway at the level of the oral cavity. An undersized or posteriorly positioned mandible will result in inadequate anterior support of the tongue. The mandible is observed and position is assessed relative to the maxilla. The oral cavity is visualized using a tongue depressor or examiner's finger. The position and size of the tongue is noted with reference to the child's ability to keep the tongue within the oral cavity. A tongue that tends to oppose the palate may be intrinsically large or superiorly displaced by a mass in the floor of the mouth. The tongue should be elevated with a tongue depressor or the examiner's finger and the anterior floor of mouth inspected for masses or fullness.

The palate examination assesses structure and function. Visual examination of the palate involves noting clefts of the hard or soft palate. Digital palpation detects notching of the hard palate or thinning of the midline of the soft palate suggesting a submucosal abnormality. The soft palate is visualized to determine if the uvula is intact or whether there is a bifid uvula or prominent median raphe of the uvula supporting the possibility of an underlying muscular abnormality. Visual inspection of the oral cavity with adequate illumination is critical as digital examination alone is associated with delay in the diagnosis of cleft palate.

The airway below the level of the oropharynx cannot be directly visualized without specialized equipment; however, examination of the neck can provide valuable information regarding the larynx and hypopharynx. Visualization and palpation of the neck can reveal masses that impact upon the airway. A stethoscope can be "marched down" the airway to localize the site of an airway abnormality. The "headless" stethoscope is one in which the head of the stethoscope is removed and the open end of the stethoscope tubing is placed directly on the skin over the airway. The smaller area of the tubing allows for more precise localization of the airway abnormality.

The quality and clarity of the cry provides information regarding involvement of the vocal cords and glottis. Noisy respirations in the absence of an abnormal cry suggest that the airway abnormality spares the vocal cords.

Pediatric Airway

A history of pediatric nasal problems must clearly address the status of the airway. Oftentimes, parents or caregivers will describe a child as being "nasal" when the concern is actually nasal obstruction and "hyponasality." Observing the patient prior to beginning the physical examination can provide critical information. A child with chronic nasal obstruction may exhibit an open mouth breathing posture with audible respiration.

Chronic unilateral nasal drainage is consistent with anatomic obstruction or the presence of a nasal foreign body. Intranasal examination using a handheld otoscope or a headlight and speculum focuses upon the appearance of the mucosa, presence of secretions, or intranasal masses.

Detecting the presence of nasal airflow while a child produces "nonnasal" sounds can grossly assess hypernasality. Standard "nonnasal" sounds are "s" sounds such as "sister." Nasal airflow during the vocalization of these sounds suggests hypernasality due to a structural or functional problem.

In addition to assessing the tongue, floor of mouth, and palate, the oral cavity examination addresses the transition zone from the oral cavity to oropharynx at the level of the tonsillar pillars. Tonsil size and position is usually described on a scale from 1 to 4. The tonsils are assessed with an open mouth and relaxed position. Excessive opening of the mouth can position the tonsils in a more lateral position. The posterior and inferior extent of the tonsils

Table 222.1

Modified mallampati
1. Clearly visible tonsils, tonsillar pillars, and soft palate
2. Only visible uvula, tonsillar pillars, upper tonsil pole
3. Partially visible soft palate
4. Only visible hard palate

may be difficult to assess with a transoral examination. True tonsil size is best assessed by depressing the tongue with this physical examination technique resulting in good correlation between subjective and objective tonsil size.

Another system for describing the appearance of the oral cavity and orophayrnx is the Mallampati classification (*Table 222.1*). This system is primarily used for a preanesthetic airway evaluation of the airway and focuses upon the structures that are identified when the patient's mouth is open.

Phonation tends to improve the view of the oropharynx while a supine position tends to obscure the view of the oral cavity and oropharnx. This should be taken into consideration when having the parent or another adult position the child during the physical examination.

The larynx can be assessed indirectly by examining the neck. The larynx is palpated to determine its midline position or distortion due to masses or trauma. Auscultation over the larynx establishes the presence or absence of stridor due to a partially obstructed airway.

Cough

Evaluating a cough in a child relies heavily upon the history provided by the adults and the child. In the absence of signs or symptoms of an infectious process, a significant concern is the presence of an airway or esophageal foreign body. The importance of a history suggestive of a foreign body is supported by a study by Linegar in which a clinical history consistent with an airway foreign body and a negative history was associated with a positive endoscopy for a foreign body in 45% of cases.

Airway Sounds

Assessing the quality and location of airway noises assists in developing a working diagnosis for a child with a respiratory problem. An important consideration is that the intensity of the sound may not correlate with the severity of the airway situation. History provided by the parent is more likely to correctly identify the origin or location of the airway noise than identify the etiology of the noise. Parents are more likely to misidentify stridor as wheezing and attribute the airway noise to asthma rather than an upper airway problem. Parental report of wheezing correlates with a health professional's report of wheezing in less than 50% of cases.

Older children may be able to provide valuable information regarding their airway. With regard to the frequency and severity of wheezing, school-age children have been reported as being more accurate reporters of their wheezing than their parents.

The type of airway sound provides a clue as to the location of the abnormality. A "monophasic" sound suggests a structural lesion in al large airway while a "polyphonic" wheeze is more likely to be associated with extensive small airway narrowing.

A snore results from increased resistance to airflow in the nasopharynx and oropharynx. Snoring becomes more intense with increased relaxation of the pharyngeal musculature that occurs during the REM (rapid eye movement) phase of sleep.

Stridor

Stridor describes audible air movement due to partial obstruction of the airway. Characteristics of stridor are the timing relative to inspiration and expiration. The examiner notes the severity of obstruction, and the need to establish an acute intervention is determined. Pertinent history is the presence of a coexistent syndrome, chronic cough, growth abnormalities, cutaneous lesions, and neurodevelopmental problems.

223 Pulmonary Function Testing

Gabriel G. Haddad

Spirometry and Plethysmography

Pulmonary lung function testing has been useful in monitoring and diagnosing pathological processes in the lung. Hence, although pulmonary function testing rarely results in a diagnosis, it is helpful in defining the type of process (obstruction, restriction) and the degree of functional impairment in following the course and treatment of disease, and in estimating the prognosis. Such measurements of respiratory function especially in infants and young children can however be difficult because of lack of cooperation. Whether restrictive or obstructive, most forms of respiratory disease cause alterations in lung volume and its subdivisions and pressure generated.

Restrictive diseases typically decrease total lung capacity (TLC) because of lack of ability to stretch the lungs. TLC includes residual volume and vital capacity (VC). Residual volume is measured indirectly by gas dilution methods or plethysmography. VC is measured by spirometry and can be often used at the bedside to assess progression of disease such as in muscle weakness and neuromuscular disorders. Obstructive diseases produce gas trapping and thus increase residual volume and functional residual capacity or FRC.

Airway obstruction is most frequently evaluated from gas flow measurements of a forced expiratory maneuver. The *peak expiratory flow* is reduced in obstructive disease and there are numerous simple devices that perform this measurement at the bedside. This makes these devices useful for evaluating children with airway obstruction and for monitoring progress rather easily. Peak flow measurements are sometime difficult to evaluate since they require a voluntary effort. In addition, peak flows are not very sensitive as these peak flows may not be altered when the obstruction is mild or even moderate.

Gas flow measurements other than peak flows are also not always easy to perform on young children since they require that the child inhale to TLC and then exhale as fast and as much as possible for several seconds. Cooperation and good muscle strength are therefore necessary for the measurements to be reproducible. The *forced expiratory volume in 1 s* (FEV_1) correlates well with the severity of obstructive diseases. *The maximal mid-expiratory flow rate* ($MMEF_{25–75}$), the average flow during the middle 50% of the forced vital capacity, is more reliable in mild airway obstruction. The construction of flow–volume relationships during the forced vital capacity maneuvers can also be used and is particularly helpful in relating expiratory flows as a function of lung volume.

Spirometry is used to measure VC and its subdivisions and expiratory (or inspiratory) flow rates. A simple manometer can measure the maximal inspiratory and expiratory force a subject generates, normally at least 30 cm H_2O, which is useful in evaluating the neuromuscular component of ventilation. Normal values for pulmonary function tests such as VC, FRC, TLC, and residual volume are obtained from equations based on body height. Caution must be exercised to make sure that the prediction equations from which normative values are obtained are appropriate for the patient in question since often these equations are derived from studies using children that may have different skeletal structures and proportions. Flow rates measured by spirometry usually include the FEV_1 and $MMEF_{25–75}$ but more information can result from a maximal expiratory flow–volume curve where expiratory flow rate is plotted against expired lung volume. Expiratory flow rates at low lung volumes ($<$50% VC) are influenced by small airways than are flow rates at higher lung volumes. The flow rate at 25% VC (V_{25}) is a useful index of small airway function. Low flow rates at high lung volumes associated with normal flow at low lung volumes suggest upper airway obstruction.

Plethysmography is used to measure *airway resistance* (R_{AW}) or, alternatively, the reciprocal of R_{AW}, airway conductance (G_{AW}). Because airway resistance measurements vary with the lung volume at which they are taken, it is convenient to use specific airway resistance, SR_{AW} ($SR_{AW} = R_{AW}$/lung volume), which is nearly constant in subjects older than 6 years of age (normally $<$7 s/cm H_2O). The *diffusing capacity for carbon monoxide* (DLCO) is a measure of oxygen diffusion and is assessed by rebreathing from a container having a known initial concentration of carbon monoxide (CO) or by using a single breath technique. A decrease in DLCO reflects a decrease in effective alveolar-capillary surface area or a decrease in diffusibility of the gas across the

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_223,

alveolar-capillary membrane. Primary diffusion abnormalities are unusual in children but this test is most frequently employed in children with cancer exposed to toxic drugs to the lungs or to chest wall radiation. Regional gas exchange can be conveniently estimated with the perfusion–ventilation xenon scan. *Exercise testing* is a more direct approach for detecting diffusion impairment as well as other forms of respiratory disease. This testing involves a variety of measurements, including heart and respiratory rate, minute ventilation, oxygen consumption, carbon dioxide production, and arterial blood gases during incremental exercise loads. This often provides invaluable information about the functional nature of the disease. Often, a simple assessment of the patient's exercise tolerance in conjunction with other, more static forms of respiratory function testing can allow a distinction between respiratory and nonrespiratory (e.g., cardiovascular) disease in children.

The most important limitations of these function tests are related to the fact that most of them require cooperation by the patient. Hence, the interpretation is facilitated if the test conditions and the patient's behavior during the test are known. Infants and young children who cannot or will not cooperate with test procedures can be studied in a limited number of ways, often requiring sedation, which can affect the very measurements that are being made. Flow rates and pressures during tidal breathing, with or without transient interruption of the flow, may be useful to assess some aspects of airway resistance or obstruction and to measure compliance of the lungs and thorax. Expiratory flow rates can be studied in sedated infants with passive compression of the chest and abdomen with a rapidly inflatable jacket. Gas dilution or plethysmographic methods can also be used in sedated infants to measure FRC and R_{AW}.

In summary, pulmonary function tests are useful in (a) monitoring and diagnosing pathological processes such as restrictive and obstructive disease, (b) the degree of functional impairment in lung function, (c) estimating the prognosis, (d) studying the reversibility of disease as in patients with obstructive disease and bronchodilator therapy, (e) in preoperative evaluation, and finally (f) in confirmation of functional impairment in patients having subjective complaints but with a normal physical examination.

Blood Gases

Although in the presence of hypoxemia the color of the skin is changed to that of cyanosis, this usually occurs when hypoxemia is rather severe. This change in color however is often influenced by skin color, perfusion, and blood hemoglobin concentration, and the clinical detection by inspection is an unreliable sign of hypoxemia. Although blood gas analysis does not specify the cause of the condition/disease or the specific nature of the disease, this analysis is a very useful rapid test of pulmonary function as it can give an assessment of the *overall functional state* of the respiratory system. In addition, arterial blood gases can give clues about the *pathogenesis of the disease*. Blood gas exchange is evaluated by the direct measurement of arterial PO_2, PCO_2, and pH. The blood specimen is collected anaerobically in a heparinized syringe. The syringe should be sealed, placed in ice, and carried to the laboratory for immediate analysis. These measurements require arterial puncture and this is one reason why PO_2, by and large, has been well replaced to a great extent by noninvasive monitoring of O_2 saturation.

The age and clinical condition of the patient need to be taken into account when interpreting blood gas tensions. With the exception of neonates, values of arterial PO_2 $<$85 mmHg are usually abnormal for a child breathing room air at sea level. Calculation of the alveolar-arterial oxygen gradient is useful in the analysis of arterial oxygenation, particularly when the patient is not breathing room air or in the presence of hypercapnia. Values of arterial PCO_2 $>$ 45 mmHg usually indicate hypoventilation or a severe ventilation–perfusion (V/Q) mismatch. This is usually associated with a low PO_2 as well when indicative of hypoventilation. A low PO_2 with no change or a decrease in PCO_2 is usually indicative of V/Q mismatch in children.

Sleep Studies

Sleep states have an important influence on respiratory function in children and particularly in the newborn and young infant. The gold standard to assess pulmonary function, especially for obstructive sleep apnea and hypoventilation syndromes, is polysomnography. Such studies are often helpful when abnormalities of central respiratory control, muscular disorders, or respiratory complications from gastroesophageal reflux (GER) are suspected. pH probe studies are indicated and are added to such sleep studies when GER is suspected. In these studies, a pH probe is placed in the esophagus and prolonged (usually over several hours) monitoring is undertaken. These studies, which usually include the simultaneous assessment of ventilatory effort (pressure or volume), airway gas flow, blood gases or O_2 saturation, and sleep state (EEG, EOG, and EMG), are also useful

in the diagnosis and management of disorders of respiratory control and nocturnal hypoxemia and hypercapnia in children with chronic and ill-defined respiratory disease.

224 Diagnostic Imaging and Procedures

Julie Ryu

Chest Radiographs (CXR)

Chest radiographs are the most commonly performed imaging tests in children. When interpreting a CXR, a systematic approach is often helpful.

1. Lung volume: An overview of lung volume can give clues to the general respiratory state such as hypoventilation (low volumes) or air trapping (increased volumes).
2. Symmetry: Asymmetric lung volumes can indicate either ipsilateral or contralateral lung pathology (pneumothorax, lobar pneumonia, etc.) versus symmetric (general or diffuse processes such as viral infection, muscle weakness, etc.).
3. Airway: Is the trachea midline? The trachea may be shifted toward an area of collapse or away from an area of fluid or air collection. Is the trachea narrowed? Vascular compression or mediastinal masses can impinge on the trachea making the trachea appear narrowed or deviated.
4. Pulmonary vasculature: Are the vessels prominent? Overflow circulation due to left-to-right cardiac shunting can dilate pulmonary vessels. A pruning effect can also be seen in the peripheral vessels due to vascular constriction in conditions such as pulmonary hypertension.
5. Parenchyma: Diffuse opacities? Viral infections, pulmonary edema, or an interstitial process can appear diffusely. Localized? Bacterial infections, fungal infections, and abscesses are often localized to one area or distinct areas.
6. Pleural space: This is a potential space, so anytime it is visible it is abnormal. Pleural fluid should be assessed for loculations by ordering a lateral decubitus film with the suspected side down; if fluid is free flowing, it should spread evenly across the dependent side. If a pneumothorax or hydropneumothorax is suspected and an upright film is not helpful or possible, a lateral decubitus film with the contralateral side down (since air will rise to the highest point) may be useful.

CXRs can be extremely helpful as an initial diagnostic tool, but often additional diagnostic imaging is required to diagnose the condition suspected. Common uses for other diagnostic tools are summarized in ◉ *Table 224.1* and discussed in detail in their respective sections.

Computer Tomography (CT)

Chest CT has significantly improved not only in image quality, but also in the speed of image acquisition making this diagnostic tool much more accessible in pediatrics. In fact, since the advent of helical/spiral CTs, the need for sedation has decreased in patients less than 6 years of age. In addition, motion artifact from respiration has improved due to faster scanning techniques. However, despite the advances in imaging, CT imaging still requires much more radiation than that of CXR; it is equivalent to 25–50 CXRs in a 2-month-old child. Newer CT scanners are able to image thinner lung sections and, therefore, require more passages to image the chest resulting in higher radiation exposure than traditional CTs. Every year, the number of chest CTs ordered has increased, which has raised the concern of the accumulative risk of neoplasms in children over time. While the benefits of a single chest CT may outweigh the overall risk of radiation exposure, it is important to remember that many pediatric patients will require multiple imaging studies over their lifetimes and therefore it is important to use it judiciously and order the most appropriate test. Fortunately, new methods to lower the risk of radiation exposure in children are continually being developed to counteract this problem.

Chest CT is currently the best diagnostic tool to investigate lung parenchyma since it is the only imaging tool that allows for a cross-sectional image of the chest. Chest CT can be helpful in investigating parenchymal disease, and it is particularly helpful when interstitial lung disease is suspected. Increased density in the parenchyma indicates a loss of air in airspaces, which may suggest an infection, mass or fluid collection. When the increased attenuation is less discrete, or "ground glass" in appearance, there is partial airspace filling which may indicate an interstitial process. Since lung volumes change with respiration, it is important to note that some images may appear worse with exhalation. When there are regional differences in density, consider air trapping especially in obstructive lung diseases.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_224,

Table 224.1
General indications

CXR: general initial study
Chest CT without contrast: imaging lung parenchyma or airway
Chest CT with contrast: nodules, cavitary lesions, sequestrations, lymph nodes
MRI/angiogram: vascular lesions, cardiac malformations
Fluoscopy: dynamic airway disorders
Ultrasound: diaphragm motility, asses pleural effusions
Bronchoscopy: visualization of airway, obtain cultures

Chest CT can also be used to identify pathology in the airways. Bronchiectasis, dilation of the bronchus, can readily be identified on CT. In addition, bronchial wall thickness and lumen obstruction can also be visualized.

Chest CT can be used to assess and treat severe pneumonias with empyema. CT-guided procedures can be helpful in the removal of loculated fluid or biopsy a lesion. The addition of intravenous contrast allows for excellent vascular imaging and can identify vascular malformations, sequestrations, and lymphadenopathy. In addition, many centers are able to reconstruct CT images to 3D images making it an excellent tool to assess anatomy.

Magnetic Resonance Imaging (MRI)

Chest MRI is rarely used to assess pediatric lung disorders since it does not image the lung parenchyma well. However, it is an excellent imaging tool to visualize vasculature and does not use any ionizing radiation as does CT and CXR but uses magnetic fields to create an image. While the advantages of MRI consist of no radiation, the time required for imaging is extensive and usually requires sedation. However, newer MR techniques such as helium-enhanced images offer potential alternatives to CT. MR imaging has been limited in the lung because the traditional MR imaging system detects hydrogen protons that are abundant in most organs but are lacking in the aerated lung. With the helium-based system, the patient inhales Helium 3 and the image is taken, detecting the existing hydrogen-based image as well as the inhaled helium. This technology therefore allows for an image that is representative of lung ventilation, much like a nuclear scan but with the resolution of a tradition MRI. While this system is not widely available, it is an example of new imaging systems currently being used to reduce radiation exposure in children with chronic lung disease that require repeated imaging.

Fluoroscopy

Airway fluoroscopy can be a useful tool in detecting airway pathologies. The advantages of airway fluoroscopy are that it requires no sedation, is quick, and can assess airway patency in real time. Thus, it is often used in the diagnosis of laryngo/tracheomalacia since the airway may appear normal on exhalation but narrows on inspiration.

Ultrasonongraphy (US)

Ultrasonography of the chest is a useful diagnostic tool that is not associated with any radiation. It can be used to distinguish chest wall masses from cystic lesion, distinguish fluid collection from pneumonia on a "white out" on CXR, and can be used to follow effusions. In addition, ultrasound can be useful in detecting diaphragm abnormalities. Ultrasound of the diaphragm can measure diaphragm thickness during contraction and therefore may be a good tool to assess patients with diaphragmatic dysfunction.

Bronchoscopy

Flexible bronchoscopy can be used as both a diagnostic as well as a therapeutic tool. In most cases, the use of a flexible bronchoscope is diagnostic. It is often used to collect bronchoalveolar fluid to identify an organism during an infection. Pediatric pulmonologists perform flexible bronchoscopy as opposed to rigid bronchoscopy which is usually performed by an otolaryngologist. The benefit of flexible bronchoscopy is the ability to reach the lower airways and the right upper lobe, which can sometimes be difficult to access with a rigid scope. Therefore, flexible bronchoscopy allows fluid samples to be obtained from a particular segment of the lung. In addition, the risk of pneumothorax and bleeding is much lower than that of a rigid scope due to the inherent flexibility of a flexible bronchoscope.

However, there are limitations to flexible bronchoscopy. The major limiting factors in pediatric flexible bronchoscopy are the size of the scope and the size of the channel. Whereas the bronchoscopes used in the adult population are able to provide excellent images in addition to a number of tools including biopsy clips, lasers, and brushing inserts, most pediatric airways are too small for these bronchoscopes. While there are currently bronchoscopes that range from 2.2 mm outer diameter and larger, the commonly used 3.5 mm bronchoscope typically

has a channel for suction (or biopsy etc.) of about 1.2 mm. While this small channel is adequate for suctioning, it is not a good tool for foreign body removal. Foreign body removal is generally a procedure performed using a rigid bronchoscope, which allows for control of the airway (and not limited to a small channel) as well as better ventilation.

Flexible bronchoscopy is a very good tool to evaluate lower airways and obtain culture specimens or cell scrapings. The procedure is safe and usually a same day procedure. Since bleeding can be a potential risk, platelet count should be at least 20 K and coagulation studies may be indicated. The patient should have nothing to eat for at least 6 h and no liquids at least 2 h prior to the procedure. Anesthesia is used to sedate the patient, and fiber-optic bronchoscope is inserted to the airways either by the nose or through an artificial airway. If inserted to the nose or laryngeal airway mask, the vocal cords can be visualized and inspected for edema or erthyema, which may suggest chronic irritation. Below the vocal cords, the trachea can be assessed for presence of tracheal rings and/or malacia. The carina, bronchi, and general mucosal appearance is noted for any swelling, friability, malacia, and quality of mucous secretions. Saline can be injected into the bronchoscope channel and the fluid sample that is obtained can be analyzed for a number of different studies. Common studies include cell count which may help identify the likelihood of infection (increased neutrophils) or certain disorders such as collagen vascular disease (increased lymphocytes). In addition to the type and number of cells present in a BAL sample, specialized studies can be performed to analyze cell surface markers and detect malignant cells. Macrophages can also be stained for lipid or hemosiderin. Lipid-laden macrophages are often present with chronic microaspiration, and hemosiderin is found in patients with hemoptysis. BAL fluid can also be gram stained, cultured for bacteria, viruses, and fungi. Although cultures can always be sent, if the patient is receiving antibiotics, the probability of identifying a bacterial organism lowers with time. Contraindications for the procedure may include a unstable airway, respiratory failure or a platelet count under 20,000. Risks include bleeding, hypoxia, and infection. Although the risk of a pneumothorax is possible, the possibility is much lower than during rigid bronchoscopy.

While bronchoscopy is a valuable diagnostic tool, new technologies have to be developed to fully utilize this modality. As imaging equipment becomes smaller and the ability to assay bronchoalveolar lavage improves, the utility of bronchoscopy will increase in the pediatric population.

225 Respiratory Failure

Gabriel G. Haddad · Erin R. Stucky

Definition/Classification

Respiratory failure is defined as failure of gas exchange to meet metabolic demands. In an otherwise healthy child, this is present when there is hypoxemia with measured arterial oxygen level (PaO_2) of less than 60 mmHg or hypercarbia with measured arterial carbon dioxide level ($PaCO_2$) greater than 50 mmHg. Other definitions distinguish between these states as *Type 1* versus *Type 2* or oxygenation versus ventilation respiratory failure. Most authorities agree that acute respiratory failure is that which develops over hours where chronic is reserved for states evolving over days or longer.

Although not all cases of respiratory failure are due to acute lung injury (ALI) or progress to the acute respiratory distress syndrome (ARDS), understanding these terms is important when evaluating respiratory failure. The 1993 American–European Consensus Conference (AECC) provided a new definition of ALI and ARDS as "a syndrome of inflammation and increased permeability that is associated with a constellation of clinical, radiological, and physiological abnormalities that cannot be explained by, but may co-exist with, left atrial or pulmonary capillary hypertension." Specifically, both are associated with a pulmonary capillary occlusion pressure of less than 18 mmHg and bilateral infiltrates on chest radiography. ARDS is characterized by more severe hypoxemia, with ALI defined by a $PaO_2/FiO_2 < 300$ and ARDS by a $PaO_2/FiO_2 < 200$, both regardless of positive end-expiratory pressure level.

Etiology

Causes of respiratory failure fall into three large categories: failure of air delivery/release (obstruction), failure of appropriate pulmonary gas exchange, and failure of neuromuscular or central control over respiratory drive. Specific causes of acute and chronic respiratory failure in children differ from those of adults. Common etiologies in acute cases include primarily large and distal airway infections, status asthmaticus, direct lung injury, or acute traumatic or medication-induced loss of central respiratory control. Chronic etiologies include congenital or acquired lung maldevelopment, systemic diseases with progressive pulmonary involvement, complex congenital heart disease, disorders of central nervous system control with loss of airway protective mechanisms, and neuromuscular disorders with respiratory muscle weakness. These states may present with failure within a short period (months of age) or evolve over years.

Epidemiology

True incidence of all-cause pediatric respiratory failure as defined above is not well documented in all countries and varies widely from 9.7 to 77 per 100,000 person-years in the United States and Europe. Pediatric morbidity and mortality from respiratory failure in developed countries is best approximated by international data on ALI and ARDS. Rates reported by the AECC and others vary from 1% to 9%, with population incidence in 100,000 person-years of 2.95–3.4 in Germany, Australia, and New Zealand to as high as 12.8 in areas of the United States and 17.9 in Sweden.

There are few published reports on pediatric respiratory failure from developing countries. Worldwide, pneumonia is the most common risk factor, and toddlers are the most commonly affected age group. The World Health Organization reports that pneumonia is responsible for about 19% of all deaths in children aged less than 5 years, of which more than 70% take place in ten countries in sub-Saharan Africa and south-east Asia.

Pathogenesis

Physiology

The most frequent cause of respiratory failure is hypoxemia due most commonly to three main pathophysiologic derangements: hypoventilation, ventilation/perfusion (V/Q)mismatch, and shunting. The PO_2 of alveolar gas is determined mostly by the balance of oxygen removal from and delivery to the alveoli, and therefore affected primarily by the level of alveolar ventilation. When

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_225,

ventilation drops in hypoventilation, oxygen levels fall and carbon dioxide levels rise, leading to a high $PaCO_2$. In contrast to hypoventilation, the $PaCO_2$ in V/Q mismatch is usually normal or low. In V/Q mismatch, areas of poor ventilation (low V) receive continued blood flow (Q), resulting in a low V/Q ratio (less than the normal ratio of 1). At baseline, there is always a small amount of intrapulmonary shunting through bronchial vessels and coronary veins. V/Q ratios vary by lung segment and by lobe, with ratios greater than 1 in the apices. However, increasing perfusion to well-ventilated areas cannot compensate for continued blood flow to poorly ventilated areas, due to limitations of the oxyhemoglobin dissociation curve (*Fig. 225.1*). Oxygen therapy can aid in less severe forms of V/Q mismatch; however, when 30% or more of blood flow is shunted, supplemental oxygen does not correct the hypoxemia. When V/Q reaches zero, a state of intrapulmonary shunting is present, where the perfused lung is not ventilated. In this state, chemoreceptors stimulate an increase in minute ventilation in an attempt to increase oxygen delivery. Pulmonary vasoconstriction causing increased pulmonary vascular resistance also occurs in an attempt to limit blood flow to unventilated alveoli. At the other extreme, when V/Q reaches infinity, ventilated lung is not perfused resulting in alveolar dead space. At baseline, there is always some physiologic dead space due to a combination of normal alveolar dead-space ventilation as well as anatomic dead space caused by air in conducting airways that does not participate in gas exchange. Pathologic increases in alveolar dead space are seen with abnormal pulmonary blood flow resulting in both hypoxemia and hypercarbia.

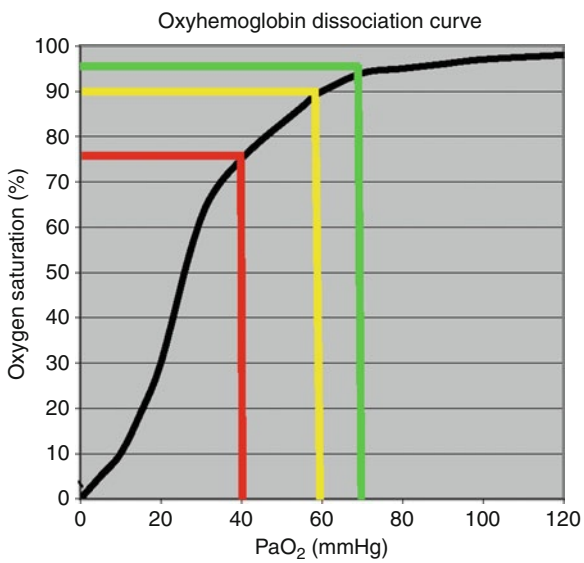

Figure 225.1
Oxyhemoglobin dissociation curve with key points noted: oxygen saturation of 94%–70 mmHg PaO_2 (green); 90%–60 mmHg PaO_2 (yellow); 75%–40 mmHg PaO_2 (red)

Ventilation failure, or failure to exhale gases, is due predominantly to a deficiency of alveolar ventilation with or without excessive production of CO_2. Compared to *Type I* respiratory failure where hypoxemia is accompanied by normal or low $PaCO_2$, *Type II* is characterized by both hypoxemia and hypercarbia. *Type II* can be thought of as excessive respiratory workload that exceeds the patient's gas exchange capacity.

Risk Factors

Children are at greater risk for respiratory failure than adults, with differences in each of the three large etiologic categories previously mentioned. Airway obstruction occurs more readily due to the relatively limited cartilage support of airway, small airway diameter, large tongue, larger and more horizontally placed epiglottis, narrow subglottis, and cephalad position of the larynx. Gas exchange is limited by fewer and smaller alveoli and fewer collateral channels for ventilation between alveoli (pores of Kohn, Lambert channels). Respiratory drive is affected by immature central respiratory control in young infants, underdeveloped respiratory muscles, and a compliant chest wall. Risk of respiratory failure is also dependent on other important components of oxygen delivery, including hemoglobin level and cardiac output.

Genetic risk factor studies have focused on predicting development of ALI and ARDS. The proinflammatory cytokine interleukin-1 (IL-1) induces expression of other cytokines and chemokines involved in the inflammatory response. IL-1 is also involved in the fibroproliferative response in ALI and ARDS. Levels of IL-1ra and IL-1 are increased in bronchoalveolar lavage and pulmonary edema fluid from adult patients with early ALI or ARDS. A genetic polymorphism in the IL-1ra gene is associated with variation in IL-1ra and IL-1 activity. In children with community-acquired pneumonia, absence of an allele at the IL-1 receptor antagonist site has been reported in association development of ALI or ARDS. Other studies of ARDS risk target angiotensin II, which in alveolar epithelial cells stimulates the production of pro-inflammatory mediators and is involved in apoptosis (programmed cell death). A polymorphism in the angiotensin-converting enzyme (ACE) gene has been found, which affects production of

angiotensin II. In animal models of ALI, deficiency of ACE is associated with reduced pulmonary edema formation and leukocyte infiltration.

Pathology

Lung pathology varies with the etiologic agent. In ALI and ARDS, specific histopathological patterns are noted. Diffuse alveolar damage is the most commonly reported pattern seen at autopsy and is defined as interstitial edema, neutrophils in diffuse distribution, alveolar collapse, and hyaline membranes. Pulmonary edema is also frequently noted, evidenced by leakage of plasma proteins and fluid into alveoli. Alveolar hemorrhage or pulmonary emboli are less commonly seen (9% and 5–20% of cases, respectively). Interstitial inflammation with monocytes, lymphocytes, histiocytes, and plasma cells and organizing fibrosis can be seen more often in HIV patients. The extent of all types of inflammation varies based on the production of pro- versus anti-inflammatory cytokines.

Clinical Manifestations

Signs and symptoms of respiratory failure include changes in vital signs, mental status, and oxygenation-ventilation status. Young infants may progress rapidly and have little cardiopulmonary reserve and limited compensatory mechanisms. Children with chronic cardiopulmonary disease who have baseline abnormal ventilation may present insidiously. During acute decompensation, these children may demonstrate only mild alterations of respiration and instead show predominantly behavioral changes. These changes are related to acute plus chronic hypoxia causing sleep fragmentation resulting in irritability, tiredness, morning headaches, and restlessness.

While specific respiratory distress scoring systems have been created for conditions such as asthma and bronchiolitis, general characteristics of respiratory compromise regardless of underlying etiology are noted in *Table 225.1*.

Cardiovascular findings accompanying severe respiratory distress or respiratory failure include tachycardia, poor perfusion, and hyper- or hypotension depending on stage of catecholamine release or depletion. Children with severe asthma may demonstrate pulsus paradoxus. Pulsus paradoxus primarily reflects a decline in left ventricular stroke volume, noted as a decline in systolic and pulse pressures upon inspiration. It may be evident by watching oxygen saturation waveform for changes of 25% or greater during respiration.

Diagnosis

Diagnosis of respiratory failure is based on interpretation of history and physical examination findings and blood gas results. Arterial blood gas (ABG) is preferred whenever reasonable, weighing the benefits of accurate PaO_2 measurement against the invasiveness of testing. While venous blood gas (VBG) measurements of pH, carbon dioxide, and base deficit differ slightly from an arterial sample, VBG has been proven as accurate as ABG where

Table 225.1
Signs and symptoms of severe respiratory distress progressing to respiratory failure (noted with *arrows*)

Parameter	Infant	Child
Respiratory rate	>70 breaths/min → erratic	>50 breaths/min → erratic
Retractions	Subcostal →intercostal; may also have suprasternal	Same as with infant
Respiratory effort	Grunting, head bobbing, nasal flaring → intermittent apnea	May prefer upright sitting position→"tripod" position, breathlessness, unable to speak
Air entry	Significantly decreased →absent especially at bases	Same as with infant
Color	Pallor →acrocyanosis → central cyanosis	Pallor → cyanotic lips and fingertips/toes
Feeding	Poor/no feeding	Signs of dehydration, history of poor intake, and/or vomiting
Mental status	Poor eye contact → lethargic	Tired or anxious→ unable to give expected answers to questions

ventilation failure is of greatest concern. Noninvasive oxygen saturation monitoring results paired with VBG are commonly used to define respiratory failure. ABG is preferably for states of shock, congestive heart failure, and congenital heart diseases.

Determination of *Type I* versus *Type II* respiratory failure aids in placing the event into one of the three large etiologic categories. *Type I* is more commonly associated with failure of gas exchange where obstruction and failure of respiratory drive are typically *Type II*. Calculating the arterial-alveolar (A-a) gradient and assessing response to oxygen therapy can also be diagnostic. The A-a gradient can be calculated using the alveolar gas equation:

$$A\text{-}a \text{ gradient} = P_AO_2 - P_aO_2(\text{arterial}), \text{where}$$
$$PAO_2 = FIO_2(P_B - 47) - 1.2(PaCO_2)$$

P_B = barometric pressure, which at sea level is 760 mmHg, dropping with increases in elevation. If the A-a gradient is elevated above the age-dependent normal range of 5–30 mmHg, then V/Q mismatch is most likely present. However, failure to resolve hypoxemia with 100% oxygen is most often associated with shunting.

Differential Diagnosis

The list of potential etiologic causes of respiratory failure is extensive (◉ *Table 225.2*). Diagnostic studies may be supportive of the etiologic diagnosis or aid in determining the extent or severity of the effects of hypoxemia or hypercarbia.

Chemistry tests	Rising serum lactate is an indicator of significant tissue hypoxia
	Elevated bicarbonate suggests chronic hypercarbia
	Low potassium, calcium, or phosphate can impair muscle function
Hemoglobin	Polycythemia suggests chronic hypoxemia
PaO_2/FiO_2 ratio	Ratio < 200 is correlated with a shunt fraction greater than 20%
Chest radiograph	Focal or diffuse infiltrates suggest pneumonia and/or ARDS
	Bilateral hyperinflation suggests asthma
	Other helpful findings: upper airway narrowing or deviation, lobar collapse, air leak, asymmetric diaphragms, effusions, cardiomegaly, pulmonary edema

Chest CT or MRI with or without angiography may be helpful in defining parenchymal or pleural acute versus chronic disease as well as vasculitis. Pulmonary embolus can usually be defined on CT angiography or V/Q scan.

Table 225.2
Etiologies of respiratory failure (selected examples in parentheses)

Failure of air delivery/release (obstruction)		
Acute infections (croup, retropharyngeal abscess, bacterial supraglottitis, or tracheitis)	*Traumatic injury* (post-extubation, foreign body)	*Congenital airway* (subglottic stenosis/web/cyst, tracheomalacia, craniofacial anomalies, vascular slings)
	Multifactorial (obesity – obstructive)	
Failure of appropriate pulmonary gas exchange		
Acute infections (bronchiolitis, pneumonia, sepsis)	*Traumatic injury* (pulmonary contusion, drowning, inhalation lung injury, pneumothorax)	*Congenital pulmonary* (lung aplasia, congenital cystic adenomatoid malformation, diaphragmatic hernia – pulmonary hypoplasia)
Systemic (lupus, Wegener's granulomatosis, cystic fibrosis, sarcoidosis)	*Multifactorial* (chronic lung disease, asthma, pulmonary embolus, pulmonary edema)	*Cardiovascular* (congestive heart failure, cyanotic heart disease)
Failure of neuromuscular or central control over respiratory drive		
Acute infections (meningitis, meningoencephalitis, CNS abscess, infantile botulism, tetanus, polio)	*Traumatic injury* (accidental or non-accidental CNS hemorrhage, CNS shearing injury, CNS anoxic injury, spinal cord trauma)	*Musculoskeletal* (diaphragmatic hernia-muscular dysfunction, scoliosis)

Table 225.2 (Continued)

Congenital CNS (apnea of prematurity, central hypoventilation syndrome, brainstem malformations, cerebral palsy)	*Multifactorial* (sedating/paralyzing medication overdose, seizures, sleep apnea, obesity-hypoventilation, stroke, electrolyte disturbances, e.g., periodic paralysis)	*Neuromuscular* (muscular dystrophies, e.g., Duchenne, metabolic myopathies, congenital myopathies, e.g., spinal muscular atrophy, neuromuscular junction disorders, e.g., Guillan-Barré)

Other testing should be targeted at the likely underlying etiologic diagnosis in consultation with pediatric subspecialists from pulmonology, rheumatology, cardiology, or neurology.

Treatment

Basic tenants of pediatric advanced life support such as the jointly published 2005 International Consensus on Cardiopulmonary Resuscitation and Emergency Cardiovascular Care Science with Treatment Recommendations and the American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care should be followed to stabilize patients with respiratory failure.

Transfer to an intensive care setting should be considered when:

- More than 50% FiO_2 is needed to maintain an oxygen saturation $\geq$ 92%.
- Evidence of respiratory distress is accompanied by tiring or exhaustion.
- A normal $PaCO_2$ cannot be maintained with available pressure support systems.
- Apnea or irregular respirations are noted.

General treatment includes prone positioning, which increases the functional residual capacity, improving lung compliance and oxygenation. Oxygenation improves within 1–2 h after position change and is usually sustained. Other treatments critical to good outcomes include maintaining adequate perfusion, resolving acidosis, stabilizing electrolytes and glucose, maximizing nutrition, delivering appropriate sedation, and minimizing exertion or energy use.

A simplistic view of treatment that addresses the three main pathophysiologic derangements of respiratory failure includes oxygen for hypoventilation, positive pressure to maximize lung volume for shunting, and one or both of these for ventilation/perfusion (V/Q) mismatch. Oxygen delivery methods in brief include nasal cannula (preferably humidified), high-flow nasal cannula, simple face mask, oxygen box or head helmet, non-re-breather mask, laryngeal mask airway, and endotracheal or nasotracheal intubation (cuffed or uncuffed). Actual FiO_2 delivered should be monitored. Blenders are often used when FiO_2 greater than 50% is required for greater accuracy in oxygen delivery. Response to treatment should be monitored by either calculating the PaO_2/FiO_2 ratio or the oxygenation index (OI) = (Mean airway pressure (MAP) $\times$ FiO_2)/$PaO_2 \times 100\%$.

Treatment for hypercarbia has more recently focused on a permissive approach toward treatment of ALI/ARDS. Adverse effects of acidosis produced by hypercarbia maybe overstated. In fact, mortality may be decreased if permissive hypercarbia in conjunction with pressure-limited reduced tidal volume mechanical ventilation is used. As long as oxygen levels are appropriately maintained, allowance of PCO_2 in the 50 s with pH as low as 7.2 have been accepted by most intensivists, and have been associated with attenuated lung injury in animal models. However, acute rises in PCO_2 or chronic rise to levels of 100 or higher are not typically acceptable. Acute rises in PCO_2 result in intracellular acidosis, pulmonary hypertension, and dysregulation of cerebral blood flow. Monitoring of treatment response should include end-tidal CO_2.

Improvement in ventilation can assist both carbon dioxide removal and oxygen delivery. Simple and effective intervention for patients with partial airway obstruction may include oropharyngeal or nasopharyngeal airways. For other airway and parenchymal disease, delivery of positive pressure is necessary. Delivery of continuous distending pressure via nasal or mask continuous positive airway pressure (CPAP) has been successful in infants with severe respiratory distress from bronchiolitis and apnea. Noninvasive positive pressure ventilation (NPPV) using bilevel positive airway pressure (Bipap) is most often used for children past infancy with poor neuromuscular control but can be used for acute chest syndrome and pneumonia in healthy and immunocompromised patients. Bipap offers different modes beyond the traditional spontaneous modality, such as spontaneous/timed, timed, or pressure control. With the latter, assisted breaths are triggered by and synchronous with the patient, and pressure delivery is limited making this mode a closer parallel to native respiration. However, the risk of iatrogenic barotrauma

resulting in pneumothorax or pneumomediastinum is greater when delivering both inspiratory and expiratory pressure with Bipap as compared to the constant pressure delivered with CPAP. Use of Bipap in ARDS is not recommended, as over 75% of patients ultimately require intubation. Use of NPPV for asthma patients is somewhat controversial. In asthmatics, the risk of barotrauma is nine times higher in those receiving some form of ventilation assistance compared to those treated without this support. However, the risk is the same whether intubated or using NPPV. In children with neuromuscular disorders on home NPPV presenting with acute decompensation, treatment may vary from changing NPPV pressures to intubation. Infants and children receiving any form of pressure support must have continuous oxygen saturation and cardiorespiratory monitoring, CO_2 assessments, and immediate access to experienced providers who can act in response to changes in pressure readings, oxygenation and ventilation, hydration status, and mental status.

For patients requiring intubation, avoidance of ventilator-induced lung injury (VILI) includes use of end-expiratory pressure sufficient to avoid atelectasis yet not cause barotrauma. High-frequency ventilation and liquid ventilation have been used with varied outcomes. High-frequency ventilation is available in three forms: positive-pressure ventilation (HPPV) (rate 60–150/min), jet ventilation (HFJV) (rate 100–600/min), and oscillatory ventilation (HFOV) (rate 180–1,500/min or 3–25 Hz).

HPPV and HFJV promote gas exchange using tidal volumes greater than dead space volume, with passive expiration. In contrast, HFOV uses tidal volumes that are less than dead space and expiration is active. Of the three, HFOV has been used most successfully in both neonatal and old-aged patients. It is being used more often as a lung protective strategy in children with ALI regardless of cause.

Special gases are of great interest, and may be used in both intubated and non-intubated patients. Heliox, a low-density combination helium–oxygen mixture, improves ventilation by improving flow through turbulent airways. Its use in non-intubated bronchiolitis patients has been associated with improved oxygenation, respiratory rate, and retractions; however, its value in intubated patients is less conclusive. The clinical limitation to heliox use is mainly the ability to maintain adequate oxygenation. For patients requiring more than 40% FiO_2 to maintain adequate oxygenation, the 60% helium is of limited benefit in reducing turbulent flow. Inhaled nitric oxide (iNO) dilates the pulmonary vasculature and has been used primarily for pulmonary hypertension. Its use requires monitoring for methemoglobinemia in patients and for toxic NO and nitrogen dioxide gas exposure in personnel. Use of iNO in other disease states has been reported to result in up to 20% improvement in short-term oxygenation but may be associated with decreased survival when given prior to extracorporeal membrane oxygenation (ECMO). ECMO is reserved for the most extremely affected patients, but has been successfully used even in patients who are immunocompromised or have cancer.

Specific treatment for ARDS must address the acute increase and imbalance between both pro-inflammatory and anti-inflammatory cytokines. Steroids have been used in cases where autoimmune diseases or viral infections result in ARDS, with varied outcomes. It is currently unclear if steroids improve acute or chronic pulmonary outcomes in ARDS.

Future considerations target treatment and genetic testing. Expanded assessment is needed of the risks of iNO use, including potential for increased oxygen and nitrogen radical formation which may damage the alveolar epithelium. Inhaled prostacyclins have been shown in adults to decrease intrapulmonary shunts. Surfactant studies to date have been underpowered but metanalysis of the studies combined shows promise with decreased ventilator days reported. Genetic testing for ACE activity may allow for use of ACE inhibitors in select patients.

Prognosis

Prognosis is highly dependent on the cause of the respiratory failure, particularly in immunosuppressed patients. Regardless of underlying chronic disease, the highest mortality rate is seen in children with ARDS, with rates of 30–50% in the United States and as high as 50–65% in developing countries. Most patients with ARDS have multiorgan system involvement and worse Pediatric Risk of Mortality (PRISM) scores. ALI not associated with ARDS carries a mortality rate of 3–35%. For surviving patients, likelihood of long-term lung disease is thought to be related to the underlying etiology; however, few studies of long-term pulmonary function testing have been performed.

Prevention

Prevention is aimed at clinician recognition of signs and symptoms of acute respiratory distress. Clinicians should be knowledgeable regarding patients at risk for progression from acute respiratory distress to respiratory failure. Prompt diagnosis and treatment of the precipitating factors and institution of respiratory support is critical to reduce avoidable acute respiratory decompensation.

Patients with chronic pulmonary disease should have monitoring of pulmonary functions and institution of home NPPV as appropriate.

226 The Pathophysiology of Cough

Gabriel G. Haddad

Physiology of Cough

Neuroanatomy and Cough Reflex

Cough receptors are fairly widespread in the tracheobronchial tree and in various sites of the respiratory system. However, the density of these receptors is highest in the larynx, trachea, and main bronchi. Receptors are also present in the nose, pharynx, paranasal sinus, ears, pleura, and diaphragm. There are no known cough receptors in the alveoli. Outside the respiratory system, the pericardium contains receptors that are capable of stimulating cough. By far, most cough receptors are of the rapidly adapting or irritant airway receptor types. Such receptors are stimulated by numerous modalities, including mechanical (e.g., touch, deformation, pressure), and chemical (e.g., smoke, ammonia, endogenous chemical mediators, mucus). The afferent fibers travel mostly through the vagus nerve but discharges from the pharyngeal receptors are carried by the IX cranial nerve and those from the nose and paranasal sinuses through the V nerve. The pericardial and diaphragm receptors are carried through the phrenic afferents. Vagal, glossopharyngeal, and trigeminal fibers synapse in the brain stem and in particular in nucleus of the tractus solitarius (TS), a main sensory station.

After making the first synapses in the TS, projections are made on motor neurons in the ventrolateral part of the medulla oblongata, that is, the nucleus retroambiguus and ambiguous. Through vagal efferents, the laryngeal, tracheal, and bronchial muscles are activated during the cough reflex. The phrenic and intercostals motor pools are also recruited to contract the respective muscles and help in building the pulmonary pressures needed. Of clinical interest are patients who have brain stem lesions and fail to have an involuntary type when their airway receptors are stimulated. These patients continue to be able to cough on command, suggesting that they can bypass brain stem nuclei and activate a set of respiratory muscles responsible for a voluntary type of cough.

Characteristics of Cough and Mucus Clearing

The actual mechanical cough is characterized by four specific mechanical phases, each of which is distinct from the others. *First*, cough starts with a very deep and rapid *inspiratory effort*. This has the effect of achieving a more optimal thoracic volume for the subsequent phases of the cough. *Second,* a phase of *compression* immediately follows the end of inspiration. This compression results from the closure of the glottis and activation of the diaphragm and chest wall muscles to compress and splint airways and build abdominal and pleural pressures. The *expression* of cough marks the start of the *third* phase, during which there is a sudden opening of the glottis, high expiratory airflow, and an explosive sound; collapse of some airways also occurs. The *fourth* phase is marked by relaxation of the musculature and reversal of pressures and caliber of airways. Although such a cascade of events occurs in the characteristic cough, each event may not occur in every cough. For example, large inspirations or very high pressures or volumes may not take place at the onset. In addition, body position affects the strength and the efficacy of cough, as the pressures reached are higher in the sitting than in the supine position. Since the role of the cough is to remove or clear the mucus and foreign objects from the airways, it is important to review the factors that render the cough effective. In general, there are various factors that are critical:

1. *Speed of airflow*: There are various speeds of airflow and these have varied effects on mucus movements. With very "slow" airflow, air is so sluggish that it forms a noncontinuous flow without affecting the transport of the mucus toward the mouth. Annular or misty airflows are much higher and continuous flows, reaching a speed of 280 m/s. These flows can be very effective. They may put enough pressure on the mucus to move it on the periciliary fluid. If the airflow is extremely high, such flows may blow the mucus into droplets.
2. *Mucus rheology*: It should be intuitively clear that the more viscous and the less elastic the mucus is, the

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_226,

more difficult it is to affect its transport. This is evident when one considers, for instance, the nature of the secretions in cystic fibrosis and chronic obstructive lung disease.

3. *Size of inspiration and expiration*: The higher the volume inspired and the shorter the expiratory phase, the higher the airflow and the higher the probability for the cough to clear secretions.
4. *Pump structure*: Since the strength of cough depends on the structure of the airways and their integrity, pathology in the airway walls may affect the ability of the cough to affect secretion movements: any exaggerated collapse of the airways during expiration should severely limit the forcefulness of the cough (e.g., tracheomalacia in the premature infant). Another good example would be the limited effect of cough in patients with bronchiectasis because of outpouchings in the airways.

From the information above, it can be seen that cough would be very ineffective in cases where the *airflow* is relatively low, such as in obstructive disease of various etiologies and nature, and when the nature of the *mucus* is affected by inflammation, debris, cellular material (DNA), and increased amount of secretion. Cough can also be jeopardized when respiratory *muscles* do not generate the necessary pressures (i.e., weak, paralyzed, fatigued) and when the *airways* cannot be well splinted because of airway wall pathology or extraluminal compression by space-occupying masses. Hence, both pulmonary and extrapulmonary disease can contribute to the inefficiencies of the cough reflex and can therefore potentially exacerbate lung diseases.

Cough and Clinical Conditions

Frequency and Intensity of Cough

The frequency of cough varies considerably from condition to condition and depending on the state of consciousness. First, it is important to realize that there is no correlation between disease severity and frequency of cough. In some studies, the number of coughs per day in patients with upper respiratory tract infections was much higher than the number seen in patients with active tuberculosis. In addition, the frequency of cough depends on the time of day and whether the individual is awake or asleep, with the frequency of cough being higher upon waking up and much lower between 12 midnight and 6 a.m., especially during rapid eye movement sleep. It is not clear also whether the sensitivity to cough increases in patients with increased cough. Adult studies have shown that in patients with productive or dry cough, such as in chronic obstructive lung disease and bronchiectasis, the dose of capsaicin needed to elicit three to five coughs is not increased. More such studies need to be performed to resolve the issue in both adults and children.

Etiology of the Cough

Often the pediatrician or pediatric pulmonologist is faced with questions pertaining to the etiology of cough. Clearly, if the child has an acute episode of an upper respiratory infection and the disease is in the acute stage, there will be little need for investigation. It is only when a condition has moved into a chronic stage that certain testing needs to be done. Chronic cough can be defined as a cough that has lasted 4 weeks or more and has not resolved. Of major importance is the need for asking the right historical questions to delineate the etiology of the disease process. Some of these are: What is the nature of the cough? Is it productive or dry? What does it sound like? What is the cough associated with? What makes it better or worse? What time of the day does it occur? Does it occur during sleep? Is it related to position? Feeding? Exercise? Cold air? Is it seasonal? Is it associated with constitutional symptoms, such as fever, weight loss? Is the cough responsive to medications such as bronchodilators? Steroids? Since the cough reflex is really a manifestation not only of pulmonary disease but also of extrapulmonary conditions, the physical exam should be complete. In particular, a complete chest, lungs, and heart exam should be done. An ear, nose, and throat exam is very important as well to rule out etiologies in these organs that can produce cough. The presence of digital clubbing would indicate chronicity, although this is not pathognomonic to any particular lung disease, and should therefore be checked.

Establishing a Diagnosis

Besides an adequate history and physical examination, some laboratory tests may be essential depending on the disease. For example, depending on the suspected etiology, some or all of the following tests should be entertained: chest x-ray and sinus films, including sinus computerized tomography; sweat chloride test; barium swallow or esophageal pH; immunologic studies; Cilia biopsy for electron microscopy studies and ciliary function (beat frequency) assessment; and pulmonary function tests

(PFTs). PFTs are important as they may give clues about occult reactive airway disease and data on whether the disease pattern is obstructive or restrictive.

One of the most important factors, however, is age. In general, the etiologies of cough may be divided into three *age groups*, based on the causes of chronic cough. For example, congenital anomalies, such as tracheoesophageal fistula, would be important to consider in the first few months of life. Similarly, viral infections, such as respiratory syncytial virus (RSV) and especially Chlamydia, are notorious at this age. In the preschool child, foreign body aspiration and reactive airway disease become important diagnostic possibilities. In the older child and adolescent, psychogenic cough and irritative cough, such as due to smoking should be considered. In addition to these conditions, infections whether viral or bacterial, cystic fibrosis (CF), aspiration syndromes from gastroesophageal reflux (GER) or lack of coordination of pharyngeal muscles, and exposure to smoke should always be entertained. Rarer conditions would include restrictive diseases, pulmonary vascular disease, and tumors. Also of importance, the determination of the etiology for the cough can be aided by association of the cough with other symptoms. Chronic illness with high fevers and repeated lung infections should lead to suspicion of immune disorders. Hemoptysis with cough is often present in CF, tuberculosis, or bronchiectasis. Recurrent episodes of cough and lung infections with ear or sinus infections should point possibly to primary ciliary disease of the airways, such as Kartagener syndrome. In addition, the nature of the cough and the associated breath sounds on chest exam should be illuminating. For example, paroxysmal coughing should point to the etiologic agents of *Chlamydia* or pertussis. Recurrent cough with wheeze should point to the presence of airway obstructive disease.

Complications of Cough

Cough, as a symptom, is an important expression of diseased or abnormal airways. Hence, it is very important to monitor the cough in order to determine the effect of therapy or the natural course of the disease entity itself. In addition, although it is important not to interfere with cough, cough in some instances can be so "abrasive" and severe that complications can result from it. These complications may be relatively benign or really severe. Complications of cough include rupture of small nasal veins or may be so severe to result in loss of consciousness, fractures, rupture, or perforation of the esophagus, bronchus, or bladder; or air in the mediastinum, peritoneum, and pleural space.

Drug Therapy for Cough

It is when cough is severe and complications are occurring from the cough itself that drug therapy is indicated. Various agents have been tried, and some have proven to be effective. Opiods are the longest known antitussive, but their mechanism of action is not well delineated. They are thought to decrease the sensitivity of the cough reflex mainly by a central effect. Antihistaminics are sedatives and can alleviate the cough associated with asthma effectively in a fashion similar to steroids and cromoglycate, although the mechanism of action of these agents is likely to be very different. Administration of local anesthetics through lozenges or sprays to blunt the sensitivity of the reflex has also been used.

227 Chest Pain

John Moore

Introduction

Because adults presenting with chest pain frequently have serious and life-threatening conditions, parents often bring their child complaining of chest pain to the emergency department or the pediatrician's office for evaluation. It is fortunate, however, that most children with chest pain have a benign condition.

Case #1

A 14-year-old female was brought to the emergency department complaining of left chest pain. She was playing soccer with her team earlier in the day and had the sudden onset of sharp left chest pain after running the field. The pain was aggravated by taking a deep breath. On shallow breathing she had little discomfort. Her examination showed no respiratory distress and her oxygen saturation was 98% in room air. Auscultation of her chest was unremarkable. A chest x-ray was obtained (*Figs. 227.1* and *227.2*). She was found to have a small left apical pneumothorax. She was admitted to the hospital and treated with nasal oxygen.

Case #2

A 10-year-old male was brought to the emergency department complaining of substernal chest pain. It was intermittent, aggravated by exercise and relieved by resting. He denied other symptoms such as palpitations and syncope. Family history was not remarkable for sudden unexplained death, syncope, or heart disease in younger members. His examination showed no distress, normal vital signs, and a grade 2 systolic ejection murmur at the left upper sternal border. His electrocardiogram in the emergency department showed left ventricular hypertrophy (*Fig. 227.3*). Cardiology consultation revealed hypertrophic cardiomyopathy. He was treated with beta blockers and followed by the cardiology service.

Epidemiology

Up to 0.6% of patients evaluated in pediatric outpatient clinics and pediatric emergency departments have a chief complaint of chest pain. The peak age of presentation is between 12 and 14 years old, and there is no sex predilection. The age of presentation is at least partially dependent on communication skills. Very young children or infants, for example, may experience pain but manifest irritability or other less specific complaints. Studies investigating the etiologies of pediatric chest pain in emergency departments and outpatient clinics suffer from lack of consistency in methods of evaluation and diagnostic categories. Nevertheless, existing studies suggest that the large majority of cases are of idiopathic, psychogenic, or musculoskeletal origin, and have a benign prognosis. Pain, caused by diseases of the respiratory system, are less common and may be more significant. Cardiovascular pain is uncommon even in emergency departments of hospitals harboring significant pediatric cardiovascular surgery programs. However, chest pain of cardiovascular origin, as in adult patients, may be caused by serious cardiovascular disease.

Pathogenesis

Chest pain is caused by inflammation, trauma, or ischemia to tissues with sensory nerve fibers in the chest cavity. The lung parenchyma and the visceral pleura of the lung are not innervated. The lung parietal pleura, however, is densely innervated by intercostal and diaphragmatic nerves, which localize pain to the pleura. This type of pain may be identified by deep inspiration but not usually by palpation. In addition, the center part of the diaphragm is innervated by the vagus nerve, and the sensory afferent fibers enter the cervical cord. Thus, pain originating from the adjacent parietal pleura may also be referred to the neck and the shoulder. Other deep viscera in the mediastinum such as the heart, pericardium, aorta, bronchi, and esophagus have sensory innervations carried via the vagus

nerve and may have somewhat irregular density and distribution of fibers such that sensation is more diffuse and more difficult for patients to describe and to localize. Skin, subcutaneous tissue, and chest wall structures (bone, muscle, and cartilage) are highly innervated by cutaneous nerves, which allow specific localization of pain to the chest wall.

Pathology and Differential Diagnosis

The differential diagnosis of chest pain in children is extensive because of the numerous chest structures which are vulnerable to pain producing stresses or pathology.

Idiopathic

Idiopathic pain is pain with no identifiable cause and without apparent pathophysiology. It has been common in some pediatric series. Idiopathic pain may be chronic or recurrent. One type of idiopathic pain known as the *precordial catch syndrome* is often classified with chest wall pain. However, because this pain has no accepted source or known pathophysiology, it should be considered to be a type of idiopathic pain. It is usually left-sided and manifested by a "popping" or "ripping" sensation of seconds to minutes duration. Deep breathing typically intensifies this pain.

Musculoskeletal Causes

Musculoskeletal chest pain has multiple causes and is extremely common. Trauma or muscle strain may be related to normal activities of daily living among rapidly growing youths. Breast enlargement or pectus deformities may accentuate these effects. *Slipping rib syndrome* is pain caused by lack of attachment of ribs 8, 9, and/or 10 to the sternum and results in their excess mobility. This causes stretch or irritation of the intercostal nerves. Costochondritis is very common and is caused by inflammation of the costochondral junctions, possibly related to growth, exercise, or trauma. It most commonly involves the second, third, fourth or the fifth costal cartilages. *Tietze's syndrome* may be a specific severe form of costochondritis. It is characterized by nonsuppurative, fusiform, or spindle-shaped swelling often at the right sternoclavicular or second chondrosternal junction. *Hypersensitive xiphoid syndrome*, caused by inflammation of the the xiphoid process, is related to trauma or strain of the abdominal muscles which insert into it. Myositis of the chest wall muscles may be caused by connective tissue disorders or by viral inflammation. *Epidemic pleurodynia* is relatively common and is caused by Coxsackie virus. Shingles is infection by herpes zoster along a dermatome distribution causing severe localized chest pain. Cutaneous vesicles may follow pain by several days. Finally, sickle

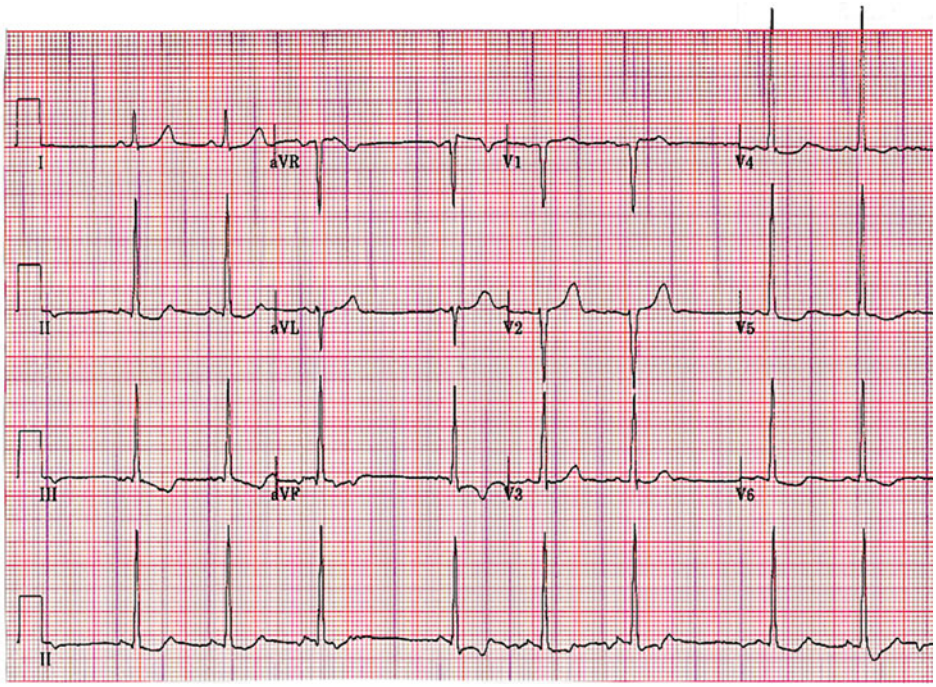

Figure 227.3
Twelve-lead electrocardiogram of 10-year-old male with substernal pain on exertion. The patient has voltage criteria for left ventricular hypertrophy (and premature atrial contractions with block)

cell disease may have numerous presentations including *acute chest syndrome*. The pathophysiology has been attributed to fat embolism, infection, or bony infarction.

Psychogenic Factors

Many children and adolescents under situational stresses or with neurotic disorders report chest pain. There may be specific identifiable stresses or a role model such as a family member or members who died or developed serious illnesses after reporting chest pain. There will often be a discrepancy between objective findings and reported symptoms. There may be primary or secondary gain from the pain, such as missing school. In addition, both hyperventilation syndrome and panic disorder may present with chest pain.

Pulmonary Disorders

Bronchitis, pneumonia, asthma, and cystic fibrosis may all cause chest pain (with accompanying dyspnea or respiratory distress) from muscle strain related to persistent cough or difficulty breathing. Bronchitis may also cause chest pain because of inflammation of the large airways. Inflammation of the parietal pleura may be a consequence of pneumonia or malignancies. Disease of the pleura may also result in pleural effusion, which further aggravates dyspnea and cough. Pneumothorax resulting in chest pain and dyspnea may occur spontaneously, with trauma, or postoperatively. It is specifically associated with Marfan's syndrome and cystic fibrosis. Airway foreign bodies may cause chest pain in younger patients related to cough and dyspnea. Pulmonary embolism, though rare in childhood, causes chest pain, dyspnea, and hemoptysis. Risk factors for thrombus formation and pulmonary embolism include taking oral contraceptives, presence of a central venous catheter, and the postoperative state.

Gastrointestinal Disorders

Esophagitis from gastric acid reflux or infection may cause chest pain. Esophageal spasm may also be a cause. Peptic ulcers and other subphrenic disease processes may also cause epigastric pain, which may be reported as chest pain.

Cardiac Disorders

The least common and perhaps most serious type of chest pain is caused by cardiac disease. There are multiple possible etiologies, but only three major pathophysiologies of cardiac chest pain: myocardial oxygen supply demand mismatch, irritation or inflammation of the pericardium, and dissection of the aorta. Other symptoms such as palpitations (suggesting arrhythmias) may be reported as cardiac pain, and pain may be associated with additional symptoms such as syncope and near-syncope. Several coronary artery diseases may cause myocardial ischemia related to inadequate coronary blood flow: Congenital defects include anomalous origin of the left coronary artery from the pulmonary artery (ALCAPA). Ischemic chest pain occurs first in infants when the pulmonary vascular resistance falls. If this disease is not detected, coronary artery collaterals may develop from the right coronary artery system and ischemic pain may occur later in life during exertion. Coronary artery fistula, another congenital anomaly, may cause pain by coronary artery steal and related localized coronary insufficiency. The most common acquired coronary artery disease is Kawasaki disease. Typical patients are toddlers or young children a small percentage of which develop coronary artery aneurysms. "Atypical" patients may be older children or teenagers. Aneurysms may predispose to coronary insufficiency by thrombus formation or by healing with areas of coronary artery stenosis. Older children and teenagers may also manifest coronary artery–related ischemic chest pain because of Prinzmetal angina (coronary artery spasm), myocardial bridging, coronary ostium stenosis, or abnormal course and origin of the coronary arteries. Coronary artery spasm may also be induced by cocaine abuse, and may rarely be caused by postoperative scarring in patients with previous cardiac surgery involving the coronary arteries or the aortic root (e.g., transposition of the great arteries). Myocardial ischemia and related chest pain may also be caused by other cardiac conditions with normal coronary arteries. These include severe left ventricular outflow tract obstruction from valve or sub-valve aortic stenosis or hypertrophic cardiomyopathy and severely depressed cardiac output related to end-stage dilated cardiomyopathy or acute severe mitral regurgitation. Mitral valve prolapse may also cause "atypical" chest pain. The pathophysiology of this pain is believed to be related to localized papillary muscle ischemia. Irritation or inflammation of the pericardium resulting in chest pain may occur in pericarditis or in myopericarditis. These conditions most often have a viral etiology, but may also be caused by bacterial infections, tuberculosis, collagen vascular diseases, uremia, and Kawasaki disease. Postpericardiectomy syndrome may occur several days or weeks after cardiac or chest surgery, and chest trauma may cause injury and inflammation to the pericardium resulting in pericardial-type pain. Finally, patients with connective tissue disorders, most commonly Marfan's disease, may experience severe chest pain from dissection of the aorta.

Malignancies

Thoracic tumors of various sorts including lymphomas and malignant cardiac tumors may cause chest pain by their mass effects.

Evaluation

Because chest pain may rarely be a prominent symptom of a serious and/or life-threatening disorder in children, chest pain should be approached seriously and should receive a thorough, systematic evaluation. A major purpose of the emergency room or clinic evaluation is to screen for serious or life-threatening disorders. In general, this may be accomplished by a thorough history and physical examination, and a few simple laboratory tests.

Keeping in mind the innervations of chest structures, the differential diagnosis, and the epidemiology of pediatric chest pain, the diagnosis or at least the diagnostic category should be strongly suggested by a detailed history of the present illness, a past medical history, a review of symptoms, and a family history. As in most pediatric evaluations, information should be obtained both from the patient directly and from adult family members or guardians. Details about the pain should be identified: acute or chronic/recurrent, severity, localization, description/character, factors which aggravate or alleviate, duration, and timing. Any associated symptoms and their relationship to the pain should be determined. Use of medications, accidental ingestions, drug abuse, and behavioral or psychiatric conditions should be solicited. History of exposure to infectious diseases, previous medical problems, chronic medical conditions, prior surgeries, and trauma should be ascertained. Family history of chest pain, cardiac diseases, sudden death, chronic pulmonary conditions, lung cancer etc., may be significant from both the pathologic and the behavioral perspectives.

A complete physical examination focusing on the chest should be performed. The physical examination should include vital signs, temperature, and oxygen saturation in room air, as well as examination of the chest wall, lungs,

heart, and abdomen. If the examination is normal or strongly suggests a relatively benign etiology of pain, then laboratory examinations may not be required. However, if there are significant alterations in vital signs or significant abnormalities on examination of specific organ systems, further evaluations and consultations are mandatory to obtain a definitive diagnosis.

Basic laboratory evaluations that may be required are usually suggested by the history and physical examination. One or more of the following tests may be needed or important to confirm the diagnosis and plan the patient's disposition: chest radiograph, electrocardiogram, complete blood count, acute phase reactants, toxic screen, and serum troponin.

Treatment

Whenever possible, a specific diagnosis should be determined. Management of pain should be directed at the cause. For the majority of cases, reassurance and symptomatic treatment with over-the-counter analgesics, heat or cold, and rest is sufficient. Patients suspected of psychopathology should be referred for mental health evaluation. Patients with chest infections may require antibiotics and, if respiratory distress is significant, inpatient care. If significant pulmonary problems, cardiac disorders, malignancies, or severe trauma are suspected, hospital admission, specialty consultation, more extensive testing, intensive care, and appropriate treatment including surgery may be required.

228 Hemoptysis

Julie Ryu

Definition

Hemoptysis is defined as coughing up blood or expectorating blood from the bronchus, trachea, or lungs. Pulmonary hemorrhages can be either diffuse or focal and be caused by a variety of etiologies. Pulmonary hemosiderosis by definition is the collection of hemosiderin-laden macrophages in the lung and therefore can result from a number of different conditions. While hemoptysis, pulmonary hemorrhage, and pulmonary hemosiderosis are often used interchangeably they have distinct definitions.

The majority of patients who present with hemoptysis are patients with cystic fibrosis. Patients with cystic fibrosis present with acute hemoptysis due to bronchiectasis; however, there are many other etiologies for hemoptysis. According to Coss-Bu et al. who looked at over 228 children presenting with hemoptysis over 65% were patients with cystic fibrosis, 16% had congenital cardiac disease, and remainder had a variety of conditions. While mild hemoptysis is not rare and often of non-pulmonary origin, life-threatening hemoptysis occurs less frequently. Massive hemoptysis is defined as greater than 300 mL of blood/24 h or 100 mL over 3 consecutive days with mortality usually due to asphyxiation.

Pathophysiology

Hemoptysis is a sign of many disease processes which can be categorized into prevalence by age as in *Table 228.1*. In addition to age, the type of bleeding, diffuse or focal, can narrow the possible etiologies for hemoptysis (see *Fig. 228.1*). Focal or localized bleeding can be associated with damage to a specific area of lung parenchyma or a large vessel (pulmonary or bronchial artery or vein). Focal bleeding can occur with any process that disrupts the endothelial integrity of a neighboring large vessel. Any process that damages a large vessel (trauma, AV malformation, foreign body, bronchiectasis, disruption of a aorto-pulmonary collateral artery in children with congenital heart disease, etc.) can result in a sudden massive hemoptysis.

The etiologies for diffuse bleeding are numerous and often more insidious in presentation. This type of bleeding can be divided into five broad categories: (1) Pressure related: cardiac failure, pulmonary edema, pulmonary embolism (acute chest syndrome in sickle-cell disease). (2) Immune related: Goodpasture's disease, Wegener's granulomatosis, systemic lupus erythematosus, Henoch-Schönlein purpura, alveolar capillaritis, Heiner syndrome/cow's milk hyperreactivity. (3) Congential abnormalities: pulmonary capillary hemangiomatosis, lymphangioleiomyomatosis. (4) Diffuse alveolar injury: any diffuse alveolar injury extending to the endothelial cells (often infectious or toxins). (5) Miscellaneous: idiopathic pulmonary hemosiderosis, coagulapathies (associated with immunocompromised patient). Diffuse bleeding is usually associated with capillary damage and therefore likely not to localize to only one area of the lung. This type of bleeding is more likely to be present in both lung fields and hemoptysis may be recurrent or massive depending on the extent of lung damage. Hemoptysis from immune etiologies may not present to medical attention until hemoptysis is significant and can be the initial presentation of a collagen vascular disorder.

Diagnosis

On physical exam, patients who have chronic pulmonary hemorrhage may present with increased work of breathing, cough, pallor, and fatigue. Patchy haziness or "whiteout" of one or more lung lobes may be apparent on chest radiograph. History can be helpful in verifying pulmonary hemorrhage; the patient may describe the blood as bright red and frothy which would be consistent with hemoptysis versus dark red which may suggest hematemesis. Stool guiac testing may be positive during active pulmonary hemorrhage as well as during gastroenteral bleeds and therefore does not rule out hemoptysis since younger patients may swallow sputum rather than expectorate it. A complete blood count may demonstrate a nonspecific microcytic hypochromic anemia in chronic bleeding but if eosinophilla is seen, Heiner/cow's milk hyperreactivity or an immune process should be considered. If eosinophilla

is detected, an elevated IgE may suggest Heiner syndrome or a hypersensitivity reaction. An immune workup may also be helpful patients with a diffuse bleeding pattern since systemic lupus erythematosus, Wegener's granulomatosis, and Goodpasture's disease can all present with hemoptysis. In addition, urine analysis for hemoglobinuria may uncover underlying nephritis, which is associated with several immune disorders.

Endoscopy and bronchoscopy can be very helpful in determining if the blood is from the GI or respiratory tract. If bronchoscopy is performed, the procedure can be diagnostic as well as therapeutic. Bronchoalveolar lavage can be evaluated for hemosiderin-laden macrophages. Alveolar macrophages can remove freed hemoglobin degradation products from ruptured red blood cells and therefore positive staining for hemosiderin is diagnostic for blood in the airway even if no frank blood is seen during the bronchoscopy. On average, hemosiderin-laden macrophages can be detected within 2–3 days and peaks around 5–6 days after the initial bleed. While flexible bronchoscopy can help localize the source of bleeding, rigid bronchoscopy should be performed if hemoptysis is massive. Rigid bronchoscopy allows for better aeration since ventilation is not through a narrow endotracheal tube but through the rigid bronchoscope. In addition, a rigid scope is preferred when removing large clots is not possible through a flexible scope's suction channel; furthermore, removing large clots can reactivate bleeding necessitating surgical intervention. Thus, bronchoscopy, flexible or rigid, can be diagnostic as well as therapeutic. Ice-cold saline or topical epinephrine (1:10,000 to 1:20,000) may be instilled through the bronchoscope to vasoconstrict vessels. Furthermore, topical thrombin and thrombin/fibrinogen solutions have also been described to abate bleeding. All of these topical solutions may be helpful in the mild to moderate bleeding but often are not sufficient for massive bleeds. Other diagnostic procedures include CT scan to help identify any underlying pulmonary or cardiac cause for bleeding. CT scan with angiography is indicated if bronchiectasis-associated hemoptysis is suspected, especially in patients with cystic fibrosis. An echocardiogram (and/or cardiac catheterization) is indicated in patients with known or suspected of cardiac disease. In all cases, the ultimate goal is to identify the underlying cause of pulmonary hemorrhage as well as to confirm that the hemoptysis is truly pulmonary in origin.

Treatment

In most cases, hemoptysis is usually mild and self-limited. However, in cases of massive or recurrent hemoptysis, the goal is to treat the underlying disease. In the acute response to hemoptysis, the first priority is to assure adequate ventilation and correct any existing coagulopathy. Due to the decreased ventilation capacity from blood in the air space, additional respiratory support may be

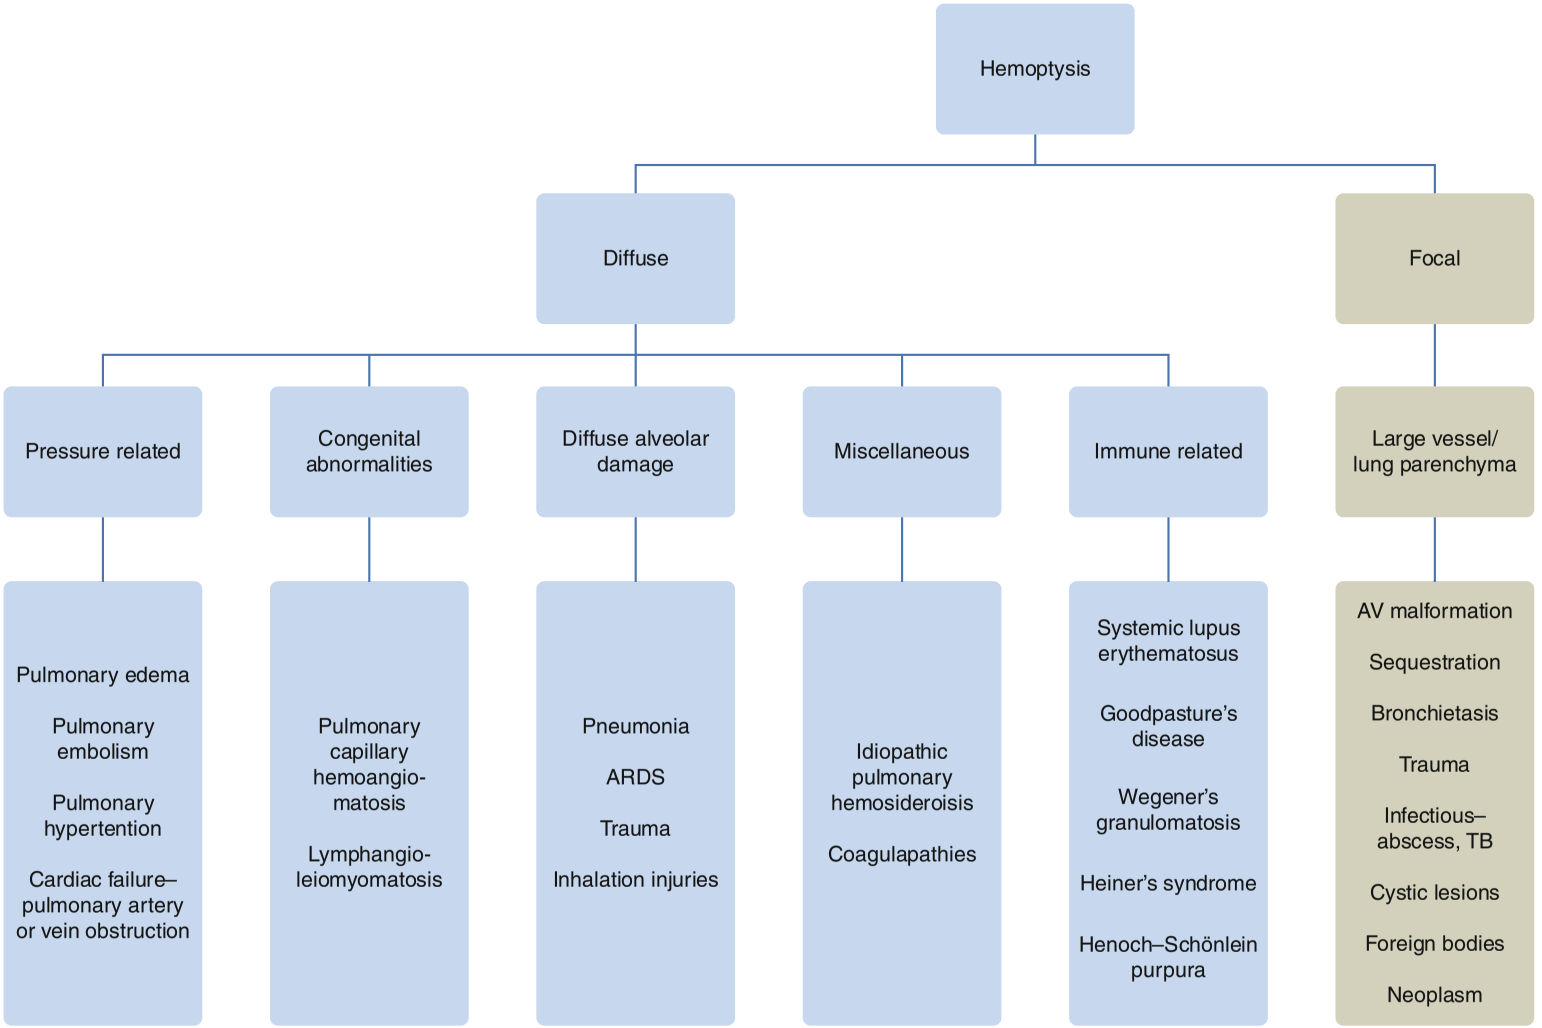

Figure 228.1
Common causes of bleeding by pattern, diffuse or localized

required. Intubation may be necessary to maintain airway patency and in some cases intubation with a double lumen endotracheal tube is required to ventilate the unaffected side of lung. However, many pediatric patients are too small for a double lumen endotracheal tube and some require high-frequency ventilation while others need extreme support such as extracorporeal membrane oxygenation (ECMO). In patients with cystic fibrosis, hemoptysis is not uncommon and is usually associated with bronchiectasis. In bronchiectasis, a bronchus enlarges due to mucous impaction. This impaction causes the adjacent bronchial vessel to stretch and become tortuous making rupture due to strain possible. Embolization of the ruptured bronchial vessel can be performed without impacting the pulmonary circulation. In extreme cases when hemorrhage cannot be controlled, lung resection may be indicated. In patients with systemic-pulmonary collateral vessels due to cardiac disease, cardiac catheterization with embolization/coiling of the ruptured vessel may be required to cease the bleeding. In cases of immune-related hemoptysis or idiopathic hemosiderosis, systemic steroids or immunosuppressive agents may be helpful in treating the underlying disease process.

Prognosis

When hemoptysis is isolated and mild, there are few if any long-term complications. However, patients with recurrent pulmonary hemorrhage or idiopathic pulmonary hemosiderosis can develop progressive pulmonary disease. Prognosis is dependent on quickly stabilizing the acute hemorrhage and treating the underlying disorder.

229 Pulmonary Edema

David Nathalang · Bradley Peterson

Definition

Pulmonary edema is the abnormal accumulation of fluid within the interstitial tissue and/or within the alveolar air spaces of the lung.

Pathophysiology

Normally, small amounts of intravascular fluid continuously leak out of the pulmonary capillaries into the pulmonary interstitium. This fluid is removed by the lymphatic system preventing the development of pulmonary edema. Pulmonary edema occurs when the lymphatic system and other fluid removal mechanisms become overwhelmed.

Fluid flow across the capillary endothelium into the surrounding interstitium is dependent on a balance between hydrostatic and oncotic pressures on both sides of the endothelium. This is described by Starling's equation for liquid movement: $Q = K_f\ (P_c - P_{is}) - K_d\ (\pi_{pl} - \pi_{is})$, where Q is net fluid movement across a unit surface area of the capillary endothelium, K_f is the capillary filtration coefficient which quantifies the ease of which fluid can pass through the endothelium, P_c and P_{is} represent the hydrostatic pressures in the capillary or interstitial spaces, respectively; K_d is the reflection coefficient which describes the membrane's permeability to proteins, and π_{pl} and π_{is} represent the oncotic pressures in the capillary and interstitial spaces, respectively. According to Starling's equation, an increase in hydrostatic pressure inside the pulmonary vasculature will increase fluid flow across the capillary endothelial layer into the interstitium. With enough fluid accumulation, hydrostatic pressure in the interstitial space will then drive fluid across the alveolar epithelium into the alveolar airspace. Also, changes in capillary filtration allow increased amount of fluid to leak across the capillary endothelium and collect in the interstitial space. Additionally, higher osmotic pressures in the extravascular space compared to the intravascular space, due to protein leakage across the endothelium, can pull fluid across the endothelium into the interstitium.

Multiple mechanisms serve to eliminate abnormal fluid accumulation in both the interstitial space and the alveolus. The lymphatic system returns fluid from the interstitial space to the central venous system and is able to increase fluid removal to a certain degree in the face of increased interstitial fluid deposition. Alveolar fluid collections are managed by sodium channels embedded in the apical surface of the alveolar epithelial cells. Sodium is transported from the alveolar airspace across the alveolar epithelial barrier, and is then actively transported into the interstitium by basolaterally oriented Na-K-ATPase channels. This process creates an osmotic gradient that encourages water flow from the alveolar airspaces back into the interstitium. A variety of factors can stimulate this mechanism, including β_2-adrenergic agonists, α-adrenergic agonists, steroids, certain growth factors (e.g., epidermal growth factor), and thyroid hormones.

Overall pulmonary edema formation will depend on the rate of fluid accumulation compared to the rate of fluid removal. While intrinsic fluid removal mechanisms can increase the rate of fluid removal with increasing accumulation, they can become overwhelmed in the face of rapid, excessive fluid buildup resulting in pulmonary edema. For this reason, acute elevations in left atrial pressure are more likely to lead to pulmonary edema than chronic elevations.

Fluid will initially collect in the perivascular and peribronchial spaces, spread to the interstitium, then accumulate in the intra-alveolar spaces. Fluid that collects in these spaces will lead to the clinical signs and symptoms of pulmonary edema, including tachypnea, dyspnea, wheezing, crackles, and cyanosis.

Etiology

Using Starling's equation, disease processes leading to pulmonary edema can be divided into two major categories: high-pressure pulmonary edema and capillary leak pulmonary edema (*Fig. 229.1*).

High-pressure pulmonary edema occurs secondary to elevated pulmonary capillary hydrostatic pressure (increased P_c). Examples of this can be seen with volume

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_229,

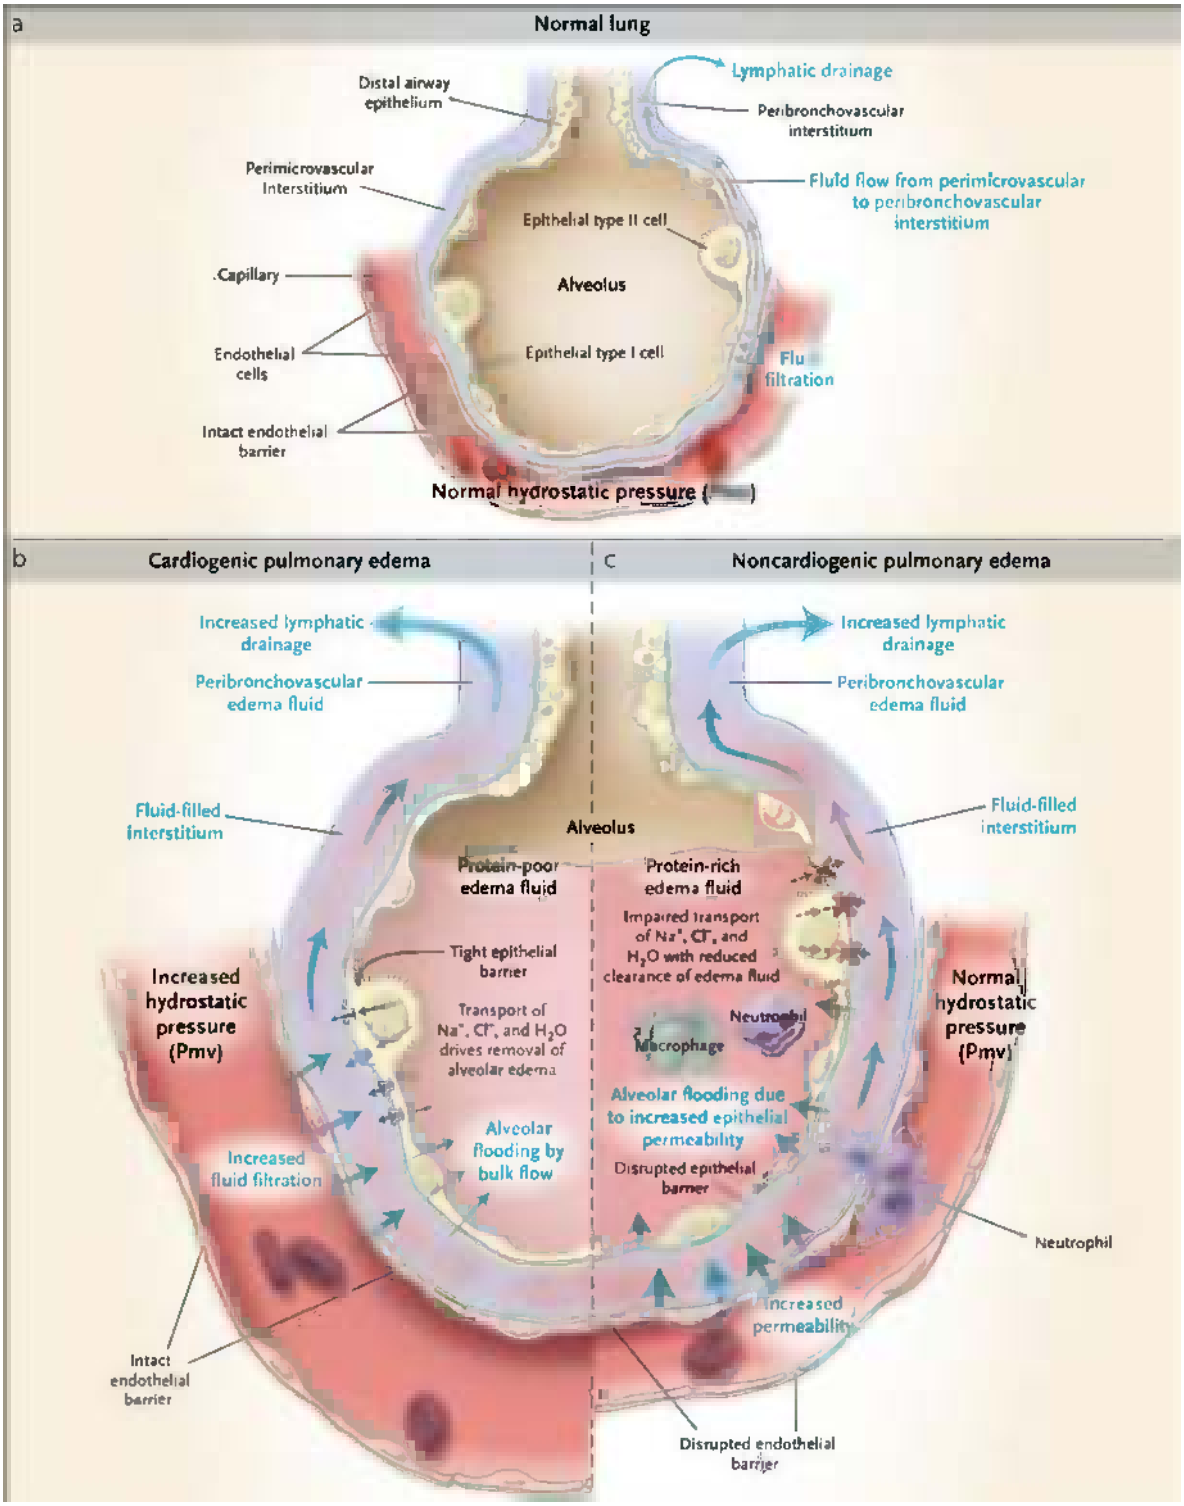

Figure 229.1
Mechanisms of pulmonary edema formation. (Reprinted with permission from Ware LB, Matthay MA (2005) Acute pulmonary edema. N Engl J Med 353:2788–2796)

overload states caused by overly aggressive fluid administration or oliguria due to renal failure. With cardiogenic pulmonary edema, a type of high-pressure pulmonary edema, elevated left atrial pressure secondary to left ventricular failure is transmitted to the pulmonary capillaries causing elevated pulmonary capillary hydrostatic pressure. This phenomenon is usually seen with left atrial pressures of 18 mmHg or higher. Endocarditis, myocarditis, arrhythmias, or any disease process that leads to left ventricular failure can bring about cardiogenic pulmonary edema. This can also occur with a normally contracting heart with an impairment of forward flow, such as aortic stenosis or mitral regurgitation, because of limited cardiac emptying and transmission of pressure to the pulmonary vasculature. Certain types of congential heart disease with large left-to-right shunts (e.g., ventricular septal defects) can cause overcirculation of the pulmonary circuit resulting in increased volume and pressure in the pulmonary capillaries.

In capillary leak pulmonary edema, damage to either the alveolar epithelial cells and/or the capillary endothelium causes an alteration of K_f, K_d, or both, leading to leakage of fluid, protein, and other molecules across the membrane. Additionally, damage to the alveolar epithelium may also impair the intrinsic sodium transport mechanism used for fluid resorption. Bacterial or viral pathogens are common causes of alveolar epithelial damage, and the resultant pulmonary edema can be worse in individuals with preexisting changes to the pulmonary vascular system, such as those seen with chronic lung disease. In addition, some infections stimulate the production of high-protein exudates in the alveolar airspaces leading to increased osmotic pressure in the alveolus and fluid accumulation. In acute lung injury and acute respiratory distress syndrome (ARDS), characterized by rapidly progressive bilateral infiltrates on chest radiography in the face of a pulmonary artery occlusion pressures below 18 mmHg, increased permeability and protein-rich edema fluid are commonly seen in the initial stages. Toxin and smoke inhalation, reactive nitrogen species, reperfusion injury, aspiration, radiation, and vasoactive substances (e.g., histamine) are also known to lead to endothelial or epithelial damage and edema formation. Several possible causes of both high-pressure and capillary leak pulmonary edema can be seen in Table 229.1.

Epidemiology

Edema formation is the result of a primary disease process leading to either high-pressure or capillary leak pulmonary edema. The incidence of pulmonary edema is related to the incidence of the inciting disease process.

Clinical Findings

History and physical findings enable determination of the severity of respiratory compromise and often point to the diagnosis and etiology of pulmonary edema.

Patients may have complaints of dyspnea, orthopnea, or cough. Patients with congenital heart disease may present with vague complaints of poor feeding, poor weight gain, diaphoresis with feeds, or even sudden cyanosis and shock-like symptoms with ductal-dependent lesions. Patients with capillary leak pulmonary edema may present with symptoms related to the initiating disease process, such as fever seen with bacterial pneumonia.

Physical findings will be related to the amount and location of pulmonary edema fluid. In children, cough and tachypnea may be the first signs of respiratory compromise. Wheezing may be noted when fluid accumulates in the peribronchial spaces in the early stages of pulmonary edema. As more fluid collects in the interstitial and intra-alveoli spaces, crackles will become apparent on exam and coughing may produce a frothy edema expectorant. Cyanosis will occur if gas exchange is severely depressed. Enlarged neck veins, hepatomegaly, peripheral edema, and abnormal heart sounds, including murmurs or gallops, may occur, suggesting a cardiogenic cause of edema formation. Abnormal rate or rhythm may occur and be the primary cause of cardiac dysfunction.

Diagnosis

Laboratory Studies

Initial labs should include a blood gas, a complete blood count with differential, C-reactive protein, chemistry panel, and B-type natriuretic peptide (BNP). These tests will help characterize the amount of respiratory distress and differentiate between cardiac, infectious, and other causes of pulmonary edema.

BNP, secreted by the ventricles in the face of increased cardiac pressures, is usually elevated in the presence of congestive heart failure. In adults, levels less than 100 pg/ml have a negative predicative value above 90% for congestive heart failure, while levels above 500 pg/ml have a positive predictive value above 90%. However, BNP levels should not be used as the sole criteria supporting a diagnosis of cardiogenic pulmonary edema, as they may

Table 229.1
Pulmonary edema by mechanism

High-pressure pulmonary edema	Capillary leak pulmonary edema	Mixed, other, or unknown mechanisms
1. Noncardiogenic a. Fluid overload i. Iatrogenic ii. Renal failure b. Increased pulmonary venous vascular resistance i. Pulmonary veno-occlusive disease 2. Cardiogenic a. Left ventricular failure i. Myocardial infarction ii. Cardiomyopathy iii. Endocarditis b. Arrhythmia c. Left-to-right shunt (Systemic to pulmonary shunt) i. Ventricular septal defect ii. Persistant ductal arteriosus d. Obstruction of left-sided emptying i. Aortic stenosis ii. Mitral stenosis e. Impaired left-sided emptying i. Aortic regurgitation ii. Mitral regurgitation f. High systemic vascular resistance	1. Infectious causes (e.g., bacterial or viral pneumonia) 2. Inhaled toxins a. Acid fumes b. Oxides of nitrogen c. High oxygen exposure 3. Circulating toxins a. Endotoxin b. Snake venom 4. Vasoactive substances a. Histamine b. Prostaglandins 5. Disseminated intravascular coagulation 6. Radiation pneumonia 7. Uremia 8. Aspiration pneumonia 9. Near-drowning and drowning 10. Smoke inhalation 11. Reperfusion injury	1. Decreased oncotic pressure 2. Decreased resorption of fluid a. Lymphatic insufficiency 3. High altitude pulmonary edema 4. Negative-pressure pulmonary edema 5. Neurogenic pulmonary edema 6. Re-expansion pulmonary edema 7. Transfusion-related acute lung injury

be elevated with other, noncardiac disease processes, such as sepsis and renal failure. Troponin levels are usually elevated with myocardial ischemia, infarct, or myocarditis, but like BNP levels, can be elevated without cardiac dysfunction.

Imaging

Chest radiography is commonly performed to confirm the diagnosis of pulmonary edema and help determine the cause of pulmonary edema. High-pressure pulmonary edema usually presents with an interstitial pattern of the infiltrates. Cardiomegaly, prominent septal lines, peribronchial cuffing, pleural effusions, and centrally distributed infiltrates are more common with cardiogenic pulmonary edema (*Fig. 229.2*). In contrast, patients with capillary leak pulmonary edema (*Fig. 229.3*) will have infiltrates that are more commonly peripheral in distribution, will present in an alveolar pattern, and will lack the characteristic cardiomegaly seen with cardiogenic causes of edema. Unfortunately, findings of the chest radiograph are mostly nonspecific to the diagnosis of either high-pressure or capillary leak pulmonary edema, as various findings may be seen with both types of pulmonary edema. Moreover, a radiograph may be affected by technique and user error, further decreasing the reliability of the chest radiograph as a means of definitive diagnosis.

Computed tomography can also be used to further visualize the lung affected and help determine the cause of pulmonary edema formation.

Monitoring

Bedside monitoring should include respiratory rate and continuous oxygen saturations, as well as temperature, heart rate, blood pressure, and hourly urine output. In more serious cases, central venous pressure should be measured which would be elevated in the case of cardiac dysfunction, fluid overload, or increased pulmonary artery resistance. If pulmonary artery occlusion pressures are measured, pressures above 18 mmHg are associated

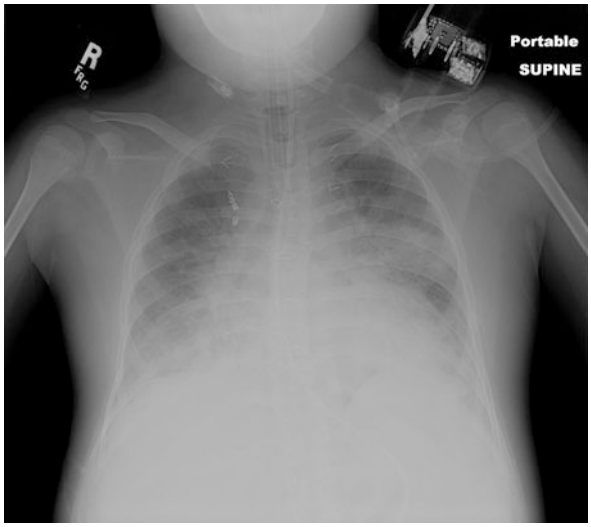

Figure 229.2
Cardiogenic pulmonary edema in a 9-year-old male with heart failure and elevated left ventricular end-diastolic pressure. Note the enlarged heart size and centrally distributed infiltrates

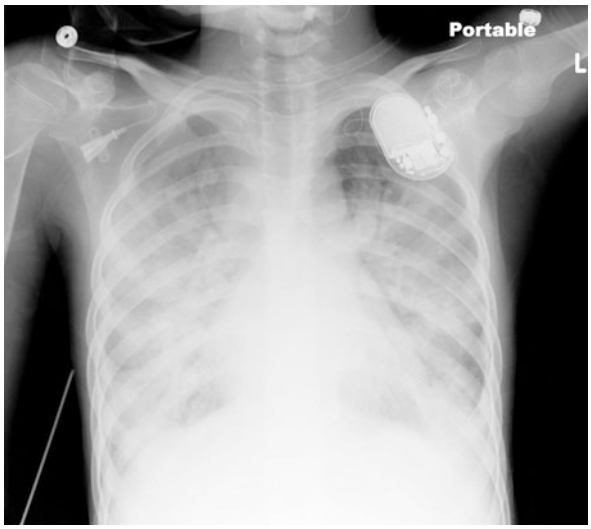

Figure 229.3
Capillary leak pulmonary edema in a 12-year-old male with early ARDS. Note the normal heart size and peripherally distributed infiltrates

with either cardiac dysfunction or volume overload and confirm high capillary hydrostatic pressure as the cause or at least a contributing factor to pulmonary edema formation.

Other bedside studies can be used to further assess the cause of pulmonary edema. Electrocardiography may suggest abnormal cardiac structure, evidence of ischemia and infract, or rhythm abnormalities. Echocardiography can evaluate cardiac function and assess for valvular dysfunction leading to increased left atrial pressures.

Treatment

General Care

Initial treatment of pulmonary edema should focus on improvement of gas exchange and resolution of any initiating disease process. Upright positioning is the easiest of all treatments to improve dyspnea. Diuretics may be used, though careful diuresis should be employed to avoid dehydration or worsening of cardiac output. Supplemental oxygen should be initiated early on in order to offset the effects of hypoxia. However, if 50% supplemental oxygen does not satisfactorily improve an individual's arterial oxygen saturation or respiratory distress then positive pressure ventilation should be employed.

One option for providing positive pressure ventilation is noninvasive ventilation as either continuous positive airway pressure (CPAP) or noninvasive intermittent positive pressure ventilation (NIPPV). CPAP provides a constant level of positive pressure throughout the respiratory cycle, effectively providing peak end-expiratory pressure (PEEP), which prevents alveolar collapse, increases functional residual capacity, and redistributes alveolar fluid. Conversely, NIPPV provides both PEEP and positive pressure during inhalation and supplies a higher level of mean airway pressure, which in turn decreases the work of breathing, increases surface area for gas exchange, and improves oxygenation. Noninvasive ventilation has been shown to improve respiratory status shortly after initiation, decrease the need for intubation, and improve hospital mortality.

Intubation and mechanical ventilation should be considered when there is hypoxia refractory to supplemental oxygen, low levels of positive pressure ventilation, or worsening clinical exam. Ventilator strategies will need to be chosen based upon the patient's disease process, e.g., lung-protective strategies using low stretch ventilation for ARDS, as inappropriate strategies using large tidal volumes have been linked to further alveolar epithelial damage and capillary leak pulmonary edema. In the case of persistent inability to oxygenate, inhaled nitric oxide and extracorporial membrane oxygenation can be considered.

Specific Treatments

Treatments for cardiogenic pulmonary edema target optimization of preload, reduction of afterload, and improvement of cardiac function. These treatments are used concurrently and are titrated to the patient's needs. Loop diuretics, such as furosemide, are commonly used to decrease preload and pulmonary capillary hydrostatic pressure. They may also have the additional effect of directly dilating pulmonary vasculature which would further decrease intravascular hydrostatic pressure. However, diuretics should be used with caution in the face of decreased cardiac output. Afterload reduction may be achieved with a direct vasodilator, such as Nitroprusside, or other medications such as Milrinone and Nesiritide, but should be avoided in hypotensive patients or when dealing with afterload-dependent lesions, such as severe aortic stenosis. Inotropic support with the use of exogenous catecholamines, such as Epinephrine, Norepinephrine, or Dobutamine, not only improves contractility but can also increase myocardial work and oxygen demand. Some medications can treat cardiogenic pulmonary edema in multiple ways. Nesiritide, a recombinant form of beta-natriuretic peptide, can improve diuresis as well as lower afterload. Milrinone, a phosphodiesterase inhibitor, not only causes afterload reduction via vasodilation, but also provides some inotropy without increased risk of tachycardia and arrhythmogenesis. It should be noted that some causes of cardiogenic pulmonary edema will require surgical repair, as in the case of a large ventricular septal defect causing pulmonary overcirculation.

With capillary leak pulmonary edema, treatments are chosen that specifically target the cause of the edema formation. Antibiotics or antivirals should be chosen in the case of infectious etiologies. Supportive therapy and mechanical ventilation will be needed for the treatment of ARDS.

Future Developments

Current research is investigating techniques that will enable the quantification of edema fluid in the lungs. Levosimendan, which increases myocardial troponin calcium binding, may be used to increase cardiac output by improving both systolic and diastolic functions and shows promise in the treatment of cardiogenic pulmonary edema. Methods to increase alveolar fluid resorption are also being investigated. Inhaled β-adrenergic agonist and certain growth factors, such as keratinocyte growth factor, have been shown to increase sodium transport across the alveolar epithelium.

Prognosis

As pulmonary edema is typically seen in conjunction with an inciting disease process, prognosis is mostly related to the severity of the primary disease.

Special Considerations

High Altitude Pulmonary Edema

Noncardiogenic, high-pressure pulmonary edema in a previously healthy individual 2–4 days after rapid ascent above 2,500 m is the hallmark of high altitude pulmonary edema (HAPE). Current theories regarding the pathogenesis of HAPE involve nonhomogenous, exaggerated hypoxic pulmonary vasoconstriction (HPV) and possible epithelial dysfunction. Due to the nonhomogenous nature of HPV seen in HAPE, certain areas of the lung undergo excessive vasoconstriction in response to hypoxia, shifting blood flow to other, less vasoconstricted areas of the lung. This leads to local overperfusion and high-pressure pulmonary edema.

Treatment is relatively conservative, with oxygen and descent being the most supported treatment for the pediatric population. Non-pharmacologic treatments in adults include portable CPAP devices as well as the Gamow bag, though pediatric experience with these treatments is limited. Medical treatments include calcium channel blockers, phosphodiesterase inhibitors, and inhaled β-adrenergic agonist, though literature supporting the use of these therapies for the pediatric population is scarce. Prevention includes gradual ascent, avoidance of strenuous activity, and adequate hydration.

Negative-Pressure Pulmonary Edema

Also known as post-obstructive pulmonary edema, negative-pressure pulmonary edema may occur during an episode of airway obstruction.

Acute airway obstruction with severe respiratory effort leads to dramatically increased negative-intrathoracic pressure during inhalation with resulting pulmonary edema. Increased negative-intrathoracic pressure is also associated with increased venous return, increased

pulmonary blood volume, and increased intravascular hydrostatic pressure which promotes edema formation.

Because symptoms are usually limited to 12–24 h, treatment is supportive. Supplemental oxygen and positive pressure ventilation should be utilized as needed.

Neurogenic Pulmonary Edema

Pulmonary edema has been associated with various types of neurological disease, including head trauma, subarachnoid hemorrhage, meningitis, status epilepticus, and cervical spine injuries.

One theory suggests that a sudden increase in α-adrenergic activity due to the neurological injury leads to systemic vasoconstriction and increased afterload on the left ventricle. Decreased emptying of the left ventricle increases left atrial pressure which is transmitted to the pulmonary capillaries and results in high-pressure pulmonary edema. Rapid increases of pulmonary vascular pressure may also cause fracturing of the vessels leading to capillary leak. Another theory proposes that inflammatory mediators released from damaged neural tissue gain access to the systemic circulation through the disrupted blood-brain barrier. These mediators increase pulmonary capillary endothelial permeability and pulmonary edema results.

The onset of neurogenic pulmonary edema is usually within hours of the initial neurological insult, but can take place days after neurological damage occurs. Edema usually resolves within 72 h, and treatment is supportive.

Re-expansion Pulmonary Edema

Sudden resolution of pneumothorax or rapid evacuation of pleural effusion may also result in pulmonary edema. This can be seen in younger patients or patients with prolonged deflation of the lung, usually of 3 or more days. And while the majority of cases occur in the collapsed lung, re-expansion pulmonary edema can occur in the contralateral lung.

According to one theory, during prolonged deflation of the lung, the capillary endothelium and basement membrane become thickened, hardening the microvasculature and decreasing its flexibility. With sudden re-expansion of the lung, the microvasculature is unable to tolerate sudden expansion of the lung and fractures, leading to leakage of fluid across the membrane. Some research suggests that oxygen free radicals, inflammatory mediators, and migrating neutrophils cause direct alveolar epithelial damage. Surfactant dysfunction may also play a role.

Treatment is again supportive. Prevention of re-expansion pulmonary edema includes limitation of the amount of fluid drained from a pleural effusion and the avoidance of excessive negative intrapleural pressures.

Transfusion-Related Acute Lung Injury

Acute lung injury within 6 h of blood product transfusion without evidence of volume overload or cardiac etiology is the hallmark of transfusion-related acute lung injury (TRALI). Fresh frozen plasma is the most common blood product associated with TRALI, though any type of blood product can be implicated.

It is possible that the interaction of donor antibodies with recipient granulocytes causes the release of various oxidases and inflammatory mediators, leading to an increase in capillary permeability. Other theories include possible proinflammatory mediators that accumulate during blood product storage prior to transfusion which are then released into the recipient. Similarly, the "two-hit" theory states that an initial insult (e.g., surgery, infection, etc.) sensitizes the endothelium, which is further activated by mediators found within the transfused product leading to endothelial damage.

Treatment is supportive with oxygen or positive pressure ventilation. Any remaining blood product should be returned to the blood bank for additional analysis.

230 Pulmonary Embolism

Julie Ryu

Pulmonary embolisms in children are rare but the incidence increases with age. In 1998, Silverstein et al. published a 25-year-retrospective review that found the incidence of pulmonary embolism in the USA to be 69 per 100,000 individuals. However, they found only four events among patients younger than 15 years during the entire 25-year study period or under 0.3 per 100,000 individuals. While other investigators have also reported an incidence rate under 0.1 per 10,000 pediatric patients annually, these figures are likely underestimated due to the difficulty in diagnosing pulmonary embolism in children. Buck et al. found that even in patients with significant pulmonary embolism only 50% had symptoms associated with pulmonary embolism and only in 14% was the diagnosis even considered.

Pathophysiology

Pulmonary embolism is defined as an obstruction in the pulmonary circulation. The impact of a pulmonary embolus is dependent on the extent of compromise to the pulmonary circulation. In adults, despite changes on ventilation/perfusion (VQ) scans, symptoms of a pulmonary embolus do not become apparent until about 50% of the pulmonary circulation is compromised. In children who develop a pulmonary embolus, the extent of compromise needed to show respiratory distress may be much less due to a child's lower respiratory reserves and likelihood of underlying conditions. While obstruction of the pulmonary circulation is the hallmark of a pulmonary embolism, the characteristics of the embolus itself may vary with different risk factors. Healthy children very rarely develop pulmonary embolisms but certain conditions may predispose a child to develop them. The type of embolus formed will be dependent on the underlying condition or risk factors. The most common type of embolism is a thrombus (blood clot), but other types of emboli include infectious (bacterial or fungi), fat, and air. While it very rare for fat emboli to occur in the healthy child, fat emboli can occur with traumas or orthopedic procedures involving the release of bone marrow from long bones. Air emboli can occur with traumas, insertion of an intravenous line, or during certain surgeries. Small venous air emboli are rarely of significant consequence since most are trapped and resorbed in the lung. Gas emboli associated with decompression sickness from diving, due to nitrogen release from the blood stream from a sudden shift in pressure, can be associated with multiple infarcts to the brain and other vital organs.

Coagulopathies, vasculitides, central venous catheters, cardiac disease, or any endothelial injury are risk factors for pulmonary embolism (see *Table 230.1*). Thus the incidences of pulmonary embolisms will likely increase in premature infants or any population that requires long-term indwelling catheters. Thrombotic emboli can lead to ventilation/perfusion mismatch and ultimately hypoxemia. When the source of thrombi is an infectious growth or clot on an indwelling catheter or prosthetic valve, thrombi can be numerous and obstruct vessels in multiple organs making the diagnosis difficult to make.

Diagnosis

The signs and symptoms of pulmonary embolism in children can be subtle and be confounded by preexisting medical conditions. Some of the more common symptoms are listed in *Table 230.2*. However, signs and symptoms alone cannot confirm the diagnosis of pulmonary embolism. In most cases, symptoms along with the presence of risk factors are needed to increase the likelihood of pulmonary embolism. The leading risk factor for a pulmonary embolism is having a preexisting condition followed by having a central venous catheter. In patients with medical conditions that are associated with coagulopathies, the risk of pulmonary embolism greatly increases. Disorders such as congenital heart disease, sickle cell anemia, collagen vascular disease, presence of lupus anticoagulants, and malignancy are some examples of conditions that increase the probability of developing a pulmonary embolism.

Studies including chest radiograph, arterial blood gas, and echocardiogram are helpful but these studies cannot definitively rule in or rule out pulmonary embolisms. Ventilation/perfusion (V/Q) scans were the most commonly utilized test in the past to assess the probability of a pulmonary embolus; low $\leq$ 10%, intermediate 25%, and

high $\geq$ 60% probability. While this imaging study is helpful in eliminating the diagnosis if the study is normal, the test is difficult to interpret when abnormal. A V/Q scan in some patients may be inherently difficult to interpret. For example, in children with congenital heart disease, blood flow may not be equally distributed throughout both lung fields at baseline thus making any assessment for a pulmonary embolism difficult to make. Pulmonary angiography is the gold standard in diagnosing a pulmonary embolus with direct visualization of any vascular filling defects. While this test may most accurately demonstrate vascular compromise, it is not available in every institution and can be both difficult to perform and interpret.

Helical (spiral) CT is now the most accessible test and is replacing pulmonary angiography as the method of choice for diagnosing a pulmonary embolism. Spiral CT with contrast can visualize the lung as well as pulmonary vasculature thereby allowing for the detection of any filling defect. In addition, due to the excellent imaging capacity of lung parenchyma, this test can help identify any underlying lung disease. However, spiral CT does have its disadvantages. A spiral CT exposes the child to both radiation and iodinated contrast. New advances in real-time MR angiography may provide alternatives in diagnosing pulmonary embolisms without radiation but currently are not readily available at all institutions.

Treatment

The treatment of pulmonary embolism due to thrombi is anticoagulation and respiratory support as needed. Anticoagulation treatment decreases the risk of further embolic events by preventing the existing thrombus from growing and causing further damage. Once a patient is hemodynamically stable, heparin is administered as a loading dose of 75–100 units/kg iv followed by an infusion rate of 28 U/kg/h iv (<1 year) or 20 units/kg/h (over 1 year of age) to maintain a PTT of 60–85 s. Afterward, oral or subcutaneous anticoagulants are given for 3 months or more depending on the patient's underlying medical condition. Low molecular weight heparin, warfarin, and vitamin k antagonists are just some long-term medications for anticoagulation. With all anticoagulants, the complications include bleeding; therefore, close monitoring of PT/PTT is required. In non-thrombotic emboli, the treatment is supportive. Sickle cell anemia related pulmonary emboli in acute chest syndrome, transfusion and supplemental oxygen or respiratory support are often required. The treatment for septic emboli is to eliminate the infection and potentially remove the infected device or prosthesis. In severe embolic events, thrombolytics or surgical embolectomy may be indicated.

231 Congenital Anomalies of the Respiratory Tract

Anthony E. Magit

Congenital anomalies of the respiratory tract present difficult and often urgent clinical situations. The increasing use of fetal imaging provides the opportunity to anticipate airway problems prior to delivery and implement complex and frequently lifesaving procedures involving several medical and surgical specialties. This chapter will address specific anomalies with respect to anatomic site.

Nasal Anomalies

Pyriform aperture stenosis presents as unilateral or bilateral anterior nasal obstruction. The obstruction is firm and exists immediately posterior to the nares. The anatomic abnormality causing pyriform aperture stenosis is bony overgrowth of the nasal lateral process of the maxilla. Associated findings with pyriform aperture stenosis include a central incisor and may be considered a form of holoprosencephaly.

Significant respiratory distress results from marked stenosis and establishing an airway may require placement of an oral airway or endotracheal intubation. The definitive diagnosis is made with a computerized axial tomogram (CAT) scan. With noncritical stenosis, the child may be managed expectantly by controlling nasal edema. Definitive management is surgical and involves the submucosal removal of bone with using either a transnasal or sublabial approach. Stenting of the nasal airway for a period of time may be necessary after surgery for pyriform aperture stenosis.

Nasolacrimal duct cysts result from obstruction of the nasolacrimal duct as the duct enters the lateral nasal wall below the attachment of the inferior turbinate. The cysts can be unilateral or bilateral and present as compressible masses attached to the lateral nasal wall. Catheters can be passed beyond the cysts and may confuse the physical examination, as the child will have nasal obstruction despite the catheter placement procedure not being consistent with a fixed nasal obstruction. Confirmation of the suspected diagnosis of a nasolacrimal cyst is achieved with a CAT scan. Management can be via nasolacrimal duct probing by an ophthalmologist or by removal or marsupialization of the cyst by an otolaryngologist. Recurrent cysts are infrequent and stenting of the nasal airway is not necessary.

Choanal stenosis or atresia denotes a compromised nasal opening at the choana, or posterior aspect of the nasal cavity at the point of entry into the nasopharynx. Choanal stenosis may be the diagnosis when the nasal airway is compromised and the only abnormality is an apparently small choana. Choanal atresia describes complete obstruction of the posterior nasal cavity. Choanal atresia can be unilateral or bilateral. The incidence of choanal atresia is between 1/5,000 and 1/9,000 live births. Pure bony atresia accounts for 30% of choanal atresia cases and mixed bony/membranous atresia in the other 70% of patients with choanal atresia.

The preferred imaging study of suspected choanal atresia is a non-contrast CAT scan. An axial view will demonstrate the atresia plate. Preparation for the CAT scan includes instillation of an intranasal decongestant and gentle suctioning of the nasal cavities to remove nasal secretions.

CHARGE association must be considered in patients with choanal atresia as approximately 30% of patients with choanal atresia have CHARGE association.

Bilateral choanal atresia creates an airway emergency in the newborn as newborn infants are considered obligate nasal breathers. Passage of nasal catheters into the nasopharynx will not be successful with choanal atresia. Atresia plates may consist of bone or mucosa. Atresia plates consisting primarily of mucosa, tend to have some abnormalities of bone, either in the form of widening of the posterior nasal septum, the vomer, or with medialization of the lateral aspect of the choana. In premature infants or those with other craniofacial anomalies, placement of a tracheostomy to establish an airway may be indicated prior to surgical repair of the choanal atresia. Surgical repair of choanal atresia can be performed via a transnasal or transpalatal approach as determined by the specific anatomy of the child and the preference of the surgeon. Nasal stents are typically left in place for several weeks following the repair.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_231,

Unilateral choanal atresia resulting in unilateral nasal obstruction is compatible with an adequate airway in a newborn and may not pose an urgent airway situation. Unilateral choanal atresia may not be identified in a newborn infant and only discovered as part of an evaluation for chronic unilateral rhinorrhea. Repair of unilateral choanal atresia can be approached similarly to the management of bilateral choanal atresia.

Astomia and Microstomia

Astomia and microstomia can present in isolation or concurrently with other craniofacial abnormalities. A newborn with other airway abnormalities resulting in respiratory distress makes microstomia more significant when needing to establish an airway. The degree of microstomia may make orotracheal intubation impossible and require either nasotracheal intubation or placement of a tracheostomy. Feeding may be adversely affected my microstomia and alternative approaches for nutrition may be necessary.

Several syndromes are associated with microstomia, including holoprosencephaly, oro-palatal dysplasia, hemifacial microsomia, and Freeman–Sheldon syndrome.

Tongue

The tongue can present as a congenital airway anomaly due to intrinsic hypertrophy or because of the presence of a congenital lesion. Lingual hypertrophy or macroglossia can be associated with an underlying syndrome. Beckwith–Wiedemann syndrome includes macroglossia that is usually symmetric and presents as an enlarged tongue typically extruding from the mouth. Despite macroglossia, patients with Beckwith–Wiedemann may have minimal or nonexistent airway or feeding difficulties. Surgical management of the patient with Beckwith–Wiedemann may be delayed for several years if the patient does not have airway or feeding difficulties. Airway problems become more likely when the base of tongue, rather than the anterior aspect of the tongue, is hypertrophic.

Lesions involving the tongue causing lingual enlargement include vascular and lymphatic malformations. Lymphatic malformations involving the tongue may be detected by fetal ultrasound (*Fig. 231.1*). Lymphatic malformations consist of cystic spaces that are prone to rapid fluctuations in size. Lymphatic malformations involving the tongue are associated with airway obstruction, feeding problems, and bleeding from the mucosal surfaces. The management of lymphatic malformations involving the tongue is extremely challenging and a tracheotomy may be required to secure the airway. Management of the lingual lymphatic malformation may require multiple surgical modalities, including partial glossectomy.

Figure 231.1
Lymphatic malformation involving the tongue and floor of mouth

Macroglossia is found with many other conditions. These include hemihyperplasia, cretinism, Down syndrome, mucopolysaccharidoses, neurofibromatosis, and multiple endocrine neoplasia. Macroglossia associated with these conditions may become more significant as the child grows and with progression of the specific disease process. The airway implications of macroglossia require frequent monitoring, often including polysomnography to assess the degree of airway obstruction.

Lingual thyroid can present as a posterior tongue mass. Lingual thyroid results from failure of complete descent of the thyroid from its fetal position at the foramen cecum of the tongue to the normal location anterior to the trachea. Lingual thyroid is present in 1/200,000 of the general population and 1/6,000 of patients with thyroid disease. Patients with a lingual thyroid can be euthyroid, hypothyroid, or hyperthyroid.

Oral Cavity

Anterior floor of mouth masses can present at birth with airway or feeding difficulties. Midline masses are likely to be epidermoid or dermoid cysts. Masses found in the anterior floor of mouth presenting lateral to the midline are most likely to be mucoceles or ranulas. These cystic lesions are pseudocysts and result from salivary mucin extravasating into surrounding tissue. Ranulas are the

result of leakage from the sublingual glands. Ranulas that extend beyond the mylohyoid muscle and into the neck are referred to as plunging ranulas. The management of ranulas consists of surgical removal of the sublingual gland with aspiration of the pseudocyst. Alternative therapies include injection with sclerosing agents.

Mandible

Median mandibular clefts are rare conditions with less than 70 reported cases.

Anomalies of the mandible may be associated with other craniofacial characteristics or present as an isolated problem. Airway obstruction results from inadequate anterior projection of the mandible due to micrognathia, a small mandible, or from retrognathia, a posteriorly positioned mandible. The result of inadequate anterior projection of the mandible is posterior positioning of the tongue. Micrognathia is one characteristic of patients with Pierre Robin sequence, Treacher Collins syndrome, Nager syndrome, and hemifacial microsomia.

Pierre Robin sequence is an example of micrognathia often resulting in airway problems. The consequence of micrognathia in Pierre Robin sequence is posterior placement of the tongue during gestation resulting in a "u" shape cleft of the palate and airway obstruction and feeding problems after birth. The airway may be managed with positioning of the child in a prone position to minimize the posterior tongue displacement or by placing an orogastric tube to assist in keeping the base of tongue forward. Mandibular growth may eventually lead to a normal mandible. When conservative measures do not provide an acceptable airway, placement of a tracheostomy or mandibular distraction may be required in the newborn period. Approximately 20% of infants with Pierre Robin sequence have significant airway problems, and one report cites a tracheotomy rate of 12% due to airway obstruction.

A technique used to improve mandibular projection with the intent of avoiding a tracheostomy is distraction osteogenesis of the mandible. This approach may have limited value in infants with craniofacial syndromes due to the presence of lower airway problems or temporomandibular joint anomalies.

Larynx

Congenital laryngeal anomalies can present with airway distress as well as feeding difficulties. Laryngeal abnormalities are present in 1/2,000 to 1/10,000 live births. The most common congenital laryngeal anomalies are laryngomalacia, vocal cord paralysis, subglottic stenosis, and laryngeal webs.

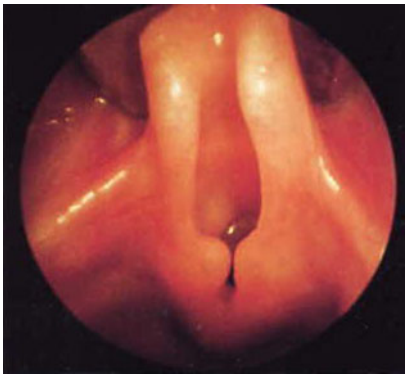

Figure 231.2
Endoscopic view of laryngomalacia with characteristic omega-shaped epiglottis

Laryngomalacia is used to describe the collapse of supraglottic structures upon inspiration. The clinical presentation of laryngomalacia is inspiratory stridor with a "staccato" characteristic (*Fig. 231.2*). Stridor is typically exacerbated with agitation, feeding, and being in a supine position. Placing the infant in a prone position or administering "jaw thrust" may mitigate stridor. In the majority of infants with laryngomalacia, the stridor will become transiently worse over several months with gradual resolution. Laryngomalacia can have various findings on laryngoscopy, including anterior prolapse of the arytenoids on inspiration, shortened aryepiglottic folds pulling the epiglottis posteriorly, as well an omega-shaped epiglottis. Approximately 15% of infants with laryngomalacia have a second airway abnormality, specifically subglottic stenosis, tracheal stenosis, or tracheomalacia.

The diagnosis of laryngomalacia is made with awake flexible laryngoscopy or by laryngoscopy under anesthesia. The decision to proceed with bronchoscopy to evaluate the entire airway is based upon clinical concerns regarding significant airway compromise. Signs of airway problems other than uncomplicated laryngomalacia are cyanosis, poor weight gain, difficulty in feeding, and acute respiratory distress. Uncomplicated laryngomalacia rarely requires surgery. When indicated, surgical procedures to treat laryngomalacia involve cutting the aryepiglottic (AE) folds with or without removing redundant mucosa from the epiglottis or arytenoids. Although aryepiglottoplasty is a relatively simple procedure, patients with hypotonia or underlying neurologic conditions can develop dysphagia

postoperatively and a swallow study may be indicated prior to surgical intervention.

Vocal cord paralysis is the second most common congenital laryngeal anomaly in some series. Vocal cord paralysis is unilateral in 30–62% of cases and bilateral in 48–62% of cases. Congenital, unilateral vocal cord paralysis is usually idiopathic. Newborns with unilateral vocal cord paralysis present with a hoarse or breathy cry. The left vocal cord is more often involved, presumably due to the longer course of the left recurrent laryngeal nerve.

Awake transnasal or transoral flexible laryngoscopy is sufficient to make the diagnosis in most cases. When copious secretions or obstructing supraglottic structures compromise visualization of the glottis, laryngoscopy with general anesthesia may be necessary. A swallow study should be considered after making the diagnosis of vocal cord paralysis to assess for laryngeal penetration or frank aspiration. Most infants with unilateral vocal cord paralysis maintain an adequate airway without surgical intervention. The contralateral, normal vocal cord may compensate adequately and spontaneous movement of the vocal may occur over months or several years.

Bilateral vocal cord paralysis presents with biphasic stridor. Respiratory problems associated with bilateral vocal cord paralysis included tachypnea, oxygen desaturation, and biphasic stridor. The cry tends to be relatively normal as the vocal cords tend to be in a paramedian position with functional opposition of the vocal cords. A swallow study to assess laryngeal penetration or aspiration with feeding should be considered. Bilateral vocal cord paralysis is an indication for imaging the central nervous system. An Arnold–Chiari type II with a myelomeningocele is the most common neurologic finding in children with bilateral vocal cord paralysis.

Interventions required to maintain adequate respiration range from supplemental oxygen to placement of a tracheostomy. Infants managed without a tracheostomy require close observation as the airway may deteriorate with time. Spontaneous vocal cord motion may be detected after months or years, with reported cases of vocal cord motion after 11 years. Reconstructive procedures exist for improving the airway in older children.

Laryngeal webs describe the condition of blunting of the anterior glottis (*Fig. 231.3*). Laryngeal webs present with an impaired cry as a result of abnormal vocal cord vibration. Laryngeal webs may be thin and limited to the level of the glottis, or thick and extend to the anterior subglottis. Webs that are thin can be managed with surgical lysing of the web; although, some degree of blunting may occur as a result of healing. Webs that extend to the subglottis are associated with subglottic stenosis and stridor with respiratory embarrassment more common than with isolated webs. Laryngeal webs with subglottic extension are more likely to be associated with a syndrome and a geneticist should be consulted to assist in establishing the diagnosis of an underlying genetic condition. Webs with subglottic involvement are more difficult to manage and may require extensive laryngeal surgery with the expectation of a less than normal voice.

Figure 231.3
Anterior laryngeal web in a patient with DiGeorge syndrome

Laryngeal clefts denote a defect in the posterior larynx between the arytenoids with more severe clefts extending through the cricoid cartilage and into the trachea. Sixty percent of infants with laryngeal clefts have additional airway abnormalities, including tracheoesophageal fistulas and tracheomalacia. Newborns with laryngeal clefts may present with dysphagia or coughing while feeding as a result of liquids being aspirated because of inadequate airway protection. The radiographic finding of a feeding tube displaced anterior toward the trachea suggests the presence of a laryngeal cleft.

A swallow study will establish the diagnosis of aspiration. The initial assessment may consist of awake, flexible laryngoscopy to visualize the larynx; however, direct laryngoscopy under anesthesia is necessary for an adequate examination. The classification scheme for laryngeal clefts is based upon the extent that the cleft extends into the trachea. The Benjamin–Inglis classification system describes type I to IV clefts. This classification system reflects the extent of the cleft, I being above the level of the cricoid IV extending into the trachea.

The initial management of a newborn with a laryngeal cleft may require placement of a gastrostomy tube with or without a tracheostomy. Definitive management involves surgical repair of the cleft. Type I clefts may be managed medically with gastroesophageal reflux treatment and close observation. Type I clefts may be treated endoscopically without the need for a tracheostomy. Clefts involving the cricoid cartilage can be managed in some cases with anti-reflux medication and a feeding tube. Surgical repair of larger clefts are more likely to be managed with an open surgical procedure.

Newborns with congenital subglottic stenosis have stridor of varying degrees related to the extent of the stenosis. The size of the newborn subglottis supports the role that a small degree of edema can impact the airway. One millimeter of edema will reduce the cross-sectional area of the subglottis to 32% of a normal airway.

Biphasic stridor exists due to impaired air movement on inspiration and expiration. The cry is typically normal, as the glottis is not involved. Subglottic stenosis is diagnosed with direct laryngoscopy as awake, flexible laryngoscopy does not provide for sufficient visualization of the subglottis.

Medical management for a noncritical airway includes close monitoring, supplemental oxygen, and empiric management of gastroesophageal reflux if indicated. Surgical interventions for critical subglottic stenosis include tracheostomy or laryngotracheal reconstruction. The type of surgical intervention chosen to manage a critical subglottic stenosis is based upon multiple clinical factors, including the weight of the child, the degree of stenosis, and the presence of pulmonary disease. Congenital subglottic stenosis can resolve spontaneously as the child grows. One approach to managing critical subglottic stenosis is placement of a tracheostomy with close monitoring with the anticipation for eventual removal of the tracheostomy tube after growth of the subglottis. The trend for the past several decades has been early airway reconstruction. Newborns may be managed with laryngotracheal reconstruction rather than a tracheostomy based upon their weight and pulmonary status. Newborns with concurrent medical conditions may require a tracheotomy for a period of time to allow for the management of concurrent medical conditions. The most common medical conditions requiring management are gastroesophageal reflux and primary pulmonary disease.

Subglottic stenosis is more common in specific populations of patients, including patients with Down syndrome. The degree of subglottic stenosis is described either by the percent reduction in the area of the subglottis or by the size of endotracheal tube that can be passed through the subglottis.

Tracheomalacia

Tracheomalacia is a functional disorder with collapse of the trachea with or without involvement of the bronchi. Tracheomalacia tends to be overdiagnosed when the actual airway disorder is more proximal. The cough associated with tracheomalacia is characteristically "vibratory" or "brassy." Patients may have evidence of bacterial bronchitis and pneumonia with radiographic findings including air trapping or radiographic densities.

The disorder may be due to an intrinsic problem with tracheal cartilage or secondary to external compression from aberrant vessels. Some degree of tracheomalacia exists in patients with tracheoesophageal fistulas (TEF) before and after repair. Patients with congenital heart disease and stridor represent of group of patients at risk for tracheomalacia due to vascular anomalies.

The diagnosis of tracheomalacia is made with airway endoscopy or dynamic radiographic imaging. The endoscopist must have experience in recognizing tracheomalacia and not inadvertently stent open the airway with the bronchoscope and therefore lessen the degree of tracheal collapse. Vascular anomalies associated with tracheomalacia are assessed with an esophagram when a vascular ring is suspected or with a contrast CAT scan to provide information regarding vessels anterior and posterior to the trachea. The CAT scan should be done on a spontaneously breathing patient without intubating the trachea as this can compromise the radiographic appearance of the trachea.

Management of tracheomalacia is guided by the severity of the airway obstruction. Mild forms for tracheomalacia may only become symptomatic when the child has an acute illness and medical management can be episodic. Medical management may include supplemental oxygen, bronchodilators, steroids, continuous positive airway pressure (CPAP), bilevel positive pressure (BiPap), or treatment for an acute respiratory illness. Tracheomalacia with sustained symptoms may require chronic CPAP or BiPap during sleep.

Severe forms of tracheomalacia refractory to medical management require more aggressive surgical interventions. The types of surgical interventions include aortopexy to suspend the trachea, tracheotomy to reduce airway resistance, and facilitate mechanical airway support, management of aberrant vessels, and placement of

airway stents. The use of airway stents is controversial and associated with difficult management issues. The majority of cases of tracheomalacia will improve with time; however, the management of the airway can be extremely challenging and require flexibility in changing the treatment strategy when interventions are not successful.

232 Acute Bronchiolitis

Erin R. Stucky

Definition/Classification

There is no single worldwide accepted definition of bronchiolitis. In general, bronchiolitis is an acute, seasonal respiratory illness most classically associated with crackles, wheezing, respiratory distress, and varying degrees of hypoxia. In the United States, the American Academy of Pediatrics (AAP) definition is typically used, which focuses on presence of wheeze in infants 1 month to 2 years of age. A diagnosis of bronchiolitis should be limited to infants with a first episode of wheezing. Although current accepted definitions allow this diagnosis to be given to infants under age 2, many argue only less than 1-year-olds should be considered. In the United Kingdom, Australia, and New Zealand, the Scottish Intercollegiate Guideline Network (SIGN) recommendations are followed, which focus on presence of crackles in infants under age 1 year. Wheezing infants in these countries are not given the diagnosis of bronchiolitis making true global population comparisons difficult.

Etiology

Viruses, in particular Respiratory Syncytial Virus (RSV), are the predominant cause of bronchiolitis. Viral frequencies vary by age, with RSV most common in less than 1-year-olds and rhinovirus more commonly detected in 1–2-year-olds. Parainfluenza, bocavirus, influenza, adenovirus, and human metapneumovirus are other common encountered pathogens. Almost one quarter of bronchiolitis episodes involve more than one pathogen. Atypical bacteria have been reported, but true incidence is unknown as testing for these pathogens is not typically performed. Up to 40% of tracheal cultures obtained on infants requiring intensive care demonstrate a bacterial pathogen, most often Haemophilus influenza, *Streptococcus pneumoniae*, or *Staphylococcus aureus*.

Epidemiology

Bronchiolitis is the most common discharge diagnosis for infants in the United States, accounting for over 400,000 hospitalizations annually. Despite differences in definition of bronchiolitis between the AAP and the SIGN, some incidence rate comparisons can be made. Rates and causative agents are similar in the United States, United Kingdom, Greece, Portugal, Saudi Arabia, and other parts of the world. Up to 15% of infants will present for care for bronchiolitis in the first year of life, with 1–2% requiring hospitalization. With immunoprophylaxis, admission rates in the United States for preterm infants have decreased by over 75%, and for those with chronic lung disease and congenital heart disease by approximately 40%.

Pathogenesis

The genetics of underlying chronic pulmonary diseases that may first present due to provocation by bronchiolitis are covered in other chapters (Lung Injury in the Premature Infant and BPD; Asthma; Chap. 237, "Cystic Fibrosis"). Important discoveries specific to bronchiolitis suggest a role for both pathogen-specific invasiveness and host immunomodulation. Certain adenovirus and even rhinovirus serotypes have been associated with more significant morbidity in different countries. How this information can be used to adjust treatment is currently undetermined. The central role of the immune response is becoming clearer as susceptibility genes for innate and adaptive immunity and airway remodeling have been reported. Specific single nucleotide polymorphisms (SNPs) have been associated with both increased susceptibility and severity to RSV, with some notably more apparent in preterm infants. Vitamin D metabolites function as immunomodulators, and therefore deficiency of this vitamin is under consideration as a risk factor for poorer clinical outcome. These insights may play a role in future prevention and treatment strategies.

Pathology

Despite being caused by varied pathogens alone or in combination, the impact on the airways is similar.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_232,

Mucus production, bronchospasm, acute inflammation, epithelial necrosis, and mucosal edema are found from the nasal passages to the bronchioles. More severe inflammation and destruction is associated with invasive viral pathogens, co-viral infections, or bacterial superinfections. The cytokine-driven influx of neutrophils combined with the inhibition of neutrophil apoptosis result in high levels of neutrophil elastase and myeloperoxidase enzymes, causing mucus secretion and airway edema. Animal models suggest certain viruses, such as human metapneumovirus and RSV may persist in nerves, available to be triggered in future exacerbations. Though not yet proven in humans, the potential for latent viral reactivation and its relationship to development of chronic lung disease is under consideration.

Clinical Manifestations

Most infants begin this illness with symptoms typical of an upper respiratory infection. Over the subsequent 1–3 days, symptoms evolve to include those of the lower respiratory tract. Common clinical features include wheezing, rales, rhonchi, cough, coryza, tachypnea, cyanosis, fever, and evidence of respiratory distress such as retractions, nasal flaring, grunting, and head bobbing. Young infants are obligate nose-breathers and can demonstrate significant distress from nasal swelling and secretions. Poor oral intake and fussiness are typically seen. Apnea may precede respiratory symptoms, especially in preterm infants. Symptoms may resolve in a few days or persist for 1–2 weeks or even longer in those with underlying pulmonary disease. Progression to respiratory failure occurs in 3–8% of admitted patients.

Diagnosis

The most commonly cited diagnostic and therapeutic guidelines are from the AAP and SIGN. Both state that diagnosis is made clinically using the definitions and signs and symptoms noted above. Routine laboratory testing including complete blood count, chemistries, and viral studies are not recommended. However, there are instances where rapid viral testing may be of value: if antibiotic use in the neonate can be discontinued more rapidly, if coinfection is thought to be prognostic, or if cohorting is necessary in certain medical environments. In addition, community-wide testing of symptomatic infants for RSV at the beginning and end of the average 16-week season can inform local immunoprophylaxis decisions. Test sensitivity is 80–90%, affected by varied methods of specimen collection (nasal wash, scraping, and swabs), transport, and storage.

Chest radiography is often performed yet of unproven value and is not recommended in routine evaluation of patients with mild symptoms. Classic findings are nonspecific but may be supportive of a diagnosis of bronchiolitis and include atelectasis, hyperinflation, and peribronchial cuffing. Radiologist interpretation may use phrases such as "infiltrate versus atelectasis" which is associated with increased antibiotic use that has not been proven to speed recovery or change ultimate clinical outcome.

Differential Diagnosis

A diagnosis of bronchiolitis does not preclude an acute dual infection or first presentation of an underlying chronic disease. Most of the critical history and physical examination elements helpful in determining the severity of disease or eliciting alternate diagnoses have been previously noted in Table 1 of the chapter on Wheezing. Crackles, rather than wheezing, however, may be the primary disease manifestation. Presentation during the respiratory season, state of hydration, perfusion, respiratory effort, and oxygenation status are particularly important components of the global assessment. Fever may be present or absent.

Rates of dual infection for infants less than 60 days of age are low but not insignificant (blood, 1–2%; urine, 2–7%; cerebrospinal fluid, 0–2%). At this time, it is recommended that infants under 28 days of age with fever have traditional "fever without source" testing of blood, urine, and cerebrospinal fluid. For infants 28 to approximately 60 days of age, testing is more controversial, and therefore many of these infants have only blood and urine samples obtained. Tracheal aspirate gram stain and culture for bacterial pathogens should be obtained on appropriate infants. Compared to proven bacterial pneumonia, distinguishing viral pneumonia from bronchiolitis clinically or radiographically is often not possible. For most cases not requiring intensive care, differentiating between these is not relevant for treatment or prognosis.

The clinician must judiciously reassess infants and monitor response to traditional supportive therapies in order to determine if testing or specialty consultation is warranted. Overall, the population prevalence of alternate diagnoses is low but not insignificant (congenital vascular diseases, 1–3%; tracheobronchial anatomic abnormalities, 2–12%). The number of these that are symptomatic in infancy that could present with symptoms characteristic

Table 232.1
Commonly Considered Differential Diagnoses, Testing, and Consultation

Organ System	Comments	Testing/Consultation
Congenital Pulmonary Anatomic/Genetic		
Larygnotracheal cleft Tracheoesophageal fistula (TEF) Tracheal web or ring Tracheal stenosis Tracheomalacia*	• Stridor noted with higher level anomalies • Cough, feeding difficulties with TEF • Tracheomalacia symptoms worse in supine position	• Testing: Chest x-ray, high resolution airway film, direct laryngobronchscopy, barium swallow • Consults: otolaryngology, pulmonology * Tracheomalacia may be primary or secondary; associated cardiovascular anomalies should be considered
Bronchial stenosis Bronchomalacia Bronchial cyst Hemangioma	• Symptoms worse in supine position • Hemangioma symptoms with age	• Testing: Chest x-ray, bronchoscopy, chest CT • Consults: surgery, pulmonology
Diaphragmatic hernia	• Chronic respiratory symptoms	• Testing: Chest x-ray • Consults: surgery, pulmonology
Cystic fibrosis Alpha-1 antitrypsin deficiency	• Recurrent respiratory illnesses • Failure to thrive	• Testing: Chest x-ray, sweat chloride, genetic testing • Consults: pulmonology, gastroenterology and nutrition, endocrinology
Congenital Cardiovascular Anatomic		
Cardiovascular rings, slings (double aortic arch; anomalous left coronary artery; anomalous innominate artery; right aortic arch; anomalous left pulmonary artery; aberrant left subclavian artery) Congenital heart disease with aberrant pulmonary circulation or congestive heart failure (partial or total anomalous venous return)	• Symptoms worse with neck flexion • Noisy breathing since birth • Mild to severe persistent hypoxia • Signs of congestive heart failure • Severe tachypnea	• Testing: Static imaging - Chest x-ray, chest CT or MRI (with or without 3D reconstruction). Dynamic imaging - flexible bronchoscopy, video fluoroscopy (with or without contrast), esophagram, echocardiogram • Consults: cardiology, cardiothoracic surgery, otolaryngology, pulmonology
Multi-factorial		
Chronic lung disease	• Chronic daily symptoms possible • History - preterm or neonatal lung injury	• Testing: Chest x-ray, pulmonary function tests, blood gas analysis • Consults: pulmonology
GERD with aspiration (idiopathic/developmental; neurologic; anatomic/obstructive)	• Cough, feeding difficulties • If associated with hypotonia, may be part of generalized neuromuscular disorder	• Testing: None; may consider swallow study as needed to rule out oromotor dysfunction; consider GERD as manifestation of anatomic abnormalities listed above • Consults: None (idiopathic); others based on underlying condition

of bronchiolitis is unclear. The most significant differential diagnoses and possible testing or consultation are noted in *Table 232.1*. It should be stressed that these diagnoses may be made *in addition* to infectious bronchiolitis. Consultants should be pediatric subspecialists unless emergent access is needed and not available.

Treatment

Hospitalization should be considered for those at higher risk based on age (preterm infants under 35 weeks gestation or any infant less than 3 months), chronic underlying condition, or acute signs of respiratory distress or systemic

instability (lethargy, dehydration). Inpatient treatment is supportive, with enteral nutrition or IV fluids, humidified oxygen, suctioning, and positioning in a level of comfort. An example treatment flow diagram is shown in *Fig. 232.1*. Optimal minimum oxygen saturation levels have not been rigorously tested and in practice vary between 88% and 96% depending on sleep state and elevation relative to sea level. Minimum oxygen saturation levels suggested by national societies are greater than 90% (AAP) or 92% (SIGN) or at the patient's baseline level. Beta-agonist or racemic epinephrine treatments with normal or hypertonic saline are of limited to no value in most infants with no underlying disorder. However, they may be trialed particularly in the emergency department setting, using a respiratory scoring system to assess outcomes. Blood gas testing of infants with worsening respiratory scores may help assess failure of ventilation and guide interventions. Pressure support in the form of high-flow nasal cannula or noninvasive ventilation with nasal continuous positive airway pressure (NCPAP) opens collapsed airways, thus improving ventilation and oxygenation. Apneic patients may also benefit from the stimulation provided by pressure support. Apneic preterms may stabilize with use of stimulant medication as well. Helium–oxygen mixtures with and without NCPAP has been reported to improve respiratory scores and may avert intubation.

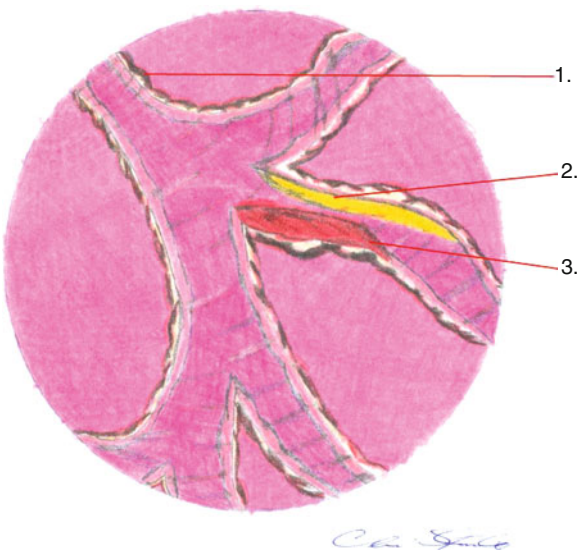

Figure 232.1
Airway involvement in bronchiolitis: (1) bronchoconstriction, (2) mucus production, (3) inflammation

Antibiotics should be reserved for treatment of highly suspected or proven extrapulmonary infections, infants under 28 days with fever at risk for concomitant bacterial infection awaiting bacterial culture results, or those with highly suspected or proven secondary bacterial pulmonary infections based on tracheal aspirate culture. Limited studies suggest the rate of bacterial pulmonary coinfection in intubated patients is as high as 50%. Antiviral therapies, including use of immunoprophylaxis at high levels as a treatment, as well as surfactant therapy have been studied in small populations and may be of benefit for more severely ill or intubated patients.

Treatment typically targets acute symptoms; however, avoidance of longer-term inflammation during lung remodeling may be important in patients with underlying chronic pulmonary disease or at risk for development of asthma. For most patients, steroid use after bronchiolitis does not avert future wheezing episodes. Steroid and leukotriene inhibitors may however be helpful in a subset of atopic patients. Steroids have also been noted to assist those with rhinovirus, although this may be due to the association of underlying risk for asthma with that virus. Use of macrolides for anti-inflammatory effect has also been suggested.

Prognosis

Episodes of bronchiolitis are typically self-limited; however, both acute morbidity and long-term outcomes vary greatly among infants. Complications may be due to the infectious agent, infant's own immune response, consequences of treatment, stress and instability of an underlying condition, or a combination of these factors. Initial oxygen saturation less than 90% and tachypnea (respiratory rate >70) have been associated with more severe disease. Prognosis is typically associated with the underlying state, with various reported odds ratios of intensive-care need highest in infants under 6 weeks (OR 2–4), preterm (OR 4–7), or having chronic pulmonary, cardiac, or immunologic disorders (OR 15–21). Death is rare (<3%) and occurs most often in patients with chronic diseases. Predicting which otherwise health term infant will develop acute respiratory failure is however difficult. For the term otherwise healthy infant with bronchiolitis, outcomes are very good with no demonstrable long-term impact on lung function and no increase in number of future respiratory illnesses. However, some infants who will be ultimately diagnosed with asthma present for the first time with bronchiolitis, particularly those with rhinovirus. Response to trial of beta-agonist

therapy, severity of bronchiolitis presentation (need for admission), atopy, and a family history of asthma or atopy may be clues to future asthma.

Prevention

Avoidance of smoke exposure, breast feeding, and hand washing are suggested methods to prevent both acquisition and spread of viral-induced bronchiolitis. Hospital staff should follow infection control recommendations for droplet precautions which include gown, mask, and glove use. Immunoprophylaxis during the respiratory season (typically November through March in the United States) of at-risk infants should follow national guidelines. Those with chronic cardiopulmonary diseases, immunodeficiency, and premature birth at less than 35 weeks gestation under 6 months postnatal age are typically targeted. The clinician is encouraged to review current guidelines for the most up-to-date information on use. Maternal immunoprophylaxis has been attempted with limited success in research settings but is an important model for disease prevention in the future.

233 Management of the Wheezing Infant

Erin R. Stucky

Definition/Classification

Wheezing is a common respiratory complaint in childhood, with an estimated 25% of infants having at least one episode of wheezing by age 1 year. Wheezing is defined as a high-pitched somewhat musical sound caused by variable obstruction within the intrathoracic respiratory system, predominantly involving the bronchi and bronchioles. Wheezing can be monophonic – single tone from obstruction of the large caliber airways – or polyphonic with varied pitches from obstruction of airways of differing diameters. It should be distinguished from other sounds such as stertor, stridor, rales, rhonchi, and rubs, each with its own association with specific locations within the respiratory system. Wheezing is continuous throughout a phase of the respiratory cycle, and although it is most associated with expiration, it can be heard on both inspiration and expiration. Although wheezing is commonly associated with primary pulmonary disturbances, influences from outside the pulmonary tree may also cause a change in airway dynamics that result in production of this noise.

Epidemiology

Assessing prevalence of wheezing episodes leading to healthcare visits is difficult given the varied underlying causes of this clinical sign. Available prevalence information is biased due to many reasons such as coupling of "asthma" and "wheezing" search terms, the limited numbers of studies in many countries, inconsistent coding, and infrequent inclusion of the infant age group. However, the data on older children does demonstrate interesting differences and similarities between countries. All countries show graded decreases in prevalence with increasing age from toddler to teen. Reported rates vary significantly between countries from $<2\%$ in Ethiopia to 5–14% in Kenya, with other countries varying from 10% (Mexico, China, Palestine) up to 20% (Finland, Ireland, United States, Israel, United Kingdom, New Zealand, and Fiji) for a similar preteen age group.

Pathogenesis/Genetics

A comprehensive summary of the pathogenesis of wheezing is beyond the scope of this chapter. However, certain findings to date may be of value for the clinician. Low birth weight, prematurity, and respiratory distress syndrome are well known to forecast repeated wheezing within the first year of life. Each of these may be the outcome of an underlying factor that leads to wheezing as well, or may be a state that places the infant at risk for wheezing after birth due to adaptation to the ex utero environment and exposure to therapeutic interventions. Maternal and maternal–fetal factors of high levels of IL-8 in cord blood, maternal eczema, and cesarean section have been independently associated with development of wheezing by age 1. Maternal asthma is a more significant predictor of infant wheeze than the paternal counterpart. Combined, these suggest that both the imbalanced heritability of wheezing potential and the exposure to inflammatory mediators in the immediate newborn period have significant influence on ultimate development of wheezing in the infant.

Pathology

Aberrant airflow through critically narrowed airways is the predominant cause of audible or auscultated wheezing. Changes to the bronchi and bronchioles may be due to a fixed obstruction causing airway compression or due to acute changes such as mucus plugging, airway or interstitial edema, or constriction of bronchial smooth muscle. Each results in variable airflow speed through affected airways. This variability in aerodynamics causes sound to be transmitted, in contrast to normal respirations, which are silent due to simple linear flow with consistent velocity. Infants are at particular risk for airflow obstruction due to simple physics. Airway resistance is inversely related to the radius of the lumen to the fourth power, so even a small decrease in airway diameter in an infant can cause a dramatic increase in resistance. Compliant bronchial cartilage also allows for collapse. In this setting, the next inspiration is begun before full expiration is achieved causing air trapping.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_233,

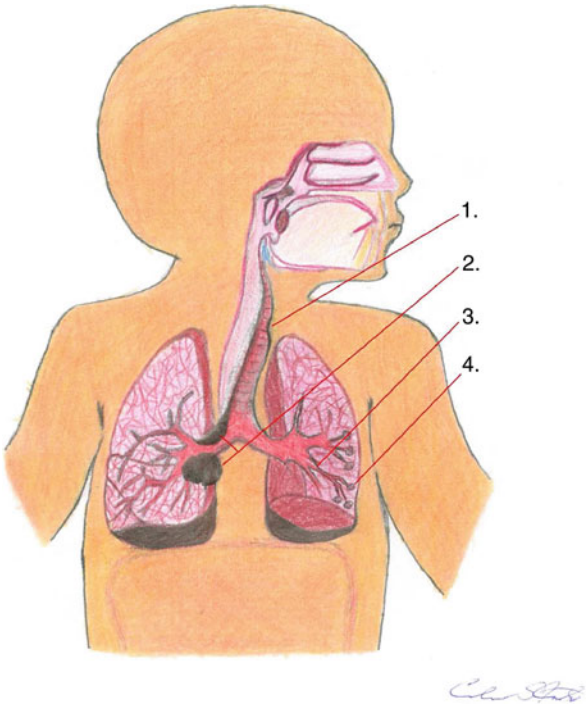

Figure 233.1
Airway involvement in wheezing. *1* intrathoracic tracheal compression, *2* bronchiolar compression, *3* alveolar hyperinflation, *4* intraluminal and external compression

Wheezing may be due to fixed obstruction resulting in turbulence at one or more sites, or may be sporadic, with patchy involvement of the airways in an inconsistent manner. Both may present with exacerbations of varying severity at different times in a given patient. Although commonly perceived as a small airway phenomenon, obstruction of the intrathoracic trachea or bronchi also can result in wheezing. Typically, large airway obstruction does not cause hypoxemia compared to small airway involvement where ventilation–perfusion mismatch results in changes in oxygen delivery to the body. In addition to causes of wheezing directly related to problems of the pulmonary tree, external compression may result in wheezing and other associated respiratory signs and symptoms that may be impossible to distinguish from the former (*Fig. 233.1*).

Clinical Manifestations

Two general patterns of wheezing are commonly noted – episodic and unremitting. Episodic is defined as discrete events lasting 2–4 weeks in duration, between which the child is well. Unremitting or persistent wheezing is characterized by triggered severe episodes between which symptoms associated with exercise, cold air, or emotional outburst (crying or laughing). These two general patterns are more often considered when evaluating wheezing of older infants and addressing the potential diagnosis of asthma.

Isolated wheezing should be distinguished from that associated with other respiratory noises of the upper tract, as the latter may more often involve anomalies of the entire airway. The physical examination should be repeated after a therapeutic intervention, as in cases of severe distress wheezing may not be audible until aeration improves. A thorough history and physical examination should be performed to elicit evidence of severity of respiratory distress, assess the need for urgent basic supportive treatment, and obtain supporting information for a differential diagnosis. Specific elements to consider are noted in *Table 233.1*.

Differential Diagnosis

More commonly considered potential etiologies of wheezing include primary pulmonary, extrapulmonary, and systemic sources, which are noted in *Table 233.2*. The diagnostic approach should take into account the history and physical examination elements as well as age. Although less common, distress due to congenital anatomic malformations present most often in the first few months of life and are critical to not overlook.

Acute, self-limited infectious sources of wheezing in infancy are extremely common. Bronchiolitis and pneumonias are discussed in more detail in other chapters. Infections due to tuberculosis and pertussis are more subacute to chronic in nature. Pertussis typically present with cyanotic episodes and classic repetitive cough or episodes of apnea, with subacute wheezing more often following this initial diagnostic presentation. Infections-associated mediastinal adenopathy may have parenchymal involvement; however, the asymmetry produced by focal compressing adenopathy may be a valuable physical exam finding.

Congenital anatomic/genetic causes may be apparent immediately after birth (tracheal stenosis, some tracheoesophageal fistulas) or present with growth of the infant (hemangiomas) and/or in association with influence or failure of normal physiologic drop in pulmonary vascular resistance (congenital heart diseases, vascular rings/slings). Vascular rings are often associated with "noisy

Table 233.1
Signs and symptoms to elicit from the history and physical examination

History element	Consideration
Symptom detail: progression and/or change in noise pattern, cough/choking, change with position (prone/supine), associations with feeding/febrile illnesses/environmental exposures	• Obstructing growth • Inadequate airway development such as bronchomalacia • GERD with associated aspiration • Acute infectious respiratory illnesses
Birth history: prematurity, intubation, or suctioning at delivery, ventilator assistance	• Underappreciated chronic lung disease • Airway injury • Upper airway obstruction
Family history: asthma, allergy, heritable pulmonary diseases	• Atopic diseases • Genetic disorders such as cystic fibrosis
Past medical and surgical history: past use of/response to bronchodilators, recurrent otitis media or sinusitis, tonsillectomy/ adenoidectomy, admission for ALTE, gastroesophageal reflux disease (GERD), cardiovascular disease, diaphragmatic hernia	• Nasopharyngeal obstruction masquerading as lower tract wheezing • GERD with associated aspiration • Underdeveloped pulmonary system • Aberrant pulmonary vascular flow
Review of systems: appetite, weight gain, stool pattern, emesis, rashes, smoking exposure, maternal (prenatal), and infant pollution/inhalant exposure	• Systemic genetic disorders such as cystic fibrosis • Atopic or irritant-induced symptoms from aeroallergens and pollutants
Physical examination element	**Finding**
General appearance, including facies	• General state • Airway anatomic issues
EENT	• Evidence for atopy • Nasal obstruction/pallor • Oropharyngeal anomalies
Vital signs including weight for height, respiratory rate, pattern, retractions, oxygen saturation	• Failure to thrive • Effort/severity of distress • Cyanosis
Skin	• Vascular malformations • Eczema
Chest wall, cardiopulmonary exam including lung auscultation, cardiac murmurs/rubs/gallops, perfusion, hepatomegaly	• (A)symmetry of wheezing, phase (inspiratory/ expiratory), associated sounds • Deformations of chest wall • Congestive heart failure • Evidence for cardiovascular diseases
Abdominal distention/ scaphoid, bowel sounds, masses	• Abdominal tumor • Evidence for diaphragmatic hernia
Extremities	• Clubbing
Neurologic exam	• Hypotonia/swallowing dysfunction

breathing since birth" and are frequently underlying causes of secondary tracheobronchomalacia.

GERD with aspiration of refluxate is not uncommon, and is most often idiopathic or "developmental" resulting from a combination of effects such as immaturity of lower esophageal sphincter function and the angle of the gastroesophageal junction. Aspiration of oropharyngeal secretions due to poor swallowing coordination may be seen in infants with prolonged periods of feeding disruption (complex congenital heart disease), developmental delays, or global motor control with the latter group often demonstrating aspiration from both above and below.

Although commonly considered to be primary pulmonary disorder, cystic fibrosis is a systemic genetic disorder with varied phenotypes, the most significant presenting early in infancy with recurrent pneumonias and failure to thrive. Newborn screening in many but not all states has been of great value in identifying these children and offering intensive respiratory therapies and nutrition management.

Other primary pulmonary disorders of importance are chronic lung disease and asthma. Chronic lung disease is most often the result of prematurity with most complications seen in the extreme preterm infant. However even a near-term infant may have recurrent wheezing with respiratory infections. Although asthma is not traditionally diagnosed in infancy, those meeting criteria with appropriate elimination of other diagnostic considerations are labeled and treated as asthmatic.

Diagnostic testing is guided by age, history, and physical examination findings. Basic evaluation includes a plain

Table 233.2
Commonly considered etiologies of wheezing in infancy

Primary pulmonary		
Infectious	**Congenital anatomic/genetic**	**Allergic/immunologic**
• Bronchiolitis[a,b] (viral, atypical most common) • Pneumonia[b] (viral, atypical most common) • Pertussis/parapertussis	• Larygnotracheal cleft • Tracheoesophageal fistula • Tracheal web or ring • Tracheal stenosis • Tracheomalacia • Bronchomalacia • Bronchial stenosis • Bronchogenic cyst • Hemangioma	• Asthma[b]
Multifactorial	**Trauma**	**Neoplastic[c]**
• Chronic lung disease[a,b]	• Foreign body • Inhaled irritant	• Hamartoma • Lipoma • Bronchial adenoma
Extrapulmonary		
Infectious	**Congenital anatomic/genetic**	**Neoplastic[c]**
• Compression due to reactive adenopathy (such as in tuberculosis or fungal infections)	• Hemangiomastosis • Diaphragmatic hernia • Cardiovascular rings, slings • Congenital heart disease with aberrant pulmonary circulation or congestive heart failure	Tumor compressing tracheobronchial tree: • Thymic tumors • Teratoma • Hemangioma • Pericardial cyst • Lymphoma • Hernia • Angiomas • Neurogenic tumor
Multifactorial		
• GERD with aspiration[a,b] (idiopathic)		
Systemic		
Allergic/immunologic	**Congenital anatomic/genetic**	**Neoplastic[c]**
• Anaphylaxis	• Hemangiomatosis • Cystic fibrosis • Alpha-1 Antitrypsin deficiency	• Compression due to infiltrative adenopathy, metastases
Multifactorial		
• Aspiration with/without GERD (secondary to swallowing dysfunction/hypotonia, GI obstruction, others)		

[a]Commonly diagnosed at <3 months
[b]Common diagnosed at 3 month to 2 years
[c]Rare causes

posterior–anterior and lateral chest radiograph and oxygen saturation. GERD is a clinical diagnosis, although testing to rule out alternate diagnoses may be indicated. Rapid testing for infectious agents should not preclude further evaluation if warranted by the severity or chronicity of the clinical presentation. Airway compression is assessed with upper GI series or direct laryngobronchoscopy with echocardiogram, contrast 3D chest CT, contrast MRI or angiography often used for confirmation of vascular anomalies. Flexible bronchoscopy is used to diagnose anatomic abnormalities, assess airway injury, or obtain diagnostic biopsies. Genetic testing, bedside swallow study, sweat test, rigid bronchoscopy, and other imaging studies should be performed based on diagnostic considerations.

Treatment, Prognosis, and Prevention

Treatment is targeted to the etiology. For all diagnoses, prevention of further exacerbations and lung damage is paramount. Avoidance of passive smoke exposure and environmental irritants is important for all infants who wheeze. Studies of antihistamine and steroid use to prevent future wheezing events and allow for proper airway remodeling in viral-induced wheezing offer mixed results. As a heterogeneous group, wheezing early in life may not predict future wheeze. Over half of patients with severe early wheeze are symptom-free by age 5.

234 Acute Upper Airway Obstruction

Anthony E. Magit

Acute airway obstruction can be the result of infection, an acute inflammatory condition, trauma, or a structural abnormality. Every level of the airway is subject to conditions that can result in obstruction, from the nose to the lower airway.

Nose

The newborn infant is considered to be an obligate nasal breather, and respiratory distress at the time of delivery may be due to bilateral nasal obstruction. With the absence of detectable nasal airflow, the placement of an oral airway or laryngeal intubation will bypass the obstruction. The ability of infants to establish nasal breathing when challenged by nasal obstruction has been addressed with a research study. Newborns may exhibit spontaneous oral breathing as well as oral breathing when confronted with nasal obstruction. Oral breathing was detected in 40% of newborns after acute, bilateral nasal occlusion.

A toddler or older child experiencing nasal trauma usually has a transient episode of epistaxis with mild to moderate nasal congestion due to inflammation, secretions, or dried blood. The majority of children with nasal trauma retain some degree of nasal airflow. Acute nasal obstruction due to trauma may be the result of a septal hematoma. Severe nasal obstruction following trauma raises concerns for a septal hematoma that describes a collection of blood located between the septal cartilage and perichondrium. The patient presents with soft tissue occlusion of both nasal vestibules. The distinction between an anterior nasal septal deflection and a septal hematoma is made by failure of transillumination of the septum with a septal deflection. A hematoma prevents transillumination with a light or otoscope and prompts immediate referral for drainage of the hematoma to relieve the obstruction and lessen the likelihood of abscess formation and eventual loss of cartilage and loss of nasal support.

Oral Cavity

Obstruction of the airway at the level of the oral cavity may be due to acute enlargement of the tongue. Trauma to the tongue with hematoma formation can compromise the airway when the base of the tongue is involved. Acute management involves establishing an airway, which may require transoral or transnasal intubation. An emergent tracheostomy may be necessary if the airway cannot be intubated and the patient has signs of respiratory distress. A preexisting lesion that involves the tongue may become infected or experience acute bleeding resulting in an airway emergency. An example of such a lesion is a lymphatic malformation involving the tongue.

Acute problems involving the floor of the mouth have the potential to acutely obstruct the airway. Ludwig's angina is an acute infectious process usually associated with adults who have an aggressive infection of the anterior floor of mouth with a tendency for the tongue to secondarily obstruct the airway. In the majority of situations, the primary infection is dental. Infections involving the anterior floor of mouth in child can have similar clinical presentations with the primary infection resulting from intraoral trauma or infection of a preexisting lesion, including lymphatic malformations and congenital cysts.

Acute inflammation of the anterior floor of mouth from any etiology needs immediate attention as airway obstruction can occur rapidly. The patient should be kept in a closely monitored setting with the necessary resources for intubation or establishment of a surgical airway if the airway becomes compromised.

Tonsil and Adenoid Disease

Most patients with clinically significant tonsil and adenoid hypertrophy have chronic airway problems resulting in obstructive breathing while asleep. Critical obstruction at the level of the pharynx can result from acute increase in the mass of lymphoid tissue as found with infectious adenotonsillitis. An example of this situation is mononucleosis with fulminate lymphoid hyperplasia. Acute management may require intubation and medical management with systemic steroids and the addition of empiric antimicrobial treatment if clinically indicated.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_234,

Peritonsillar abscess describe a collection of purulent material adjacent to the tonsil capsule. The classic triad of a peritonsillar abscess consists of trismus, peritonsillar edema, and deviation of the uvula away from the side of the abscess. Patients commonly present with a muffled or "hot potato" voice. The diagnosis is based upon the clinical examination, and imaging studies are rarely necessary.

Management consists of aspiration of the peritonsillar area. If no fluid is aspirated, then the area is incised and the opening explored with a hemostat. All aspiration attempts and incisions are kept medially to avoid injury to vessels located lateral to the tonsil. Management of a peritonsillar abscess can be done using local anesthesia in a cooperative teenager or preteen. Younger children will require general anesthesia for any aspiration or incision of the peritonsillar area.

Foreign Bodies

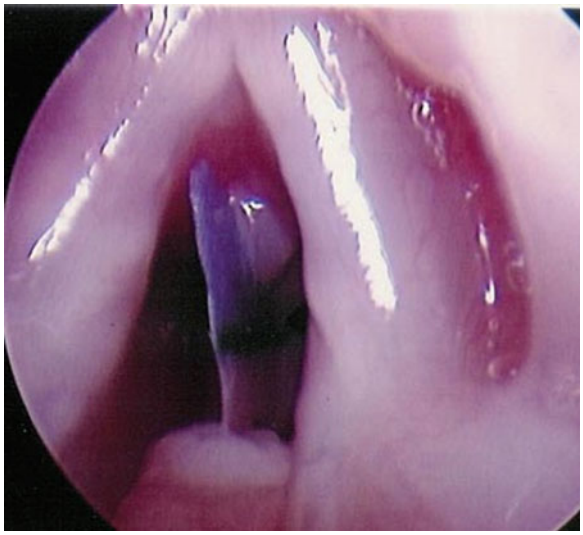
Nasal foreign bodies are unlikely to cause bilateral, complete nasal obstruction. Nasal foreign bodies are associated with unilateral rhinorrhea with decreased nasal airflow. A nasal foreign may result in granulation tissue and scarring if left for a prolonged period of time. Button batteries pose a significant risk of permanent damage to the nose, including a nasal septal perforation, after a brief period of time. Concerns about a button battery in the nose raise the question of whether a radiograph is indicated to assess a nasal foreign body if removal may be delayed.

Oral Cavity and Pharynx

Spherical objects have the potential of obstructing the airway at the level of the oropharynx. Children may present with an inability to manage oral secretions and respiratory distress. A finger sweep performed to remove an oral foreign body not effectively dislodged after striking the back or compressing the chest may result in edema of the epiglottis with exacerbation of the airway situation.

Laryngeal Foreign Bodies

Foreign bodies involving the larynx can cause dysphonia due to involvement with the vocal cords (◉ *Fig. 234.1*). Vocal quality can vary as the foreign body can move with respiration. Despite a period of normal phonation, concern for a laryngeal foreign body should not diminish and a thorough evaluation of the airway is necessary.



◘ Figure 234.1
Foreign body in the glottis with adjacent granulation tissue

Tracheobronchial Foreign Bodies

The acute onset of a cough without an infectious prodrome or subsequent to a choking episode raises the possibility of an airway foreign body. A child with the ability of placing an object in its mouth has the ability to introduce a foreign body into the aerodigestive tract. Older siblings can facilitate younger children having access to potential foreign bodies. A child with a suspected foreign body without evidence of an acutely compromised airway requires thoughtful management with the development of a diagnostic and therapeutic plan. Patients should be maintained in a monitored setting until definitive intervention.

History is the primary reason to proceed with airway endoscopy. One study reported that 45% of children with a history consistent with a foreign body and a negative chest x-ray had a positive endoscopy for a foreign body. Despite false negative chest x-rays, a chest x-ray is indicated as part of the clinical evaluation to provide information regarding the type of foreign body and the degree of pulmonary disease.

One radiographic finding consistent with airway foreign body aspiration is hyperinflation of lung distal to a foreign body. Hyperinflation occurs when air enters the distal airway on inspiration as the airway dilates around the foreign body while air becomes trapped on expiration as the airway collapses around the foreign body. The pathophysiology of air trapping and hyperinflation is an illustration of a "ball valve" effect of a partially occluding foreign body. Atelectasis and complete collapse of lung

distal to a foreign body can occur if the foreign body causes complete occlusion of the airway.

After the acute onset of a coughing or choking episode, the child may appear asymptomatic. One explanation for the absence of signs or symptoms of a foreign body could be that the child displaced the foreign body from the airway. A more concerning scenario is that the foreign body moved to allow sufficient air movement despite remaining in the airway. Despite the absence of persistent signs or symptoms of a foreign body, an endoscopic examination may be warranted if the history of aspiration is convincing.

Specific types of foreign bodies deserve special consideration. Vegetative matter can contain substances that cause significant airway inflammation. Peanuts are an example of a commonly aspirated foreign body. Peanut oil causes airway irritation within a relatively short period of time, and airway endoscopy may reveal mucosal edema and granulation tissue. Another feature of vegetative matter is the tendency to become hydrated secondary to airway secretions and assume a greater mass than when initially aspirated.

Epiglottitis

Inflammation of the larynx and subglottis can cause acute airway obstruction. The epidemiology of acute infectious laryngitis has changed since the introduction of the Haemophilus influenza type B (Hib) vaccine. Acute infection of the epiglottis associated with Haemophilus influenza type B infection has the clinical presentation of drooling, dysphagia, and airway distress. Patients with suspected epiglottis must be kept in a monitored setting and quickly placed in an environment where intubation or a surgical airway can be placed. The radiographic finding associated with epiglottitis is the "thumbprint" sign on a lateral neck x-ray as a result of edema of the epiglottis. The recommended management of a patient with epiglottis is intubation and antimicrobial therapy directed at Haemophilus influenza type B.

The widespread implementation of the Hib vaccine in the early 1990s has dramatically reduced the incidence of infectious epiglottitis. Episodes of epiglottis have declined more than 99%. The cases of H. flu epiglottitis that occur may be secondary to individuals who were either not vaccinated or did not respond to the vaccine.

Noninfectious etiologies of epiglottis include exposure to hot foods or liquids, caustic agents, foreign bodies, smoke inhalation, or angioedema. Most cases of angioedema involving the larynx occur in patients between the ages of 11 and 45 years of age with the first episode occurring in the teenage years.

Croup

Unlike patients with epiglottis, individuals with croup are more likely to have a viral prodrome. Patients with croup present with a "barking" or "seal-like" cough. The radiographic finding associated with croup is a "steeple" sign on an anterior–posterior high kilovolt radiograph of the larynx. The endoscopic appearance of croup is the double vocal cord sign reflecting marked edema of the subglottis. In a child, a relatively small degree of edema can result in clinically significant airway obstruction. One millimeter of mucosal edema in a preschool-aged child will reduce the size of the subglottis by 50%.

Croup is the most common cause of stridor and in some series accounts for 15% of pediatric emergency department visits. Intubation is required in less than 5% of patients with croup and hospital admission ranges from 1.5% to 31% of patients. Approximately 5% of individuals with croup will have more than one episode.

An important element of the medical history is a history of intubation, whether for surgical procedures or for respiratory problems. Airway endoscopy in the acute setting is not usually indicated. Airway endoscopy in the acute setting may be necessary when the patient does not respond to the usual management for croup. Indications for elective airway endoscopy include repeated episodes of croup or croup in the setting of previous intubation. Previous intubations, whether for a brief or a prolonged period of time, can result in subglottic stenosis, subglottic cysts, or other abnormalities.

Medical management of croup consists of systemic steroids and inhaled epinephrine. Patients managed as outpatients should be observed for several hours after receiving epinephrine because of the possibility of rebound edema of the subglottis. The efficacy of cool mist for humidification of the airway has not been confirmed despite its common use.

Acute inflammation of the subglottis referred to as croup is usually caused by parainfluenza with 80% of cases associated with parainfluenza types I, II, or III. Parainfluenza I is associated with 50–80% of patients hospitalized for croup.

Tracheitis

Bacterial tracheitis is usually the result of infection with *Staphylococcus aureus* or *Streptococcus pyogenes*. Bacterial tracheitis does not have specific clinical signs or symptoms to distinguish it from other acute airway infections. The diagnosis of bacterial tracheitis should be considered in

patients who present with the clinical presentation of croup without responding to routine management suggesting a nonviral etiology. Patients with bacterial tracheitis often require intubation in addition to appropriate antimicrobial treatment. The emergence of bacterial tracheitits as the leading cause of life-threatening infection airway infection may parallel the epidemiology of parainfluenza infection and resistant bacterial infections affecting the airway.

Subglottic Hemangioma

Subglottic hemangiomas are a form of vascular malformation that can present as "atypical croup" or as a "croup masquerader." Subglottic hemangiomas are not present at birth and experience growth after 1 or 2 months of life. The natural history of subglottic hemangiomas consists of a period of rapid growth followed by spontaneous resolution. Respiratory distress and eventually airway obstruction result from rapid growth of the hemangioma. Subglottic hemangiomas respond to systemic steroids with involution or cessation of growth while steroids are being administered.

Clinical characteristics that suggest a nonviral etiology of croup include croup in an infant less than 4 months of age and croup presenting in the spring or summer, when parainfluenza infection is rare. A typical history for subglottic hemangioma is a child who is treated with steroids for croup with recurrence of symptoms after completion of steroids. When the response to steroids is slow or met with recurrent symptoms, consideration must be given for a noninfectious etiology of croup and airway endoscopy should be considered. Management of subglottic hemangiomas consists of surgical and medical therapies. Left untreated, subglottic hemangiomas are likely to cause airway obstruction and respiratory distress.

Children with subglottic hemangiomas may also have cutaneous lesions or diffuse involvement of the airway. Patients with cutaneous hemangiomas in the "beard" or cervicofacial region have an approximate 60% chance of having a subglottic hemangioma.

Recurrent Respiratory Papillomatosis

The most common benign neoplasm found in the pediatric larynx is recurrent respiratory papillomatosis (RRP). Patients present with hoarseness that may be associated with respiratory distress. Infants are thought to acquire the disease from mothers infected with human papillomavirus (HPV) during labor and delivery. HPV may not become symptomatic until the child is several years old.

The possibility that a child's hoarseness is due to HPV is an important reason to examine the larynx of a child with hoarseness rather than assume that the hoarseness is due to a less concerning problem such as vocal fold nodules. Multiple strategies exist for managing RRP, including repeated laryngoscopies and debulking procedures. Additionally, adjuvant medical treatments have been utilized extensively with the intent of reducing the number of operative procedures. The epidemiology of RRP is likely to have a marked reduction in incidence with the increasing use of HPV vaccine among adolescent females.

235 Bronchopulmonary Dysplasia (BPD)

Julie Ryu

Etiology/Epidemiology

Bronchopulmonary dysplasia (BPD) is a chronic lung disorder that can occur in premature infants who require respiratory support early in life. Since the ability to support premature infants has improved over the last few decades, the number of premature babies in the United States has steadily increased since 1990. According to the March of Dimes and the CDC population census, there were approximately 530,000 infants born under 37 weeks gestation or 12.7% of births in the United States in 2006 alone. Despite medical advances, prematurity is still the leading cause of death in the first month of life. Infants, who survive, can develop profound medical and neurocognitive problems that never fully recover. Respiratory distress is often seen in the premature infant since lung development starts in utero but continues into the first few years of life. Infants who require respiratory support such as surfactant, mechanical ventilation, and supplemental oxygen are at risk for developing chronic respiratory problems (such as BPD) beyond the acute respiratory distress events.

Pathology/Pathogenesis

Bronchopulmonary dysplasia is a pulmonary disorder, first described by Northway et al. in 1967. It is a disorder that affects premature infants who have immature lungs that require supplemental oxygen and mechanical ventilation. When BPD was originally described in 1967, this group of patients consisted of infants with severe hyaline membrane disease, prolonged mechanical ventilation with high positive pressure ventilation and high oxygen concentrations. Previously, BPD was defined as having respiratory symptoms requiring oxygen and an abnormal chest radiograph at 36 weeks corrected age (gestational age plus chronological age). On autopsy, these patients had profound lung abnormalities that were evident throughout the lung from trachea to the parenchyma.

Bronchopulmonary dysplasia is a condition that develops after a culmination of chronic injury to the lung with subsequent insufficient healing. Pathology can start at the trachea from injuries from intubation and repeated suctioning resulting in ulcerations, development of granulation tissue, and subglottic stenosis. In addition to the narrowing that might occur, the trachea can also become dilated due to high pressure ventilation. Patients can develop a "floppy" airway (tracheamalacia), or stretched out trachea (tracheomegaly), or both, due to this barotrauma. In addition, stretch-injury can occur beyond the level of the trachea. Due to the uneven distribution of pressure delivered to the lung by mechanical ventilation, compliant areas are ventilated with more volume, while other less-compliant sections are not ventilated; therefore, cystic areas can occur adjacent to atelectatic areas in the same patient. Lung compliance heterogeneity is due to several factors including prematurity, surfactant deficiency, obstruction, and lung remodeling due to repeated lung injury. Surfactant deficiency is a key reason for the heterogeneity seen. Many premature infants are born prior to adequate surfactant levels. Surfactant is secreted by alveolar type II cells which helps reduce surface tension and therefore prevents alveoli collapse on exhalation, but sufficient levels are not produced until around 35 weeks gestation. To overcome this lack of surfactant, infants were mechanically ventilated with high positive pressures to inflate the lungs. In addition to the heterogeneous ventilation, perfusion is also not uniform and does not necessarily correspond to the areas receiving the most oxygen, therefore not correcting the hypoxia but now adding barotrauma and oxidant injury. As a consequence to these stressors, lung epithelia cells become injured starting a cascade of events that may lead to remodeling of the lung. Epithelial and endothelial cell injury can impair cell permeability allowing for increased susceptibility to infections as well pulmonary edema. In response to cell death, the body responds by releasing growth factors, cytokines, and inflammatory cells to remove the injured cells and fight infection. However, since the injury is often more extensive than the body's ability to heal, cells denude off creating an exudative process that further increases an influx of inflammatory cells and further contributing to poor gas exchange by obstructing air flow. Ultimately, as

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_235,

the assaults to the lung abate and the body begins to heal, lung remodeling occurs resulting in fibrosis, metaplasia, and bronchial smooth muscle proliferation.

Today, BPD or chronic lung disease (CLD) affects infants born at younger ages, lower supplemental oxygen concentrations, and less barotrauma, thus necessitating a revision of the old definition. Currently, just prior to delivery, pregnant women are given systemic steroids to help accelerate lung maturity and stimulating surfactant production in the fetus. Exogenous surfactant is also now readily available and has dramatically changed the face of BPD. The application of exogenous surfactant has allowed for more uniform lung ventilation with lower positive pressures. In addition, the trend in most centers is toward noninvasive ventilation even in the extremely premature infants to reduce the barotrauma injuries. These infants are now supported with nasal continuous positive airway pressure (NCPAP) and supplemental oxygen. This strategy of ventilation minimizes barotrauma, provides adequate oxygen levels, but does not correct the body's PCO_2, and thus this method of ventilation is often referred to as "permissive hypercapnia." With all the changes in clinical practice and the shift to younger premature infants, the old definition of BPD has become less useful. An infant born at 27 weeks gestation will require oxygen for a month and develop chest radiograph changes but may have a better respiratory status than an infant born at 35 weeks requiring the same support. Therefore a new definition of BPD was required to accommodate the changes in the premature population and the changes in clinical practice since 1967.

In 2001, the National Institute of Health organized workshop to characterize the "new" BPD and have now adjusted the criteria to account for younger premature infants and advances in medical technology. The results of the workshop were published by Jobe et al., and the "new" BPD definition now takes into account gestation age at birth and divides premature infants into two major categories, younger and older than 32 weeks gestation. For infants born before 32 weeks, BPD is assessed at 36 weeks post menstrual age or at discharge to home (whichever comes first) and having required at least 28 days of oxygen since birth. For infants born after 32 weeks, they are assessed at 28–56 days of life or at discharge to home (whichever comes first) and again having required at least 28 days of oxygen since birth. BPD is further categorized in both groups as mild if at time of assessment they are on room air, moderate if they require less than 30% supplemental oxygen, and severe if they need more than 30% oxygen or any invasive or noninvasive mechanical ventilation.

Even though the definition and even the risk factors of BPD have shifted, the molecular pathways involved for both "old" and "new" BPD are still largely unknown. Despite the necessity of these treatment modalities, the combination of immaturity, free radical oxidant injury and barotrauma created by mechanical ventilation still contribute to the development of new and old BPD. And although the histology of new BPD has shifted from the striking fibroproliferative disease of old BPD to one that consists of fewer and more simplified alveoli, the insults associated with new BPD still occur during a critical time in lung development, thus affecting both alveolar and vascular development. Human lung development can be characterized in four stages that begin in the prenatal period but continues well after birth. The final stage of lung development is alveolarization, when alveoli are formed, which begins around the 36 week of gestation and continues to about 2 years of age. Since premature infants by definition are born before 37 weeks gestation, lung injuries prior to term may have a profound impact on lung development, thus explaining why some infants continue to have respiratory problems well beyond the initial insult and into childhood. These alterations in lung development can result in persistent abnormalities in pulmonary mechanics with lower lung compliance and airway obstruction. In fact, Doyle et al. who looked at 147 subjects with a mean age of 18.9 years found that subjects who had BPD as infants had a greater chance of having a decreased forced expired volume in 1 s/forced vital capacity ratio $<75\%$ as compared to non-BPD subjects (42.4% vs. 16.4%), even if lung volumes were not significantly different. Vascular development can also be compromised in the infant with BPD. Vascular cells are very sensitive to inflammation and oxygen levels, and therefore the oxidant injury that occurs during vascular development can increase smooth muscle proliferation and increase pulmonary vascular resistance. Thus infants with BPD are at higher risk for developing left or right ventricular hypertrophy and pulmonary hypertension.

Treatment and Management

Maintaining good oxygen saturations is a key component of the treatment of BPD. Maintaining oxygen saturations above 92% is not only important in respiratory status but also for growth. Supplemental oxygen should be provided not only if the patient's daytime saturation is below 92%, but oxygen saturation may be normal when awake but below 92% when asleep; therefore it is important to assess nighttime oxygen saturations in any child with

persistent respiratory symptoms and/or with poor weight gain. While the optimal oxygen saturation (92–94% vs. >94%) in the infant with BPD is still under debate, below 92% is not recommended.

Infants who require prolonged supplemental oxygen may benefit from diuretic therapy. Diuretics, such as furosemide, have been shown to improve respiratory mechanics independently of their ability to reduce pulmonary edema. However, furosemide has been associated with nephrocalcinosis as well as electrolyte imbalances and, therefore, has limited its uses in the treatment of BPD after hospital discharge. Alternative diuretics such as spironolactone and thiazide are often used in combination to obtain a diuretic effect with less electrolyte disturbances and therefore are often prescribed as an outpatient medication.

Bronchodilators are also often used in infants with BPD and can be helpful during acute wheezing episodes, but it is uncertain if the use of bronchodilators in these patients improves long-term pulmonary function. Systemic corticosteroids, as a treatment for BPD, are controversial and can be associated with numerous adverse effects such as impaired lung growth and neurodevelopmental consequences. However, since some infants with BPD respond to bronchodilators and exhibit symptoms similar to reactive airway disease, this subpopulation may benefit from inhaled corticosteroids.

Since the key treatment for BPD is growth, good nutrition is an essential. It is important to maintain adequate nutrition since most of lung development occurs before age 2. While weight is important, body length is equally if not a better indicator of lung growth. The term infant typically requires 100 kcal/kg/day while infants with BPD may require 140 kcal/kg/day for adequate weight gain. Feeding can be challenging in infants with severe BPD since many will have oral aversion from an immature or inadequate swallowing coordination. In addition, infants with severe BPD may be fluid sensitive and therefore cannot tolerate the volume of feeds that are required to achieve the desired nutritional level.

Furthermore, many infants with BPD suffer from gastroesophageal reflux or have dysphagia which can exacerbate any underlying lung disease by through chronic microaspiration. A diagnosis of reflux can be made clinically and treated with a histamine H2-receptor antagonist, but additional promotility agents may be required in some cases. When aspiration is suspected, a dysphagia study is essential to identify which textures the patient may safely swallow. In severe cases of dysphagia with aspiration, a gastrostomy tube may be necessary to ensure both adequate nutrition and to eliminate the risk of aspiration.

Infants sent home with a diagnosis of BPD often require a readmission to the hospital in the first 2 years of life. Infants with BPD have impaired pulmonary mechanics and low lung reserves, and therefore many require more respiratory support during an upper respiratory infection than their term counterparts. Respiratory Syncytial Virus (RSV) infections can be devastating in these patients, and therefore RSV vaccination is recommended. In addition, influenza vaccinations are recommended annually for the patient as well as his/her caregivers. Hand washing and limited contact with ill individuals are also effective strategies to reduce the probability of respiratory infections.

While many infants with BPD have abnormal chest radiographs on hospital discharge which can consist of hyperinflation, peribronchial cuffing, or patchy interstitial infiltrates, these findings are nonspecific and usually improve with time. Due to the nonspecific findings, routine chest radiograph is not usually recommended when the patient is asymptomatic. Blood work is also not done routinely but may be indicated in patients on diuretics or those whom chronic hypoventilation is suspected. An elevated bicarbonate level may indicate a metabolic compensation for respiratory acidosis and deserves further evaluation. Infants on supplemental oxygen/respiratory support or suspected of chronic hypoventilation, annual echocardiograms may be helpful in monitoring for right ventricular hypertrophy and signs of pulmonary hypertension.

While respiratory symptoms are a key component of BPD, it is a disorder that can result in multiple medical and cognitive problems. These infants often require services including occupational and physical therapy, and are followed by a number of specialists.

Outcomes and Prevention

Infants who do well in the first 2 years of life without recurrent respiratory infections generally do well clinically. However, studies have shown that 25% of adolescents with a history of BPD are more likely to have reduced airway flows, decreased lung compliance, and diminished exercise capacity as compared to age-matched controls without a history of BPD. Therefore it is not surprising that many infants with BPD develop asthma-like symptoms. Further studies are needed since the defining characteristics have changed and older studies may not be representative of the "new" BPD. Despite medical advances, specific medications are not available for infants with BPD, but treatment is supportive and nonspecific. Currently, the emphasis is for the prevention of BPD, and many studies are ongoing looking at new strategies to prevent this disorder. These

strategies include less-invasive ventilation such as permissive hypercapnia, but additional studies are required to assess the long-term consequence of prolonged hypercapnia during lung development. Other studies have stressed the importance of prophylactic rather than rescue surfactant. Antioxidants such as recombinant superoxide dismutase (CuZnSOD) may prevent the oxidant injury that is associated with the development of BDP4). In addition, vitamin A is often given to preterm infants for its nutritional and antioxidant properties. Others are investigating the use of nitric oxide as a tool to prevent pulmonary vascular injury. While these are only a few examples of the modalities currently under investigation, all of these new prevention strategies have been developed to target the pathways believed to be involved in the development of BPD. As the understanding of the pathophysiology of BPD improves, new medications and treatment strategies are emerging demonstrating the importance of further research on this important topic.

236 Pneumonias

Erin R. Stucky · Meerana Lim

Definition/Classification

Defining pneumonia is particularly difficult in young children in whom other lower respiratory tract infections are common. The World Health Organization (WHO) defines pneumonia clinically, in the following stages: Stage I, fever $\geq$38°C and tachypnea (>50 breaths/min for 2–11 month olds and >40 breaths/min for 1–5 year olds); Stage II, with addition of chest indrawing; and Stage III, with addition of inability to drink and/or central cyanosis. The British Thoracic Society defines community-acquired pneumonia (CAP) as the presence of signs and symptoms of pneumonia in a previously healthy child due to an infection which has been acquired outside hospital. In the developing world, "acute lower respiratory infection" (ALRI) is used, given the limited access to obtaining a chest radiograph (CXR).

Etiology

The etiology of pneumonias in children outside the immediate newborn period varies based on age group, environment, exposures, and underlying comorbid risk factors.

Pneumonia can be caused by microorganisms, irritants, or unknown causes. Infectious etiologies include bacteria, viruses, atypical organisms, fungi, and parasites. The exact infectious etiology of the pneumonia is often not known because this would require an invasive procedure to obtain a specimen for culture. Without a culture, other clinical features and diagnostic study results are used to help make a clinical diagnosis and to guide appropriate therapy. The most commonly reported viral causes are biased due to available testing, but include influenza A or B, rhinovirus, respiratory syncytial virus (RSV), human metapneumovirus (hMPV), and parainfluenza. In the post-pneumococcal vaccine era in the United States, increased rates of invasive pneumococcal pneumonia during the respiratory viral infection season has been reported in association with RSV, influenza, adenovirus and hMPV. Viral causes that are of concern in countries without consistent immunization practices, or in immunocompromised hosts with cancer, primary immunodeficiency, or human immunodeficiency virus (HIV), are varicella and measles.

Epidemiology

According to the WHO, pneumonia is a significant cause of child mortality worldwide, responsible for approximately 2 million deaths each year, of which almost three-quarters are in developing countries. The WHO's Global Burden of Disease Update 2004 reports diarrhea and pneumonia as the leading causes of mortality in children under 5 years of age. In 2008, pneumonia accounted for 14% of deaths in infants less than 28 days of life according to the WHO. In Europe and Australia, incidence is reported at 3.6–6.8% of children less than 5 years of age, with similar hospitalization rates of 41–42%.

Although diagnostic testing is usually limited in practice, studies in the United States and Europe demonstrate that viruses are involved in up to two-thirds of CAP, of which approximately half are mixed viral–bacterial infections. In limited studies in developing countries, rates of the more broadly defined ALRI are reported, with viral causes at approximately 50%, the majority due to RSV. Influenza's impact worldwide varies with the yearly strain antigenic drift, with epidemics and pandemics seen when antigenic shift occurs. New viral etiologies continue to emerge, such as the coronavirus severe acute respiratory distress syndrome (SARS). The clinician must be attentive to outbreaks of respiratory diseases across the globe given the ease with which pathogens travel on human hosts (air travel) and through natural sources (global air streams).

Pathogenesis and Pathology

The most frequent histopathologic findings in major airways with viral pneumonia are congestion, inflammation, necrosis of bronchial epithelium, and hemorrhage. Viral pneumonias affect the lung through direct invasion, causing mucosal inflammation and damaging ciliary clearance allowing secondary bacterial infection to occur more readily.

In severe cases, extensive involvement of the bronchoepithelial cells and mucous glands of trachea, bronchi, and larger bronchioles, and submucosal mononuclear inflammatory infiltrates can be seen. Neutrophilic and monocytic inflammation and extensive secondary

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_236,

bacterial pneumonia is reported from autopsies of pediatric influenza patients.

Clinical Manifestations

Typical signs and symptoms include fever, diminished breath sounds, rales, retractions, tachypnea, hypoxemia, and cough. In general, higher fever with a rapid onset is seen in bacterial pneumonia; however, there are many exceptions to this. Viral pneumonia, particularly those caused by influenza, may present with high fevers and chills. *Chlamydia trachomatis* and *Bordetella pertussis* infections are frequently afebrile. A fever many days into a respiratory illness accompanied by worsening symptoms may suggest a secondary bacterial infection after a primary viral illness.

While the characteristic post-tussive inspiratory whoop of whooping cough may help make this diagnosis in school-age children, it is usually not present in very young infants and adults. A productive cough, particularly if associated with large volumes of purulent secretions, is suggestive of a bacterial pneumonia, whereas a dry, nonproductive cough is more likely to be a viral process. In very young children and infants, sputum characterization can be difficult as they are likely to swallow their sputum. If sputum can be expectorated, a culture of the expectorate may be helpful in the diagnosis and treatment of pneumonia.

Poor feeding or poor oral intake is common (~75%), as are vomiting (30–45%), abdominal pain (up to 20%), and dehydration (25%).

Physical Exam

The physical exam for pneumonia may not be as helpful in an infant versus and older child or teenager. The most common findings include fever and tachypnea. Tachypnea has been associated with a sensitivity of 50–85% for diagnosis of lower respiratory tract infection with specificity of 70–97%. In children who have been symptomatic for over 3 days, tachypnea has a sensitivity of 74% and a specificity of 67% for pneumonia confirmed by chest x-ray.

Tachypnea age specific norms recommended for use:

- 60 breaths/min in infants younger than 6 months
- 50 breaths/min in infants 6–11 months old
- 40 breaths/min in children 12–59 months old
- 30 breaths/min in febrile children 5 years of age and older

Decreased breath sounds may occur in the area of a lobar pneumonia. Normal breath sounds may be auscultated in up to 20% of children due to transmission of normal breath sounds across the relatively small thorax; yet they may have complete collapse or consolidation on CXR. Crackles are frequently suggestive of bacterial pneumonia, which are not uncommon in infants with RSV pneumonia. This is the sound of alveoli opening and/or by air bubbling through fluid in the small airways during inspiration. Wheezing may be present; however this sign may be noted in many lower respiratory tract diseases. Dullness to percussion may be heard over an area of focal consolidation. Egophony or increased resonance can be auscultated over an area of consolidation or over a large effusion. The patient is asked to say "e" and what is heard by stethoscope is "a" due to altered transmission of noise through fluid versus air. Chest pain, usually pleuritic, worsened by deep breaths and cough, may also be present.

Diagnosis

Diagnosis of pneumonia in the ambulatory setting is often made clinically, especially where access to radiology services is limited. According to the British Thoracic Society, CXR should not be performed routinely in children with mild uncomplicated acute lower respiratory tract infection. Correlation between clinical assessment of diminished breath sounds and consolidation on CXR is overall poor at only 50–60%.

Neither clinical signs and symptoms nor CXR aid in differentiating between viral and bacterial pneumonias. However, some associations between CXR reports and infectious etiologies may be helpful in treatment decisions. Lobar consolidations are frequently associated with a bacterial pneumonia, whereas a bilateral diffuse interstitial appearance may be more suggestive of Pneumocystis pneumonia, Legionella, or a viral process. Pneumonia caused by Staphylococci in the pediatric population may be associated with pneumatoceles, bronchopleural fistulas, and empyema, although none of these should be considered pathognomonic. Mycoplasma pneumonia usually has a diffuse bilateral interstitial appearance on radiograph, although it can also be seen with lower lobe consolidations and effusions. The preferred imaging is for two views of the chest, frontal (usually posteroanterior), and lateral (to see the retrocardiac area) for initial evaluation. In cases where there is complete opacification of the hemithorax or when there is a complicated pneumonia, computed tomography and/or sonography may also be employed. Recurrent pneumonias and those that are resistant to therapy are candidates for further imaging.

Laboratory testing in ambulatory patients is not routinely indicated, but some studies may be helpful for hospitalized patients (Table 236.1). Lab testing for viruses by real-time (RT) PCR can be valuable in patients at risk for more severe complications of disease who may require more intense monitoring due to underlying cardiac, immune, or chronic pulmonary disorders. Routine laboratory testing for ambulatory children is not indicated. Inappropriate secretion of antidiuretic hormone (SIADH) may be more common than previously thought, found in up to 20% of patients (Table 236.2).

Patients with significant pleural fluid should have specimens sent for gram stain, viral testing, aerobic and anaerobic bacterial culture, with consideration for mycobacteria and fungal cultures at the direction of infectious disease consultation. Sensitivity of latex agglutination studies for *Streptococcus pneumoniae* and *Haemophilus influenzae* type b (Hib) on pleural fluid vary with method and range 77–91%.

For immunocompromised hosts, evaluation for invasive viral infections such as varicella, herpes simplex, and coronavirus should be considered along with parasitic, protozoal, and fungal infections, and in consultation with infectious-disease experts.

Table 236.1
Pneumonia-causing organisms by age

Neonates	Common organisms	Group B streptococcus, gram negative enteric bacteria, cytomegalovirus, *Ureaplasma urealyticum*, *Listeria monocytogenes*, and *Chlamydia trachomatis*
	Less common organisms	*Streptococcus pneumoniae*, group D streptococcus, and anaerobes
Infants	Common organisms	RSV, parainfluenza viruses, influenza viruses, adenoviruses, metapneumovirus, *Streptococcus pneumoniae*, *Hemophilus influenzae*, *Mycoplasma pneumoniae*, and *Mycobacterium tuberculosis*
	Less common organisms	*Bordatella pertussis* and *Pneumocystis jiroveci*
Preschool children	Common organisms	RSV, parainfluenza viruses, influenza viruses, adenoviruses, hMPV, *Streptococcus pneumoniae*, *Hemophilus influenzae*, *Mycoplasma pneumoniae*, and *Mycobacterium tuberculosis*
	Less common organisms	*Chylamydia pneumoniae*
School-age children	Common organisms	*Mycoplasma pneumoniae*, *Chylamydia pneumoniae*, *Streptococcus pneumoniae*, *Mycobacterium tuberculosis*, parainfluenza viruses, influenza viruses, and adenoviruses

Differential Diagnosis

Alternate diagnoses may be both pulmonary and non-pulmonary. For young infants with wheezing and acute respiratory distress, bronchiolitis is the most common diagnosis. Acute respiratory distress may be the result of aspiration of a foreign body, inhalation lung injury, or spontaneous pneumothorax. Non-pulmonary considerations include leukemic infiltrates, congestive heart failure, metabolic acidosis with compensatory tachypnea, asthma, or in appropriate areas malaria. Failure to improve as expected with usual therapy should trigger consideration of both uncommon infectious organisms as well as underlying condition such as HIV or pulmonary anatomic abnormality. Recurrent pneumonia bears a further work-up, depending on the associated signs and symptoms. Underlying diagnoses to consider include: cystic fibrosis, congenital malformations (cystic adenomatoid malformations, pulmonary sequestrations, foregut duplication cysts), immotile cilia syndrome, right middle lobe syndrome, immunodeficiency (congenital or acquired), hemorrhage, vascular malformations, and dysfunctional swallow. In these cases, treatment of the underlying disease is an important part in the prevention of further pneumonias and long-term consequences of recurrent lung infections.

Treatment

Patients not hospitalized should be reevaluated by their primary care practitioner within 24–48 h. Admission should be considered for patients with need for supportive care (oxygen, intravenous hydration, suctioning) or at risk for progression of respiratory disease or potential instability of underlying chronic condition. Specific admission criteria suggested include oxygen saturation less than 92%; respiratory rate >70 breaths/min in infants/50 in

Table 236.2
Commonly performed laboratory testing

Study	Value	Comments
RT-PCR viral (NPA; tracheal)	Influenza treatment can be initiated; discontinuation of antibiotics can be considered	Nasopharyngeal aspirate (NPA) technique influences result; overall sensitivity 80–95%
RT-PCR atypical (NPA; tracheal)	Mycoplasma and Chlamydia pneumonia treatment can be initiated	Not available at many hospital sites
Viral culture (NP, tracheal most common)	Definitive diagnosis of active viral infection	Requires special transport media, processing time, not available at many hospital sites; rarely positive in face of a negative viral PCR
Paired acute and convalescent serology (blood)	Can detect acute infection of some viruses; more reliable result for *M. pneumoniae* than single IgM	Requires blood testing at presentation and at 3 weeks
RT-PCR (blood)	*S. pneumoniae* most often tested	May be negative when paired serology demonstrates acute exposure
C-reactive protein (CRP); Procalcitonin (PCT)	Higher levels seen in typical bacterial infection	Cutoff levels below which typical bacterial disease is not likely to have not been well documented for CRP or PCT
Complete blood count		White blood cell count and band forms do not correlate well with etiology
Electrolytes	For severely dehydrated or ill patients	Hyponatremia, acidosis, and hypoglycemia are not uncommon in severely ill patients
Blood culture	Supportive of more systemic disease	Rarely positive (1–10%); however, it is recommended in any patient with probable bacterial infection

children, grunting or apnea, poor feeding/inability to feed, and concern for caregiver ability to assess respiratory distress. Pulse oximetry should be performed on all hospitalized children.

Antibiotics will be given empirically despite the fact that this approach likely leads to overuse of antibiotics in the general population. Antibiotic choice is typically based on the patient's age and commonly encountered organisms causing infection in that age. It is important to remember that for neonates, early-onset GBS disease is usually severe and almost always includes pneumonia as part of the disease presentation. Treatment of suspected or proven viral pneumonia is typically supportive. Chest physiotherapy (postural drainage, percussion of the chest, or deep breathing exercises) does not affect length of hospital stay, duration of fever, or CXR findings in patients with pneumonia. Sitting upright may help to expand lungs and lessen respiratory symptoms in children with respiratory distress.

For patients with suspected or proven influenza pneumonia, antiviral therapy with oseltamivir is indicated to both treat the patient and to limit spread of the disease. Other pathogen-specific therapies include vitamin A for measles pneumonia, acyclovir for varicella, and ribavirin for SARS and severe RSV. Steroid use is controversial but has been used in severely ill patients in intensive care settings.

Prognosis

Duration of hospital stay is associated with clinical severity rather than etiology. Although acute inflammatory markers (CRP, PCT) are higher in bacterial disease, levels do not correlate with severity of disease.

Follow-up CXR is indicated only for lobar collapse or round pneumonia to document complete resolution and thereby confirm absence of anatomic abnormality or tumor.

Prevention

Primary prevention includes strict infection control measures, immunization, and avoidance of exposures and lung irritants that increase susceptibility to respiratory pathogens. Hand washing and covering the mouth while coughing continue to be significantly effective measures to reduce

spread of disease. Crowding and smoke exposure are associated with increased risk of viral infections, particularly in young infants. Chemoprophylaxis for certain types of pneumonia may be indicated in select populations such as immunocompromised patients, and those with asplenia and certain cardiac disorders. Guidelines for routine vaccination against Hib, *Streptococcus pneumoniae*, and varicella, as well as yearly influenza prevention should be followed. Immunoprophylaxis against RSV should be given to appropriate infants following national guidelines.

237 Cystic Fibrosis

Kathryn Akong · Meerana Lim

Etiology/Epidemiology

Cystic fibrosis (CF) is a genetic disorder that affects multiple organ systems, most notable are the lungs and GI tract. It is known to be caused by mutation of one single gene, known as the Cystic Fibrosis Transmembrane Conductance Regulator (CFTR) gene on chromosome 7, which encodes an ion channel important for chloride and bicarbonate transport across epithelia. Inheritance follows the classical Mendelian autosomal recessive pattern. Therefore, affected patients have mutations in both alleles of the CFTR gene, one inherited from each parent. However, the severity of disease is extremely variable from patient to patient, even among those with identical CFTR mutations. This variation is likely multifactorial, related to differences in compliance to medical regimens, environmental exposures, and the effect of other genes that modify the CF phenotype. The etiology of CF multisystem disease is still not completely understood, but the hallmark of the disease is the production of thick, tenacious secretions, particularly in the airways and GI tract. This is related to imbalance of ion and water transport across these epithelial structures due to CFTR mutations.

First described in the 1930s, CF is a relatively common disease, affecting 30,000 people in the USA and 70,000 worldwide. The carrier frequency is highest in the Caucasian (European descent) population (1 in 30), with the Hispanic population second (1 in 46). It is also found at much lower frequencies, albeit not negligible, in the African population (1 in 65) and Asian populations (1 in 90). The most recent data from the CDC suggests that the incidence of CF is 1 in 2,500–3,500 live births in non-Hispanic whites, and approximately 1 in 3,700 overall.

The earliest presentation of CF is meconium ileus, which can be identified shortly after birth as abdominal distension and lack of passage of meconium in the first days of life. This is the presenting symptom in approximately 15–20% of children with CF. In children without meconium ileus, the most common presenting signs include those of exocrine pancreatic insufficiency (failure to thrive, persistent diarrhea, chronic abdominal pain) and airway inflammation (prolonged cough, recurrent wheezing). The median age of diagnosis based on clinical symptoms (other than meconium ileus) is approximately 14.5 months, often after many other diagnoses have been entertained. The overall median age of diagnosis is 5.3 months, which includes children presenting at birth with meconium ileus, or diagnosed through newborn screening programs, or because of a known family history.

There are now over 1,800 different mutations of CFTR that have been described. By far, the most common mutation in CFTR is a deletion of phenylalanine at position 508 (called delta F508, or ΔF508), which accounts for about two-thirds of the mutations found in CF patients. The other one-third of mutations is comprised of over 1,000 different mutations, all found at much lower frequencies. There are alleles that may be more frequent in certain populations due to founder effect, but none approaches the frequency of ΔF508.

Genetics of CF

Although CF is a disease caused by mutation in a single gene, complexity arises in the vast number of different mutations in the gene that may, or may not, actually cause disease. This is in stark contrast to another monogenic disease, sickle cell anemia, where a single point mutation is the sole variant known to cause the disease.

Strictly speaking, the term "mutation" refers to any change in the nucleotide sequence of a gene. There is no assumption of the functional consequence of the change in sequence, thus mutations may be classified as deleterious, neutral, or even beneficial. The term "polymorphism" refers to variations in gene sequence that have achieved a certain frequency in a population and do not have any overt deleterious consequence. Distinguishing between a disease-causing mutation and a polymorphism has proven to be extremely difficult in CF. Many factors play a role in the manifestation of disease in CF, including the specific organ that is affected (some organs are more affected by certain types of allelic variations), as well as the role of modifier genes on the CF phenotype. This is compounded by the vast array of novel CFTR mutations discovered through genetic sequence analysis, the majority of which have no known or predicted clinical

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_237,

consequence. The effects of such phenomena are further discussed in the context of newborn screening for CF.

CFTR mutations can also be classified by the type of defect predicted to occur. In some cases, a missense or frameshift mutation can lead to an early stop codon and defective production of a complete protein product (class I mutation). Mutations that cause defective posttranslational protein trafficking or maturation (class II) or protein regulation (class III) are also predicted to cause disease. In contrast, mutations that affect the conductance function of the protein product (class IV) or that lead to decreased (but not absent) functioning protein product (class V) can have varied degrees of clinical manifestations, including normal sweat chloride and pancreatic sufficiency.

Diagnosis

Newborn Screening

Beginning in 2005, many states in the USA had implemented mandatory newborn screening programs for CF. During 2010, all states and the District of Colombia had mandatory newborn screening programs in place. The push for mandatory screening of all newborns for CF arose from the premise that early intervention, even prior to overt symptoms, can alter the course of the disease in a positive way. The data show that early intervention does improve growth and nutritional parameters, but the effect on respiratory status and progression of lung disease is as yet unproven.

The exact protocol for screening differs slightly from state to state. Generally, screening begins with testing a blood spot for elevated immune reactive trypsinogen (IRT) levels, which has a sensitivity of ~88% and specificity of ~99.5% for detecting cystic fibrosis. If this is positive, then this may be followed by a repeat IRT level, or by DNA testing for CFTR mutations (see Genetic Testing, below). Once an infant is identified as possibly having CF by newborn screening, further confirmatory diagnostic testing and counseling should be done at an accredited CF Center.

Sweat Chloride Test

The most commonly used diagnostic test for CF is the sweat chloride test. This test is based on the fact that the epithelium lining the sweat ducts reabsorbs chloride from the fluid as it travels up the sweat duct to the skin. This chloride reabsorption is dependent on functional CFTR at the apical surface of the epithelial cells. In CF, where there is loss of functional CFTR, the sweat produced by the skin has higher levels of chloride. Typically, patients with CF have sweat chloride levels over 60 mEq/L. However, in infants, levels above 30 mEq/L are considered abnormal.

The sweat chloride test is noninvasive. It involves the application of a tiny, painless electrical current to the skin (usually the forearm) to stimulate sweat production. The test is usually done as an outpatient, and typically can be completed in less than 1 hour. Neonates may not produce enough sweat to be diagnostic, so the earliest recommended age to test if CF is suspected is 2–4 weeks of age. Any infant tested in the first month of life may require a second test later on for confirmation, as the test is less reliable in early infancy.

Genetic Testing

If the sweat chloride test is nondiagnostic, or positive, the next step is often genetic testing to identify specific mutations in the CFTR gene. In the case of a nondiagnostic sweat test, this further testing is done in order to determine if there are two disease-causing mutations present. If this is the case, then the patient meets criteria for a positive diagnosis of CF.

In the case that the diagnosis is made with sweat testing, genetic testing is often pursued because it may give some limited additional prognostic information, but more importantly, new therapies are being developed that are specific to certain mutations or classes of mutations. Thus, in the future, it will become more important to know the genotype of every patient in order to tailor therapy. An additional benefit of genetic testing is the ability to easily screen other family members for known mutations.

There are many different types of genetic tests commercially available. It is important to know the limitations of these different tests in order to interpret the results obtained. If the mutations in a given family are known, then other family members can be screened by looking specifically for these mutations. If there are no known mutations in a family, then a screen using a panel of 20–50 of the most common mutation can be done. The limitation to this is that there are patients for whom the sensitivity of these panels is much lower due to the differences in mutations found in certain ethnic groups compared to non-Hispanic Caucasians. There is also full gene sequencing (exons and splice sites) available to screen more comprehensively for mutations in the CFTR gene. While full gene sequencing can detect ~97–98% of mutations, it will not detect large gross deletions or duplications. If only one mutation is detected with full gene sequencing, the sample can also be screened for large deletions or duplications using different methods.

Nasal or Rectal Potential Difference

This is a functional test for the presence of CFTR, based on the ability of CFTR to regulate the potential difference across epithelial structures. It is not routinely used as a screening test due to the fact that it is somewhat invasive. The test involves one electrode that is placed on the nasal mucosa of the inferior turbinate, and another subcutaneously on the forearm, connected to a voltmeter to measure the potential difference. A potential difference less than −40 mV is considered abnormal.

Special Considerations

According to the CF Foundation, a diagnosis of CF can be made if the patient has suggestive signs and symptoms, *or* a positive family history, *or* a positive newborn screen, *and* evidence of CFTR gene or protein abnormality, i.e., abnormal sweat chloride test, abnormal nasal potential difference, or two CF disease-causing mutations in *trans*.

As newborn screening and gene sequencing have become more routine, a new diagnostic challenge has arisen. This is related to cases where an infant has a positive newborn screen, but normal or borderline sweat chloride level. In these cases, genetic testing is usually performed to determine if there are two disease-causing mutations. However, ambiguity arises when novel mutations, or mutations with unknown clinical consequences, are discovered. In an otherwise asymptomatic infant, making the diagnosis of CF on these grounds has been controversial. In a statement by the CF Foundation in 2009, a new diagnostic entity was proposed to address this issue. For infants who are asymptomatic, have elevated IRT on newborn screening, and have at least one mutation that is not clearly "disease-causing," the term "CF-Related Metabolic Syndrome" (CRMS) has been proposed. There are also proposed guidelines for surveillance and management of these infants, because if signs or symptoms of CF were to develop, they would be given the diagnosis of CF and managed accordingly.

Symptoms/Pathology/Pathogenesis

Lung Disease

Lung disease significantly contributes to the morbidity associated with CF and is the most common cause of mortality. It is for this reason that CF is managed primarily by pediatric pulmonologists, even though many other organ systems are also affected. The hallmark of CF lung disease is thick, tenacious mucus that accumulates in the large, medium, and small airways. This thick, stagnant mucus layer inevitably becomes a nidus for acute bacterial infections and, eventually, chronic bacterial colonization.

In conjunction with persistent bacterial colonization, there is also a chronic inflammatory state mediated primarily by neutrophils in the CF airways. Neutrophils are essential to the lungs' ability to fight infection; however, there is a price paid in host tissue damage. This is especially true in the case of chronic neutrophilic inflammation, in which there is prolonged exposure to released reactive oxygen species and other damaging inflammatory mediators. There still remains a "chicken and egg" question of which arises first, airway bacterial colonization or airway inflammation. Regardless of the inciting factor, it is clear that the ongoing neutrophilic inflammation in the airways over time leads to airway remodeling, fibrosis, bronchiectasis, and, thus, obstructive lung disease.

Onset of respiratory symptoms varies from patient to patient, but can be present early in infancy. Symptoms can include chronic wet cough, prolonged cough after respiratory illnesses, wheezing, dyspnea on exertion, and chest pain or tightness. Over time, patients with CF may experience episodic exacerbations of their lung disease. While the exact etiology of these exacerbations is still not completely understood, they are often precipitated by a concurrent acute respiratory infection (viral, bacterial, or other) or by inadequate airway clearance and adherence to maintenance therapies. Respiratory exacerbations are characterized by increase in cough, change in quality or quantity of mucus production, increased dyspnea (especially with exertion), and usually an associated worsening in airways obstruction (i.e., decreased FEV1 on spirometry). There may or may not be other systemic signs or symptoms such as fever, weight loss, fatigue, and anorexia.

Progression of CF lung disease over time is the rule rather than the exception. The rate of progression varies and is thought to be related to many factors, such as genetics, environmental exposures, nutritional status, and adherence to medical therapies. There have been certain factors that have been shown to be associated with an accelerated rate of decline of lung function. One of these is colonization of the airways with Pseudomonas aeruginosa, particularly the mucoid phenotype. For this reason, routine surveillance cultures are obtained, and measures are taken to eradicate Pseudomonas at each new acquisition to prevent or delay colonization. Methicillin-resistant Staphylococcus aureus (MRSA) colonization is also emerging as a possible factor associated with accelerated decline in lung function,

though this is still under active investigation at this point in time. Another well established factor that contributes to decline in lung function over time is nutritional status. Thus nutritional and growth parameters are carefully monitored, and often aggressive measures are undertaken to correct deficits, such as supplemental feedings with gastrostomy tubes.

Respiratory failure is the most common cause of mortality in CF. Patients with extensive bronchiectasis and fibrosis may become hypoxemic and hypercapneic. In such severe lung disease, other complications may arise, such as hemoptysis (which may be massive) or pneumothorax.

Pancreatic Disease/CFRD

Exocrine pancreatic insufficiency is often the earliest presentation of cystic fibrosis. Patients will usually develop pancreatic insufficiency and chronic malabsoption within the first year of life. Symptoms and signs include chronic abdominal pain and cramping, abdominal distension, diarrhea, steatorrhea, and failure to thrive. Laboratory studies may reveal deficiencies in fat-soluble vitamins.

Exocrine pancreatic insufficiency in CF is a result of production of thick secretions and obstruction of the pancreatic ducts and acini leading to their destruction. Approximately 10–15% of CF patients do not develop pancreatic insufficiency, and this phenotype is usually associated with mutations where there is reduced, but not abolished, CFTR function. There are also certain mutations that are more associated with the predisposition to chronic pancreatitis, or recurrent acute pancreatitis, which then eventually leads to pancreatic insufficiency later in life. The diagnosis of CF should be considered in patients with idiopathic recurrent or chronic pancreatitis, even in the absence of other manifestations of the disease. Interestingly, a significant proportion of patients with idiopathic chronic pancreatitis are carriers of CFTR mutation, suggesting a degree of haplotype insufficiency related to pancreatic disease.

Patients with CF are also at high risk to develop endocrine pancreatic insufficiency, i.e., CF-related diabetes (CFRD). The incidence increases with age, and currently half of CF patients over age 30 have CFRD. The presentation of CFRD increases during times of stress, e.g., respiratory exacerbation, which is the rationale for screening during acute exacerbations in the hospital. The etiology of CFRD is insulin deficiency, not insulin resistance. The pathogenesis is distinct from diabetes mellitus type 1 and 2, and is thought to be related to apoptosis of β-islet cells and defective secretion of insulin from surviving islet cells. Oxidative stress is thought to play a key role in this process, but the exact mechanisms are still elusive. Genetic factors also play a role, including non-CFTR genotypes. Hormonal milieu may also play a role as epidemiologic studies show a higher predisposition to develop CFRD in females as well as increased risk in patients with increased systemic steroid use. Despite the increased incidence of CFRD with increased age, mortality in patient with CFRD is still primarily related to respiratory failure, not cardiovascular disease.

Other Clinical Manifestations of CF

Sinus disease: As part of the respiratory tract, the sinuses are also frequently obstructed with thick mucus and colonized with bacteria. Persistent inflammation can lead to the formation of nasal polyps, which when present should raise consideration of CF. Patients often require surgical intervention for chronic sinusitis symptoms that do not improve with conservative measures.

GI disease: Patients may also have complications of intestinal obstruction due to thick, adherent mucus and fecal material, similar in mechanism to meconium ileus in the newborn, called distal intestinal obstruction syndrome (DIOS).

Less frequently, there can be chronic biliary obstruction leading to the development of cirrhosis of the liver and eventually even liver failure.

Fertility: The development of the vas deferens in males is exquisitely sensitive to CFTR mutation, and the majority of males with CF are azoospermic, and thus infertile. Women with CF can have thick cervical mucus that prevents pregnancy, but this condition can usually be overcome by the use of artificial insemination or in vitro fertilization.

Treatment and Management of Lung Disease

Secretion Clearance

CF lung disease is characterized by the production of thick mucus that is difficult to clear from the airways. The maintenance therapies for CF lung disease have been directed at mobilizing this thick mucus from the airways. This can be accomplished by mechanically assisting clearance of the mucus, via external chest wall percussion/oscillation (manual chest percussion or mechanical external chest wall

oscillation) or oscillating positive expiratory pressure (PEP), using devices such as intrapulmonary percussive ventilation (IPV) or a flutter valve.

In addition to mechanically aiding mucus clearance, there are also therapies that help by making mucus less thick and more easily cleared. One such therapy is inhaled dornase alfa, which acts by breaking down the extracellular DNA, making airway secretions less thick and sticky. Another such therapy is inhaled hypertonic saline, which is thought to act by hydrating airway mucus thus making it less viscous.

Inhaled bronchodilators are also routinely used in conjunction with other airway clearance therapies. The rationale is that when airways are maximally patent, mucus can be more easily cleared. Also, there is some evidence that inhaled bronchodilators may also enhance ciliary function and airway clearance.

Anti-inflammatory Medications

The progressive destruction of the lungs in CF is due to ongoing, relentless neutrophilic inflammation in the airways. Thus, it makes sense that anti-inflammatory therapies have been considered and studied for the treatment of CF. However, studies of the use of corticosteroids have shown modest benefit in lung disease, but with intolerable side effects with long-term use. For this reason, these medications are not routinely used for CF lung disease. High-dose ibuprofen has been shown to improve lung function in children with CF with mild to moderate lung disease. The concerns about side effects have limited widespread use of this therapy.

One medication that has been shown to be helpful in preserving lung function over time via anti-inflammatory effects is the antibiotic azithromycin. The mechanism of action is still not clear, though it is widely thought to be immunomodulatory as opposed to antibacterial. It is well tolerated, and long-term side effects are minimal.

Antibiotics

A hallmark of CF lung disease is chronic airway colonization with bacteria, with Staphylococcus aureus and Pseudomonas aeruginosa being the predominant organisms. There have been aerosolized formulations of antibiotics developed for the chronic treatment and suppression of bacteria in the airways. Only two are currently FDA approved for use in cystic fibrosis: inhaled tobramycin (TOBI) and inhaled aztreonam (Cayston). These are only used for maintenance therapy and not for treatment of acute exacerbations.

Acute pulmonary exacerbations are common in CF and are typically treated with systemic antibiotics. Attempts are made to tailor treatment based on airway culture results. However, data show that there is little correlation between response to antibiotic and susceptibility of cultured organisms. If the symptoms are relatively mild, a course of oral antibiotics could be considered. However, for a severe exacerbation or one that has not responded to an adequate course of oral antibiotics, IV antibiotics are required. It is standard to treat acute exacerbations for 2–3 weeks at a time. Combinations of aminoglycosides, cephalosporins, carbapenems, and extended-spectrum beta-lactams are frequent choices for treatment. Over a lifetime, a CF patient will have been exposed to large amounts of antibiotics, so surveillance for cumulative toxicity is recommended.

Lung Transplant

Progression of CF lung disease in many cases leads to respiratory failure and death. When lung disease is severe, some patients consider the option of a lung transplant. These operations are high risk and only performed at specialized tertiary care centers with specialists trained in post-transplant care. While these operations may provide a prolongation and improved quality of life, it is not a cure for CF. The management of post-transplant patients is beyond the scope of this publication.

Treatment and Management of GI Disease

Pancreatic Enzyme Replacement Therapy

One of the earliest manifestations of CF is pancreatic insufficiency. It is treated with exogenous preparations of pancreatic enzymes that are taken orally with each meal. The dose is titrated to the amount required to prevent malabsoption symptoms such as steatorrhea or abdominal pain and bloating. Typically, doses are not to exceed 2,000 units of lipase/kg/meal, as higher doses can lead to complications such as intestinal strictures. Inadequate dosing may increase the risk of DIOS. The efficacy of the pancreatic enzymes can be enhanced with the concurrent use of gastric acid-lowering medications, such as proton-pump inhibitors. This is because the enzymes work best at a higher pH.

Since patients with CF are at high risk for nutritional failure, due to malabsoption as well as increased metabolic demand, they are also treated with high-calorie, high-protein diets to maintain normal growth parameters. Some patients require supplementation with calorie-dense foods such as shakes, etc., and some even require alternate means of enteral intake, such as a gastrostomy tube for caloric supplementation.

Vitamin Supplementation

The malabsorption of fat also leads to malabsorption of fat-soluble vitamins A, D, E, and K. Despite supplementation with enzymes and vitamins, fat-soluble vitamin deficiency is relatively common. These deficiencies can be seen by laboratory measurement before the onset of clinical signs and symptoms, and so surveillance is recommended as part of routine CF care. Most of these vitamin deficiencies respond to oral supplementation. Dietary modifications may also be utilized as part of the treatment plan.

Gastroesophageal Reflux Disease (GERD)

GERD has been reported in as many as 90% of patients with CF. The majority of these cases are symptomatic and can be difficult to manage. Medical management in the form of proton-pump inhibitors are usually the first line of therapy along with dietary and behavioral modifications as with any patient with GERD. For those with persistent symptoms that are impacting growth or lung function, surgical therapy may be recommended.

Outcomes and Prognosis

The prognosis for a baby born today with CF is better than even a decade ago, and continues to improve every year. The median life expectancy in 2008 was 37.4 years, a number than continues to go up as new therapies emerge. Thus, this statistic would not be applicable to a baby born today with CF, as he or she will likely reap the benefits of new advancements and therapies.

It is often difficult to provide an accurate prognosis for patients with CF, as there is so much variability in the course and severity of disease. With current standards of care, patients with CF are very likely to live well into adulthood and live full and productive lives. Overall, there is every reason for an optimistic outlook for the future of CF patients.

238 ALTE and Sudden Infant Death Syndrome

Ami Doshi · Erin R. Stucky

Definition

Apparent life-threatening event (ALTE) is defined as "an episode in the first year of life that appears potentially life-threatening to the observer and is characterized by some combination of color change, apnea, alteration in muscle tone, choking or gagging." Although ALTE has been dubbed "near miss sudden infant death syndrome" (SIDS), this is misleading. SIDS is "a sudden death in a child without historical, physical, laboratory, or post-mortem findings that explain the cause of death." ALTE is a witness-defined entity with myriad potential causes, most often benign and nonrecurrent. The relationship of ALTE to SIDS has been questioned in the past, however current literature suggests SIDS in patients with a history of ALTE are most likely to be undiagnosed derangements of metabolism or central respiratory control. ALTE may be accompanied by true apnea (cessation of breathing for $>$20 s) or periodic breathing (three or more pauses of greater than 3 s each with less than 20 s of normal respiration between pauses), thereby making these events pathologic.

Etiology

Multiple underlying causes can result in an ALTE. The common final pathway involves an inability to control respirations, either due to local issues, systemic influences, or both. Airway obstruction may occur from secretions, refluxed material, or impinging mass. Failure of normal breathing patterns may be caused by systemic effects such as seizure, central nervous system respiratory dysfunction, or loss of normal cardiopulmonary circulation. While up to 50% of ALTEs are deemed idiopathic, common discharge diagnoses include gastroesophageal reflux disease (GERD up to 50%), lower respiratory tract infection and seizure (each approximately 10%), with cardiac disease, metabolic disorders, non-accidental trauma, and pertussis being among less common diagnoses.

Epidemiology

The true incidence of ALTE is unknown. Current estimates are based on information limited to infants brought for medical evaluation, and further are more often assessed retrospectively from discharge diagnoses. ALTE is estimated to have an incidence of 0.5–6% in the USA with similar reported rates in Austria and Italy. Median age at presentation is 3 months, although ALTE has been considered for infants up to 1 year of age. Preterm infants are more at risk, with immature control over respiratory drive. SIDS peaks at a similar time (3–5 months) with 90% occurring within 6 months of age. SIDS occurs at an incidence of 0.54 per 1,000 live births in the USA and at a rate of less than 0.2 per 1,000 births in Japan and the Netherlands.

Pathogenesis

Most recent research on the etiopathogenesis of SIDS suggests a role for 5-HTT genotypes; however, a single unifying genetic predisposition, with or without environmental trigger, has not been proven. For the clinician, metabolic diseases (such as medium chain acyl-coA dehydrogenase and very long chain acyl-coA dehydrogenase deficiencies), cardiac conduction disturbances (such as prolonged QT syndrome), and abnormalities of the pons and cerebellum are the diagnostic groups most reported in association with SIDS.

Pathology

Although deemed an abnormal event, ALTE is often due to appropriate reflexive glottic closure to avoid aspiration, or is an understandable result of a systemic stressor or local airway obstruction. True pathology specifically related to ALTE therefore lies in aberrant nervous system respiratory control. Most easily understood are the preterm infants, who have delayed autonomic brainstem maturation and parasympathetic control resulting in variable respiratory and heart rate responses to hypercarbia and hypoxia in

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_238,

and out of sleep. Preterm sleep states mature to equal those of terms infants at about 38 weeks postmenstrual age (PMA), with variability noted in some as late as 53 weeks PMA. Reports note SIDS siblings spend less time in quiet sleep while infants born to mothers who smoked during pregnancy have more awake periods and disturbed arousal processes. The relationship between control of sleep state and centrally mediated ALTE and true SIDS is however not yet completely clear.

Pathologic findings on autopsy in SIDS include external findings of frothy, blood-tinged fluid at the nares (in 50%), cyanosis, and anterior hypostatic staining suggesting face-down position. Autopsy also demonstrates pulmonary congestion and edema, thymic petechiae, and persistent hepatic erythropoiesis, all more common in SIDS cases than controls. Additional histologic findings include upper respiratory tract inflammation and focal fibrinoid necrosis of the larynx. Abnormalities of the central nervous system, particularly in the arcuate nucleus and regions of the brainstem, have also been noted on autopsy.

Clinical Manifestations: Symptoms, Signs

In addition to the general features mandated by the definition of ALTE, presentations may include evidence for specific causes as noted in *Table 238.1*.

Diagnosis

ALTE describes a chief complaint rather than a specific diagnosis. As such, no criteria beyond the definition exist for the diagnosis of ALTE itself. Rather, evaluation is directed at determining the underlying cause of the ALTE (see Differential Diagnosis, below). According to the consensus document of the European Society for the Study and Prevention of Infant Death, "there is no standard minimum work-up in the evaluation of an ALTE."

SIDS remains a diagnosis of exclusion, by definition only applicable when thorough review of clinical history, death scene, and clinical autopsy reveal no other diagnosis. In particular, metabolic disease and non-accidental trauma must be considered and ruled out in SIDS patients.

Differential Diagnosis

The differential diagnosis of ALTE is broad, and should be considered in the context of findings from the history and physical examination (*Table 238.2*).

Viral respiratory infections may cause infants to have difficulty managing secretions and may result in obstructive events presenting as ALTE. RSV may cause apnea prior to the onset of typical upper respiratory symptoms. Pertussis can also present as ALTE consisting of apneic or cyanotic episodes, with or without cough.

Apnea is a well-known presentation of seizure in infancy. Seizure accounts for approximately 10% of ALTE in various studies. Other CNS disorders including hemorrhage and hydrocephalus can present as ALTE with apnea, hypotonia, or changes in level of consciousness. Cardiac dysrhythmias, congenital heart disease, and cardiomyopathy may manifest as ALTE characterized by cyanosis, pallor, apnea, or loss of consciousness.

A thorough history and physical examination (*Table 238.1*) critically contributes to the final diagnosis in 70% of ALTE patients. In addition to these elements, these infants should, at a minimum, undergo cardiopulmonary monitoring with event recording and bedside nurse observation and documentation. Testing should be guided by findings from the initial history and physical examination. While most infants with ALTE undergo a variety of common tests, such as complete blood count, basic metabolic panel, urinalysis, and chest x-ray, it has been demonstrated that only 6% of tests performed ultimately contribute to making the diagnosis. As such, testing should be targeted toward a specific working diagnosis. Gastroesophageal reflux can be diagnosed clinically without testing, as recommended by the North American Society for Pediatric Gastroenterology, Hepatology and Nutrition. Upper GI should be reserved for concerns of anatomic anomalies, obstruction, or malrotation. History consistent with seizure or abnormality on neurologic exam should prompt EEG and neuroimaging. Pertussis or rapid viral PCR may help establish diagnosis of infection if positive. Concern for sepsis warrants blood, urine, and spinal fluid culture. Initial cardiac evaluation should include electrocardiogram to evaluate for dysrhythmia or ventricular hypertrophy, chest x-ray, and possibly echocardiogram based on degree of suspicion for structural heart lesion. Social work and child protection team consults, skeletal survey, toxicology labs, and ophthalmologic exam are indicated for concern for non-accidental trauma. Pneumocardiogram can establish central apnea or dysfunction of respiratory control, or aid in further delineation of events noted on the hospital monitor. In several situations, subspecialty consultation prior to ordering studies may be indicated.

Table 238.1

Signs and symptoms to elicit from the history and physical examination

History element	Consideration
Symptom detail: color (cyanosis, pallor, ruddy; peripheral/central), cough/choking, respiratory effort, position and location (prone/supine, crib), associations with feeding/febrile illnesses/environmental exposures, tone and movements during and after event, duration, interventions, recovery time	Perceived severity of event
	Swallowing dysfunction, overfeeding
	Inadequate airway development such as bronchomalacia
	GERD with associated aspiration
	Acute infectious respiratory illnesses
	Seizure
	Disruption of cardiovascular circulation
Birth history: prematurity, poor feeding	Immature respiratory drive
	Global neurologic delay
	Upper airway obstruction
Psychosocial history: family stressors, primary care provider visits, past domestic violence or referral to child protective services, drug abuse (past and current)	Non-accidental trauma
	Neglect
	Exposure to drugs
Family history: cardiac diseases, seizures, heritable disorders, SIDS, fetal demise	Seizure disorder
	Heritable disorders such as prolonged QT syndrome
	Metabolic disorder
Development, medical and surgical history: milestones, previous admission for ALTE and cause, gastroesophageal reflux disease (GERD), cardiac disease, gastrointestinal surgery, CNS disorder	Global neurologic delay
	GERD with associated aspiration
	Systemic-pulmonary vascular shunting, vascular shunt blockage
	Worsening hydrocephalus or ventricular shunt malfunction
	SIDS risk
	GI obstruction
Review of systems: feeding, weight loss, recent illness, smoking exposure, severity of past illnesses, medication use	Metabolic disorder
	Toxic ingestion
Physical examination element	**Finding**
General appearance, including facies	General state
	Airway anatomic issues
EENT	Nasal obstruction
	Oropharyngeal anomalies
Vital signs including weight for height, respiratory rate, pattern, retractions, oxygen saturation	Failure to thrive
	Signs of infection
	Cyanosis
Cardiopulmonary exam including lung auscultation, cardiac murmurs/rhythm, perfusion, hepatomegaly	Congestive heart failure
	Evidence for cardiovascular diseases
Abdominal distention, bowel sounds	Obstruction
Neurologic exam	Hypotonia/swallowing dysfunction
	Increased tone or asymmetric exam

Table 238.2
Differential diagnosis of ALTE

Idiopathic[a]	Infectious	Gastrointestinal
Often diagnosed as "Normal"	Respiratory[a] (RSV, pertussis, others)	GERD[a]
	Meningitis, meningoencephalitis	Gastric volvulus
	Sepsis	Intussusception
Cardiac	**Neurologic**	**Respiratory**
Dysrhythmias (supraventricular tachycardia, Wolf-Parkinson-White, prolonged QT syndrome, post-operative bundle branch blocks, others)	Seizures[a]	Obstructive apnea
Congenital heart disease (critical coarctation, blocked shunts, aortic and pulmonary outflow tract obstructions, others)	Oromotor dysfunction	Breath-holding spells
Cardiac contractility problems (myocarditis, cardiomyopathy)	Congenital brain malformations (Chiari Types II and III, hindbrain and brainstem)	Congenital airway malformations (laryngotracheomalacia, laryngeal clefts, others)
	Hydrocephalus with obstruction	
	Ventricular shunt malfunctions	
	Respiratory control (prematurity, central hypoventilation)	
Trauma, Toxins, Abuse	**Metabolic/Endocrine/Renal**	**Other**
CNS bleed (accidental or non-accidental)	Inborn errors of metabolism (urea cycle defects, galactosemia, fatty acid oxidation disorders, multiple carboxylase deficiency, methylmalonic aciduria, glycogen storage diseases)	Foreign body aspiration
Munchausen by proxy	Electrolyte and mineral disturbances (congenital adrenal hyperplasia, renal tubular acidosis, others)	Electrolyte disturbances, dehydration (due to inappropriate mixing of formula)
Severe Failure to Thrive (due to neglect)	Endocrinopathies (thyroid, parathyroid, others)	Anemia
Ingestions or Exposures (prescribed, over-the-counter cold preparations, accidental ingestions, smoking exposure)		Oncologic central nervous system (CNS) tumors

[a]Most common

Treatment

Although some suggest ALTE patients can be evaluated without hospital admission, current standard practice is to admit all infants for cardiorespiratory monitoring. Observation with monitoring allows for documentation of further events, which may lead to diagnosis. Given the parental anxiety resulting from ALTE, education regarding ALTE, the underlying cause if known, and likelihood of recurrence is critical. Additionally, all parents of infants admitted with ALTE should receive cardiopulmonary resuscitation (CPR) training. Specific treatment should target the underlying diagnosis. Communication and follow-up with the patient's primary care provider after hospital discharge is also central to providing ongoing education and allaying parental anxiety.

Home monitoring of infants with ALTE is controversial. If monitoring is indicated, equipment with an event recorder should be used. Parents should be educated that home monitoring has not been proven to prevent SIDS. Current national guidelines suggest it may be warranted in some ALTE patients who are at high risk for recurrent events. High-risk groups include premature infants at high risk of recurrent apnea, bradycardia or hypoxia,

technologically dependent infants, those with unstable airways, symptomatic chronic lung disease, or rare disorders of breathing regulation. Premature infants should be monitored to 43 weeks post-conceptual age or cessation of severe events.

Prognosis

Prognosis and therefore mortality for ALTE depends on the cause, with highest mortality linked to neurologic (central hypoventilation, seizures) and cardiac (dysrhythmias) causes. There seem to be no long-term effects on development for most patients, with the small number of minor neurologic abnormalities noted in the toddler period resolving by 10-year follow-up.

Recurrence of ALTE is also dependent on the underlying diagnosis. An estimated 10% of ALTE patients will have a recurrent event, with 2.5% readmitted within 30 days of discharge. It has been suggested that a diagnosis of GERD or cardiovascular condition may be a risk factor for readmission with ALTE.

An estimated 1–7% of infants who die of SIDS have a history of ALTE, with higher risk associated with two or more unexplained ALTEs. However, no firm relationship has been established between ALTE and subsequent SIDS. ALTE and SIDS differ in predominant age affected (days to 1 year versus 2–3 months), most common state during the event (awake versus asleep), and peak timing (8 am–8 pm versus midnight–6 am). Also arguing against a relationship between SIDS and ALTE is the absence of a demonstrated decrease in ALTE with interventions to prevent SIDS such as the back-to-sleep campaign.

Prevention

Prevention of ALTE relies on prevention, where possible, of potential causes of ALTE. Proper immunoprophylaxis against respiratory viruses and pertussis which may trigger an ALTE in term or preterm infants should be given. In infants prone to gastroesophageal reflux, small frequent feeds and remaining upright for a period following feeding may prevent related choking episodes presenting as ALTE.

Studies of epidemiological and physiologic risk factors for SIDS have not elucidated predictive characteristics that could be used to screen for high-risk infants. Current national guidelines recommend several interventions that have been targeted at modifiable risk factors. The back-to-sleep campaign has resulted in a decrease in the rate of SIDS but not ALTE, with some concern for increased events in infants with GERD. Avoidance of tobacco smoke exposure, during pregnancy and in infancy, is considered key in prevention of both ALTE and SIDS.

239 Upper Airway Obstruction and Hypoventilation During Sleep

Gabriel G. Haddad

Upper Airway Obstruction during sleep and hypoventilation or OSA/H is a common medical problem in adults, and this has now been increasingly recognized in children. It is a disorder of breathing during sleep characterized by prolonged partial upper airway obstruction and/or intermittent complete obstruction (obstructive apnea) that disrupts normal ventilation during sleep and normal sleep patterns. If unrecognized and untreated, it can lead to impaired daytime functioning as well as more serious complications, such as developmental delay, dyslipidemia, insulin resistance, and poor growth. A number of research studies on animal models and children have been very helpful in understanding not only the etiology of this condition but also the repercussions on overall health.

Epidemiology

OSA/H occurs in children of all ages, from newborns to young adults, with estimates of prevalence rates of about 2%. Although this condition spans the whole age spectrum in children, the peak incidence is in the preschool age group (2–5 years), a period when adenotonsillar tissue is the greatest in relationship to airway size. The incidence in males and females is similar in prepubertal children, which is in contrast to OSA/H in adults, where the disorder is more common in males, until about menopause in females, when the incidence increases in women. Among otherwise healthy children, obesity, upper and lower respiratory problems (e.g., chronic rhinitis and asthma), and the African American ethnicity are independent risk factors for OSA/H. For obese children in general, the severity of OSA/H correlates with the severity of obesity. Positive family history of OSA/H in other family member(s) is also a risk factor for OSA/H in childhood.

Etiology

Anatomic factors that increase resistance to airflow predispose to upper airway collapse and OSA/H. The most common anatomic predisposing condition in children is adenotonsillar hypertrophy, and more recently obesity and increasing fat in the pharynx. Many other predisposing nasal, pharyngeal, and craniofacial abnormalities occur less frequently. Even when the structure of the upper airway is normal, if coordinated activation of inspiratory and oropharyngeal dilator muscles does not occur, then children are predisposed to OSA/H. The most common functional process contributing to OSA/H is rapid eye movement (REM) sleep. Apnea frequency, apnea duration, and hypoxemia are almost always more severe during REM sleep as compared with NREM sleep. Childhood conditions associated with either anatomic and/or functional causes of OSA/H include *craniofacial abnormalities* (e.g., Pierre Robin sequence and Crouzon syndrome), genetic syndromes (e.g., hypotonia and short neck in trisomy 21), *skeletal disorders* (e.g., achondroplasia), *storage diseases* (e.g., Hunter syndrome), children with morbid *obesity* or Prader–Willi syndrome, and other *neurologic disorders* (e.g., cerebral palsy). Children with these conditions and diseases should be periodically assessed for the development of signs and symptoms of OSA/H.

Functional Pathogenesis

OSA/H occurs when there is failure to maintain upper airway patency, usually during sleep, which in turn affects blood gas homeostasis. In addition, this affects sleep architecture and results in sleep fragmentation. During inspiration, airflow is not augmented by increased negative pressure downstream, even when inspiratory pressure-generating muscles contract more forcefully. During inspiration, a negative pressure is generated within the pharynx, owing to activation of the diaphragm and intercostals muscles and mucosal adhesion forces. Collapse of the upper airway from the force of this negative pressure is prevented by simultaneous activation of the oropharyngeal dilator muscles such as the genioglossus muscle that protrudes the tongue. OSA/H occurs when an imbalance

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_239,

in these forces favors negative oropharyngeal pressures during inspiration. Upper airway muscle tone (oropharyngeal muscle) decreases during sleep, then to a greater degree during REM sleep, thus explaining the increased vulnerability of the upper airway to collapse during this sleep state. In fact, it is the combination of neuromuscular inactivation (or lack of full activation) superimposed on structural narrowing that contributes to the development of OSA/H. For example, the presence of adenotonsillar hypertrophy does not ordinarily cause airflow obstruction during wakefulness. However, decreased airway tone that occurs when a child goes to sleep, superimposed on adenotonsillar hypertrophy, can lead to significant airway obstruction. Conditions that decrease the caliber of the upper airways, such as in micrognathia, retrognathia, macroglossia, fat deposition from morbid obesity or a congenitally small midface or nasopharynx, all narrow the airways. Increased resistance from swollen nasal turbinates or choanal stenosis also predispose to obstruction. This, as well as an increase collapsibility or an alteration in neural control of the upper airway or central ventilatory drive, contribute to the development of obstruction. Episodes of partial or complete airway obstruction result in impaired gas exchange with hypoxemia and hypercapnia. This impaired gas exchange in conjunction with decreased airflow is potent stimuli for increased ventilatory effort and upper airway muscle activity leading to arousal. Arousals may appear in the form of movement or changes in the electroencephalogram (EEG). Following arousal, airflow is restored, blood gases are normalized, and sleep resumes, but the cycle of airway collapse starts again. Compared with adults with OSA/H, fewer cyclic arousals are seen in children in spite of continued hypoventilation and blood gas disturbances throughout the night. This may, in part, explain the relatively low incidence of daytime sleepiness in young children with OSA/H. Another difference from OSA/H in the adults is that there is usually not a complete obstruction in children with OSA/H, although the partial obstruction results in potentially significant blood gas abnormalities. Children with central nervous system abnormalities associated with impaired ventilatory or arousal responses to hypoxemia, hypercapnia, and/or airflow obstruction (e.g., Chiari II malformations) or children with sedative medication or general anesthesia have increased vulnerability to severe OSA/H.

The development of OSA/H can have serious cardiorespiratory and neurobehavioral consequences. Chronic hypoxemia can lead to polycythemia, growth failure, increased pulmonary artery pressure and pulmonary hypertension. Recurrent arousals can lead to sleep fragmentation, loss of normal sleep patterns, and excessive daytime sleepiness. Importantly in children, OSA/H has been associated with daytime sequelae, including inattentiveness and hyperactivity, behavioral problems, and impaired school performance. Indeed, often when the OSA/H is corrected, children hyperactivity is reduced or eliminated and school performance improves.

Clinical Manifestations

A number of common clinical manifestations of OSA/H include snoring and restlessness during sleep with or without frequent awakenings. Children may sleep in unusual positions to help maintain a patent upper airway, for example, with the neck hyperextended. Typically, loud snoring is the symptom that most disturbs and alerts the parents. Mouth breathing is also common among children. However, most children with OSA/H breathe normally while awake.

Habitual snoring, the most common symptom of OSA/H, ranges from 3% to 12% in children. However, it is important to realize that not all habitually snoring children have or are at risk for the development of OSA/H. The spectrum of severity (ranging from snoring to congestive heart failure, which is rare) is related to the degree of upper airway obstruction or presence of hypoxemic episodes. However, because of a more subtle presentation in children than in adults, children often have an unexpected degree of airway obstruction, impairment of gas exchange, and sleep disturbance that is difficult to predict from the clinical history and physical examination alone. Children with the more severe presentation also have noisy, mildly labored awake breathing that clearly worsens with sleep. As described above, parents usually describe the child's sleep as paced with cyclical snoring which becomes louder and louder, followed by silence, a snort, an arousal, and resumption of snoring. When snoring is associated with nocturnal breathing difficulties such as respiratory pauses and snorts and repeated arousals, these symptoms are highly suggestive of OSA/H in children. However, some children with serious OSA/H have minimal noisy breathing, and diagnosis depends on the physician's high index of suspicion.

Some of the less common symptoms include daytime hypersomnolence resulting from sleep fragmentation that occurs with OSA. Poor school performance is increasingly recognized as being associated with OSA/H. There is debate as to whether these neurocognitive deficits are the

result of a poor night's sleep secondary to frequent arousal and hence inability to concentrate in school or the result of hypoxemia that occurs during sleep in these children.

Clinical examination features associated with OSA/H include dysmorphic facies, mouth breathing, hyponasal speech, macroglossia, cleft palate, or enlarged tonsils. A pectus excavatum deformity can develop in long-standing upper airway obstruction. Morbid obesity mechanically loads the chest wall and narrows the upper airway, but OSA/H is not a consistent feature of obesity. Although rare, excessive somnolence in some children can occur during the physical examination, and this requires urgent evaluation.

Diagnosis

The diagnosis is often delayed for several reasons: (a) absence of awake symptoms; (b) a sleep history is not obtained; (c) symptoms of snoring are considered benign or inconsequential; and (d) young children may not generate the loud snoring noises similar to those in the adult. Parental reports of habitual snoring should be investigated. A sleep and breathing history is mandatory for any child with a medical condition that is at risk for OSA/H, especially trisomy 21, craniofacial anomalies, achondroplasia, or other neuromuscular disorders.

OSA/H cannot be diagnosed from clinical history alone. Snoring, reports of difficulty breathing, and enlarged tonsils are not necessarily reliable indicators of the presence or severity of OSA/H in children. Furthermore, the physical examination may be entirely normal and cannot exclude OSA/H when the clinical history suggests otherwise. Pulse oximetry is insensitive because of the shape of the O_2-dissociation curve. An overnight recording of multiple physiologic sensors during sleep (Polysomnography or PSG) is considered the gold standard for the diagnosis of OSA/H. PSG is especially useful in confirming the diagnosis, in determining the severity of OSA/H, and in documenting the efficacy of treatment. PSG in children, especially very young or special needs children, requires skilled, well-trained, child-friendly sleep technicians in family-centered environments. However, PSG may not be required for diagnostic purposes in all patients, especially when the diagnosis is rather clear. For example, PSG may not be necessary when a child has noisy, awake mouth breathing, and tonsils that occlude most of the pharyngeal space; is excessively sleepy; and is observed by skilled personnel to have signs of airway obstruction and hypoxemia. PSG is useful in (a) establishing the diagnosis when the clinical manifestations are not conclusive as above; (b) confirming the presence and severity of airflow obstruction, especially in patients undergoing surgery since prior knowledge of severity can help determine the appropriateness of outpatient surgery versus overnight in-hospital observation; (c) determining the optimal level of CPAP needed to manage OSA/H; and (d) children considered "high risk" such as children with morbid obesity, craniofacial anomalies, and genetic disorders. Laboratory findings may include polycythemia and respiratory acidosis with a metabolic alkalosis, especially in those children when hypoxemia extends to wakefulness. Right ventricular hypertrophy on electrocardiography and dysfunction on echocardiography are seen only in severe OSA/H. A lateral soft tissue radiograph of the neck can identify adenoidal tissue.

Several disorders should be considered in the *differential diagnosis* of OSA/H or may coexist with this problem. Breathing difficulty associated with nocturnal asthma or upper airway obstruction from gastroesophageal reflux may be confused with OSA/H. Stridor caused by anatomic airway problems, such as laryngomalacia, vascular ring, intraluminal masses, and vocal cord dysfunction, should be considered.

Treatment

Adenotonsillectomy is the most common therapy for OSA/H in children with adenotonsillar hypertrophy. However, the treatment for a particular child depends on the underlying abnormalities, the site of obstruction, and the presence or absence of contributing neurologic or functional abnormalities. When adenotonsillar hypertrophy is present, the majority of otherwise healthy children without major risk factors experience resolution or significant improvement after adenotonsillectomy. Children with severe OSA/H who benefit from surgery often demonstrate "catch-up" growth. However, children with underlying problems, such as trisomy 21, craniofacial disorders, and extreme obesity, or who present before 2 years of age are at risk for incomplete resolution of OSA/H after adenotonsillectomy. Even without these risk factors, the parents and physicians of children who have had adenotonsillectomy should be aware that either persistent or recurring symptoms of OSA/H need reevaluation, including reassessment for adenoidal regrowth and possible need for repeat adenoidectomy or other treatments.

Medical management with nasal CPAP is an option in children in whom adenotonsillectomy fails, thus avoiding

the need for tracheostomy. PSG is required to select the appropriate pressure level to relieve obstruction. CPAP should not be the first-line treatment when adenotonsillar hypertrophy is present, and there are no absolute contraindications to surgery. CPAP can be useful in the obese child in whom weight loss is desirable but difficult to achieve. Supplemental oxygen may relieve the hypoxemia associated with OSA/H but is clearly insufficient to address the underlying obstruction and hypoventilation. Treatment of nasal obstruction with topical nasal steroids can reduce snoring and OSA/H severity in some children awaiting surgery. Steroids and antibiotics may be useful adjunct in the acute management of infected pharyngeal tissues that have compromised upper airway patency.

If severe upper airway obstruction is present in both wakefulness and sleep, then tracheostomy is the treatment of choice, particularly when vocal cord dysfunction, impaired swallowing, or absent laryngeal protective reflexes exist. Tracheostomy may be necessary for severe OSA/H complicated by cor pulmonale when CPAP is unsuccessful or not tolerated.

There is increasing pediatric experience with treatment by mandibular distraction osteogenesis as an alternative to long-term tracheostomy. Definitive maxillomandibular reconstructive surgery for children with craniofacial disorders is another therapeutic option but is usually postponed until facial growth is complete. Pediatric experience with uvulopharyngoplasty has been limited to children with muscular hypotonia and oropharyngeal tissue redundancy, but no controlled studies using objective measures of efficacy have been performed.

240 Primary Ciliary Dyskinesia

Gabriel G. Haddad

Primary ciliary dyskinesia (PCD) comprises those respiratory disorders having in common the malfunction of airway cilia. The abnormality in PCD results from inherited primary structural defects in the cilia that lead to repeated and chronic lung and sinus infections. The ciliary malfunction in PCD is not a result of acquired repeated pulmonary infections, conditions in which the ciliary abnormalities revert to normal, unlike in PCD. About 50% of patients with PCD have *Kartagener syndrome*: situs inversus, chronic sinusitis and otitis, and airway disease leading to bronchiectasis. Approximately 25% of patients with situs inversus have PCD.

Normal Structure and Function of Cilia

Cilia are finger-like structures that extend from the epithelial membranes into the lumen of airways. They have a diameter of ¼ μ and a length of ~300 μs. On each epithelial cell in the airway, there are about 200 cilia. Each cilium has different parts such as a *trunk*; a *basal body*, where the cilia attach to the cell; and a *crown*, which is a specialized structure presumed to be important in cilia attachment to mucus for its movement. The trunk of each cilium is made of an outer cell membrane and axonemes or cytoskeletal protein structures. The latter form a circular array of nine microtubules in pairs with an additional central pair (9 + 2 structure). Each peripheral pair attaches to the adjacent one via dynein arms. Spokes are also cytoskeletal proteins that join peripheral and central microtubules. Airway cilia are located on cells in the nose, sinuses, ears, and airways. The density of cilia varies with location, with the majority of cells (50–80%) in the large airways having cilia, far fewer cells in the lower airways having cilia, and with no cilia in alveolar cells. The frequency of ciliary beating (*beatquency*) is 1–20 Hz, with the higher beatquency occurring in the larger airways.

In humans, there are at least six types of cilia: airway, ventricular, embryonic, olfactory, photoreceptor, and sperm flagellum. Whereas the embryonic and photoreceptor cilia contain nine microtubular doublets and no central singlets (9 + 0 structure), the other types of cilia share the peripheral structures (nine microtubular doublets) with two central singlets (9 + 2 structure). Although various cilia are present in various parts of the body, their function is related to propelling fluid. For example, airway cilia propel mucus in the airways; ventricular cilia are located on the ependymal lining of the brain ventricles and propel cerebrospinal fluid (CSF). Embryonic cilia are located in the embryonic node and presumed to propel morphogens and establish, at this early stage, a morphogenic gradient that is crucial for the development of embryonic sidedness. Abnormal ciliary function and structure lead to disease conditions: an association between ciliary dyskinesia, hydrocephalus, and mental retardation in four male siblings in a Jordanian family has been reported and might be caused by a mutation that affects pulmonary toilet and fluid movement in the lung and CSF. Abnormal embryonic nodal cilia result in situs inversus.

At the outset of the beating cycle, cilia bend at the base and move backward, perpendicular to the surface. Subsequently, they extend ("slide") while rotating in a forward motion. These movements, which are clockwise three-dimensional rotations, are made possible by adenosine triphosphate (ATP) hydrolysis and the dynein arms, which are ATPases. When visualized under microscopy, airway cilia are seen to coordinate their activity regionally, and *waves of ciliary movements* (many cilia together) occur. How the coordination of ciliary movements is achieved not only within a cell but across cells on the surface is not well understood.

The main function of airway cilia is to transport, through its beating movements, mucus toward the mouth. The effectiveness of this function depends on the beatquency, the composition and thickness of the periciliary fluid and mucous layer above it, and the coordination of ciliary movements. There are a number of neurochemicals that modulate ciliary beating by increasing beatquency, such as β-adrenergic compounds, bradykinins, and serotonin. Alternatively, lowering airway humidity significantly lowers the frequency of ciliary beating. In addition, increasing bacterial loads decreases its beatquency.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_240,

Abnormal Cilia

It is estimated that there are >250 polypeptides in the ciliary structure and primary ciliary dyskinesia is most likely based on the absence of one or several ciliary cytoskeletal proteins that can affect the motion and/or the beatquency of the cilia. The structural abnormalities of these disorders can be observed and detected with electron microscopy. Ciliary ultrastructual changes in PCD include the lack of dynein arms, microtubular transposition, compound cilia, random ciliary orientation, abnormal length of cilia, radial spoke, and nexin link defects. It is important to differentiate transient ciliary defects involving only a subset of cilia (such as acute and chronic respiratory inflammation) from true congenital defects. In classical PCD, there is an *absence of both inner and outer dynein arms*, resulting in a complete dynein arm defect. *Partial dynein arm defects* (in which either inner or outer arms are not visualized) or *defects in central doublets* are generally not associated with situs inversus and appear to occur as isolated genetic abnormalities. *Radial spoke defects* are much more difficult to visualize but are generally considered to be a legitimate entity in this spectrum of ciliary abnormalities. *Random ciliary orientation* is when the sole ultrastructural defect is that the central doublets are arranged in a random orientation. Ciliary motility studies have shown that structural defects and findings may not correlate with function. For example, cilia from patients with Kartagener syndrome are immotile. By contrast, single arm defects may show coordinated movement, although ciliary beatquency will be slower than normal. Random axis orientation of cilia results in uncoordinated random movement.

Genetics

Estimates of PCD prevalence range from 1/15,000 to 1/60,000 live births. It is probably the third most common form of inherited chronic airway disease of Caucasian children, after cystic fibrosis (CF) and genetic immunodeficiency states. Cases have been reported from multiple ethnic and racial groups including populations from Japan, China, and northern Africa. The inheritance pattern of most PCD cases is autosomal recessive, although there are reported cases of autosomal dominant or even X-linked modalities. The prevalence and the pattern of inheritance are most likely not as well appreciated (and underestimated) since only a few mutations have been discovered and there are a great many patients that still belong to an "idiopathic" category of chronic lung disease.

A number of genes have been hypothesized to be at the basis of PCD. *DNAH5* is an axonemal dynein heavy chain gene localized on chromosome 5p (5p14–5p15). This gene is very long (79 exons) and codes for a protein of 4,624 amino acids. It is expressed in lung and kidney and, to a lesser extent, in brain and testis. Several homozygous and heterozygous mutations were found in PCD families. A number of individuals in these families also had situs inversus. *DNAI1*, another gene on chromosome 9 (9p13–21), is highly expressed in trachea and testis and is a long gene, with 20 exons. It encodes for an intermediate chain found in the outer dynein arms. Several other mutations in other PCD families have also been found, such as substitution of conserved bases and deletion of base pairs in exons. A third gene (*DNAH11*), which also encodes a heavy chain dynein in the outer arm, maps to the seventh chromosome (7p21) and has been associated with PCD.

Clinical Manifestations and Diagnosis

Individuals with PCD may start having symptoms in early life. They often have unexplained respiratory distress during the newborn period with nasal congestion, rhinitis, and cough. The disease is so varied that these patients may survive to adulthood without overt chronic sinusitis, ear infections, and airway disease symptoms. The most common complaints and symptoms in children are related to a productive cough, sinusitis, and otitis. A feature that is helpful in differentiating PCD from CF is repeated bouts of acute otitis media. Nasal polyps or clubbing is present in ≈20% of patients. Many children with PCD experience frequent wheezing and have an initial diagnosis of asthma. The hallmark symptom is a chronic, often loose or productive cough. Pneumonia may supervene, and lower respiratory tract disease can progress to weight loss, diminished exercise tolerance, and bronchiectasis. Respiratory failure is uncommon as are lung complications such as pneumothorax and hemoptysis in childhood, but lobar atelectasis occurs frequently. Males are frequently infertile (abnormal sperm flagella) and display absent or poor sperm motility; females are at increased risk for ectopic pregnancy.

PCD should be suspected in children with chronic or recurring upper and lower respiratory tract symptoms, especially in the presence of substantial middle-ear disease. Pulmonary function testing of older children yields a typical obstructive pattern. Radiographic or CT imaging is very useful as it shows often the involvement of the paranasal sinuses. Chest radiographs may demonstrate overinflation, bronchial wall thickening,

and peribronchial infiltrates and often atelectasis and consolidation. Bronchiectasis is a late manifestation and is best detected by CT scanning. The presence of a right-sided heart (situs inversus) in a child with chronic respiratory tract symptoms is virtually diagnostic, but this configuration occurs in only 50% of these patients.

Scrapings or brushings of nasal mucosa can be examined directly by light or, preferably, by phase-contrast microscopy for evidence of motility. In most PCD tissue specimens, little or no ciliary motion is seen. *The gold standard* is documentation of abnormal structural elements, such as missing *dynein* arms or random orientation of cilia in nasal or bronchial biopsies or scrapings on electron microscopic examination. To avoid confusion with acquired ciliary changes, mucosal specimens should be obtained after an acute respiratory tract infection by at least 2–3 weeks since some structural abnormalities are also observed after injury to ciliated epithelial cells by viral infection. Ultrastructural evaluation should be reserved for highly suspicious cases. Of interest is that exhaled nitric oxide (NO) is markedly *decreased* in patients with PCD as compared with patients who do not have PCD, particularly those with cystic fibrosis, idiopathic bronchiectasis, sinusitis alone, and normal controls. A low NO measurement may not be diagnostic, but a high level suggests a disease other than PCD.

Treatment and Prognosis

Therapy is mostly symptomatic. Chest physiotherapy assists the clearance of mucus and antibiotics should be prescribed for evidence of infection of sinuses or lower airways. The choice of antibiotics is best dictated by identification and sensitivity testing of pathogenic organisms. Oral antibiotic administration and bronchodilators can be effective. Children should be examined several times each year and followed by periodic chest radiographs and serial pulmonary function testing. Sinus and middle-ear symptoms refractory to medical therapy deserve consultation with an otolaryngologist. Surgical intervention may be helpful in selected cases. Prevention of lung infection by measles, pertussis, influenza, and, possibly, pneumococcal vaccines is highly desirable. Avoidance of cigarette smoke and other airway irritants is important. Progression of lung disease appears to be much slower for patients with PCD than for those with CF. With proper treatment, disabling lung disease can often be avoided for long periods. A normal life span is possible.

241 Inhalation Lung Injury

Erin R. Stucky

Definition/Classification

Inhalation lung injury is that induced by inhalation of irritant particles or gases, resulting in airway damage and respiratory compromise. The focus of this chapter is on acute exposure. Although fungi can produce microbial volatile organic compounds (VOC) resulting in irritant symptoms, most effects are due to hypersensitivity pneumonitis from chronic exposure, which is beyond the scope of this chapter.

Etiology

Inhalation lung injury may be caused by small and large particle or gas exposure. Although most exposures are accidental, preteens and teens may purposefully inhale paint, gasoline, and other toxins. The most common pediatric inhalation exposures are chlorine gas (chlorine bleach, industrial accidents, and swimming pools), silica particles, grain and fertilizer dust, hydrocarbons, and wood smoke.

Manufacturing accidents may expose children to elements such as sulfur and chlorine. Copper, zinc, and iron dust on roads from brake wear as well as diesel emissions containing elemental carbon, hydrocarbons, trace metals are causes of chemical pneumonitis noted worldwide. Less common but of great concern are exposures of children to weapons used in warfare such as mustard gas.

Epidemiology

Exposure types vary by development (urban vs rural) and country. Silica particles in cosmetics and cleaning substances combine to represent almost 20% of all poison control calls in the United States. Common urban exposures include smog and lead whereas pesticides and crop particulate dusts are more common in agricultural areas. Wood smoke as well as high viscosity (such as paraffin oil) and low viscosity (such as gasoline) hydrocarbon exposures are seen worldwide. Kerosene lung injury is the most commonly reported hydrocarbon exposure in developing countries. Children may be exposed as a single acute event, or chronically which can lead to different lung pathology.

Pathogenesis

Most acute inhalant injury is due to the inciting agent; however, host response may have an effect on outcome. Atopic children respond to toxic inhalation exposure with increased Immunoglobulin E release, mast cell degranulation, and cytokine-induced inflammation. In animal models, exposure to common gases is associated with increased proinflammatory cytokine, mucus production, and lung airway hyperreactivity. There is some information to suggest that this can be reversed by action of short inhibiting RNAs (siRNAs). Other animal studies are on the protective effect of nitric oxide synthase on acute lung injury. Both of these findings may be models for future research in humans.

Pathology

Water soluble compounds are absorbed by the nasal passages and trachea, where less soluble particles travel to the alveoli and cause distal damage. Particle size is also important in determining the distribution of damage, as small (0.5–3 μm) sized particles travel more readily to the alveoli. For gases, lower viscosity compounds diffuse more widely and cause more damage. Lung injury is the result of recruitment of neutrophils, airway inflammation, mucus production, protein leakage, and macrophage and bronchiolar cell death. Within 24 h, plugs of mucus, fibrin, and cellular debris can obstruct first larger and then smaller airways. Studies from more significant toxins such as mustard gas demonstrate glutathione depletion and free radical generation.

Secondary bacterial pneumonia is not commonly seen in most pathology specimens. It may be seen in up to 90% of smoke inhalation patients, however, usually at 1–2 days after the initial insult. Other abnormalities on biopsy such

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_241,

as pulmonary fibrosis, giant cells, and non-necrotizing granuloma formation should raise suspicion of subacute or chronic toxin exposure.

Clinical Manifestations

Signs and symptoms of inhalation injury are both general and source-specific. Symptoms usually present within a few hours but may be delayed up to 3 days postexposure.

Common manifestations include cough, tachypnea, abnormal oxygen saturation (<90%), nasopharyngeal congestion with secretions, and may progress to stridor, rales, wheezing, and more significant upper and lower respiratory distress or failure. Young children may vomit, and often have both ingested and inhaled the irritant. Fever presenting within a few hours is usually secondary to inflammation whereas that developing within several hours to 1–2 days is more likely due to secondary infection. Hypoxemia and pulmonary function may worsen after 24 h as airways fill with debris. Lethargy is more common than irritability for all age groups.

Specific signs may be noted with smoke exposure such as ash and residue on lashes and in nostrils. Hemoptysis is occasionally seen with more caustic basic elements and gases. Older children may also complain of chest pain or headache from carbon monoxide toxicity. Hydrocarbons are often ingested and inhaled, and therefore vomiting and eructation may have an accompanying odor.

Diagnosis

Although there are no specific international guidelines for diagnosis, American and European toxicology associations agree that fever, hypoxemia, interstitial infiltrates on chest imaging, decreased CO-diffusing lung capacity (DLCO), and negative bronchoalveolar lavage (BAL) cultures are the hallmarks of inhalation lung injury. In most cases, DLCO and BAL are not performed, and diagnosis is made based on history of or suspicion for relevant exposure, physical examination, and chest x-ray. Common supportive studies are noted in *Table 241.1*.

Table 241.1
Common findings in inhalation lung injury

Study	Typical finding
Chest x-ray	May be normal initially; bilateral interstitial infiltrates, most often lower lobes; pulmonary edema
Chest CT	As in chest x-ray; diffuse airspace disease
Blood gas	Hypoxemia greater than hypercarbia
Complete blood count	Leukocytosis
Basic chemistries	Metabolic acidosis
Advanced studies	**Utility**
Bronchoscopy with lavage (biopsy in rare cases)	Grading extent of mucosal damage; bacterial cultures to rule out infection; pulmonary toilet (burn patients); biopsy evidence for chronic exposure
Carboxyhemoglobin or rapid CO breath analysis (if available)	Assess for carbon monoxide poisoning

Differential Diagnosis

Children almost always present with a history suggestive of acute inhalant exposure. Differential diagnoses in unclear cases include infectious pneumonias, pulmonary hemorrhage, pulmonary embolism, aspiration pneumonia/pneumonitis, pulmonary contusion, or occasionally systemic cholinergic effects from ingested mushrooms. The time course for evolution of inhalant lung injury may help support this diagnosis. Resolution of symptoms may occur in cases of mild exposure in as little as 8 h. A chest x-ray may demonstrate diminished infiltrates within this time frame in contrast to aspiration and pulmonary hemorrhage that take 24 h or longer to improve. Differential diagnosis of subacute or chronic inhalant lung injury is beyond the capacity of this chapter but in brief includes mycobacteria pneumonia, autoimmune diseases, and other forms of interstitial pneumonia.

Treatment

Patients who are asymptomatic after an exposure still require monitoring for 6–8 h to assure no evolution of symptoms. Both the American Academy of Clinical Toxicology and the European Association of Poisons Centres and Clinical Toxicologists state gastric lavage is contraindicated due to aspiration risk. Immediate care is focused on decontamination and control of the airway (*Table 241.2*). Healthcare workers should wear protective gear to prevent self-contamination. Oxygen should be

Table 241.2
Common therapies for inhalation lung injury

Treatment	Indication
Clothing removal; bathing	Decontamination; repeated washing may be indicated for toxins with potential for significant skin absorption
Oxygen to keep saturation >90%	Hypoxemia
Beta-agonist	Bronchospasm
Steroids (inhaled, systemic)	Controversial; decrease airway and systemic inflammation
Intravenous fluids, nutrition	Hydration to meet increased insensible losses; significant electrolyte imbalance and nutritional deficiencies can be seen in burn victims
Bed rest	Decrease metabolic demand
Antibiotics	Positive BAL bacterial culture; may be used empirically in some severe burn victims

given to maintain normal saturations obtained by an appropriate monitor. Worldwide, access to saturation monitoring is inconsistent, limiting critical use of oxygen therapy.

Nebulized heparin combined with the mucolytic agent N-acetylcysteine has been used in some centers for burn patients to improve pulmonary function and decrease the incidence of re-intubation. Noninvasive positive pressure ventilation or intubation should be provided to support non-cardiogenic pulmonary edema. However, autopsy results suggest pressure may cause mucus to be pushed into the lower airways and delay mucus transport out of the smaller bronchioles, increasing risk of secondary pneumonia.

Routine early antibiotic or steroid use is not recommended for hydrocarbon inhalation exposures. Published data from the United States, France, India, Israel, and other countries, however, suggest the use of antibiotics in up to 40% of these patients. The high rate of pulmonary bacterial superinfection of burn patients mandates prompt treatment covering typical ventilator-associated organisms and nosocomial pathogen.

Antidotes for specific exposures are limited but may include inhaled bicarbonate for chlorine gas exposure and 100% oxygen for carbon monoxide poisoning. These therapies should be managed in consultation with a toxicologist and pulmonologist whenever possible.

Follow-up care for patients requiring more than transient inpatient respiratory support should include chest x-ray to demonstrate resolution of infiltrates and pulmonary function testing at 1 month post insult.

Prognosis

Young children are at greater risk for inhalation lung injury than adults due to the increased respiratory rate and immature lung development and immune systems. Short-term outcomes are worse for patients presenting with significant hypoxemia and in those with underlying pulmonary disease or atopy. Secondary pneumonia is reported to occur in as many as 60% of intubated burn patients and leads to prolonged inpatient stay. Increased morbidity and mortality in smoke inhalation burn victims is associated with greater thermal airway burn and acute respiratory distress syndrome (ARDS).

Wheezing and increased work of breathing with exertion are commonly noted for 1–3 weeks after exposure to most inhalants. Bronchiectasis and chronic lung disease have been reported in children in particular with chlorine and smoke exposure. A concern for the impact of cytokine induction on development of cancers has also been recently raised; however, the impact of inhalant lung injury on development of future cancer is not clear.

Prevention

Toxin avoidance should be part of all well child healthcare visits. Clinicians should ascertain risk of agriculture, manufacturing, airborne pollutant, and roadway exposures and counsel accordingly. Adequate ventilation is necessary when using an enclosed fireplace or kerosene heater. Chemical cleaners, lamp oils, and cosmetics should be kept out of reach of children, preferably in a locked cabinet. Preteens and teens should be educated on inhalant risks.

242 Pulmonary Complications of Bone Marrow Transplant

Julie Ryu

Pulmonary Complications of Bone Marrow Transplant

As the technology for bone marrow transplant (BMT) improves, the indications for transplant continue to grow beyond the usual realm of oncology. This section will address some of the pulmonary complications that can arise from bone marrow transplant. Although there are now a number of types of bone marrow transplant including autologous, allogeneic, and stem cell varieties, this section will not address the complications that can arise within the subtypes of bone marrow transplant but address the complications that can arise within the respiratory system as a whole. Pulmonary complications can be categorized within the timeline of the BMT, as pre-engraftment and post-engraftment phases.

Pre-engraftment Complications

The pre-engraftment phase is the phase within the first 2 months after BMT. Respiratory complications during this period are usually due to impaired mucosal barrier function created by immunosuppressive and radiation therapy that may have been given prior to BMT to improve engraftment especially in allogeneic bone marrow recipients. *Pulmonary edema* is common, especially soon after BMT, and may be precipitated by a number of factors. In addition to any decreased mucosal barrier function, aggressive hydration, parental nutrition, infection, cardiac dysfunction (from anthracyclines), and impaired renal function may all contribute to the development of pulmonary edema. Pulmonary edema can also facilitate the development of respiratory distress syndrome or a non-infectious idiopathic pneumonia syndrome. *Idiopathic pneumonia syndrome* occurs in about 5–10% of adults undergoing BMT and the diagnosis is made only after bronchoalveolar lavage (BAL) is negative for bacterial, viral, and fungal cultures. This pathologic process can occur as an interstitial pneumonia or of diffuse alveolar injury. The incidence of idiopathic pneumonia is highest around 2 weeks after transplant but can also present after 6–7 weeks. While the causes for idiopathic pneumonia are unknown, they may be related to the preconditioning chemotherapy or an immune response to an allogenic transplant. Treatment for idiopathic pneumonia is supportive.

Another pulmonary complication that can occur during the pre-engraftment phase is a *diffuse pulmonary hemorrhage*. Fortunately, this complication occurs less frequently in children than in adults but is associated with a high mortality rate. These patients are more often recipients of allogeneic BMT and present within the first month after BMT. These patients present with sudden and progressive dyspnea, hypoxia, and crackles. On bronchoalveolar lavage, frank blood can be seen along with neutrophilia on cell count despite being neutropenic on a peripheral complete blood count. Treatment for diffuse alveolar hemorrhage consists of supportive care and systemic steroids.

Pulmonary and hepatic veno-cculusive disease can also present during the pre-engraftment phase. This condition affects children and is associated with intimal fibrosis. While fibrinolytics can be used, the pathophysiology is still unclear and current treatments options may not be effective.

Post-engraftment Complications

Approximately 10–20% of all children who receive BMT develop long-term pulmonary complications. The most common pulmonary complication is chronic lower airway obstruction. *Bronchiolitis obliterans* (BO) is a disorder that presents with dyspnea, cough, and/or exercise intolerance. It is characterized by lower airway constriction that does not respond to bronchodilators. The pathophysiology of this disorder is still unclear but risk factors include chronic graft-versus-host disease, early post-transplant viral infection and advanced age of the

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_242,

recipient. BO generally presents about 1–2 years after BMT but can occur as early as 90 days after transplant. While the symptoms are not specific for BO, pulmonary function testing, imaging studies, and/or lung biopsy can make the diagnosis. High resolution CT scans demonstrate a heterogeneous pattern of areas of hyperaeration with bronchial dilation along with areas of hypoaeration with increased density or "mosaic perfusion." On lung biopsy, BO is characterized by bronchial submucosal and peribronchial fibrosis that results in lumen narrowing and obliteration of the bronchioles and small bronchi. Airflow obstruction is seen on pulmonary function testing with a decrease in FEV_1 and FEV_1/FVC ratio. Immunosuppression is the main treatment for BO. Steroids, calcinuerin-inhibitors, azathiprine, and macrolide antibiotics are often used as treatment options to augment immunosuppression but steroids are often ineffective. While BO is generally seen as a steroid non-responsive condition, inhaled steroids may alleviate some symptoms without improving pulmonary function testing. In addition, infliximab, a tumor necrosis factor alpha (TNFa) blocker also shows some promise in slowing the decline in pulmonary function associated with BO.

Restrictive lung disease can also present as a long-term complication of BMT. Unlike the patients with obstructive disease, patients with restrictive disease are usually asymptomatic and are only discovered on routine pulmonary function testing. Some contributing factors include infection and pulmonary veno-occlusive disease. *Pulmonary veno-occlusive disease* usually occurs during the pre-engraftment phase but can extend into the post-engraftment phase and can result in pulmonary hypertension and pulmonary edema which contribute to the restrictive process. The most common cause for restrictive lung disease are cytotoxic drugs and irradiation. The most common offending agents include alkylating agents such as cyclophosphamide, methotrexate, busulfan, and CCNU/BCNU.

Bronchiolitis obliterans with organizing pneumonia (BOOP) is now referred to as *cryptogenic organizing pneumonia* (COP). Unlike BO, COP is a restrictive process that responds to steroid therapy. COP differs from BO in that it is characterized by a mild to moderate inflammatory process with polypoid plugs of loose organizing connective tissue in the alveolar ducts and bronchioles. Imaging studies reveal patchy infiltrates on CXR and a restrictive pattern on pulmonary function testing. Infectious etiologies should be ruled out since they can present similarly to COP.

Table 242.1
Common infectious organisms associated with BMT

Pre-engraftment: Usually not respiratory infections	Post-engraftment
Fungal: *Candida* *Aspergillus*	Fungal: *Aspergillus* *Pneumocystis* pneumonia (PCP) *Mycobacterium tuberculosis*
Bacterial: Gram negative: *Pseudomonas* Gram positive: *Staphylococcus aureus, Streptococcus viridians, Enterococcus*	Bacterial: Similar to pre-engraftment organisms *Legionella*
Viral: Herpes simplex virus	Viral: Cytomegalovirus (CMV) Varicella zoster virus (VZV) Adenovirus Epstein–Barr virus (EBV)

Infections

Bronchoscopy with alveolar lavage can be very helpful in identifying organisms that cause pneumonias post-BMT. The procedure is minimally invasive and can be performed to identify an organism. However, the ability to detect a bacterial organism in a bronchoalveolar lavage (BAL) sample decreases inversely with time on antibiotics. A lavage should be done to differentiate a BOOP from an infectious pneumonia. In addition, a BAL can be helpful in detecting fungal and pneumocystis pneumonias (PCP). See *Table 242.1* for a list of organisms classified into pre- and post-BMT.

243 Near Drowning and Drowning

Matthew S. Wilder · Erin R. Stucky

Definition/Classification

The nomenclature of drowning has long been a source of debate and confusion. In an attempt to solve this problem, the World Congress on Drowning convened in 2002 and developed guidelines for the definition of drowning. Drowning is defined as "a process resulting in primary respiratory impairment from submersion/immersion in a liquid medium." In addition, terms that have previously been confusing, such as "near drowning," "wet drowning," "dry drowning," and "secondary drowning" should not be used, and the term "drowned" should be reserved for those persons who die from drowning.

Epidemiology

Seventy-five percent of the earth's surface is water, making it one of the most common sources of environmental injury to humans. Consequently drowning has been a cause of unintentional injury and death across all continents, especially in children. Drowning causes substantial morbidity and mortality that varies with location, age group, activity, and type of body of water.

According to the World Health Organization (WHO) Global Burden of Disease estimates that 175,000 children under the age of 20 years died in 2004 worldwide as a result of drowning. Approximately 98% of these deaths occurred in low and middle-income countries. Fatality rates also vary worldwide, from less than 1% in high income European countries to over 10% in low-income countries of the Western Pacific Region including China, Philippines, and Vietnam. In developed countries the age distribution of fatal drowning is bimodal, peaking in toddler and adolescent years. Studies in specific countries reveal that drowning is the leading cause of injury death in children age 1–2 years in the USA and 1–9 years in Bangladesh. Worldwide, the fatality rate for boys is approximately twice that of girls.

In the USA, racial disparities have been noted with higher rates of drowning reported in black male children. Infants are more likely to drown in baths and buckets, 1–4-year-olds in swimming pools, and older children and adolescents in natural bodies of water such as ponds, lakes, rivers, and beaches. Activities associated with teen drowning include boating, swimming, and diving. Alcohol and illicit drug use are also associated with an increased risk of teen drowning.

Pathogenesis

Although there is no direct pathogenetic association with drowning, increased incidence is seen in certain medical conditions. Children with mental or physical handicaps are at increased risk, as they may not adhere to water safety instructions and require extra supervision. The risk for drowning in those with seizure disorders is estimated at 4–14 times that of other children. In contrast to these children where the known underlying state is a precursor to drowning, it is thought that children with certain genetically determined dysrhythmias have their cardiac event subsequent to submersion. Specific channelopathies have been reported in association with submersion-induced syncope or cardiac arrest. Often the drowning event was the first presentation of the underlying prolonged QT abnormality or catecholaminergic polymorphic ventricular tachycardia.

Pathophysiology

The sequence of events that lead to drowning has been well described in both animal models and humans. A drowning episode begins upon submersion/immersion. Initially, there is a period of panic, struggle to stay above water, and voluntary breath-holding. However, hypercarbia and hypoxia eventually drive an involuntary gasp of air. If water is aspirated, laryngospasm may occur, causing further ventilation difficulties but temporarily preventing aspiration. If the victim is not rescued, this phase is followed by a period of involuntary respiratory efforts accompanied by aspiration of water, which may persist for many minutes before respiratory arrest. Convulsions and muscle spasms may occur before eventual cardiac arrest and death (*Fig. 243.1*).

Aspiration of water produces loss of surfactant and lung compliance, inflammation in the lower respiratory tract, non-cardiogenic pulmonary edema, ventilation/perfusion

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_243,

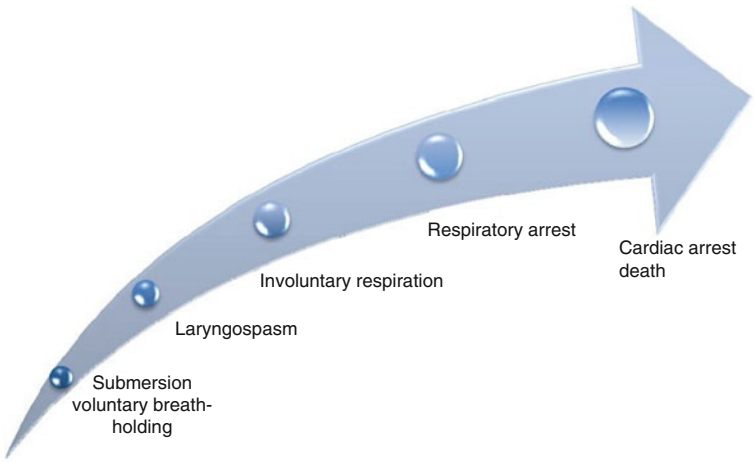

Figure 243.1
Progression of events in drowning

(V/Q) mismatch, intrapulmonary shunting, acute lung injury (ALI), and eventually the acute respiratory distress syndrome (ARDS). This spectrum leads to hypoxic-ischemic insult and end-organ damage. Animal models demonstrate that anoxia in drowning causes an abrupt fall in cardiac function and cardiogenic shock, demonstrated by a rise in pulmonary capillary wedge pressure, central venous pressure, and pulmonary vascular resistance. Hypoxic-ischemic injury, along with hypothermia, can lead to cardiac dysrhythmias including sinus bradycardia and atrial fibrillation, progressing to ventricular fibrillation and asystole. Drowning victims may also develop "cold stress diuresis," leading to hypovolemia. The natriuresis is of tubular origin and may be due to impaired renal autoregulation and/or natriuretic peptide release from hypoxic-ischemic injury.

Clinical Manifestations

Signs and symptoms are predominantly cardiorespiratory and neurologic and vary greatly based on submersion time. Ingestion of water is common, and vomiting usually accompanies rescue.

Respiratory distress may be initially subtle, with elevation of respiratory rate without hypoxemia. Victims of more significant events may present with rales, hypoxemia, and retractions. Pulmonary complications can evolve over a 24–48 h period. Neurologic manifestations vary from fussiness to obtundation. The central nervous system (CNS) is extremely susceptible to hypoxic-ischemic injury in drowning. This can manifest acutely with signs of elevated intracranial pressure.

Hypothermia may further complicate the clinical situation. Conductive and convective heat loss in water cannot be compensated for by thermoregulatory mechanisms. After core body temperature decreases below 35°C, disorientation and lack of muscle strength impair the victim's ability to fight the submersion and self-rescue. While this is more common in colder climates, core body temperatures will be lowered even in warmer water.

Diagnosis

Diagnostic studies focus on defining the extent of the injury. Despite water ingestion, electrolyte abnormalities occur in less than 15% of drowning victims; however metabolic acidosis is common. All patients should have a chest X-ray and oxygen saturation monitoring. A chest radiograph may detect acute changes, usually a pattern of nonspecific, bilateral alveolar infiltrates. Commonly performed studies in most patients requiring rescue include CNS imaging, electrocardiogram (ECG), and blood gas analysis. CT is normal in approximately 80% of patients. If abnormal, however, it can be distinguished from trauma because of lack of hemorrhage and presence of diffuse loss of grey-white matter differentiation, bilateral basal ganglia edema, or infarct.

Differential Diagnosis

Most children arrive at the emergency department with a history of accidental submersion. Drowning as a result of child abuse must also be considered if the history is not

consistent with the injury or plausible based on the age of the child. For teens, toxicology screen and blood alcohol level may be warranted. For any ambulatory patient, an ECG or EEG may be indicated to identify prolonged QT syndrome, other dysrhythmia, or seizure which may have precipitated a fall into water. Cardiac rhythm disturbance after submersion can also occur, and should be considered in patients with an unexpected drowning. Head trauma occurring before or after submersion must be considered for any patient with appropriate history, environmental risk, or bleeding noted on CNS imaging.

Treatment

Immediate treatment goals are to limit hypoxia, cardiovascular compromise, and hypothermia. After initial stabilization, pulmonary, neurologic, and other end-organ sequelae should be addressed.

Prehospital Care

Cardiopulmonary resuscitation (CPR) with cervical spine precautions should be instituted as soon as possible on scene. Even bystander CPR may improve outcome. The coexistence of spinal cord injury is rare but should be suspected, especially in unwitnessed drowning or traumatic drowning such as diving or surfing. After initial stabilization, the victim should be transferred to an emergency medical facility.

Emergency Department (ED) Care

In the emergency department, goals of therapy include continuing resuscitation and performing pulmonary and neurologic assessment. Noninvasive monitoring of vital signs and oxygen saturation are routine. For patients that are awake and alert, monitoring for decompensation may be sufficient. Any patient with a history of submersion greater than 1 min, experienced apnea or cyanosis, or required resuscitation should be admitted to the hospital. For all other patients, if after 6–8 h of observation there have been no symptoms, the chest radiograph is normal, and vital signs and oxygen saturation have been stable, the child may be discharged home. Those with even subtle abnormalities, however, should be admitted for a 24-h period to monitor for progression of symptoms. For patients with serious respiratory distress or failure, more invasive airway management including intubation may be indicated to manage hypoxia and hypercarbia. Fluid status should be assessed and the patient kept euvolemic. For suspected trauma, consultation with a trauma surgeon is indicated. Patients with respiratory distress or impaired neurologic status should be admitted to a pediatric intensive care unit for monitoring and further treatment.

Hospital Care

Specific intensive care management is beyond the scope of this chapter. However, it is important for general clinicians to understand some basic concepts. *Pulmonary* care focuses on keeping patients well oxygenated using supplemental oxygen. The goal for any intubated patient with lung disease, including ALI and ARDS, is to maximize oxygenation and ventilation while minimizing continued injury to the lungs induced by barotrauma and volutrauma. Thus, minimal ventilator settings are preferred. Chest radiography can help visualize improvement or decompensation. However, parameters such as increase or decrease in ventilator support and oxygenation/ventilation analyses are better indicators of clinical change. *Infections* of the lungs due to bacteria or fungi may complicate the clinic picture, but prophylactic antibiotics are not recommended as this may only worsen resistance. *Hemodynamic* instability due to cardiogenic shock and hypovolemia due to renal losses may require careful fluid management and inotropic agents. An echocardiogram to assess cardiac function can guide therapy. *Neurologic injury* due to hypoxic-ischemic brain insult can be compounded by further hypoxia, ischemia, increased intracranial pressure, cerebral edema, and brain metabolic demand. Supplemental oxygen should be used to limit hypoxia. In the 1970s, hyperventilation, hypothermia, and barbiturates were touted as optimal treatment for hypoxic-ischemic injury. However, later studies found that none of these treatments improved outcomes. Goal $PaCO_2$ should be 30–35 mmHg. Re-warming to euthermia remains current practice at most institutions. Induced coma is not recommended unless for seizure activity.

Prognosis

Prognosis is related to the duration of submersion, quality and promptness of resuscitation, and clinical status upon arrival to the ED. Many patients suffering minor events with recovery in the field have no long-term sequelae. Of those surviving, approximately 10% will have severe neurologic sequelae. A longer need for CPR, submersion

time greater than 15–25 min, initial arterial pH less than 7.1, and unconsciousness upon arrival to the ED have each been associated with poorer outcome. Up to 20% of children who arrived to the ED unconscious are discharged with moderate to severe hypoxic-ischemic encephalopathy. Nonreactive pupils on arrival to the ED and severe neurologic deficit (Glasgow Coma Score <5) upon admission to the intensive care unit may be the two best independent clinical predictors of poor neurologic outcome. An abnormal head CT is particularly significant, with an initial abnormal CT associated with mortality and a subsequent abnormal CT at 24–48 h after an initial normal study associated with persistent vegetative state or death in most children.

Prevention

An overwhelming majority of drowning cases worldwide are unintentional and preventable. The WHO 2008 World Report on Child Injury Prevention suggests interventions based on the Haddon Matrix of risk factors applied to childhood drowning: victim and caretaker factors, agent factors, physical environment factors, and socioeconomic factors. Healthcare providers should educate patients and caregivers on the importance of formal swimming instruction and water safety. Studies from the USA, China, and Bangladesh suggest that swimming lessons are protective. In the adolescent population, education on the danger of risk-taking behaviors such as alcohol consumption and swimming should be addressed. Lifeguards/lifesavers and caregiver supervision must be stressed. Personal flotation devices that are approved by a governing body should be used. In addition, access to potential sites of drowning should be limited, including properly locking gates for pools. Finally, governments should have specific campaigns focused on drowning awareness and prevention that take into consideration the regional epidemiology and risk factors.

244 Neuromuscular Diseases

Paula Costanzo · Sung Min Park

Abbreviations: *BMD*, Becker muscular dystrophy; *DCM*, Dilated cardiomyopathy; *DMD*, Duchenne muscular dystrophy; *IPPB*, Intermittent positive pressure breathing; *IPV*, Intrapulmonary percussive ventilator; *NIV*, Noninvasive ventilation; *NMD*, Neuromuscular disease; *SDB*, Sleep disordered breathing; *SMA*, Spinal muscular atrophy; *SMN*, Survival motor neuron

The diagnosis of neuromuscular disease encompasses several disorders. Many of these diseases have common characteristics and treatment regimens. The identified deficits require similar support and ongoing multidisciplinary intervention. Although the focus of this chapter will be on neuromuscular diseases most commonly seen in pediatrics, the interventions described are used in other disease states with shared symptomology.

Etiology/Epidemiology

Incidence varies depending on disease. Duchenne muscular dystrophy is the most commonly seen muscular dystrophy in pediatrics. The incidence is approximately 1 in 3,000 male births. Becker muscular dystrophy is less common and has a milder more protracted course. BMD and DMD share a common x-linked gene location. DMD presents in early childhood with initial delay and subsequent loss of developmental milestones. Progression in muscle weakness and wasting occur in DMD with most patients becoming wheelchair bound by age 10–12. In DMD, death usually occurs in late teens to early twenties primarily as a result of respiratory insufficiency. Fewer die related due to cardiomyopathy. In BMD, boys may remain ambulatory until adolescence or as early adulthood. Death in BMD is also related to cardiopulmonary dysfunction, in thirties to forties.

Spinal muscular atrophy is a neurodegenerative disease commonly presenting in infancy or early childhood. Transmitted by an autosomal recessive gene and manifested by degeneration of spinal cord motor neurons with extensive muscular atrophy and weakness. It is second in frequency of NMD seen in children. Carrier frequency has been estimated at 1 in 50 to 80, with an incidence of 1 in 6,000 to 10,000 worldwide according to the SMA foundation. There are 4 types of SMA. SMA1 or Werdnig–Hoffmann disease is usually identified in early infancy and is the most aggressive form. Manifestations include severe hypotonic, poor head control, generalized weakness, weak cry and cough, fasciculation of the tongue, absent deep tendon reflexes, difficulty with swallow, feeding and secretion control. Without intervention death usually occurs before age 2. SMA type 2 is identified from ages 6 to 18 months, with loss in developmental milestones. Usually the child is unable to stand without assistance, and becomes wheelchair dependant. In both SMA types 1 and 2, chest x-rays reveal a bell-shaped chest. SMA 3 is a milder form of the disease with survival into adult life. Those not recognized until adulthood are identified as SMA 4.

Pathogenesis/Pathophysiology

DMD and BMD are X-linked recessive disorders caused by mutations in the dystrophin gene on the X chromosome at Xp21. Dystrophin is made up of proteins and complex sugars. In BMD, there is some dystrophin as compared to none in DMD. Lack of dystrophin causes progressive muscle wasting and weakness. Dystrophin is a large gene that bridges the inner surface of the muscle scleroderma. Without dystrophin the muscle scleroderma is less stable.

Muscles undergo repeated cycles of damage/necrosis and regeneration with ultimate inactivation of the regeneration process causing muscle fibrosis. In DMD there is a progressive loss of muscle function. Initial presentation is usually a result of motor delays or an abnormal gait. Normal milestones are usually obtained until the child starts to walk. Progressive muscle weakness is seen affecting the lower extremities before the upper extremities. Other typical findings in DMD include Gower's sign, pseudo hypertrophy of calf muscles, scoliosis, intellectual impairment, progressive cardiomyopathy, and worsening lung function in adolescence. Other NMDs may be more static in nature.

Spinal muscular atrophy is a group of degenerative disorders of the lower motor neurons. SMA is most

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_244,

commonly caused by deletion or mutation of the survival motor neuron 1 gene (SMN1), which is located on the 5q13 chromosome. SMN1 is responsible for the production of a protein needed in motor neuron function. Without a working protein, lower motor neurons along the spinal cord degenerate leading to progressive muscular weakness and atrophy. Classification of SMA is based on age on onset, severity of disease, and course of illness. Type one and two are the types seen most often in pediatrics.

Despite varied clinical presentation and genetic characteristics, progression of NMD often necessitates more frequent medical intervention. Although there is no cure for these disorders; and treatment is directed toward maintaining maximum function possible, prompt treatment of intercurrent illness, and maintaining quality of life. Gene analysis has become the primary tool for accurate identification of specific NMD with testing for a mutation, deletion, or duplication within a gene. In DMD, a deletion in the dystrophin gene is not always seen. A muscle biopsy may be needed if gene analysis is not definitive. In SMA, the SMN gene usually shows deletions of exons 7 and 8. Muscle biopsy shows denervation atrophy. Serum CK sometimes used in screening may be normal or elevated in both SMA and DMD.

Management and Treatment

Ongoing management of NMD requires a multidisciplinary approach. Most pediatric facilities have specialty clinics with medical and other specialists available to address current and anticipated needs of these patients. Medication treatment is respiratory based on treatment of symptoms and is mainly for the management of intercurrent respiratory illness. Clinical trials in both SMA and DMD are ongoing as well as gene therapy. There is no definitive treatment at present. In DMD, corticosteroids have shown to be effective in improvement in muscle strength in the short term with a dose of 0.75 mg/kg/day. Improvement in strength was noted within 10 days of onset of steroids and maintained for up to 18 months. There were also indications that steroid therapy was beneficial in preservation of respiratory muscle strength and cough efficiency.

Respiratory Management in NMD

Pulmonary function testing is useful in ascertaining baseline values and identifying decline in lung function. Respiratory muscle weakness influences PFT values. Patients with NMD demonstrate a restrictive pattern when lung volumes are evaluated. Initial worsening in PFTs is expected at the loss of ambulation abilities. American Thoracic Society guidelines for the DMD patient suggest evaluation by a physician specializing in pediatric respiratory care twice yearly after confinement to a wheelchair, fall in vital capacity below 80% predicted, and/or age 12 years. Weak or ineffective cough in NMD contributes to impairment in respiratory tract secretion clearance. This is a concern both in chronic and acute illness states. Inability to clear secretions sufficiently can result in atelectasis or pneumonia. There are manual and mechanical means to facilitate airway clearance. Manual techniques include positioning, chest physiotherapy (CPT), and cough assist maneuvers such as supporting or pushing on the upper abdomen or pushing the knees to the chest in conjunction with the patient's own cough. The mechanical insufflator-exsufflator (cough assist) is a device that assists in clearing retained secretions by delivering gradually increasing pressure to the airway then shifting to negative pressure with high expiratory flow rates that expel secretions in those with ineffective coughs. An oral suction device may be needed to extricate secretions from the mouth. Intrapulmonary percussive ventilation (IPV) helps to clear retained secretions by delivering rapid high flow short bursts of air into the lungs creating occult oscillation of the chest wall. Intermittent positive pressure breathing (IPPB) delivers positive pressure with or without aerosolized medication. IPV and IPPB can be used with a mouthpiece or mask. Other devices may include sSmart or the Thairapy vest which deliver high frequency mechanical oscillations to the chest wall. Inhaled bronchodilators and inhaled steroids may be used in conjunction with these therapies. Systemic steroids may also be used to treat acute respiratory distress or if due to underlying reactive airways disease.

Individuals with neuromuscular disease are at higher risk for sleep disordered breathing. Muscle wasting and weakness including intercostal and diaphragmatic muscles contribute to chronic respiratory insufficiency. Decrease in ventilatory drive and increase in upper airway resistance are seen. Tidal volume is reduced which leads to reduction in oxygenation and increase in CO_2. With progressive NMD, patients may need both day and nighttime ventilatory assistance. Polysomnography (sleep study) can identify appropriate abnormal oxygenation, hypoventilation, and carbon dioxide (CO_2) retention. Degree of pulmonary insufficiency may be identified in the context of a hospital stay when during recovery from a respiratory illness the child is unable to be weaned

successfully from ventilation. NMD patients using NIV are able to avoid some routine hospitalizations. Reduction in hospital stays including intensive care (ICU) admissions can decrease healthcare costs, and keep the patient in their preferred home environment. Caregivers of those with NMD are advised to contact their pulmonologist if they are using NIV more frequently. NMD patients with identified symptoms of SDB (headache, daytime somnolence, fatigue) reported improvement in symptoms following routine use of NIV. BiPAP (bi-level positive airway pressure) is the most frequently used type of NIV in pediatrics. Once initiated annual reevaluation with polysomnography will determine if adjustments in settings are indicated.

Invasive ventilation such as tracheotomy and ventilator support may be used in those patients unable to be successfully treated with other methods of support. Discussions of quality of life should be initiated prior to these measures.

Cardiology Management

Cardiomyopathy and cardiac rhythm disturbances are commonplace in individuals with DMD and BMD. Electrocardiographic abnormalities are seen in 90% of individuals with Duchenne or Becker muscular dystrophy. Dilated cardiomyopathy occurs in up to 90% of DMD patients 18 years or older. DCM is considered responsible for 20% of deaths in DMD. Pathological changes in the heart consist of necrosis, fibrosis, and fatty replacement of the muscle. Symptoms of cardiac dysfunction may be vague. Fatigue, weight loss, gastrointestinal complaints, and sleep disturbances may be signs of cardiac dysfunction. Female carriers are also at risk for cardiomyopathy. Cardiology evaluation is recommended at the time of confirmed diagnosis of DMD and at least biannually, beginning at approximately age 10 years or at the onset of cardiac symptoms. Cardiology input should also be initiated if surgical intervention is needed or with systemic steroid, which may affect blood pressure.

Nutritional Management

Nutritional intervention should include surveillance of appropriate weight gain, body mass index, and assessment of swallow function. Bulbar dysfunction is seen in spinal muscular atrophy. Inability to consume sufficient calories orally is also a common problem in SMA. Recommendations from the Consensus Statement for Standard of Care in Spinal Muscular Atrophy recognized problems of: feeding and swallowing, gastrointestinal dysfunction/dysmotility, growth and undernutrition and overnutrition, and concerns of aspiration in those with chronic respiratory problems. Individuals with DMD may be obese or malnourished. Obesity can put further stress on the respiratory system. Swallow evaluation (dysphasia study) is indicated in those individuals experiencing feeding-related difficulties. Risk of aspiration can be evaluated during this study as well as determination of appropriate consistency of liquids needed for safe oral intake. If aspiration is revealed alternative methods of feeding may be necessary. Percutaneous gastrostomy tube placement is an alternative to if oral feedings are deemed unsafe or inadequate. Some families opt to continue oral feedings even if aspiration risk is determined, if feeding is thought to be enjoyable to the individual. Constipation is a common issue in NMD due to lack of muscle tone. Juices and laxatives as well as a high fiber diet may be used. In addition a bioscopy bisacodyl or other rectal suppository can be effective in stimulating bowel movements.

Orthopedic Management

Surgical intervention for treatment of scoliosis in NMD is considered if spinal curvature is severe enough to cause discomfort or impair lung function. Orthopedic evaluation throughout childhood can help with determination of most appropriate time of surgery to achieve optimum correction. Pulmonary function should be determined prior to surgery. Scoliosis surgery often improves sitting balance, endurance, and appearance. Tendon releases may also be considered in DMD to prolong ambulation. Ongoing evaluation by physical therapists is helpful in evaluation and timeliness of orthotics and wheelchair use. Occupational therapy focuses on activities of daily living and maintaining functional abilities as long as possible.

Immunizations

Routine childhood immunizations are important in maintaining heath and avoiding illness. Annual influenza vaccines should be obtained. Pneumococcal and varicella vaccines should be considered.

Education, Psychosocial, and Palliative Care

Education about the affecting disease should start soon after diagnosis. Families should be referred for genetic

counseling. Expected disease course and outcomes should be discussed. Identification of community organizations, such as the Muscular Dystrophy Association can be offered as a resource to families. Medical social workers are often available in muscle disease specialty clinics. They can assist in guiding difficult discussions aimed at treatment options including surgeries, ventilation, tracheostomy, and quality of life. Anticipatory guidance is important in allowing the patient and family to consider possible choices in treatment of their disease prior to a crisis situation. The goal of palliative care is to maintain quality of life, relieving physical, psychological, emotional, and existential suffering. When available treatments no longer achieve desired outcome, and quality of life is diminished, care is transitioned to end of life or hospice care, with comfort of the patient being the primary goal. Support from medical professionals, family, and others involved in the individuals life help with the transition.

Duchenne muscular dystrophy and spinal muscular atrophy types one and two are the most common neuromuscular diseases seen in pediatrics. Management of neuromuscular disease is directed at maintaining functional abilities, treatment of symptoms, supportive care, and maintaining quality of life. A multidisciplinary approach is important in achieving optimal care. Attention should be focused on medical and psychosocial needs of the patient and family, with identification of the most appropriate intervention for each unique situation.

Cardiology

Mark B. Lewin

245 Fetal Cardiology and Neonatal Transition

Margaret MacMillan Vernon

Knowledge of the fetal, transitional, and neonatal circulations is integral to successful evaluation of the cardiovascular system and understanding the pathophysiology of congenital heart disease (CHD).

Fetal Cardiology

Cardiac Embryology

The cardiovascular system is the first organ system to reach functional maturity in the human embryo. The heart begins as a straight tube, developing by 20 days post conception when the embryo is no longer able to satisfy its nutritional requirements by diffusion alone. The heart tube is oriented in a caudocranial direction with segments which will become, in order, the atria, the left ventricle, the right ventricle, and the truncus arteriosus. The truncus arteriosus is the precursor to the aorta and main pulmonary artery (MPA). The tube elongates and then complex looping and septation follow. By the eighth week post conception, cardiogenesis is essentially complete and ventricular contraction – the fetal heart beat – can be detected by transvaginal ultrasound at that time. *Abnormal looping and incomplete septation form the basis for many forms of congenital heart disease.*

Fetal Circulation

The fetal circulation differs from the postnatal circulation in several ways; nearly all of which are attributable to the fundamental difference in the site of gas exchange (oxygen uptake and carbon dioxide removal) between the fetus and the newborn. In the fetus, both gas exchange and the absorption of nutrients occur in the placenta. In the healthy newborn, gas exchange occurs in the lungs and nutrient absorption occurs in the gastrointestinal tract.

In the fetus, oxygenated blood returns to the body through the umbilical vein having just taken up oxygen in the placenta. As the blood within the umbilical vein approaches the liver, the majority flows through the ductus venosus directly into the inferior vena cava before entering the right atrium where preferential streaming occurs. In the right atrium, blood originally from the ductus venosus flows across the foramen ovale into the left atrium and left ventricle, whereas blood from the abdominal inferior vena cava joins that from the superior vena cava and flows preferentially through the tricuspid valve into the right ventricle.

The blood entering the left ventricle is then pumped across the aortic valve and into the ascending aorta where it supplies the coronary, carotid, and subclavian arteries (and hence the heart, brain, and upper body) with relatively richly oxygenated blood.

Blood entering the right ventricle is then pumped across the pulmonary valve and into the main pulmonary artery. Because the lungs are fluid-filled and offer high resistance to flow, most of the blood passes not to the lungs, but through the ductus arteriosus and into the low-resistance descending aorta. Here it mixes with blood from the ascending aorta before ultimately returning to the placenta for oxygen uptake by way of the two umbilical arteries.

Unique Features of Fetal Circulation

1. In the fetus, oxygen-rich umbilical venous blood and oxygen-poor systemic venous blood mix at several sites before being pumped into the systemic arteries. These in utero *shunts*, including the ductus venousus, foramen ovale, and ductus arteriosus, assure the preferential delivery of oxygen-rich blood to the metabolically active tissues of the heart and brain. Abolished soon after birth, their in utero existence permits fetal survival and even thriving in the presence of complicated congenital heart disease. Postnatally, there is essentially no mixing of the pulmonary venous and systemic venous blood.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_245,

From a hemodynamic standpoint, the widely patent foramen ovale and ductus arteriosus result in equalization of the pressures between the right and left atria and similarly in the right and left ventricles. This is in distinct contrast to postnatal hemodynamics.

2. In general, the oxygen content of the blood in the fetus is considerably lower than that of a neonate or child. Blood in the umbilical vein has the highest concentration of oxygen, about 80%, gradually decreasing by the mixing in of desaturated blood as it courses from the placenta to the organs of the fetus and back to the placenta. The blood returning to the placenta not surprisingly then has the lowest content of oxygen, with a saturation of approximately 58%.

   This difference in oxygen content is due to the relatively poor efficiency of the placenta in comparison to the lungs as an organ of gas exchange. To compensate, fetal blood is composed of a high percentage of fetal hemoglobin which has a substantially higher oxygen affinity and lower p50 (the partial pressure of oxygen at which 50% of it is oxidized). This unique composition facilitates oxygen uptake at the relatively low pO2 levels of the placenta.
3. Cardiac output (CO) is determined by heart rate (HR) and stroke volume (SV): CO = HR × SV. Postnatally, alterations in heart rate as well as stroke volume, via changes in filling pressure (preload), resistance against which the ventricles contract (afterload), and myocardial contractility, allow for significant adjustments (multifold increases) in cardiac output to meet the increased requirements of a physiologic stressor.

   The fetus however, has a limited capacity to adjust cardiac output in response to stress. The fetal myocardium is relatively stiff and as a result an increase in preload does not increase cardiac output significantly and an increase in afterload markedly decreases cardiac output. Thus, the fetus relies on an increase in heart rate almost exclusively as a response to stress.

Indication for *in utero* Evaluation of the Cardiovascular System

As ultrasonographic technology has advanced and experience has been gained, more and more anomalies are being detected *in utero*. Currently, most pregnant women undergo an ultrasonographic evaluation close to midpregnancy. Typically performed between 16 and 22 weeks gestation, this ultrasound includes an assessment of fetal growth as well as an anatomic survey used to screen for major developmental anomalies. As part of this survey, the fetal cardiovascular system is evaluated. The heart is visualized, rate and rhythm noted, and a four-chamber view is obtained. The recognition that adding evaluation of both ventricular outflow tracts can significantly increase the detection of major structural heart disease has led to inclusion of them if technically feasible.

If an abnormality is identified during this screen, or at any point during a pregnancy, a comprehensive *in utero* evaluation of the cardiovascular system is recommended.

While the majority of fetal cardiovascular evaluations are requested for incomplete midtrimester anatomic screens or a suspected abnormality, a variety of maternal or fetal disorders may place a fetus at increased risk for congenital heart disease (*Table 245.1*) and *in utero* evaluation is recommended in these scenarios as well.

Infrequently a rhythm abnormality prompts consultation as well. *In utero* the fetal heart rate varies widely, from as low as 80 beats per minute during periods of rest to 160 beats per minute during periods of activity. Most commonly, the heart rate however is between 120 and 140 beats per minute. Variability is essential and is an indication of fetal well-being. Occasionally a skipped beat, early beat, or series of such will be noted during a routine prenatal evaluation. While frequently benign, their presence often prompts further evaluation for confirmation. Premature atrial contractions which can be either conducted or blocked account for the vast majority of

Table 245.1
Indications for *in utero* evaluation of the cardiovascular system

Maternal indications	Fetal indications
Family history of CHD including prior child or pregnancy with CHD	Abnormal obstetrical screening ultrasound
Maternal Diabetes	Extracardiac abnormality
Exposure to teratogens	Chromosomal abnormality
Exposure to prostaglandin synthetase inhibitors (ibuprofen)	Arrhythmia
Infection (Rubella, Coxsackie, Parvovirus B19)	Hydrops fetalis
Autoimmune dx (Sjogren's, Systemic Lupus Erythematosus (SLE))	Ultrasound screen: Increased first trimester nuchal translucency
Familial inherited disorder (Marfan's, Noonan's)	Multiple gestation and suspicion for twin–twin transfusion syndrome
In vitro fertilization	

such Doppler findings, however occasionally a fetus will be noted to have a persistently fast or slow rhythm. Fetal bradycardia can be seen in association with complex congenital heart disease or maternal antibody–mediated inflammatory disorders such as systemic lupus erythematosus (SLE) or Sjogrens syndrome. Fetal tachycardia can be seen in the setting of a primary rhythm disturbance, most commonly supraventricular tachycardia, or as a consequence of fetal heart failure due to a variety of primary etiologies including fetal anemia or myocarditis.

Following these guidelines, ~5% of pregnancies are referred for a comprehensive *in utero* cardiovascular evaluation and the proportion of congenital heart disease diagnosed prenatally has dramatically improved. Nowadays, reported rates of prenatal diagnosis frequently approach 50% whereas as recently as the early 1990s, the rate of prenatal diagnosis was less than 10% of infants undergoing cardiac surgery in the first month of life. Unfortunately, despite these strides, many babies postnatally diagnosed with congenital heart disease are born with no identified risk factors (including an identified concern at the mid-gestation anatomic screen) and cardiac anomalies continue to be one of the most frequently missed lesions *in utero*.

Figure 245.1
Four-chamber view of a normal fetal heart. All four chambers are visible with relative symmetry in size between the ventricles and atria. The right ventricle is identified by the presence of the moderator band and increased myocardial trabeculations in comparison with the left ventricle. A pulmonary vein is seen entering the left atrium from the right lung field. The descending aorta is seen directly behind the left atrium

In utero Evaluation

Echocardiography is the main diagnostic modality used to evaluate the fetal heart. The optimal timing for performance of a comprehensive transabdominal fetal echocardiogram is 18–20 weeks gestation. In select cases earlier, including late in the first trimester, evaluation may be possible. Evaluation late in gestation is often complicated by a more "fixed" fetal position which may limit the available acoustic windows and thus the completeness of the evaluation.

Similar to a pediatric transthoracic echocardiogram, a fetal echocardiogram involves assessing cardiac anatomy in a sequential fashion, obtaining standard views of all cardiac structures. Initial imaging establishes fetal position (vertex, breech, or transverse). Once fetal left and right are established, the fetal abdominal situs is confirmed as well as the position of the heart within the thorax. While uncommon as a whole, congenital heart disease and abnormalities of laterality (heterotaxy syndrome) are commonly found together. The cardiovascular system is then evaluated beginning below the diaphragm in the abdomen and ending at the thoracic inlet as a series of imaging planes. The four-chamber view (◉ *Fig. 245.1*) is the most important in a comprehensive examination of the fetal heart. In this view, cardiac position, size, rate and rhythm, and qualitative contractility can all be assessed. Additionally many congenital heart defects can be detected. After a four-chamber view is obtained, attention turns to visualization of the left and right ventricular outflow tracts and an assessment of ventriculo-arterial concordance (◉ *Fig. 245.2a, b*). Establishing the origin of the main pulmonary artery from the right ventricle and the aorta from the left ventricle is mandatory. The aortic and ductal arches are then evaluated. Finally, the systemic and pulmonary venous return are evaluated.

Structures are evaluated in orthogonal imaging planes in order to form a composite picture of the heart including any identified malformation as the primary goal of fetal echocardiography is to identify any existing abnormality *in utero*. In addition to obtaining clear two-dimensional (2D) pictures of each structure, flow is evaluated with color Doppler and pulse Doppler. Valve regurgitation and/or stenosis can be detected and valve leaflet motion

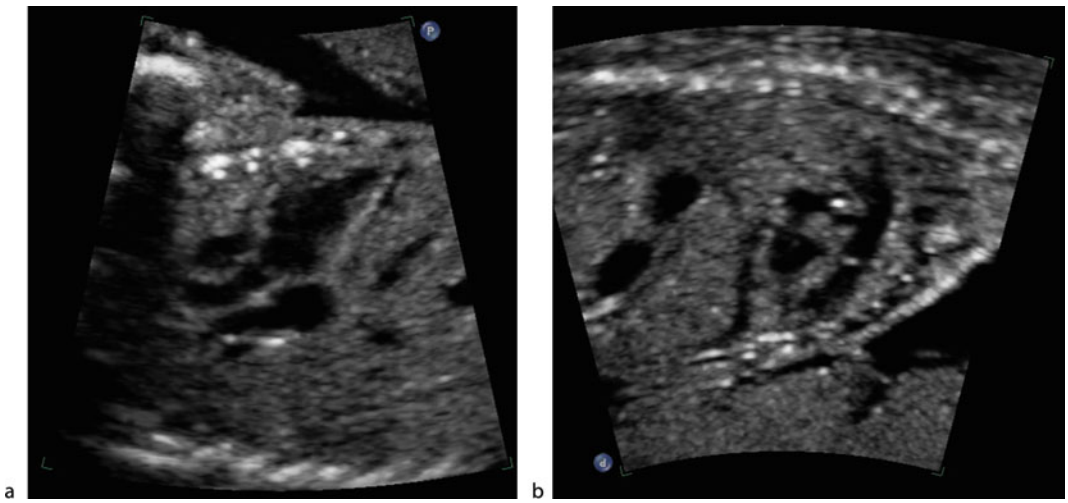

Figure 245.2
(a) The left ventricular outflow tract in a normal fetal heart. The aorta is seen arising from the left ventricle. (b) The right ventricular outflow tract in a normal fetal heart. The main pulmonary artery (MPA) is seen arising from the right ventricle. The right pulmonary artery is seen as the first branch off the MPA which continues as the ductus arteriosus in this image

observed. From 2D images, structures can be measured and compared with established normals for varying gestation ages.

Once a comprehensive assessment of the cardiac anatomy is complete, the heart rate and rhythm are documented (*Fig. 245.3a, b*). The rate and rhythm of the fetal heart are evaluated by mechanical surrogate events, specifically the movement of the atria and ventricles or blood flow across valves. By convention, the heart rate is established by measuring the time between successive aortic Doppler profiles. As a result of the normal orientation of the aortic and mitral valves, a Doppler cursor can be placed just beneath the aortic valve and pick up both aortic outflow and mitral inflow. Measuring the time between the onset of the a wave and the aortic outflow is referred to as the mechanical PR interval and is an accepted mechanical surrogate for the postnatal ECG PR interval, allowing for normal sinus rhythm to be inferred *in utero*.

Prenatal Counseling

If an abnormality is diagnosed *in utero*, counseling includes a discussion of the anatomic malformation and frequently the increased risk for extracardiac anomalies and chromosomal or genetic abnormalities. In addition, treatment options, including surgical strategy, and long-term outcomes are discussed. As part of this initial consultation the options of pregnancy termination and neonatal comfort care are discussed if locally available. Going forward, patients are evaluated serially, often at 6–8 week intervals to assess for fetal well-being, growth, and *in utero* evolution of the lesion. As a pregnancy advances toward full-term, perinatal management plans can be created to smooth the transition to the postnatal time period.

Genetics

Many congenital heart lesions are isolated; however others are frequently associated with a clinical syndrome or identifiable chromosomal abnormality. For decades it has been widely recognized that certain cardiovascular lesions are commonly seen in association with a distinct set of facial features or organ system anomalies.

With each passing year, the ability to ascribe a chromosomal deletion syndrome, microdeletion, and even single gene defect to such clinical observations increases. Identification of these anomalies, from monosomies and trisomies to much smaller chromosomal abnormalities, during the prenatal time period utilizing amniocentesis or chorionic villus sampling is rapidly increasing as well.

Frequently it is the other anomalies (skeletal dysplasias, gastrointestinal abnormalities, brain malformations, etc.)

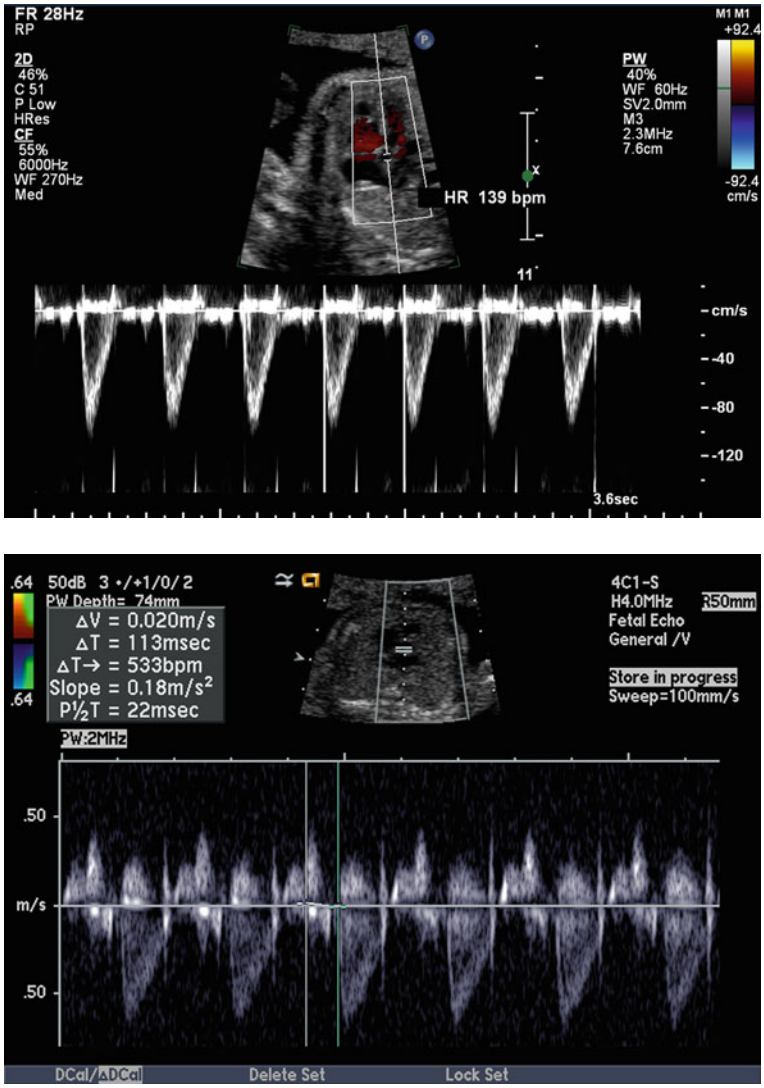

Figure 245.3

(a) The fetal heart rate (HR) is established by this Doppler tracing obtained with the sample volume just distal to the aortic valve. The time between successive beats is recorded and heart rate per minute calculated. (b) The fetal heart rhythm is evaluated by placing the Doppler sample volume just beneath the anterior leaflet of the mitral valve. In this position, Doppler tracings of both the mitral inflow and the aortic outflow are obtained and a mechanical PR interval can be recorded

which are detected first and only after a careful examination is the cardiac anomaly identified. Identification of the cardiac defect may however have a significant impact on the expected clinical course and ultimate outcome. Additionally, identification of a second anomaly greatly increases the chance of an underlying chromosomal anomaly or congenital malformation syndrome.

Neonatal Transition

Normal Events

Following birth, a series of profound changes involving the cardiovascular system occur. These events take place within the first hours to days of life and constitute the transitional circulation.

With the clamping of the umbilical cord, the systemic vascular resistance suddenly increases. At approximately the same time, the first cries of a healthy newborn, announce his or her arrival and signal the initiation of respiration. The lungs now assume their role as the organ of respiration. They expand and oxygen is brought to the alveoli. This results in a dramatic fall in pulmonary vascular resistance (PVR) and pulmonary arterial blood pressure and an increase in pulmonary blood flow. Pulmonary arterial blood pressure, which in the fetus was equivalent with the systemic blood pressure, drops to half of the systemic level within 24 h of birth.

The initial rapid fall in pulmonary vascular resistance is due primarily to the vasodilatory effect of oxygen on the pulmonary vasculature. The physical expansion of the lungs and increased production of vasoactive substances, mainly prostacyclin and endothelium-derived nitric oxide, also contribute to the fall. Subsequently there is a continual slow fall in PVR until adult levels are reached by 6 weeks of life as the medial layer (smooth muscle) of the pulmonary arteries thins. Ultimately, the decrease in pulmonary vascular resistance leads to an eight- to tenfold increase in pulmonary blood flow.

An increase in pulmonary venous return to the left atrium is seen with this increase in pulmonary blood flow. This results in a pressure gradient between the left and right atria and functional closure of the foramen ovale.

Within a few hours of birth, the increase in systemic vascular resistance and drop in PVR leads to a reversal of flow through the ductus arteriosus. *In utero* flow was from right to left (pulmonary artery to aorta) and now flow switches to left to right (from aorta to pulmonary artery). Soon thereafter, normally within 10–15 h of birth, as a result of increased arterial oxygen saturation, the ductus arteriosus closes although permanent closure may not take place for weeks. In addition, the ductus venosus closes as a result of lack of blood return from the placenta.

Anything increasing the PVR or delaying the fall in pulmonary vascular resistance, such as acidosis, hypoxemia, polycythemia, lung disease, or immaturity (such as premature delivery), may interfere or prolong these normal events.

Indications for Cardiovascular Evaluation

Congenital heart disease (CHD) is by definition heart disease present at birth. The majority of congenital heart defects are anatomic abnormalities, such as septal defects, stenosis or atresia of a valve or valves, hypoplasia or absence of a ventricle, or abnormal great arterial connections. Infrequently a newborn is born with an arrhythmia or cardiomyopathy. This is in contrast to adult cardiovascular disease, the majority of which is functional or rhythm-related.

CHD is one of the most serious congenital anomalies, occurring in approximately 1% of newborns. Despite near universal mid-gestation ultrasonographic screening, the majority of congenital heart disease, both subtle and more serious, is diagnosed after birth. While the vast majority of these newborns are hemodynamically stable and require no more than normal newborn care, early recognition of congenital heart disease allows for expeditious identification of those who are at risk for hemodynamic compromise.

The uniqueness of the fetal circulation has great consequences during the transitional period for those with congenital heart disease. It is during this time, that many complex lesions unmask themselves after being tolerated silently *in utero*. The symptoms of cardiovascular disease may be nonspecific, resembling more common scenarios such as neonatal sepsis or respiratory distress syndrome (RDS). When clinical events such as tachypnea, tachycardia, hypoperfusion, persistent cyanosis, or the presence of a murmur suggest an abnormality in the cardiovascular system, evaluation is warranted.

Systemic Hypoperfusion

In the simplest sense, insufficient cardiac output presents as systemic hypoperfusion and ultimately shock. Following delivery, the work of respiration and maintenance of body temperature are both assumed. Abnormalities in myocardial contractility or heart rate may present as hypoperfusion if the cardiac output fails to meet the increasing metabolic demands of the newborn.

In addition, and more frequently, infants with clinically significant aortic arch obstruction present with systemic hypoperfusion and shock following closure of the ductus arteriosus.

In utero, the left ventricle and aortic isthmus see only a small amount (~10%) of the cardiac output. The left heart is therefore developmentally particularly vulnerable. Significant narrowing or coarctation and interruption of the aortic arch together account for a relatively large proportion of congenital heart disease. Both lesions are silently tolerated *in utero* and more commonly diagnosed in the postnatal period rather than prenatally.

Persistent Cyanosis

Central cyanosis, distinguished from acrocyanosis by involvement of the warm mucous membranes, including the tongue and buccal mucosa, is abnormal. A distinctive feature between the two is that central cyanosis generally worsens with activity and increasing cardiac output (crying for instance), whereas acrocyanosis generally improves. Central cyanosis is evident when the content of reduced hemoglobin is greater than 3–5 g/dl.

Because of the low levels of circulating oxygen before birth, newborns with cyanotic congenital heart disease (*Table 245.2*) may be quite active, feeding and appearing comfortable, at oxygen levels which older children would not tolerate (PaO2 20–25 mmHg).

In addition, pulmonary arterial flow *in utero* is reduced compared with that following delivery and expansion of the lungs. Because of the resultant minimal pulmonary venous return *in utero*, anomalies of pulmonary venous return (specifically total anomalous pulmonary venous return) may easily be masked. Total anomalous pulmonary venous return is one of the cyanotic lesions unmasked when effective oxygenation and ventilation fail to improve an affected newborn's visible central cyanosis.

Alternatively, persistent pulmonary hypertension of the newborn (PPHN), occasionally referred to as persistent fetal circulation, results when the PVR fails to fall following the initiation of ventilation. Pulmonary arterial pressure and right ventricular pressure remain elevated as they were *in utero*. In PPHN, blood continues to bypass the lungs by shunting across the foramen ovale and ductus arteriosus resulting in persistent cyanosis. Several factors may disrupt the normal decrease in PVR and increase in pulmonary blood flow; these include apnea and parenchymal lung disease both of which interfere with ventilation. Meconium aspiration and severe respiratory distress syndrome are the major parenchymal lung diseases. Pneumonia and asphyxia can cause PPHN as well.

The five *T*'s of cyanotic heart disease

*T*etralogy of Fallot
*T*ransposition of the great arteries
*T*runcus arteriosus
*T*otal anomalous pulmonary venous return
*T*ricuspid atresia

Presence of a Murmur

Murmurs are very common in children. CHD is much less common, however the vast majority is diagnosed within the first week of life if not prenatally. Given the increased likelihood of a pathologic etiology, a murmur noted within the first hours or days of life warrants thoughtful investigation.

Significant semilunar valve pathology, such as aortic or pulmonary stenosis (PS), typically presents early as the entire cardiac output is ejected across the narrowed orifice. On the other hand, the murmur of a ventricular septal defect (VSD) may present early or may develop as the pressure gradient between the right and left ventricles evolves as the PVR drops.

A murmur may be normal in the transitional time period. If no other clinical concern exists, close observation may be appropriate. Within the first 24 h following birth, the ductus arteriosus closes as a result of constriction of the ductal smooth muscle. Until complete closure is achieved, a murmur may be noticed. Additionally, *in utero*, the lungs receive a relatively small proportion of the combined ventricular output and therefore the branch pulmonary arteries are relatively small. This is important in the genesis of the normal physiologic pulmonary flow murmur.

Presence of an Extracardiac Anomaly or Chromosomal Abnormality

In addition to evaluating symptomatic newborns presenting with signs suggesting cardiovascular abnormalities or abnormal transition, a comprehensive evaluation of the cardiovascular system including an echocardiogram is indicated in the assessment of a neonate with a presumed chromosomal abnormality, recognized syndrome (*Table 245.3*), or extracardiac malformation with an increased risk of associated CHD (i.e., omphalocele). Additionally, a neonate with a condition which may adversely impact the cardiovascular function (i.e., arteriovenous malformations) warrants evaluation.

Confirmation of the absence of structural heart disease or alternatively the identification of a significant congenital heart defect can be extremely helpful to the team caring for a neonate, particularly one with a recognized extracardiac anomaly. Frequently, outcome may be impacted by the presence of CHD. Detection of CHD allows for development of a comprehensive management strategy.

Table 245.3
Commonly recognized syndromes associated with congenital heart disease (CHD)

Syndrome	Lesion
Trisomy 21	VSD, AVSD
Trisomy 13	VSD, PDA
Trisomy 18	VSD, PDA
45 XO (Turner)	Coarctation of the aorta, AS
DiGeorge	IAA, truncus arteriosus, TOF
Williams	Peripheral PS, supravalvar AS
Noonan	PS, ASD, HCM
VACTERAL	VSD, TOF
Fetal Alcohol	ASD, VSD, TOF
Infant of a diabetic mother	HCM, TGA, VSD
Marfan	MVP, aortic aneurysm

AS aortic stenosis, *ASD* atrial septal defect, *AVSD* atrioventricular septal defect, *HCM* hypertrophic cardiomyopathy, *IAA* interrupted aortic arch, *MVP* mitral valve prolapse, *PDA* patent ductus arteriosus, *PS* pulmonary stenosis, *TGA* transposition of the great arteries, *TOF* tetralogy of Fallot, *VSD* ventricular septal defect

The Premature Neonate

The incidence of persistent patency of the ductus arteriosus increases with decreasing gestational age at birth. In the premature infant where the clinical course falls outside that typically encountered, ensuring the absence of structural heart disease is crucial. Additionally, in the present era, echocardiographic assessment is considered the standard of care before medical treatment of a presumed patent ductus arteriosus (PDA).

Evaluation of the Cardiovascular System

A brief period of observation is essential in developing a general assessment of overall health.

A varying degree of acrocyanosis or blueness of the hands and feet is the rule rather than the exception following delivery. Although the precise etiology is unknown, acrocyanosis is likely secondary to a difference between the cutaneous arterial and venous vessel tone. In a newborn with acrocyanosis, pulse oximetry will be normal as it estimates arterial oxygenation defined as the percentage of hemoglobin molecules bound by oxygen. Frequently obtaining an accurate tracing with corresponding heart rate is challenging. Placing the newborn under a warming light or swaddling him or her with a warm blanket may be very helpful.

A complete set of vital signs should be obtained and recorded for every newborn. The most reproducible set of vital signals are obtained in the resting state.

The heart rate is generally faster in the newborn than during childhood. A normal resting newborn heart rate is usually over 100 beats per minute, typically between 120 and 140 beats per minute.

The respiratory rate should be counted for a full minute as rates may vary considerably. The normal respiratory rate can vary from 45 to 60 breaths per minute. Tachypnea can occur as a consequence of increased pulmonary blood flow and dyspnea, manifest as grunting, flaring of the nostrils, and intercostal, suprasternal, and subcostal retractions, as a consequence of increasing pulmonary congestion.

Every newborn should have a comparison of upper and lower blood pressures on at least one occasion. Because the subclavian arteries may arise aberrantly beyond the site of the ductal ligament, both upper extremities should be measured and compared with the lower-limb pressure. Normal lower-limb systolic blood pressure is 10 mmHg higher that the upper-limb pressure.

Mild arterial desaturation is not unusual in a normal neonate. In an otherwise healthy newborn, this transient mild desaturation is secondary to an intrapulmonary shunt through an as-yet unexpanded portion of the lungs.

Developing an organized routine in the performance of the cardiac examination is necessary so that important points are not missed or neglected. A peacefully resting or sleeping infant is essential to a complete auscultatory examination. One strategy is to concentrate first on the cardiac rhythm, establishing its regularity, before moving to an evaluation of the heart sounds and murmur recognition. Identifying the splitting of the second heart sound, not only implies the presence of two semilunar valves but also their normal anatomic configuration, is quite challenging and moves from an advanced auscultatory skill to an impossible task if the newborn is fussing or crying.

The presence of a murmur in a newborn, while not necessarily pathonomonic for congenital heart disease should increase one's suspicion. Occasionally the closure of the ductus will be audible though this should be a soft, transient murmur (not the machinery type murmur of a persistently patent ductus). Localization of a murmur source may be quite challenging. This is not surprising as the newborn heart is approximately the size of a walnut (2–3 cm in diameter).

In addition to the auscultatory examination, the presence of hepatomegaly and localization of femoral pulses are essential components of a comprehensive cardiovascular examination. Palpation of the liver edge can be aided by allowing the newborn to rest their feet on the examiner's palm and raise their toes 90° (flexing at the hips) to relax the abdominal wall muscles. Examination of the newborn abdomen is particularly important as the size of the liver offers the most reliable indicator of systemic venous congestion.

Identifying the iliac crest and then sliding the tip of the examining finger along the femoral crease often aids in identification of the femoral pulse. While frequently difficult to locate, once located the femoral pulse should be easy to palpate. Both the brachial and femoral pulses should be assessed and compared to each other.

The cardiovascular evaluation includes review of a complete set of vital signs including four extremity blood pressures and pre- and post-ductal saturation and performance of a physical examination. Frequently a chest X-ray, electrocardiogram (ECG), and/or echocardiogram are indicated to complete a comprehensive evaluation.

The normal newborn electrocardiogram (ECG) has more right ventricular force than that of an older child or adult. Newborn infants have right ventricular dominance with a thick right ventricular wall and elevated PVR secondary to a thick medial layer of the pulmonary arterioles. The thick pulmonary arterial smooth muscle gradually becomes thinner and by 6–8 weeks of age the ECG resembles that of an older child.

Echocardiography is the primary imaging modality utilized to evaluate the cardiovascular system. High-resolution images can clearly identify anatomic abnormalities and an assessment of hemodynamics can be made by applying the Doppler principle. Although echocardiography is considered a noninvasive diagnostic test, care must be taken during the performance of the echocardiogram as prolonged environmental exposure and even transducer pressure can lend to instability in vulnerable newborns. A detailed discussion of echocardiography can be found in Chap. "❯ NonInvasive Imaging."

246 Cardiovascular Genetics

Aaron K. Olson · Jeffrey A. Towbin

The goal of this chapter is to provide a review of the common genetic conditions associated with cardiovascular disease in children. Congenital heart disease can be one of the earliest recognized manifestations of a genetic syndrome. For example, interrupted aortic arch type B is often the presenting finding in patients with 22q11 deletion syndrome. Conversely, the recognition of a genetic syndrome may prompt an evaluation for congenital heart lesions, such as in Down syndrome (DS). Correctly diagnosing a genetic syndrome can provide important benefits such as detection of additional anomalies and assessment of reproductive risk for future pregnancies.

Certain genetic syndromes present with a variety of important cardiovascular complications in childhood such as cardiomyopathy or aortic root dilation. Often, these patients present for evaluation only after another family member is diagnosed. It is important to recognize that the initial cardiac evaluation may be normal, even in patients who will eventually develop serious cardiovascular complications. Therefore, ongoing cardiac evaluations are necessary for this patient population.

This chapter is not meant to be a complete review of every genetic syndrome with pediatric-onset cardiovascular disease. Many comprehensive resources are available including the online sites www.ncbi.nlm.nih.gov/omim (Online Mendelian Inheritance in Man from Johns Hopkins University) and www.genereviews.org (from the University of Washington). Of special note, hypertrophic cardiomyopathy and long QT syndrome will be discussed in other chapters of this section.

Down Syndrome

To most health-care providers, Down syndrome (DS) is the most familiar genetic syndrome associated with congenital heart disease. The vast majority of DS patients have a complete trisomy 21. Rarely, individuals may have a partial trisomy due to a chromosomal translocation or mosaicism. These chromosomal anomalies are readily detectable by karyotype analysis. Depending on age and ethnicity, patients have a typical appearance that includes microbrachycephaly, small facial features, protruding tongue, short upslanting eyes with epicanthal folds, fifth finger clinodactyly, brachydactyly, transverse palmar creases, and sparse hair. Global developmental delay of at least moderate degree is universally present. Other common clinical features include gastrointestinal anomalies, hematologic disorders, endocrine disorders, sleep apnea, and atlantoaxial instability. The reader is encouraged to consult other sources for in-depth information on noncardiac features of DS.

Congenital heart disease is present in about half of live-born DS patients. Of these, approximately 40% will have a complete atrioventricular septal defect (AVSD), which is synonymous with atrioventricular canal defect or endocardial cushion defect. When primum atrial septal defects (ASDs) and transitional AVSDs are included, this number increases to almost 60%. Other commonly encountered forms of CHD include secundum ASDs, perimembranous and muscular ventricular septal defects (VSDs), tetralogy of Fallot (with or without AVSD), and hemodynamically significant patent ductus arteriosus (PDA). In DS patients with congenital heart disease, cardiac treatment does not differ from non-syndromic patients. Commonly encountered problems in DS, which may directly affect the cardiovascular system, include thyroid abnormalities and obstructive sleep apnea. Pulmonary hypertension commonly develops if certain cardiovascular defects are not repaired during the first months of life.

Many patients with Down syndrome are diagnosed prenatally and undergo a screening fetal echocardiogram. A screening echocardiogram should be performed in patients with newly recognized DS at birth, since complete or transitional AVSD may not have a distinctive murmur at this time. A consultation with a pediatric cardiologist should be obtained if any cardiac anomaly is identified. In addition, evidence of pulmonary hypertension should be monitored, particularly in those with late repairs.

Trisomy 18 (Edwards Syndrome)

Trisomy 18 is the second most common autosomal trisomy in live-borns (after trisomy 21) and occurs in

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_246,

approximately 1 in 6,000 live births. Trisomy 18 is characterized by multiple congenital anomalies and early death. Like DS, most patients have a nondisjunction. However, unbalanced translocations and mosaicism also occur. Around 80% of live cases are found in females. Males with this trisomy have decreased pre- and postnatal survival. Neonates with trisomy 18 are often small for gestational age. Common physical findings include a prominent occiput, short palpebral fissures with droopy eyelids, micrognathia, external ear abnormalities, clenched fist, underdeveloped thumbs, short sternum, rocker-bottom feet, and redundant skin in the back of the neck. Congenital heart disease is present in between 80% and 100% of these patients. Other less common abnormalities include cleft lip and/or cleft palate and abnormalities of the bowel, kidneys, or brain structure. Patients with the mosaic or translocation forms often have fewer of these features than those with nondisjunction.

The prognosis for patients with trisomy 18 is very poor. Fifty percent die by 6 months of age and 90% die by 1 year of age commonly due to evolving symptoms related to their heart disease. Patients who live beyond infancy have severe developmental delays. Because of these features, parents may elect to terminate a pregnancy with trisomy 18 or provide only comfort care after birth.

As noted above, congenital heart defects frequently occur in these patients. The most common lesions are atrial septal defects, ventricular septal defects, patent ductus arteriosus, and polyvalvular disease. Other lesions that occur less frequently include double outlet right ventricle and hypoplastic left heart syndrome. Due to the poor prognosis, the majority of medical centers do not offer surgery to repair congenital heart defects in this population. If necessary, heart failure is managed medically. However, a few reports have described the experience with performing cardiac surgery for these patients.

Trisomy 13 (Patau Syndrome)

Trisomy 13 (also known as Patau Syndrome) occurs in approximately 1/10,000–1/15,000 newborns. Like the other trisomies, most patients have a nondisjunction, but mosaicism and translocations also occur. Patients with trisomy 13 have multiple malformations and severe developmental delay. The prognosis is extremely poor with an 82% mortality within the first month and 5% survival at 6 months of age. Like trisomy 18, many parents choose to terminate pregnancies affected with this disorder or perform comfort care in live-borns. Common characteristics include orofacial clefting, microphthalmia/anophthalmia, cutis aplasia of the scalp, and postaxial polydactyly of the limbs. Cardiac malformations are present in about 80% of individuals. The most common cardiac lesions in this disorder are atrial septal defects, ventricular septal defects, patent ductus arteriosus, and dextrocardia. Symptoms related to these lesions are a common cause of death in this population. Like trisomy 18, cardiac surgery is not usually offered due to the extremely poor long-term prognosis. However, there are a few sporadic reports of surgery for these patients. Other malformations include holoprosencephaly, omphalocele, genital abnormalities, renal defects, and seizures.

22q11 Deletion Syndrome

22q11 deletion syndrome is also referred to as DiGeorge syndrome, velocardiofacial syndrome, Shprintzen syndrome, cardiac anomaly face syndrome, or Takao syndrome. These syndromes share a common genetic origin, namely a deletion at chromosome 22q11. This abnormality results in a developmental field defect that affects derivatives of the branchial arch/pharyngeal pouch system. 22q11 deletion syndrome is characterized by aplasia or hypoplasia of the thymus, aplasia or hypoplasia of the parathyroid gland, cardiac malformations, and specific facial features. The estimated incidence is 1 per 5,950 live births.

The clinical features of the 22q11 deletion syndrome are highly variable. The most common manifestations include cardiovascular anomalies, palate anomalies, feeding disorders, speech and learning disabilities, renal anomalies, and behavioral disorders. Additional problems include hypocalcemia, immunodeficiency, skeletal abnormalities, and growth hormone deficiency. The typical facial features include tubular nose, hypoplastic alae nasi, bulbous tip nose, low set or dysplastic ears, and myopathic facies. Manifestations that present in the child include hypernasal speech, learning disabilities, behavioral disorders (such as ADHD), and psychiatric disorders (bipolar disorder and/or schizophrenia).

The most commonly encountered cardiovascular defects in this disorder include tetralogy of Fallot (TOF), interrupted aortic arch type B (IAA type B), truncus arteriosus, conoventricular septal defects, and other aortic arch anomalies. The arch anomalies include right aortic arch, cervical location, or abnormal branching patterns. These defects fall into the general category of conotruncal lesions based upon embryological development. As noted,

22q11 deletion syndrome is especially common in patients with IAA type B and is found in between 50% and 89% of patients with this specific lesion. Among patients with TOF, the deletion is more common with absent pulmonary valve syndrome or aortopulmonary collateral vessels. Patients with transposition of the great arteries or double outlet right ventricle rarely have a 22q11 deletion. The early identification of patients with 22q11 deletion is important in order to screen for disorders that may affect the immediate management such as hypocalcemia and immune defects. Patients should be given leukocyte-depleted and CMV-negative blood.

Data supports genetic testing in all infants with IAA type B, truncus arteriosus, TOF with absent pulmonary valve, TOF with aortic arch abnormalities, TOF with aortopulmonary collaterals, perimembranous VSDs with associated arch anomalies, and isolated aortic arch abnormalities. It is unclear whether testing infants with TOF without additional lesions is cost effective. Only about 6% of isolated TOF patients are estimated to have a 22q11 deletion. Therefore, a careful clinical and laboratory evaluation is indicated to identify supportive features prior to performing genetic testing. Genetic testing consists of fluorescent in situ hybridization (FISH) for the 22q11 deletion.

22q11 deletion syndrome is inherited in an autosomal dominant manner from a parent in around 6–28% of cases. The affected parent may not be identified until the diagnosis is made in their child. Importantly, a parent with the deletion has a 50% chance of transmitting this abnormality to their offspring.

Williams–Beuren Syndrome (Williams Syndrome)

Williams syndrome (WS) is an autosomal dominant disorder that occurs in about 1 per 20,000 live births. WS is characterized by specific cardiovascular defects (typically supravalvular aortic and pulmonic stenosis), infantile hypercalcemia, skeletal and renal anomalies, cognitive defects, "social personality," and elfin facies. Unrecognized hypercalcemia is a risk factor for nephrocalcinosis and can lead to renal failure. In the long term, patients are at risk for developing hypertension due to either renal artery stenosis or another yet unidentified mechanism. Approximately 90% of those with a clinical diagnosis are found by FISH analysis to have a microdeletion at chromosome 7q11.23. The clinical phenotype corresponds with deletions or alterations of specific genes within the affected region. For example, cardiovascular manifestations are associated with alterations in the elastin gene.

Because of the clinical variability and the fact that characteristic facial features are not particularly evident in infants, it is appropriate to consider FISH testing for WS in all infants with the characteristic cardiac lesions (discussed below). Most cases arise as de novo mutations.

The most common cardiovascular abnormalities include supravalvular aortic stenosis (SVAS), supravalvular pulmonary stenosis, and peripheral pulmonary stenosis. The degree of cardiovascular involvement varies widely across patients. Pulmonary lesions, especially peripheral pulmonary branch stenosis, typically improve over time and commonly predate the development of SVAS. However, SVAS is often progressive. Significant stenosis in either the pulmonary artery or aorta can cause ventricular hypertrophy and lead to heart failure. Nearly half of WS patients will require cardiac surgery, most commonly for supravalvular aortic stenosis. Current surgical management for supravalvular aortic stenosis typically involves patch augmentation to enlarge the area of narrowing. Sudden death has also been reported in these patients. Many of the deaths are associated with coronary artery stenosis and severe biventricular outflow stenosis. The mechanism of death is believed to be due to myocardial ischemia, decreased cardiac output, or arrhythmias.

Alagille Syndrome

Alagille syndrome is multisystem disorder affecting the liver, heart, eyes, skeletal system, and face. Disease severity can vary greatly between patients and even within families. The primary diagnostic feature is bile duct paucity on liver biopsy. However, this finding may not be present until after the neonatal period. Liver manifestations include chronic cholestasis, minimal liver enzyme elevation, hypercholesterolemia, or rarely liver failure. Butterfly vertebrae are the most common skeletal feature. Ophthalmological findings include posterior embryotoxon. Finally, facial features include a prominent forehead, deep-set eyes with moderate hypertelorism, pointed chin, and saddle or straight nose with a bulbous tip. These features give the face the appearance of an inverted triangle.

Cardiovascular complications are almost universally present, primarily affecting pulmonary circulation. Typical cardiac lesions include peripheral pulmonary artery hypoplasia, tetralogy of Fallot, and pulmonary valve stenosis. Tetralogy of Fallot is found in between 7% and 16% of individuals. Beyond cardiac lesions, neurovascular accidents are common with reported at rates as high as 15% and accounting for 34% of total mortality in one large

study. At this time, presymptomatic screening for CNS vascular abnormalities has not been formally recommended. However, all patients with CNS complaints should undergo vascular imaging studies.

Alagille syndrome should be suspected in any patient with hepatic abnormalities in addition to the typical cardiac lesions. To make the diagnosis, a histological finding of bile duct paucity plus three of the five major clinical criteria are necessary. The major clinical criteria include: cholestasis, cardiac defects, skeletal abnormalities, ophthalmologic abnormalities, and the characteristic facial features. If an affected first-degree relative is identified, the presence of only one feature is necessary to make the diagnosis. Unless they have already been performed, all newly diagnosed individuals should undergo cardiac, hepatic, ophthalmologic, orthopedic, hematologic, and renal evaluations.

The main reason to perform genetic testing is to offer a recurrence risk for families. The two genes have been found in association with Alagille syndrome. The most common mutation is in the *JAG1* gene, which is present in around 90% of clinically identified patients. *NOTCH2* mutations are rarely found in this disorder at less than 1% of patients. Sequence analysis is clinically available for both *JAG1* and *NOTCH2* in the United States. Interestingly, half of mutation-positive relatives of affected individuals in one study did not meet clinical diagnostic criteria.

Alagille syndrome is inherited in an autosomal dominant manner. Approximately 30–50% of individuals have an inherited mutation and about 50–70% have a de novo mutation. Prenatal testing is possible if the *JAG1* disease-causing mutation or deletion is identified in an affected family member. Although testing can determine whether or not the fetus has inherited the *JAG1* disease-causing mutation or deletion, it cannot predict the occurrence or severity of clinical manifestations.

Noonan Syndrome

Noonan syndrome (NS) is characterized by short stature, characteristic facies, and cardiovascular abnormalities. Additional features include a broad neck, chest deformity, cryptorchidism, variable coagulation defects, lymphatic dysplasias, and developmental delays of variable degrees. NS is inherited in an autosomal dominant manner, although most cases are sporadic. The incidence is estimated to be between 1/1,000 and 1/2,500 live births. There are currently four genes known to be associated with NS: *PTPN11, KRAS, SOS,* and *RAF1.*

NS does not have defined diagnostic criteria; therefore, the diagnosis is made by observation of the key clinical features. The cardinal features are: short stature, congenital heart disease, developmental delay of variable degree, broad or webbed neck, chest deformity with a superior pectus carinatum and inferior pectus excavatum, low set nipples, cryptorchidism in males, and characteristic facies. The described facial findings includes hypertelorism, posteriorly rotated and low set ears with fleshy helices, vivid blue or blue green irises, epicanthal folds, and thick or droopy eyelids. Importantly, the facial features are most apparent in the neonate and in middle childhood.

Cardiac involvement is present in 80–90% of patients. The most common cardiac complications are pulmonary valve stenosis and hypertrophic cardiomyopathy. Additional cardiac findings include secundum ASD, AVSD, mitral valve abnormalities, coarctation of the aorta, and tetralogy of Fallot. Pulmonary stenosis is found in about 60% of patients; however fewer than half require intervention. Severe pulmonary stenosis is typically treated with balloon pulmonary valvuloplasty initially, but will often require surgical valvuloplasty or valvectomy. In nonsyndromic patients, isolated pulmonary stenosis is rarely progressive beyond infancy. However, pulmonary stenosis in NS can progress beyond this timeframe. In patients requiring an intervention, lifelong follow-up is necessary especially if significant pulmonary regurgitation develops.

Hypertrophic cardiomyopathy occurs in around 20–30% of patients, sometimes coexisting with structural heart lesions. The course and prognosis for hypertrophic cardiomyopathy in NS is variable and not well understood. The hypertrophic cardiomyopathy may not develop until late in childhood and gradually progress; rarely it is rapidly progressive in infancy. Treatment is similar to other forms of hypertrophic cardiomyopathy and includes the use of β-blockers and surgery for severe outflow tract obstruction. Occasionally, heart failure will not be amenable to medical therapy and heart transplantation is required. The risk of sudden death in this population is unknown with few case reports in the literature. Of note, the largest natural history follow-up study (of 112 patients) did not identify any cases of sudden death.

As mentioned above, NS is a genetically heterogeneous disorder with four genes identified thus far. *PTPN11* is the most commonly affected gene with abnormalities identified in about 50% of NS individuals. *SOS* is the next most commonly affected gene at approximately 13%. *RAF1* mutations are found in 3–17% and KRAS is found in $<$5% of patients. Clinical genetic testing is available in North America. For the recommended genetic testing algorithm, the reader should refer to the NS review at

www.genetests.org. LEOPARD syndrome has significant overlap with NS and shares mutations in *PTPN11* and *RAF1*. LEOPARD syndrome is characterized by lentigines, ECG abnormalities, ocular hypertelorism, pulmonary stenosis, abnormalities of genitalia, growth retardation, and deafness. It is differentiated from NS by the presence of pigmentary findings.

Genotype–phenotype correlations exist within NS. *PTPN11* mutations are more common in patients with pulmonary stenosis, but uncommon in patients with hypertrophic cardiomyopathy. *RAF1* mutations are strongly correlated with hypertrophic cardiomyopathy in NS with around 95% patients developing this complication.

NS is an autosomal dominant disorder. Many affected individuals are found to have a de novo mutation. An affected parent is identified in 30–75% of cases. The risk of having additional offspring with this disorder depends on the genetic status of the parent. Prenatal testing is available if the disease-causing allele has been previously identified in an affected family member.

Holt–Oram Syndrome

Holt–Oram syndrome (HOS) is the most common of the "heart–hand" syndromes. It is characterized by skeletal anomalies of the upper limb, congenital heart disease, and/or cardiac conduction abnormalities. The incidence is 1 per 100,000 live births. Mutations in the *TBX5* gene are found in approximated 75% of affected individuals. The condition shows an autosomal dominant inheritance pattern; however, most cases result due to de novo mutations.

The diagnosis of HOS should be suspected in any patient with an upper limb defect and heart anomalies. It should also be considered in any patient with an apparently isolated septal defect and family history of upper limb abnormalities. All patients with HOS have anomalies involving the preaxial radial ray. Typically, skeletal anomalies include a triphalangeal, hypoplastic, or absent thumb. Importantly, some patients have subclinical skeletal abnormalities (such as to the carpel bone) that can only be picked up radiographically. Anomalies can be present in one or both upper limbs and can be symmetric or asymmetric.

Approximately 75% of patients with HOS have cardiac abnormalities. Secundum ASDs and VSDs are the most common structural heart lesions, but more complex lesions have also been identified. Atrioventricular conduction delays are another important feature that require lifelong surveillance. Sinus bradycardia and first-degree atrioventricular (AV) block represent the initial manifestations. AV block can progress and lead to symptoms such as syncope. Yearly ECG is recommended for all HOS patients as well as 24-h Holter monitor for those with identified conduction abnormalities.

Clinical genetic testing for the *TBX5* is available; however, failure to identify a mutation does not alter management or diagnosis. HOS is inherited in an autosomal dominant manner. Approximately 85% of diagnosed patients have a de novo mutation. Offspring of an affecting individual are at 50% risk of also being affected. Prenatal molecular genetic testing may be performed if the disease-causing mutation has been identified in an affected relative.

Muscular Dystrophy

The muscular dystrophies are a genetically diverse group of disorders that are characterized by progressive muscle weakness. The various forms of muscular dystrophy are classified by their specific gene defect, pattern of skeletal muscle involvement and unique clinical features. In the heart, the primary pathology is that of a cardiomyopathy, although abnormalities of the conduction system can occur. Duchenne muscular dystrophy (DMD) and Becker muscular dystrophy (BMD) are the largest group of muscular dystrophies that affect the heart. As such, this chapter will primarily focus on these disorders. However, a brief mention of cardiovascular problems in other muscular dystrophies will be included.

The responsible gene for DMB/BMD is called *DMD* and is found on the short arm of the X chromosome. This gene encodes for the protein dystrophin. DMD and BMD are similar disorders that differ in severity due to the amount or quality of the protein from the dystrophin gene. Patients with DMD typically express less that 3% dystrophin on skeletal muscle biopsies. BMD is a more clinically heterogeneous disorder with varying dystrophin expression. Patients with BMD can have mild to severe disabilities depending upon the specific gene mutation. The incidence of DMD is 1 in 3,500 boys while the incidence in BMD in estimated at 1 in 30,000 boys. The condition is X-linked and thereby almost exclusively affects males. However, female carriers can be at risk for muscle disease and cardiomyopathy (discussed below).

Typically, patients with DMD will begin to manifest symptoms of muscle weakness around 3 years old and nearly all are wheelchair dependent by age 12 years. The diaphragm and intercostal muscles are affected leading to poor cough, aspiration, and a predisposition to

pneumonia. DMD patients often require some form of respiratory support. IQ is typically 1 standard deviation below the normal population. Finally, survival can reach into the late teens to early twenties and is primarily determined by cardiopulmonary status.

BMD patients have later-onset skeletal muscle weakness. As such, they are not wheelchair dependent until after age 15 years and may not require one until the third decade of life. The mean age of death in BMD is in the mid-forties.

The diagnosis of DMD and BMD is beyond the scope of this chapter and is covered elsewhere. Briefly, DMD typically presents with muscle weakness starting before age 5 years old whereas BMD presents later. Creatine phosphokinase (CK) levels are typically five (BMD) to ten (DMD) times normal. After an elevated CK is found, molecular genetic analysis of the dystrophin gene should be performed. If no mutation is found, consideration for a skeletal muscle biopsy with western blot and immunohistochemistry studies for dystrophin is warranted.

Dilated cardiomyopathy (DCM) is a common feature to both BMD and DMD. Prior to the development of overt DCM, histological studies have shown cardiac muscle replacement with fat and fibrosis. The fibrosis eventually leads to ventricular dysfunction and dilation. The conduction system can also be affected by fibrosis, potentially leading to arrhythmias.

Owing to the significant physical limitations in DMD, the DCM does not usually present with the typical features of heart failure. Potential signs of heart failure in this population include altered duration and quality of sleep, pronounced fatigue, and unexplained weight loss or gain. Children with BMD have milder skeletal muscle involvement and therefore may present with more typical signs of heart failure such as activity intolerance. The cardiac exam is seldom abnormal even in the face of a significant cardiomyopathy. The incidence of DCM in DMD increases throughout the teenage years, with approximately one-third of individuals being affected by age 14 years, one-half by age 18 years, and essentially all individuals after age 18 years. In patients with BMD, heart failure is a common cause of morbidity and is the most common cause of death.

Arrhythmias and electrocardiographic abnormalities are also common. The classic EKG in older DMD patients consists of tall R waves in the right precordial leads and prominent Q waves in the left precordial and limb leads. Between 30% and 50% of children with DMD have a sinus tachycardia independent of cardiac function. Arrhythmias may eventually arise including ectopic atrial tachycardia, atrial fibrillation, transient second- and third-degree AV block, and ventricular tachycardias. The risk of sudden death due to ventricular fibrillation is increased in those with the presence of multiform premature ventricular contractions and ventricular tachycardia on Holter monitor.

Appropriate management of patients with DMD/BMD can prolong survival and improve quality of life. The predictability in the onset of cardiomyopathy and potential lack of symptoms mandate screening examinations for optimal care. The American Academy of Pediatrics published cardiac screening recommendations. In DMD, complete cardiac evaluation at least every 2 years should begin in early childhood. At approximately age 10 or at the onset of cardiac dysfunction, annual cardiac evaluation is recommended. For BMD, cardiac evaluations should begin at approximately age 10 years or at the onset of cardiac signs and symptoms. Evaluations should continue at least every 2 years as long as cardiac function remains normal.

Echocardiography is the mainstay of cardiac functional evaluation. The commonly used parameters of ventricular function include end-diastolic and end-systolic dimensions, shortening and ejection fractions, and sphericity indices. New functional measures are being developed in echocardiography and applied to muscular dystrophy patients. For example, tissue Doppler-echocardiography can show decreased systolic contraction and diastolic relaxation in DMD patients with an otherwise normal-appearing echocardiogram. It is important to note that acoustic windows are often limited in these patients due to problems such as scoliosis and chest wall adiposity. Therefore, additional assessment tools are necessary.

Cardiac magnetic resonance imaging (MRI) is another modality to evaluate cardiac function. Global and regional ventricular function is easily obtainable even in patients with difficult echocardiographic imaging. Unlike echocardiograms, cardiac fibrosis and novel early functional abnormalities can also be determined by MRI. The role of these newer markers of cardiac dysfunction detected by MRI or tissue Dopper echo in regards to treatment and prevention of DCM in this patient population remains to be established.

The approach to the treatment and prevention of cardiomyopathy in muscular dystrophy patients differs between institutions. There is still a need to establish the functional parameters that best indicate the need for starting treatment as well as long-term therapeutic outcomes. Nevertheless, some consensus has emerged around the findings of Jefferies et al. In this study, therapy was started with an angiotensin-converting enzyme inhibitor

(ACE inhibitor) once the left ventricular ejection fraction dropped below 55% or left ventricular dilation developed (>2 standard deviations from the normal value based upon body surface area). A β-blocker, typically carvedilol or metoprolol, was added if cardiac function did not return to normal values after 3 months of ACE-inhibitor therapy. This treatment algorithm resulted in stable findings in 2/29 patients, improvement in 8/29, and normalization in 19/29 (16 DMD, 3 BMD). In overt heart failure, digitalis and diuretics are added to the above therapies. Cardiac transplantation may be an option for some patients with BMD with limited skeletal muscle involvement.

As noted, arrhythmias are another potential complication. Ventricular tachyarrhythmias are often treated initially with β-blockers, followed by sotalol or flecainide if necessary. Additionally, an automatic implantable cardioverter defibrillator or automated external defibrillator may used to prevent sudden arrhythmic death.

Female carriers of the DMD/BMD are at an increased risk for developing a DCM. A consensus conference estimated that approximately 10% of female carriers will develop heart failure in the absence of skeletal muscle involvement and nearly half will develop preclinical disease. In light of this, the American Academy of Pediatrics established cardiac screening guidelines in 2005. These guidelines state that carriers should be educated as to the risk of developing cardiomyopathy and the signs of heart failure, have a complete cardiac evaluation starting in late adolescence/early adulthood, have follow-up complete cardiac evaluation every 5 years, and, if necessary, be treated similarly as male patients with DMD/BMD. Unfortunately, a recent survey demonstrated that about one-third of carriers have never had any cardiac testing.

As noted above, mutations in the *DMD* gene are associated with DMD and BMD. Commercial genetic testing for this gene is available. Virtually all males with DMD and at least 85% of males with BMD have identifiable *DMD* mutations. DMD/BMD are inherited in an X-linked manner. The risk to siblings of a proband depends on the carrier status of the mother. Carrier females have a 50% chance of transmitting the *DMD* mutation in each pregnancy. Sons who inherit the mutation will be affected, whereas daughters who inherit the mutation are carriers. After the disease-causing mutation is identified in a proband, female siblings and the mother should undergo testing for the same mutation to establish their carrier status and need for ongoing cardiac screenings. Prenatal testing for pregnancies at increased risk is also possible.

Cardiac Involvement in Other Forms of Muscular Dystrophy

The limb-girdle muscular dystrophies (LGMDs) are a genetically and phenotypically diverse group of disorders that are classified into at least separate 13 types. Routine cardiac evaluations are recommended for subtypes LGMD1B, 2E, 2F, and 2I. Cardiac complications include ECG abnormalities, conduction defects, atrial and ventricular arrhythmias, and DCM. Subtypes LGMD2A, 2B, 2G, 2H, 2J, 1A, and 1C do not have described cardiac complications and therefore do not require cardiac surveillance.

Emery–Dreifuss muscular dystrophy (EDMD) has a unique set of clinical features including contractures of the elbow, Achilles tendon, and posterior cervical muscles prior to the development of muscle weakness. Arrhythmias are an important problem in this disorder. Patients may have prolonged PR intervals, atrial fibrillation/flutter, bradyarrhythmias, and tachyarrhythmias. Some patients develop ventricular dilation. Pacemaker therapy may be necessary to treat severe or life-threatening rhythm disorders.

Marfan Syndrome

Marfan syndrome (MFS) is an autosomal dominant, systemic connective tissue disorder that affects 1 per 3,000–5,000 individuals. Multiple organ systems are affected including the eye, skeleton, skin and integument, lung, and cardiovascular system. There is a broad range of clinical severity among patients with MFS. Some patients present with a severe and rapidly progressive form starting at birth, while some are not diagnosed until after an affected offspring is found. The diagnosis of MFS is primarily based upon clinical criteria. Most patients have a mutation of the gene *FBN1*, which encodes for the extracellular matrix protein Fibrillin-1.

Typical eye disorders found in MFS include lens dislocation and myopia. Skeletal system abnormalities are characterized by joint laxity and bone overgrowth. Patients with MFS have long arms and legs compared to their trunk. Overgrowth of the ribs leads to pectus excavatum or carinatum. Scoliosis is also common. The typical facial features include a long and narrow face with deep-set eyes, down slanting palpebral fissures, malar hypoplasia, and a small chin. Patients are at risk for a spontaneous pneumothorax, orthodontia, and stretch marks.

As noted, the diagnosis of MFS is based upon a set of clinical criteria commonly referred to as the Ghent

criteria. Changes to the criteria are under preparation, but were not published at the writing of this chapter. Therefore, the reader should consult the medical literature for the updated diagnostic criteria. Genetic testing for the *FBN1* gene is possible (discussed below) and may help make the diagnosis in some situations. It is important to note that many manifestations are age-dependent, which diminishes the utility of the Ghent criteria in children. Therefore, children with some features of MFS or with a family history require repeat evaluations throughout childhood before the diagnosis of MFS is excluded.

Cardiovascular complications are the most serious aspect of MFS. Prior to effective surgical approaches for aortic root disease, over 90% of deaths in MFS were due to cardiovascular disease. Commonly encountered cardiac abnormalities include proximal ascending aortic dilation, aortic dissection, aortic valve regurgitation, main pulmonary artery dilation, prolapse of the atrioventricular valves, and mitral annular calcification. Aortic root dilation and dissection are the leading cause of morbidity and mortality. Rarely, infants and young children will have severe mitral prolapse and regurgitation leading to heart failure and potentially valve replacement.

Severe aortic root dilation can lead to a life-threatening dissection. Aortic root dilation is progressive in MFS and may not be present during the initial exam. The features associated with the greatest risk of dissection include an aortic root diameter greater than 5.0 cm, rapidly increasing aortic size (>0.5 cm/year), and a family history of early aortic dissection. These high-risk features are readily detectable during a through cardiac evaluation; therefore, surveillance screening is important to prevent catastrophic complications. In the authors' institutions, screening exams with an echocardiogram are typically performed yearly. Patients with rapidly increasing aortic dilation or an absolute aortic root measurement >4 cm require follow-up echocardiograms every 6 months.

Medical treatment is initiated once aortic root dilation is detected (Z score >2 for body surface area). The current standard of practice is to use β-adrenergic blocking agents as initial therapy, most commonly atenolol. The first and largest randomized trial on the use of β-blockers in adults with MFS was reported in the 1990s. Thirty-three treated and 38 similar untreated Marfan patients were enrolled. Patients were followed prospectively for 10.7 years in the treatment group. Medications were titrated to achieve a heart rate of <100 beats/min during submaximal exercise. The rate of growth in the proximal aorta was significantly lower in the treated patients. Overall event-free survival was not different between the groups at the end of the study; however, event rates in the treated group were significantly lower during intermediate years of follow-up. In adults, the β-blocker dose is titrated to achieve a resting heart rate of <60 beats/min assuming no bothersome side effects. Based upon expert recommendation, the dose in children is typically adjusted to maintain the heart rate at 110 beats/min during submaximal exercise.

Recently, molecular studies utilizing a mouse model of MFS have shown that upregulation in transforming growth factor-beta (TGF-β) signaling may account for disease manifestations and progression. TGF-β inhibition through either blocking antibodies or losartan prevented aortic dilation in this mouse model. Limited, nonrandomized clinical data has suggested that losartan may slow the rate of aortic dilation in children, but the patient numbers are too small to judge at present. Currently, a randomized clinical trial comparing β-blockers (atenolol) versus losartan for the treatment of aortic dilation in MFS is being conducted by the Pediatric Heart Network and NIH. It is hoped that this study will provide important therapeutic guidance for the medical management of MFS patients.

Exercise limitations are another important component in preventing catastrophic events in MFS patients. Strenuous static exercise, such as heavy weightlifting, is contraindicated due to the marked increase in aortic wall stress. Contact sports should also be avoided in patients with aortic root dilation. In general, patients with no aortic root dilation can participate in low and moderate static exercise and low dynamic activity. Once the aorta becomes dilated, only low dynamic exercises are recommended. For details about specific exercises, the reader is referred to the *36th Bethesda Conference* document for details.

The timing of aortic root surgery is critically important to prevent morbidity and mortality from acute aortic dissection. Elective replacement carries a lower risk than emergency repair of a dissection. As discussed above, the risk of dissection is proportional to the overall diameter of the ascending aorta. The American Heart Association/American College of Cardiology recommend elective surgery for an aortic root diameter >50 mm, while the European Society of Cardiology recommend surgery at a diameter >45 mm. Patients with a family history of dissection at a smaller aortic root diameter (<50 mm) or with a diameter increase greater than 5 mm/year may be considered for early elective surgery provided that the procedure is performed at a center with established expertise. The optimal timing for elective surgery in children is unknown. Fortunately, aortic dissection is rare in children with MFS under 12 years old. Commonly used surgical indications in children include aneurysms that meet adult criteria for intervention, rapid

enlargement (>10 mm/year), and progressive aortic regurgitation. Surgical intervention in all age groups includes replacement of the aortic root and valve with a valved composite graft or replacement of the root only with a valve-sparing aortic root replacement.

Mitral valve prolapse (MVP) with or without mitral regurgitation (MR) is another important cardiac complication of MFS. In the general population, MVP has an estimated prevalence of between 0.6% and 2.4%. The prevalence is increased in MFS to at least 28%. Children with MFS and MVP typically have only a small amount of MR that does not cause heart failure symptoms. However, the MR can slowly progress over time necessitating follow-up evaluations as part of the routine aortic root screening.

When significant MR is present, left ventricular enlargement and failure can ensue. While uncommon, MVP with severe MR is the leading cause of cardiovascular morbidity and mortality in young children with MFS. Indication for mitral valve repair or replacement in patients with severe MR include: clinical symptoms of heart failure; asymptomatic patients with left ventricular enlargement and/or diminished ejection fraction; new onset atrial fibrillation (presumably due to left atrial enlargement); and pulmonary hypertension.

Children often present for evaluation of MFS based upon a family history of the disease. Therefore, it is important to understand the genetics of this disease. MFS is inherited as an autosomal dominant condition. It is estimated that about 75% of patients have an affected parent and the remaining cases arise from a de novo mutation. *FBN1* is the only known causative gene. Genetic testing is commercially available for *FBN1*. Mutation detection frequency is between 70% and 93%. The diagnosis of MFS remains primarily clinical. However, a positive genetic test can confer the diagnosis in a patient with one major organ system involvement and minor involvement of a second. Genetic testing is also useful for screening presymptomatic individuals (like those sent for evaluation based only upon a positive family history) when the pathological mutation within a family is known. If the patient has the same mutation as the affected relative, then continued cardiovascular monitoring is necessary. However, if they do not have the mutation, then follow-up evaluations are probably not necessary. Prenatal and preimplantation genetic testing is available.

Loeys–Dietz Syndrome

Loeys–Dietz syndrome (LDS) is a recently described connective tissue disease associated with arterial aneurysms and dissections as well as skeletal manifestations. Importantly, aortic dissection can occur at diameters smaller that those observed in MFS.

TGFBR1 and *TGFBR2* are the only genes currently known to be involved in this disorder. These genes code for the transforming growth factor beta-receptors 1 and 2. Unlike MFS, arterial aneurysms and tortuosity are often present at sites distant from the aortic root. Other common manifestations include a bifid uvula or cleft palate, ocular hypertelorism, craniosynostosis, translucent skin, pectus excavatum or carinatum, scoliosis, joint laxity, and arachnodactyly. Females are at risk for uterine rupture during pregnancy.

Specific diagnostic criteria for LDS have not been established. Typically, the diagnosis is rendered when a patient has findings from some of the commonly affected organ systems in addition to identification of a disease-causing mutation on genetic testing. The four main groups of clinical findings are vascular, skeletal, craniofacial, and cutaneous. Vascular findings include aortic root dilation or dissection and distal arterial aneurysms and tortuosity. Skeletal manifestations include pectus excavatum or carinatum, scoliosis, joint laxity, arachnodactyly, and talipes equinovarus. Craniofacial findings include ocular hypertelorism, bifid uvular/cleft palate, and craniosynostosis. Finally, cutaneous features include translucent skin, easy bruising, and dystrophic scars. It has been our practice to perform genetic testing on patients with aortic root dilation who have any features from the other main groups of clinical findings. Some patients with aortic dilation and dissection have mutations in the *TGFBR1/2* genes without other features of LDS. Therefore, consideration should be given for genetic testing in families with multiple members with only aortic or other arterial dilation. Finally, it has also been our practice to consider genetic testing for the *TGFBR1/2* in patient that have had aortic dissections at diameters less than 5 cm, unless another causative condition is identified.

LDS is often divided into two subtypes. Patients with LDS type I (around 75% of LDS patients) do not typically have cutaneous abnormalities. LDS type II constitutes the remaining patients and does not typically have craniofacial findings with the exception of isolated bifid uvula. There is considerable overlap between the subtypes.

The most important complication in LDS is aortic root dilation and dissection. As noted above, dissection can occur at aortic dimensions that are not considered high risk in MFS. Additionally, aortic dissections have been reported in infancy and early childhood. Around half of LDS patients have dilation or tortuosity in the arterial tree away from the aortic root. Notably, these distal

lesions are not detected by echocardiogram. These features differentiate the vascular disease in LDS from MFS. Additional cardiac malformations include patent ductus arteriosus, atrial septal defects, and bicuspid aortic valve.

Most practitioners employ an aggressive screening regiment to monitor aortic and distal aneurysmal growth. Echocardiographic evaluation of the aortic root is recommended every 6 months. Due to the potential for distal aneurysms, imaging of the vascular tree from the head to the pelvis with either an MR or CT angiogram should be performed at diagnosis and at least yearly thereafter.

No therapeutic trials have been published on the prevention of aneurysmal dilation in LDS patients. Medical management is based upon the recommendations for MFS. Most patients are managed with either β-adrenergic blocking agents or losartan. Exercise recommendations are similar to MFS.

Elective aortic root replacement has been utilized in LDS to prevent catastrophic aortic dissection and rupture. Williams and colleagues published their surgical experience with this disorder in 2007 and offered elective surgical guidelines. The reader should consult this manuscript for complete details. Briefly, elective aortic root replacement is recommended when the maximal diameter reaches 4.0 cm in adults or adolescents. In children, elective root replacement is recommended when the aortic root Z-score exceeds 3.0 or the diameter is expanding by greater than 0.5 cm/year. The authors made an effort to delay surgery in children until the aortic annulus exceeded 1.8 cm in order to allow for the placement of graft that would accommodate patient growth. An extensive family history of dissection at a smaller diameter versus no dissection at a larger diameter may allow the clinician to modify these recommendations for select patients. No early surgical deaths were reported in this series. However, some patients died of a dissection prior to undergoing surgery. About one-third of surgical patients required an additional operation during the study period illustrating the importance of lifelong surveillance of the vascular tree.

A recent paper suggested that the risk for dissection may differ between *TGFBR1* and *TGFBR2* mutations. In this study, 30 patients with *TGFBR1* mutations were compared to 77 with *TGFBR2* mutations. The data suggested that patients with *TGFBR2* mutations are more likely to dissect at aortic diameters less that 5.0 cm than those with *TGFBR1* mutations. In fact, no patients with a *TGFBR1* mutation had a dissection at an aortic diameter less than 5 cm in this series. Future elective aortic root replacement recommendation may take this finding into account. However, more studies are necessary to validate this result.

Like MFS, many children present for evaluation based upon a positive family history. LDS is an autosomal dominant condition and offspring have a 50% chance of inheriting this condition from an affected parent. *TGFBR1* and *TGFBR2* are the only known causative genes. Commercial genetic testing is available in North America. It is currently estimated that about 95% of patients with typical findings of LDS have a positive genetic test. *TGFBR2* accounts for about 75% of the causative mutations. Approximately, 75% of probands have LDS as the result of a de novo mutation. However, family members should have screening evaluations with experts in LDS to determine whether they are at risk for the diagnosis.

Turner Syndrome

Turner syndrome (TS) is caused by loss of all or part of one X chromosome in females (45 X or 45X/46XX). The birth incidence is estimated at 1 per 2,000 live births; however many fetuses with this condition are lost during pregnancy. The main features of TS include short stature, early ovarian failure, and congenital heart defects. Lymphatic abnormalities are common in the neonate and lead to neck webbing, protruding ears, loose nuchal skin, low hairline, puffy hands and feet, and deep-set nails. Renal anomalies are often present and all patients should have a screening renal ultrasound. Many patients receive growth hormone therapy to treat the short stature associated with this syndrome. The diagnosis of TS is typically based upon the presence of the above clinical findings with confirmatory karyotype analysis. Because mosaicism is common, an adequate karyotype should include at least 30 cells.

Both congenital and later-onset cardiac defects are found in TS. Left-sided obstructive lesions are the major associated congenital lesions. Bicuspid aortic valve with or without stenosis is present in approximately 15–25% of TS patients. Coarctation of the aorta (∼10%) may cause early hemodynamic impairment potentially necessitating surgery or interventional catheterization. Interestingly, neck webbing is associated with bicuspid aortic valve and coarctation of the aorta in this condition. Mitral valve abnormalities (∼5%) and hypoplastic left heart syndrome (rare) are additional left-sided lesion described in this syndrome. Other congenital heart lesions found in TS include atrial and ventricular septal defects and partial anomalous pulmonary venous connection. Due to the clinically subtle nature of some of these lesions (such as bicuspid aortic valve), a screening echocardiogram should

be performed after the diagnosis of TS is made. Treatment of specific congenital cardiac lesions in TS does not differ from non-syndromic patients.

Aortic dilation, dissection, and rupture are a well-described phenomenon in TS with aortic dilation present in around 30%. Unlike MFS, the most significant dilation usually occurs in the ascending aorta (as opposed to the aortic root in MFS). Most cases of aortic dissection in TS are associated with bicuspid aortic valve, repaired aortic coarctation, or hypertension. However, TS alone is a risk factor for aortic dilation and dissection. TS patients experience aortic dissection at rates greater than the general population and at younger ages (as early as age 25 years). Dissection usually occurs at aortic diameters less than 5.0 cm. The assessment of aortic dilation must take into account the short stature that is a part of TS. One method is to use the aortic size index (ASI). This measurement consists of the ascending aortic diameter (measured either by echocardiogram, MR, or CT angiogram) divided by the body surface area. In a prospective study on aortic dissection in TS, three episodes of dissection occurred in a total of 158 patients monitored for 3 years. The dissections occurred in patients who were in their 40s and had aortic diameters between 3.8 and 4.8 cm. These patients would not have met criteria for elective aortic replacement according to the standards established in MFS. However, all had ASI ratios greater than 2.5 cm/m^2. This represented 33% of all patients with ASI greater than 2.5 cm/m^2 in the study. The authors concluded that evaluation for aortic replacement should occur when the ASI reaches 2.5 cm/m^2. They also recommended aortic measurements every 6–12 months once the ASI reaches 2.0 cm/m^2. It is unknown whether β-blockers or losartan can effectively diminish the rate of aortic dilation in this condition, however they are still commonly used.

Current screening guidelines recommend aortic imaging at least every 5 years and at the onset of hypertension. The majority of women with TS are infertile. However, some may become pregnant with donated oocytes and assisted reproductive technology. Pregnancy is associated with a high risk for dissection; therefore, aortic imaging should be performed prior to and throughout pregnancy.

247 Murmur Evaluation

Jeffrey A. Conwell

Finding a cardiac murmur during a physical examination can be a source of frustration and anxiety for a pediatric provider. Perhaps even more challenging than correctly identifying the source of a new murmur is explaining the finding to the parents of the patient. A systematic approach to evaluating cardiac murmurs allows the development of tools to help identify pathologic and nonpathologic murmurs and provides a framework for discussing findings with parents to provide reassurance or the need for further evaluation.

Definition

A cardiac murmur is audible turbulent sound waves in the range from 20 to 20,000 Hz that originate from the heart and vascular system. Most murmurs are just the normal sound of blood flowing through the heart and blood vessels, but murmurs may also occur due to structural heart disease such as a ventricular septal defect. Murmurs in a structurally normal heart are often termed as flow, functional, innocent, or benign. Murmurs occurring from a structural heart defect are termed "pathologic" or "organic" and are usually described by the structural defect that they arise from.

Epidemiology

Cardiac murmurs are a common finding during a pediatric cardiac examination with up to 70–80% of children having a murmur at some point in time. The incidence of structural heart disease is less than 1%, so the vast majority of murmurs are normal or innocent murmurs. With such a high incidence of normal murmurs, a pediatric provider is certainly guaranteed to hear a cardiac murmur on a frequent basis.

Evaluation

Once a murmur is heard, a systematic approach is required to adequately evaluate the murmur. The approach should allow the pediatric provider to develop a good differential diagnosis, evaluation, and treatment plan. As in all patient encounters, evaluation should begin with a history and physical examination.

History

A careful history may provide clues that distinguish a murmur related to a structural defect from an innocent murmur. The history should include questions regarding pregnancy and delivery, family history, past medical history, growth and development, as well as cardiovascular symptoms (*Table 247.1*).

The age of a patient when a murmur was first noted may be helpful in developing a differential diagnosis. Murmurs heard immediately after birth and that persist are more likely to be pathologic in nature than those heard first at a few years of age. Murmurs associated with semilunar (aortic or pulmonary valve) valve stenosis are often noted in the immediate newborn period. A ventricular septal defect murmur may be heard in the first few days or weeks of life, but usually not shortly after delivery. A benign vibratory or Still's murmur is frequently first heard at a few years of age.

The general health of the child with suspected structural cardiac disease is important. Growth of the patient should be assessed as the rate of growth may be impacted in patients with pulmonary overcirculation (congestive heart failure) from large left to right shunts. Feeding difficulties are often the first evidence of pulmonary overcirculation and include disinterest in feeding, excessive fatigue, diaphoresis, a change in pattern of respiration, tachypnea, or dyspnea. These findings are exacerbated during feeds, as this is when the baby is "exercising." Babies with pulmonary overcirculation may take frequent breaks while feeding to "catch their breath" as well as become more tachypneic and diaphoretic during feeds. Most infants take a feed within 10–15 min with rare breaks. Babies with congestive heart failure may take 20 min or longer to finish a feed. Inquire about the feeding pattern, including volume, frequency, and duration to complete a feed. Quantifying the total caloric intake is

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_247,

Table 247.1
Pediatric cardiac history

Prenatal history	Infection

often helpful so also check the calorie content of formula for infants. Occasionally, early developmental milestones can be delayed, especially gross motor milestones.

Inquire about complications during pregnancy and delivery including questions about maternal medications, maternal infections, diabetes, fetal growth, and results of fetal ultrasounds. Maternal medications such as epilepsy medications, warfarin, and lithium increase the risk of fetal structural cardiac disease (*Table 247.2*).

Table 247.2
Maternal medications associated with cardiac defects

Alcohol	ASD, VSD
Lithium	Ebsteins
Retinoic acid	Conotruncal malformations
Valproic acid	ASD, VSD, AS, PA/IVS, CoA
Warfarin	ASD, PDA

ASD atrial septal defect, *VSD* ventricular septal defect, *AS* aortic stenosis, *PA/IVS* pulmonary atresia with intact ventricular septum, *CoA* coarctation of the aorta, *PDA* patent ductus arteriosus

Maternal diabetes, especially if poorly controlled, increases the risk of a ventricular septal defect. Abnormal findings on fetal ultrasound or fetal echocardiogram may require follow-up after delivery. Rubella infection early in pregnancy increases the risk of structural cardiac defects. Poor fetal growth may indicate a syndrome or other problem increasing the risk of a heart defect.

Details about the delivery and surrounding events are also important. A delivery that was difficult with signs of fetal or neonatal distress may result in a murmur heard shortly after birth from tricuspid valve regurgitation. Gestational age is relevant as premature infants are more likely to have a patent ductus arteriosus and a murmur from physiologic peripheral pulmonary stenosis. Birth weight allows assessment of both prenatal and postnatal growth. Low birth weight is suggestive of in utero growth problems, syndromes, or in utero infection. Large for gestational age infants are often seen in pregnancies where the mother has diabetes (see *Table 247.3*).

Past medical history should assess for any chronic medical problems. History of structural defects in another organ system may increase the risk of congenital heart disease. Patients with left to right shunt lesions (atrial septal defects, ventricular septal defects) may have a history of recurrent respiratory infections or pneumonia. In older patients, a history of recurrent throat infections may suggest rheumatic heart disease as the etiology for the murmur.

Family history of congenital heart disease, particularly in first degree relatives (mom, dad, or siblings) significantly increases the risk of having congenital heart disease. Overall, the incidence of congenital heart disease is 0.8%. If there is a first degree relative with congenital heart disease, then the risk increases to around 2–3%. However certain types of defects pose a substantially higher risk.

Table 247.3
Syndromes and cardiac defects

Syndrome	Cardiac defect
Down	AVSD, VSD, PDA, TOF
Turner	Coarctation of the aorta, AS
Williams	Supravalve AS, pulmonary artery stenosis
Noonan	PS, HCM
Marfan	MVP, MR, AI, dilated aortic root
DiGeorge	Aortic arch anomalies, TOF, truncus arteriosus
Infant of diabetic mother	HCM, VSD
VACTERL	VSD, ASD, PDA, TOF
Trisomy 18	VSD, PDA, DORV
Trisomy 13	VSD, ASD, PDA

ASD atrial septal defect, *VSD* ventricular septal defect, *PDA* patent ductus arteriosus, *TOF* tetralogy of Fallot, *AS* aortic stenosis, *PS* pulmonary stenosis, *HCM* hypertrophic cardiomyopathy, *MVP* mitral valve prolapse, *MR* mitral regurgitation, *AI* aortic insufficiency, *DORV* double outlet right ventricle

For example, the recurrence risk may be as high as 15–20% if the mother has a history of aortic stenosis. Some genetic syndromes have associated cardiac disease. For example, Marfan syndrome is autosomal dominant in transmission, so if there is an affected parent, half of the children may be affected. A family history of rheumatic fever places the child at increase risk of having rheumatic fever themselves.

Family history should also include questions regarding early or sudden death and history of cardiomyopathy. The latter may be asked best as "anyone in the family with thick hearts or enlarged hearts?" A family history of cardiomyopathy, particularly in a first degree relative warrants referral to a pediatric cardiologist for evaluation.

Symptoms

Assessment of patients found to have a cardiac murmur includes looking for any symptoms that may be related to structural heart disease. Although, the presence of cardiac symptoms with a murmur does not always indicate there is structural heart disease and many patients with structural heart disease are asymptomatic. If a right to left shunt is present, then cyanosis may be noted. Changes in exercise tolerance, chest pain, or syncope in older patients with murmurs may warrant referral to pediatric cardiology for evaluation.

Young children with large left to right shunts may have tachypnea, dyspnea, and puffy eyelids as signs of pulmonary overcirculation or congestive heart failure. The tachypnea is typically worse with feeds and may be associated with diaphoresis. Edema in young children may be noted on the back or as facial puffiness while older children will have lower extremity or dependent edema.

One of the more concerning symptoms that should raise the suspicion of cardiac disease is central cyanosis. Central cyanosis or cyanosis of the mucous membranes or trunk may indicate the presence of a right to left cardiac shunt. This is not the acrocyanosis commonly seen in the normal newborn or the older infant who is cold stressed with the discoloration limited to the extremities. Some fair-complexioned children may have perioral cyanosis when cold which is a benign condition similar to newborn acrocyanosis and is not clinically significant. If there is a history of cyanosis, then asking about details surrounding the event and duration of cyanosis may be helpful in determining an etiology. Any patient with a history of cyanosis should have an oxygen saturation checked during the evaluation.

A decrease or change in exercise tolerance may result from structural heart disease of almost any type. One way to assess exercise tolerance in children is to ask if the child keeps up with their peers when playing. Onset of symptoms, severity, and progression of limitations should be determined. Just because a patient has a change in exercise tolerance does not necessarily mean there is a cardiac reason for the change.

When evaluating older children and adolescents, inquire about chest pain, particularly with exercise, as well as episodes of dizziness, lightheadedness, and syncope. Syncope is especially concerning if it occurs with exercise and without warning. Any of these symptoms coupled with a cardiac murmur is more likely to warrant evaluation by a cardiologist.

Physical Examination

Vital Signs

The physical examination should start with a complete set of vital signs including height, weight, blood pressure, respiratory rate, heart rate, and for neonates, oxygen saturation. Vital signs are preferably obtained in a resting state, since resting vital signs are more reproducible and comparable. If vital signs are obtained in the crying child, then a notation should be made in the chart.

Height and weight should be performed and plotted on an appropriate growth curve to compare to normal values for age and sex. Plot the measurements with any known historical measurements such as birth weight to determine if a patient has been growing well or has fallen on the growth curve.

Blood pressure should be obtained in the right upper extremity and a lower extremity, at a minimum, when evaluating patients for a suspected pathologic cardiac murmur. The right arm is preferred, as the left arm may be involved in a coarctation of the aorta and give a falsely low reading. The blood pressure cuff should be of an appropriate size for the extremity with the width of bladder 40–50% of the circumference (or 125–155% of the diameter) of the limb and bladder length of 80–100% of circumference. The correct size cuff is important. If the blood pressure cuff is too small, the blood pressure obtained will be artificially high so it is better to err with a cuff that is too large than too small.

Auscultation is the preferred method for blood pressure measurement, however, most clinics utilize oscillometric devices to measure blood pressure as these devices are convenient to use and decrease interobserver variability. The blood pressures obtained by an oscillometric device tend to be higher than those obtained manually.

Blood pressure in the upper extremity is best obtained in a patient who has been sitting for 3–5 min, the back supported, feet on the floor, and the arm supported at heart level (level of the right atrium). The average of two to three blood pressure measurements should be used. Following these guidelines will increase the likelihood of having a true resting blood pressure.

For the lower extremity blood pressure, the patient should be supine and an appropriate-sized cuff applied to either the calf or thigh (same rules for cuff size as for the arm). In children, the lower extremity systolic blood pressure should be equal to or slightly higher than the upper extremity blood pressure, often exceeding the upper extremity blood pressure by 5–10 mmHg. If the systolic blood pressure in the lower extremity is lower than the upper extremity by more than 10 mmHg, then a coarctation of the aorta may be present.

The pulse pressure, or the difference between the systolic and diastolic blood pressure may be altered in some types of congenital heart disease. A widened pulse pressure is seen in aortic insufficiency, patent ductus arteriosus, and arteriovenous malformations and results in bounding pulses. Decreased pulse pressure occurs in poor cardiac function.

The heart rate and respiratory rate should be taken for a full minute rather than 15 s and multiplying by 4, as there can be significant variation, particularly in younger children. Tachycardia may be seen in patients with large shunt lesions or decreased cardiac function. Tachypnea can occur secondary to increased pulmonary blood flow in left to right shunt lesions such as a ventricular septal defect or a patent ductus arteriosus. Increasing pulmonary congestion can cause the development of grunting, nasal flaring, and intercostal and subcostal retractions, although most tachypnea associated with pulmonary overcirculation is "quiet tachypnea."

Oxygen saturation should be obtained as part of the evaluation of a murmur in infants in the first couple months of life and in all patients presenting with tachypnea or complaints of cyanosis. Low oxygen saturations in infants with a heart murmur suggests the possibility of cyanotic heart disease.

Cardiac Examination

The cardiac physical examination should be performed in a systematic manner to assure complete evaluation of the patient. The physical examination typically begins with inspection.

Inspection

Much information can be obtained by simple inspection of a patient, a "quick look" when seeing the patient initially. General appearance should be assessed including whether the patient looks well or sick. Is the patient fussy or playful? Look for any obvious findings consistent with chromosomal abnormality or possibility of a syndrome. Assess the respirations looking for tachypnea or increased work of breathing. An idea of the child's general nutritional status can also be obtained during this initial look.

Cyanosis can be evaluated by looking at the mucous membranes and, in older patients, the nail beds. Cyanosis is associated with desaturation of 5 g of hemoglobin and is difficult to detect unless the oxygen saturation is less than 85%. If there is long-standing cyanosis, then digital clubbing may be present. Clubbing is uncommon in early infancy.

Inspect the chest, assessing for any asymmetry. Patients with long-standing cardiomegaly may develop a precordial bulge on the left side of the chest. In Marfan syndrome, patients may have pectus excavatum or

carinatum. Scoliosis may alter the position of landmarks such as the cardiac apex. Chest wall abnormalities may alter findings on electrocardiogram and chest x-ray.

A visible cardiac impulse may also be seen during chest inspection and implies hyperdynamic ventricular function.

Palpation

Palpation of the chest should be performed with the most sensitive part of the hand. For some, this is the metacarpals and for others the fingertips. The point of maximal impulse should be noted, usually it is found in the midclavicular line in the fourth intercostal space in children up to 4 years of age and the fifth intercostal space in older children. The impulse may be displaced medially when there is right ventricular dominance or laterally displaced in patients with left ventricular volume overload (left to right shunts, aortic insufficiency, and mitral valve regurgitation).

Palpation also allows assessment for increased precordial activity such as a ventricular tap or heave. A tap is a more focal increased impulse typically related to hypertrophy of a ventricle whereas a heave is a diffuse impulse that occurs when there is volume overload of a ventricle.

A thrill may be felt in association with a murmur and is a palpable vibratory sensation. Thrills can be found anywhere in the precordium, suprasternal notch, supraclavicular area, and over the carotid arteries. The location of the thrill usually correlates with the structural cardiac lesion causing a cardiac murmur. A thrill from a ventricular septal defect will be at the left lower sternal border, pulmonary stenosis at the left upper sternal border, and aortic stenosis at the right upper sternal border.

A palpable second heart sound may be noted in pulmonary hypertension or from anterior positioning of the aorta, such as in transposition of the great arteries. The first heart sound may be palpable in hyperdynamic states from any cause, including exercise and fever. Heart sounds may be felt during palpation in infants or patients with thin chest walls and does not necessarily indicate cardiac pathology.

Pulses should be assessed in both the upper and lower extremities. Take care to note if pulses are easily palpable, and if regular in rate; also note the quality of the pulse. A coarctation of the aorta should be suspected when the lower extremity pulses are not equal in quality to that of the right upper extremity. Bounding pulses (easily palpable) reflect runoff lesions such as aortic insufficiency or a patent ductus arteriosus, but can also be seen in patients with sepsis. Diminished pulses in all extremities is suggestive of ventricular dysfunction.

Abdominal palpation should assess the size of the liver. In young children the liver may be at the costal margin or just below. If the liver is enlarged, this may be a finding suggesting congestive heart failure (*Table 247.4*).

Table 247.4
Selected aspects of the cardiac physical exam

Inspection		General appearance and nutritional state
		Color
		Clubbing
		Respiratory rate, dyspnea, retraction
		Chest wall abnormalities
		Chromosomal syndromes
		Hereditary and nonhereditary syndromes
		Other systemic malformations
		Diaphoresis on forehead
Palpation	Pulses	Increased, decreased, bounding
		Rate, rhythm, amplitude, symmetry
	Chest	Apical impulse
		Point of maximal impulse
		Precordial activity
		Thrills
	Abdomen	Hepatomegaly
Auscultation	Lungs	Rales
		Rhonchi
		Wheezes
		Stridor
	Cardiac	Murmurs
		Gallops
		Clicks
		Rubs

Auscultation

Auscultation of the heart is a skill learned over weeks to months with the help of an experienced instructor and seeing a sizable number of patients. There is no substitute for practice. Once the skill of assessing cardiac murmurs

and sounds is mastered, ongoing practice is required to maintain those skills at a high level. Auscultation of the heart should be performed sitting, supine, and standing if possible. Sometimes, specific maneuvers may be required to bring out a cardiac murmur.

Proper equipment and the correct setting to perform auscultation are essential. A good stethoscope has both a bell for low frequencies and a diaphragm for high frequencies. The tubing should be long enough (12–18 in.) to be able to perform auscultation comfortably but not too long to diminish sounds. The most important part of the stethoscope, and often neglected, is good fitting and comfortable ear pieces. The ear pieces need to be comfortable and completely occlude the external auditory canal. Which stethoscope works best is an individual perspective, but it is always best to use your own stethoscope.

To maximize the chances for successful auscultation the exam room should be quiet and free from distractions. Both the patient and the examiner should be comfortable. It is hard to concentrate on the exam if performing bodily contortions. The patient should be unclothed, or at least the stethoscope should be placed on the skin. Modesty may require the patient to be in an exam gown. Younger children may be a challenge to examine as they may become fussy or cry during the exam. With small children try simple maneuvers to calm or ease the patient. Consider having an assistant aid in distracting the patient to allow the examiner to focus on the exam. Sometimes, starting with auscultation may be best if the patient appears apprehensive or uncooperative.

Auscultation should occur at least in the four main areas familiar to most providers, pulmonary, aortic, mitral, and tricuspid areas, but should not be limited to just these areas. Additional areas to examine are both infraclavicular areas, both carotids, the axillae in the fourth or fifth intercostal space, and the posterior chest inferior and medial to the scapula. Each area should be examined with the patient sitting, standing, and lying down.

It is important to develop a systematic approach to auscultation to be thorough and note all findings in a patient. One approach to make the exam more manageable is to break down the cardiac cycle listening to only one part at a time. Focus on S1 first, then on S2. Listen to systole and then to diastole for additional sounds or murmurs. Listening to each part of the cardiac cycle should be performed in each area and with the patient supine, sitting, and standing. In infants, it is easy to become distracted by breath sounds. Listen to the breath sounds first, and then see if there are any other sounds present. A complete auscultatory examination may take up to 5–10 min to complete properly.

Cardiac Sounds

The first heart sound (S1) is caused by the closure of the mitral and tricuspid valves (atrioventricular valves). The first heart sound is low-pitched and relatively long compared to the second heart sound. Under most circumstances, the tricuspid component is inaudible because of the low pressure of the right ventricle and closure of the tricuspid valve occurring almost simultaneously with the mitral component. Thus, normally S1 is a single crisp sound. S1 is best heard at the apex and precedes systole and the carotid pulsation. To assist with determining which heart sound is S1, the carotid pulsation can be palpated and S1 is always the heart sound that precedes the carotid pulsation.

Normal splitting of S1 may be noted in some pediatric patients in the tricuspid area. A normal split of S1 needs to be differentiated from an ejection click or an S4 gallop. In normal splitting of S1, the splitting is less noticeable as one moves laterally and should not persist at the anterior axillary line. If still present at the anterior axillary line, then one should suspect presence of an ejection click. Ejection clicks are often at a fixed interval to S1, while a split S1 should vary with the respiratory cycle, increasing with inspiration. Usually, heart sounds are lower pitched than ejection clicks. Fixed splitting of S1 may occur in patients with interventricular conduction delays, bundle branch block, and ventricular rhythms where one ventricle contracts earlier.

A loud S1 can be associated with high cardiac output states such as anemia, thyrotoxicosis, arteriovenous fistula, fever, exercise, anxiety, and epinephrine administration. S1 may be decreased in intensity in low cardiac output states such as hypothyroidism, cardiomyopathy, myocarditis, and shock or when there is increased chest wall thickness or pericardial fluid present.

The second heart sound (S2) is produced by closure of the semilunar valves (aortic and pulmonary). The aortic valve closure (A2) occurs earlier and is louder than the closure of the pulmonary valve (P2). Normally, there is variation in the splitting of S2 related to the respiratory cycle. During inspiration the right ventricle fills more. As a result, the second component of S2 (P2) comes later, splitting S2. In exhalation, the right ventricle fills less resulting in P2 coming earlier with A2 and P2 occurring nearly simultaneously resulting in S2 usually becoming a single sound. This normal or physiologic splitting of S2 (splitting during inspiration and single during expiration) is best appreciated at the high left sternal border in the second to fourth intercostal spaces.

There are some variations in S2 worth noting. A wide and fixed split S2 is noted in patients with an atrial septal defect. This occurs from increased volume flowing through the right heart and a decreased variation in right ventricular volume with respiration. Additionally, the right ventricle is dilated resulting in further distance for electrical activity to travel and excite the right ventricle, resulting in delay of right ventricular emptying. As a result of these physiologic changes, the pulmonary component of S2 continues to occur later than the aortic component resulting in a "fixed split S2."

Similarly, any physiologic change that delays right ventricular emptying may result in a widely split S2. This includes right ventricular outflow tract obstruction (pulmonary valve stenosis or subvalve stenosis), severe mitral valve regurgitation (shortened left ventricular ejection time), dilation of the main pulmonary artery (diminished recoil forces on the pulmonary valve, delaying closure), right bundle branch block, and premature ventricular contractions originating from the left ventricle.

A loud S2 occurs with increased diastolic blood pressure and decreased viscosity of the blood (anemia). It may result from a loud A2 or P2. A loud P2 may be heard in patients with pulmonary hypertension. A loud A2 can be heard in systemic hypertension, coarctation of the aorta, transposition of the great arteries, and aortic insufficiency.

Patients with a single semilunar valve (aortic atresia, pulmonary atresia, truncus arteriosus) will have a single S2. Patients with transposition of the great arteries, tetralogy of Fallot, or other cardiac defects that move the aorta anteriorly can result in a loud single S2. Due to the fast heart rate in newborns, it is often difficult to appreciate if there is a single S2.

Paradoxical splitting of S2 can also occur with A2 heard after P2. This is sometimes noted in left bundle branch block, paced beats, Wolff–Parkinson–White syndrome, aortic stenosis, left ventricular outflow tract obstruction, and a patent ductus arteriosus. The reason for paradoxic splitting in these conditions is the delay in emptying of the left ventricle by either electrical or anatomic changes.

Systolic ejection clicks are medium- to high-pitched sounds which closely follow S1. They are associated with abnormalities of the semilunar valves or sometimes with dilation of the aorta or pulmonary artery. Clicks are high-pitched sounds, best appreciated with the diaphragm of the stethoscope.

Aortic clicks are generally unchanged by the respiratory cycle and are called constant early systolic ejection clicks. Aortic clicks can be heard at the second right intercostal space but are often heard best at the apex. The differential diagnosis for a patient with an aortic click includes a dilated aorta, aortic stenosis, and bicuspid aortic valve.

Pulmonary ejection clicks may fade out or disappear with inspiration and are called variable early systolic ejection clicks. Pulmonary clicks tend to be heard best at the left upper sternal border (second intercostal space) during expiration. The differential diagnosis for a patient with a pulmonary ejection click includes pulmonary valve stenosis or a dilated pulmonary artery.

A mid-systolic click is a high-pitched sound occurring in mid-systole usually associated with mitral valve abnormalities such as mitral valve prolapse. If there is associated mitral valve regurgitation with the mitral valve prolapse, then a regurgitant murmur can be heard after the mid-systolic click. The click should come later in systole with squatting and heard better with the patient standing or with held expiration (*Table 247.5*).

Gallops may also be heard during the cardiac cycle. An S3 gallop occurs at the end of rapid early diastolic filling, secondary to limitation of longitudinal expansion of the ventricular wall. This is a low-frequency sound with a dull or thudding quality that increases with inspiration, and is heard best at the apex or just medial to the apex of the heart with the patient lying supine or on their left side. An S3 gallop can be a normal finding in children, but a loud S3 suggests pathology. Increased intensity of S3 occurs in excitement, anemia, or a large left to right shunt.

S4 gallops occur late in diastole and are associated with atrial contraction. An S4 gallop can be a normal finding in a well-trained athlete or elderly patients. It is usually heard best with the patient recumbent, at the apex, and during expiration utilizing the bell of the stethoscope. Differential diagnosis for a patient with an S4 gallop includes pulmonary hypertension, pulmonary stenosis, Ebsteins anomaly

Table 247.5
Clicks

Click	Etiology	Location	Maneuvers
Aortic	Dilated Ao, AS, bicuspid AoV	Apex	No respiratory variation
Pulmonic	Dilated PA, PS	LUSB	Louder in expiration (variable)
Mid-systolic	Mitral valve prolapse	Apex	Increased with standing

Ao aorta, *AS* aortic valve stenosis, *AoV* aortic valve, *PA* pulmonary artery, *PS* pulmonary valve stenosis, *LUSB* left upper sternal border

of the tricuspid valve, tricuspid valve atresia, total anomalous pulmonary venous return, and complete heart block.

A summation gallop (combination of S3 and S4) is often more intense than either component. It is the most common gallop noted in pediatric patients and is commonly associated with heart failure from large left to right shunts. A summation gallop is pathognomonic for Ebsteins anomaly of the tricuspid valve.

Other Sounds

Patients with pericarditis may have a pericardial friction rub that originates when inflamed visceral and parietal pericardium come into contact. A rub has been described as having a sandpaper-like grating quality. Friction rubs can be intermittent, heard in diastole, systole, or continuously. They are usually best heard along the left sternal border and at the apex with the patient leaning forward. Pericardial friction rubs are best noted with the diaphragm and may be accentuated with inspiration.

Pericardial knocks are associated with restrictive physiology such as restrictive pericarditis. Knocks are a high-pitched sound that occurs prior to an S3 gallop and is best appreciated with the diaphragm. They can be increased in intensity by increasing venous return.

An opening snap is the term associated with the opening of the mitral valve in mitral stenosis from rheumatic heart disease. This sound occurs after the second heart sound and is best appreciated in the mid-precordium in the fourth left intercostal space. An opening snap may also occur with tricuspid valve stenosis. Opening snaps are uncommon in childhood (*Table 247.6*).

Murmur

A complete description of a murmur includes a number of features: location, timing, loudness, type, pitch, quality, and transmission. Given a complete description, most cardiac murmurs can lead to a specific diagnosis, even without an echocardiogram.

Location

Most practitioners are familiar with the usual areas of auscultation to include the pulmonary, aortic, mitral, and tricuspid areas. The pulmonary area is at the left upper sternal border or left second intercostal space at the sternal edge. The aortic area is at the right upper

Table 247.6
Heart sounds

Loud S1	Short PR interval
	Mitral stenosis
	Hyperkinetic states (anemia, thyrotoxicosis, arteriovenous malformations, fever, exercise, anxiety, epinephrine administration)
Changing intensity S1	Atrioventricular dissociation (complete AV block)
	Atrial fibrillation
Soft S1	Long PR interval
	Decreased contractility of left ventricle
	Severe aortic regurgitation
	Mitral regurgitation
	Thick chest wall
	Pericardial effusion
Fixed split S2	Atrial septal defect
Paradoxically split S2	Severe aortic stenosis
	Hypertrophic cardiomyopathy
	Left bundle branch block
	Severe left ventricular systolic dysfunction
	Wollf–Parkinson–White syndrome
	Patent ductus arteriosus
Wide physiologic split S2	Mitral regurgitation
	Large ventricular septal defect
	Pulmonary stenosis
	Right bundle branch block
	Ebsteins anomaly
Single S2	Pulmonary hypertension
	Single semilunar valve (pulmonary atresia, aortic atresia, truncus arteriosus)
	P2 not audible (transposition of the great arteries, tetralogy of Fallot)
	Severe aortic stenosis
Loud A2	Severe hypertension
	Aortic dilation
	Coarctation of the aorta
	Transposition of great arteries
	Aortic regurgitation
Soft A2	Valvar aortic stenosis
Loud P2	Pulmonary hypertension
Soft P2	Pulmonary stenosis
	Tetralogy of Fallot
	Tricuspid stenosis

Table 247.6 (Continued)

S3	Left ventricular or right ventricular systolic dysfunction
	Mitral regurgitation
	Aortic regurgitation
S4	Left ventricular or right ventricular diastolic dysfunction
Opening snap	Mitral stenosis
Clicks	Aortic – bicuspid aortic valve, dilated aortic root
	Pulmonic – pulmonary valve stenosis, dilated main pulmonary artery
Pericardial knock	Constrictive pericarditis
Pericardial friction rub	Pericarditis

sternal border or second right intercostal space at the sternal edge. The mitral area is at the apex or fifth intercostal space in the midclavicular line. The tricuspid area is at the left lower sternal border or fourth and fifth intercostal spaces at the sternal edge. Location of a murmur should be described by where it is the loudest (point of maximal intensity) not by where it is heard by transmission.

Although these are the four primary areas for auscultation, the cardiac examination should not be limited to these four areas. Additional areas to auscultate include the infraclavicular areas, over the carotid arteries, each axilla (at about the fourth and fifth intercostal space), and the posterior aspect of the chest just medial and inferior to each scapula. Examining all these areas allows for full evaluation of a cardiac murmur (*Table 247.7*).

Table 247.7
Murmurs by location

Location	Murmur
LUSB	Pulmonary valve stenosis
	Atrial septal defect
	Peripheral pulmonary stenosis of newborn
	Pulmonary flow murmur
	Pulmonary artery stenosis
	Aortic stenosis
	Tetralogy of Fallot
	Coarctation of the aorta
	Patent ductus arteriosus
	Total anomalous pulmonary venous return
	Partial anomalous pulmonary venous return
RUSB	Aortic valve stenosis
	Subaortic stenosis
	Supravalve aortic stenosis
LLSB	Ventricular septal defect
	Endocardial cushion defect
	Still's murmur
	Hypertrophic cardiomyopathy
	Tricuspid valve regurgitation
	Tetralogy of Fallot
Apex	Mitral valve regurgitation
	Mitral valve prolapse
	Aortic valve stenosis
	Hypertrophic cardiomyopathy
	Still's murmur

LUSB left upper sternal border, *RUSB* right upper sternal border, *LLSB* left lower sternal border

Timing

Murmurs can occur in systole, diastole, or be continuous. At times this is difficult to assess, particularly in younger patients or patients with high heart rates. Palpating a pulse while performing auscultation may allow one to determine the timing of a murmur. Also, a continuous murmur does not mean it is always present; instead the murmur just needs to spill past S2 into diastole to qualify as continuous. Murmurs can occur early, mid, or late in either diastole or systole:

- Early systolic murmurs start abruptly but taper and disappear before S2 and are associated with a small muscular ventricular septal defect that becomes occluded during systole.
- Mid-systolic murmurs are the most common type of murmur heard and include the benign flow murmurs and murmurs associated with aortic or pulmonary stenosis.
- Mid- to late systolic murmurs begin midway through systole and are often heard in association with mid-systolic clicks and insufficiency of mitral valve prolapse.
- Early diastolic murmurs are from aortic insufficiency or pulmonary insufficiency and have a decrescendo pattern.
- Mid-diastolic murmurs are typically flow rumbles from increased flow across the atrioventricular valves associated in large shunt lesions such as ventricular septal defects.

Table 247.8
Cardiac murmur timing

Timing in cardiac cycle	Murmur
Mid-systolic	PPS, PS, AS, HCM, COA, ASD
Early systolic	Muscular VSD that closes in systole
Late systolic	MR associated with MVP
Holosystolic	VSD, MR, TR
Early diastolic	AI, PI
Mid-diastolic	Flow rumble
Late diastolic	MS, TS
Continuous	PDA, AVM
To and fro	AS/AI, PS/PI

PPS peripheral pulmonary stenosis, *PS* pulmonary stenosis, *AS* aortic stenosis, *HCM* hypertrophic cardiomyopathy, *COA* coarctation of the aorta, *ASD* atrial septal defect, *VSD* ventricular septal defect, *MR* mitral valve regurgitation, *MVP* mitral valve prolapse, *TR* tricuspid valve regurgitation, *AI* aortic insufficiency, *PI* pulmonary insufficiency, *MS* mitral valve stenosis, *TS* tricuspid valve stenosis, *PDA* patent ductus arteriosus, *AVM* arteriovenous malformation, *AS/AI* aortic stenosis/aortic insufficiency, *PS/PI* pulmonary stenosis/pulmonary insufficiency

- Late diastolic murmurs are typical of mitral or tricuspid valve stenosis and occur with atrial contraction.

Diastolic murmurs are always felt to be pathologic in origin.

See *Table 247.8* for timing of common murmurs.

Shape/Configuration

Shape, configuration, or type refers to the characteristic pattern of the murmur seen on phonocardiology. This is where the terms "crescendo," "crescendo-decrescendo," "decrescendo," "holosystolic," etc., come from. Systolic murmurs are either ejection (crescendo-decrescendo) or regurgitant (holosystolic). Diastolic murmurs are generally regurgitant or flow rumbles. Continuous murmurs result from communication between any two structures where one has a higher pressure than the other throughout the cardiac cycle. The term "continuous" refers to a murmur that spills past S2 into diastole, rather than a murmur that is always present. The terminology used to describe murmurs can be confusing. *Table 247.9* explains some of the descriptive terms that you may encounter.

Systolic ejection murmurs are crescendo-decrescendo or diamond-shaped murmurs which can be turbulent, grating, or musical. Usually, they represent blood being accelerated then decelerated through a semilunar valve or blood vessel, since the pressure driving the blood along has to accelerate as it builds up to the pressure already present in the downstream vessel. Systolic ejection murmurs are characteristic of turbulence at the semilunar valves (aortic or pulmonary valve stenosis, flow murmurs) or great arteries (supravalve stenosis).

Table 247.9
Murmur descriptions and terminology

Murmur type	Other terminology
Systolic ejection	Crescendo-decrescendo
	Mid-systolic
	Diamond shaped
Holosystolic	Pansystolic
	Regurgitant systolic
	S1 coincident
	Plateau
	Rectangular shaped
	Long systolic
Innocent	Functional
	Benign
	Innocuous
	Physiologic
	Normal
	Flow

S1 first heart sound

Systolic regurgitant murmurs are usually holosystolic but can end before the second heart sound as in the case of muscular ventricular septal defects. Holosystolic or regurgitant murmurs are shown diagrammatically as a rectangular symbol. There is no crescendo-decrescendo quality since there is very little pressure in the downstream chamber, so the murmur starts with the first heart sound, and it may be difficult to appreciate the first heart sound at all. Examples of holosystolic murmurs are mitral valve regurgitation, tricuspid regurgitation, and ventricular septal defects.

Continuous murmurs result from a communication between two structures where there is always a pressure gradient in the same direction. In patent ductus arteriosus, arteriovenous malformations, aortopulmonary windows, collaterals, and shunts, there is continuous flow since there is a gradient from the systemic to the pulmonary side during both systole and diastole. In these lesions the murmur will have an accentuated systolic component. A continuous murmur may also occur in the venous

system due to stenosis in the systemic veins resulting in a continuous, low-pitched murmur. Venous continuous murmurs will have much less systolic accentuation.

Diastolic regurgitant murmurs result from the backward flow of blood through an incompetent aortic or pulmonary valve. They are early in diastole and as the arterial pressure drops, the intensity of the murmur falls, giving a decrescendo quality. Diastolic regurgitant murmurs are always considered pathologic.

Diastolic flow rumbles are very low-pitched sounds during diastole that correspond to flow across the mitral or tricuspid valves. Rumbles usually occur in lesions with an increased amount of flow across an atrioventricular valve, such as large atrial septal defect or large ventricular septal defect, but may also occur in patients with tricuspid or mitral valve stenosis. The intensity of the murmur may increase toward mid to late diastole as the atria contract.

To-and-fro murmurs are the combination of a systolic ejection murmur and a diastolic regurgitant murmur, as is common following repair of pulmonary stenosis, or in patients with aortic stenosis and aortic insufficiency. A to-and-fro murmur is different from a continuous murmur, even though there is a murmur in systole and diastole.

Loudness

The loudness (intensity) of cardiac murmurs is typically described using a 6-point scale. An intensity of 1 means the murmur is noted only after concentrating, a grade 2 murmur is noted easily, and grade 3 is very easily noted. In grade 4, there is a palpable thrill associated with the murmur, a grade 5 murmur can be heard with the stethoscope on edge on the chest, and a grade 6 murmur can be heard with the stethoscope off the chest (*Table 247.10*). A 4-point scale for describing diastolic murmurs is used by some people.

Table 247.10
Murmur intensity

Grade	
1	Only noted when concentrating
2	Easily heard
3	Very easily heard
4	Easily heard and associated thrill
5	Heard with stethoscope on edge on chest
6	Heard with stethoscope off the chest

Loudness of a murmur is a function of the distance from the stethoscope, the energy in a turbulent stream of blood, amplitude of the sound, and the medium the noise travels through. The amount of turbulence and therefore the intensity of a murmur are dependent on the size of the orifice or size of vessel through which blood flows, the pressure difference or gradient across the narrowing, and the blood flow or volume across the site. As sound radiates from the source, intensity decreases with the square of the distance. The tissue that the sound travels through has an impact on the loudness. Fat dampens higher frequency sounds more than dense material such as bone. If lung tissue is positioned between the heart and chest wall, only the loudest sounds will be heard.

The loudness of the murmur does not necessarily indicate underlying structural heart disease. Most innocent murmurs are grade 2 or less in intensity, but sometimes can be grade 3. Grade 4 or higher murmurs are unlikely to be innocent.

Pitch or Frequency

Pitch refers to the highest frequency audible in the murmur and is a function of the gradient across a narrowing. In general, the higher the pressure gradient across a narrowing, the higher the pitch of the murmur. Usually pitch is described as low, medium, or high, although using terms like medium to high is common.

Quality

Quality refers to the timbre (harmonics or overtones) of a murmur. Murmurs can be described as turbulent, blowing, grating or harsh, or musical.

A turbulent murmur refers to the "white noise" or hissing sound that the majority of murmurs have and is caused by disturbed blood flow. The sound is similar to the sound the water in a garden hose makes when it is kinked.

Blowing murmur refers to a high-pitched turbulent murmur that sounds like air escaping from a punctured tire. Mitral regurgitation is a typical blowing murmur.

A turbulent murmur with multiple clicks throughout systole may be described as grating or harsh and sounds like a credit card being dragged across cement. Typical harsh murmurs are pulmonary valve stenosis, patent ductus arteriosus, and truncus arteriosus.

The term "musical" is applied to murmurs with a predominant harmonic frequency that some describe

as a squeak, seagull's cry, or as a twanging of a string. Another term that is commonly used is vibratory. The most common murmur with vibratory quality is a Still's murmur. Occasionally small ventricular septal defects have a slight vibratory component. The vibratory or musical part of the murmur is felt to be caused by resonance of structures within the heart or the blood itself.

Transmission or Radiation

Transmission or radiation refers to other areas on the chest where the murmur can also be heard. This is different than the point of maximal intensity or location described earlier. Usually, the radiation of a murmur is in the direction of the blood flow. For example, in pulmonary stenosis the murmur radiates from the left upper sternal border to the lungs, a mitral regurgitation murmur radiates from the apex to the left axilla, aortic stenosis murmur radiates from the right upper sternal border to the carotids, etc.

Maneuvers

There are a variety of maneuvers that can be performed at the bedside that allow the murmur to be heard better and help to further define the etiology of the murmur. Maneuvers tend to change the volume of blood flow through the heart. The simplest of the maneuvers is patient position, hence the recommendation to examine a patient sitting, supine, and standing. Other maneuvers include Valsalva, exercise, respiration, transient arterial occlusion, response after a premature ventricular contraction, and use of amyl nitrite.

Postural changes are the easiest maneuvers to perform as this only requires the patient to sit, stand, or lie down, making it very likely the patient will comply. Standing is similar to the strain phase of a Valsalva causing a decrease in venous return, decrease in stroke volume, decreased systemic vascular resistance, and an increase in heart rate. These physiologic changes make the murmur of hypertrophic cardiomyopathy and the mid-systolic click of mitral valve prolapse increase in intensity. Murmurs that are flow related such as pulmonary flow murmur, aortic stenosis, aortic regurgitation, and mitral regurgitation murmurs are decreased in intensity with standing.

Squatting increases systemic vascular resistance, increases venous return, and increases stroke volume while decreasing heart rate. These physiologic changes decrease the murmur associated with hypertrophic cardiomyopathy and increases the flow-related murmurs of aortic stenosis, mitral regurgitation, aortic regurgitation, and pulmonary flow murmur.

A supine position favors immediate increased systemic venous return to the right heart and shortly after to the left heart. There is an increase in stroke volume which increases the intensity of many murmurs, including a Still's murmur and the benign pulmonary flow murmur of adolescence. The supine position may also bring out the tricuspid valve diastolic murmur (flow rumble) associated with an atrial septal defect and increases the intensity of the murmurs of a patent ductus arteriosus and pulmonary valve stenosis.

The left lateral supine position with the patient rolled up onto their left side while lying on the exam table brings the heart closer to the lateral chest wall and raises the intensity of mitral valve murmurs, both regurgitation and stenosis. This position also increases an S3 gallop.

Other maneuvers to assist in cardiac auscultation require cooperation by the patient or equipment but may assist in determining the etiology of a murmur. A Valsalva maneuver has four physiologic phases but is clinically a two-part process with a strain phase and a release phase. Phase I occurs as strain commences lasting only 1–3 s and is usually undetectable at the bedside. In phase II of the Valsalva, there is a decrease in systemic venous return, blood pressure, and pulse pressure. Right heart filling is decreased and cardiac output decreases. After 3 or 4 s, there is arterial and venous constriction and increased heart rate. This part of a Valsalva is clinically appreciable. Phase III begins with release of the strain which is very brief and difficult to perceive at the bedside. Phase IV is composed of an overshoot of systemic blood pressure which causes a decrease in heart rate, which can be easily detected at the bedside. Venous return is increased above the baseline prior to the Valsalva and there is a time delay between the filling of the right ventricle and the left ventricle. Right-sided cardiac murmurs usually return to baseline in one to four cardiac cycles, left-sided murmurs in five to ten cycles.

Valsalva maneuver (phase II) decreases both systemic and pulmonary venous return to the heart and is particularly effective in reducing an innocent Stills murmur and decreases the intensity of all left-sided murmurs except mitral valve prolapse and hypertrophic cardiomyopathy. In the release phase of Valsalva (phase IV), the murmurs of mitral valve prolapse and hypertrophic cardiomyopathy are decreased.

Exercise is another simple bedside maneuver that can be used to evaluate the cardiac system. The easiest exercise to perform is a sustained isometric handgrip without Valsalva which causes an increase in heart rate, systemic

vascular resistance (blood pressure), and an increase in cardiac output. These physiologic changes increase the murmurs of mitral stenosis, mitral valve prolapse, mitral regurgitation, ventricular septal defect, and aortic regurgitation with no change in an aortic stenosis murmur. The first and second heart sounds, and gallops will also become louder during this maneuver.

Respiration changes the amount of venous return to the heart and how close the heart is to the chest wall, making some murmurs easier to appreciate. In general, right-sided events are louder on inspiration and left-sided events are louder on expiration. Inspiration causes a decrease in intrathoracic pressure resulting in increased systemic venous return and increased right ventricular stroke volume. This increase in flow in the right heart increases the murmurs of tricuspid regurgitation, tricuspid stenosis, pulmonary stenosis, and pulmonary regurgitation. Notably, a pulmonary ejection click will decrease with inspiration. During expiration, lung volume is decreased and the heart moves closer to the chest wall making the murmurs of aortic regurgitation, mitral regurgitation, and aortic stenosis easier to appreciate.

The next few maneuvers are not likely to be practical in the primary care setting, but are discussed to be complete.

Transient arterial occlusion can be performed with two manual blood pressure cuffs on the upper extremities inflated to 20 mmHg above the patient's blood pressure. This results in increased afterload but no change in systemic vascular resistance, heart rate, cardiac output, or right atrial pressure. The murmurs of aortic regurgitation, mitral regurgitation, and ventricular septal defect are increased. This maneuver requires manual blood pressure cuffs which may not be available in the clinic and may be difficult to perform in young children.

If a patient is having premature ventricular contractions, they may be used to help evaluate cardiac murmurs. For auscultation, the important part of a premature ventricular contraction is the beat following the ectopic beat. The pause after the ectopic beat increases left ventricular filling time, ventricular contractility is enhanced, and aortic diastolic pressure is lower. So, following a premature ventricular contraction there is an increase in the murmur of hypertrophic cardiomyopathy and aortic stenosis but no change in the murmur of mitral regurgitation. This maneuver is only helpful if the patient is having premature ventricular contractions.

Utilization of amyl nitrite is rare in the clinical setting but is included here for completeness. Amyl nitrite inhalation initially causes a decrease in systemic vascular resistance and blood pressure with increase in stroke volume and cardiac output. These physiologic changes decrease the murmurs of mitral regurgitation, aortic regurgitation, ventricular septal defect, and patent ductus arteriosus but increases aortic stenosis murmur. Late effects of amyl nitrite are an increase in heart rate with even further increase in cardiac output and increase in venous return causing the murmurs of mitral stenosis, tricuspid regurgitation, and pulmonary stenosis to increase.

Innocent Murmurs

Innocent heart murmurs are a common finding on examination of children and there are four benign systolic murmurs and two benign continuous murmurs. In general, benign cardiac murmurs are grade 3 or less in intensity, never have an associated thrill, and never occur solely in diastole. Most of the innocent murmurs are accentuated by increased cardiac output related to fever, anemia, or activity (*Table 247.11*).

The benign murmur common to early infancy is referred to as peripheral pulmonary artery stenosis or pulmonary flow murmur of newborns. Prior to birth, there is minimal flow into the branch pulmonary arteries so the branches are relatively small. Also, the branches arise from the main pulmonary artery at a sharper angle than seen later in life. After birth, there is a marked increase in pulmonary blood flow often creating a murmur as the blood makes the turn from the main pulmonary artery into the branch pulmonary arteries. The murmur of peripheral pulmonary stenosis is often initially heard at a couple of weeks of age when the physiologic nadir of the blood count occurs.

Table 247.11
Characteristics of innocent cardiac murmurs

Grade 1–2/6
Left sternal border
Systolic ejection murmur
Normal intensity and physiologic splitting of S2
No other cardiac sounds or murmurs
No evidence of ventricular hypertrophy or dilation
Murmur does not increase with Valsalva or squat to stand
Asymptomatic
Family history negative for HCM or sudden death

HCM hypertrophic cardiomyopathy

A peripheral pulmonary stenosis murmur is usually louder in the axillae and back, but may be heard anteriorly at the left upper sternal border. The murmur is ejection in character and grade 1 or 2 in loudness. The pitch of the murmur is similar to breath sounds and may be difficult to separate from the rapid respiratory noises in infancy, so can easily be missed. This murmur can be differentiated from valvar pulmonary stenosis as there is no associated ejection click. It is more common in premature infants and often resolves by 6–9 months of age. If the murmur persists past this age, then consider a diagnosis of true branch pulmonary artery stenosis, Williams syndrome, or congenital rubella.

A Still's murmur is a common vibratory murmur heard in children, most often between the age of 2 and 6 years. It can however be heard in infancy and may persist into adolescence. Still's murmurs are low to medium in pitch, maximal at the left lower sternal border and out to the apex, and typically grade 1–3 in loudness. The murmur is usually louder and the vibratory component easier to appreciate when the patient is supine. In some children the murmur may only be noted in the supine position.

The defining feature of a Still's murmur is the vibratory component. The murmur is named after George F. Still who described the murmur in 1909 as "a twanging sound, very like that made by twanging a piece of tense string." The murmur is often described as musical in nature and usually resolves by adolescence. A Still's murmur will be louder in conditions with increased cardiac output, so when a patient is seen for evaluation of a fever, the murmur may be heard for the first time.

A pulmonary flow murmur is a common murmur heard in late childhood and adolescence, ages 8–14 years. It is a crescendo-decrescendo murmur heard best at the left upper sternal border without further radiation and usually grade 2–3 in loudness. The murmur is more pronounced in patients with pectus excavatum or kyphoscoliosis, likely due to the right ventricular outflow tract being closer to the chest wall. It also seems to be more common in athletic individuals who may have an increased stroke volume.

In addition to a pulmonary flow murmur, the differential diagnosis of a murmur at the left upper sternal border would include one related to an atrial septal defect or to pulmonary valve stenosis. In an atrial septal defect, there is a fixed split S2 and there may be an increased right ventricular impulse on palpation. With pulmonary valve stenosis, there often is an ejection click present and the murmur tends to be of a longer and higher grade than in the benign flow murmur.

A murmur related to the carotids, or a carotid bruit, can be heard in children and young adults. It is a crescendo-decrescendo murmur heard best above the clavicles and radiates to the neck. Carotid bruits are low to medium in pitch, of abrupt onset, brief, and maximal in the first part of systole. The murmur is felt to be due to flow from the common carotid into the internal and external carotid arteries. Unlike carotid bruits heard in adults, this is a benign finding in children.

A venous hum is a common continuous murmur heard in children 2–6 years of age. It is usually loudest in the infraclavicular area and more common on the right side. The murmur is low in pitch and louder in diastole. A venous hum murmur is often only heard with the patient sitting upright and will dissipate with gentle occlusion of the internal jugular vein on the same side of the neck as the murmur is heard or turning the head toward the side of the murmur. The murmur may be accentuated by having the patient look away from the side of the murmur. A venous hum is thought to occur from flow from the internal jugular vein into the superior vena cava.

A mammary arterial soufflé is a continuous murmur that can occur in late pregnancy and in lactating women, and can rarely occur in adolescence. The murmur is a continuous noise audible maximally on the anterior chest wall, starting in systole and extending well into diastole. There is usually a distinct gap from S1 before the murmur begins. The murmur is high pitched, may vary considerably from day to day, and may decrease with firm pressure from the stethoscope (*Table 247.12*).

Pathologic Murmurs

The following is a brief overview of cardiac murmurs associated with some of the more common structural cardiac defects. For further details on other exam findings and natural history, please see the respective chapter for the cardiac lesion.

The murmur associated with an atrial septal defect is not related to the flow across the atrial septum, but due to an increase in flow across the pulmonary valve. The murmur is grade 1–3, best at the left upper sternal border, medium pitched, and ejection (crescendo-decrescendo) in nature. The murmur may radiate to the lung fields (axillae and back). The finding setting the murmur of an atrial septal defect apart from a benign pulmonary flow murmur is fixed splitting of S2. This is due to decreased variability of right ventricular volume with respiration

Table 247.12
Innocent heart murmurs

Murmur	Age	Timing	Loudness	Location	Pitch	Other
Still's	2–6 years	Systolic	1–3	LLSB, Apex	Low to medium	Vibratory
PPS	Newborn	Systolic	1–2	Axillae and back	Low to medium	
Pulmonary flow murmur	Older children and adolescents	Systolic	1–3	LUSB	Medium	Normal S2, no ejection click
Carotid bruit	Children and young adults	Systolic	1–3	Supraclavicular radiating to neck	Low to medium	No ejection click, occ. thrill
Venous hum	2–6 years	Continuous	1–2	Subclavicular	Low	Dissipates with supination or gentle occlusion of jugular vein
Mammary soufflé	Late pregnancy and lactating women	Continuous	1–3	Anterior chest over breast	High	Varies significantly day to day

LLSB left lower sternal border, *LUSB* left upper sternal border

and an enlarged right ventricle resulting in prolonged ventricular contraction. Additional findings seen in some large atrial septal defects are a diastolic flow rumble associated with flow across the tricuspid valve and an increased right ventricular impulse. Patients with atrial septal defects are often asymptomatic and the murmur is often picked up during routine examination in childhood.

A ventricular septal defect (VSD) murmur is a holosystolic murmur usually heard best at the left lower sternal border, grade 1–6, high pitched, and harsh in nature. The murmur can radiate to the right lower sternal border and to the apex. A palpable thrill may be present. With large ventricular septal defects, a gallop may be present on auscultation and increased precordial activity noted on palpation. There may be a diastolic flow rumble associated with increased flow across the mitral valve. VSD murmurs are rarely heard in the first couple of days of life with the exception of small muscular VSDs where the flow is directed anteriorly. Most VSD murmurs are noted by 2–4 weeks of age.

A patent ductus arteriosus (PDA) murmur is described as a continuous machinery-like murmur heard best at the left upper sternal border or left infraclavicular area, medium to high in pitch, grade 1–6, that can radiate to the back. The murmur may also sound like other murmurs heard at the left upper sternal border such as pulmonary valve stenosis. The key to differentiate the murmur from pulmonary stenosis is that it is continuous, that is, it spills into diastole. Additionally, there may be widened pulse pressures (bounding pulses) and increased left ventricular activity. Patients may have a flow rumble across the mitral valve and a systolic ejection murmur across the aortic valve because of increased flow in the left heart. A PDA murmur may initially be only heard in systole due to the minimal pressure gradient seen in diastole. As the pulmonary vascular resistance decreases to normal levels in the first few weeks of life, the more classic continuous nature of the murmur will be noted.

A pulmonary stenosis murmur is a systolic ejection murmur at the left upper sternal border ranging from grade 1 to 6, with a medium to high pitch. The pitch of the murmur correlates to the degree of valvar gradient: the higher the pitch, the higher the gradient. Usually there is an ejection click associated with valvar pulmonary stenosis. An increased right ventricular impulse may be noted on palpation. A thrill may be present in the suprasternal notch or upper left sternal border.

The murmur of aortic stenosis is a systolic ejection murmur heard best at the right upper sternal border. It is high pitched ranging from grade 1 to 6, harsh in nature, and radiates to the carotids. There is usually an aortic ejection click at the apex. A thrill may be present at the right upper sternal border or in the suprasternal notch. An increased left ventricular impulse may be noted by palpation.

A murmur from mitral valve regurgitation is holosystolic and heard best at the apex with a grade ranging from 1 to 3. The murmur is high pitched and blowing in nature, radiating to the left lower sternal border, left axilla, and left posterior chest. When associated with

Table 247.13
Selected cardiac lesion murmurs

Lesion	Location	Timing	Loudness	Pitch	Shape/type	Radiation
ASD	LUSB	Systolic	1–3	Medium	Ejection	Occ. lungs
VSD	LLSB	Systolic	1–6	Medium to high	Holosystolic	RLSB, apex
PDA	LUSB	Continuous	1–6	Medium to high	Machinery	Lungs
PS	LUSB	Systolic	1–6	Medium to high	Ejection	Lungs
AS	RUSB	Systolic	1–6	Medium to high	Ejection	Carotids
MR	Apex	Systolic	1–3	High	Holosystolic	Left axilla
CoA	Left back	Systolic or continuous	1–3	Medium to high	Ejection or continuous	
HCM	LLSB	Systolic	1–3	Medium	Ejection	RUSB

ASD atrial septal defect, *LUSB* left upper sternal border, *VSD* ventricular septal defect, *LLSB* left lower sternal border, *PDA* patent ductus arteriosus, *PS* pulmonary stenosis, *AS* aortic stenosis, *RUSB* right upper sternal border, *RLSB* right lower sternal border, *MR* mitral regurgitation, *CoA* coarctation of the aorta, *HCM* hypertrophic cardiomyopathy

mitral valve prolapse, there is a mid-systolic click prior to the murmur being noted.

Coarctation of the aorta gives a variable murmur that is rarely greater than grade 3. It is a systolic ejection type murmur, maximal at the left scapula or just below, but may be heard anteriorly at the left upper sternal border. There is an increase in left ventricular activity on palpation, and decreased lower extremity pulses. If the coarctation is severe, there may be a continuous murmur present. A murmur associated with a coarctation may not be noted until the ductus closes (24–48 h for functional closure) and may not be readily heard until complete remodeling of the aorta has occurred in several weeks.

Mitral valve prolapse is not truly a murmur, but a mid-systolic click associated with prolapse of the valve leaflets. Additionally, mitral valve prolapse may be associated with a murmur of mitral regurgitation occurring after the click.

The murmur associated with hypertrophic cardiomyopathy is a grade 1–3 systolic ejection murmur that is medium in pitch and heard best at the mid or lower left sternal border. The murmur increases when going from a squat to a stand or during the strain phase of a Valsalva (*Table 247.13*).

Murmur Evaluation

Once a cardiac murmur has been noted on physical examination a systematic approach is required to evaluate the murmur. The initial part of the evaluation should be to perform a careful cardiac examination to allow for a full description of the cardiac murmur and any associated findings. Benign cardiac murmurs tend to occur in isolation, without other cardiac exam findings, symptoms, or concerning history. Pathologic murmurs, however, are frequently not found in isolation and often have other physical exam findings, symptoms, or positives in the history to indicate possible structural heart disease. These findings include cardiac symptoms (tachypnea, poor growth, etc.), ejection clicks, gallops, the murmur being only in diastole, or positive family history.

Although many providers will feel that their auscultation skills are limited in evaluation of cardiac murmurs, pediatricians do a good job in screening cardiac murmurs. Of patients referred by pediatricians for pediatric cardiology evaluation of a cardiac murmur, 20–30% are found to have structural heart disease, a rate much higher than the incidence of congenital heart disease (0.8%). Pediatricians also correctly classify murmurs as either benign or pathologic 80% of the time, though they are less accurate with the specific diagnosis.

There are different approaches that providers may take to further evaluate cardiac murmurs. Options include referral of all murmurs to a cardiologist, refer only murmurs felt to be pathologic, evaluating with a chest x-ray and electrocardiogram and only referring patients with abnormal studies, or performing an echocardiogram on all patients with a murmur. Of these strategies, referral of murmurs to a cardiologist may be the best and most cost-effective approach. The cardiologist can listen to the patient and determine if an echocardiogram is warranted. Cardiologists can determine pathologic murmurs by physical examination alone with a sensitivity of 92%, but the sensitivity increases to around 97% with selective

utilization of echocardiogram. This approach identifies all significant structural cardiac disease, but may miss hemodynamically insignificant structural defects such as small atrial septal defects or mild valvar abnormalities.

While an echocardiogram is the most sensitive test to determine if a patient has a structural defect as the etiology of a cardiac murmur, it is also the most expensive way to evaluate a murmur. Echocardiography costs about ten times that of a cardiology consultation, so performing echocardiograms on all patients with heart murmurs is not cost effective. Additionally, often a relatively benign disease may be discovered such as a small atrial septal defect. If it is determined that an echocardiogram is needed for a pediatric patient, the study is best performed in a pediatric echocardiography laboratory and interpreted by a pediatric cardiologist. Echocardiograms performed in an adult echocardiography laboratory may not be as detailed in evaluating the anatomy and may miss structural heart disease.

Classic teaching is that a chest x-ray and an electrocardiogram should be performed to assist in defining the etiology of a murmur. However, both of these studies have low sensitivity in detecting structural cardiac disease. Chest x-ray has a 60% false positive rate and 20% false negative rate in pediatric patients. The low sensitivity makes electrocardiograms and chest x-ray poor screening tests for evaluation of congenital heart disease in the asymptomatic patient so are probably not warranted. If these studies are used as part of the evaluation, they are best interpreted by a pediatric cardiologist.

Age of the patient when the murmur was initially noted may assist in deciding about further workup or referral. Murmurs are frequent in newborns with up to 60% having a murmur noted during a careful examination. Some of these murmurs are transient in nature, coming from tricuspid valve regurgitation or a closing patent ductus arteriosus. Murmurs heard in the immediate newborn period that persist to 1 week of age may be related to structural cardiac disease. Utilizing persistence of a newborn murmur to 1 week of age in an otherwise asymptomatic infant as a screening strategy will pick up 60% of all structural heart disease and any life-threatening cardiac disease. Any infant with a murmur should also have an oxygen saturation check and if less than 95% should be considered for further evaluation. Pathologic murmurs noted in the immediate newborn period include stenosis of the pulmonary valve or aortic valve. A pathologic murmur not noted until a few weeks of age may be related to a ventricular septal defect.

For a murmur initially noted at 2–4 years of age, the most likely diagnosis is an innocent murmur, such as a Still's murmur. If the murmur has the classic vibratory quality at this age, then there is little need for referral since that finding is diagnostic. However, parental anxiety about the murmur may be an indication for referral.

If a cardiac murmur is discovered on physical examination, then a complete description of the murmur is essential and should include location, timing, loudness, type, pitch, quality, and transmission. A complete description will allow the development of a limited differential diagnosis. Assess the patient for additional cardiac sounds or exam findings suggesting structural cardiac disease as the etiology of the murmur. The patients past and family history should be reviewed for any positives that may indicate a structural heart defect. If the murmur is consistent with one of the benign cardiac murmurs, the patient is asymptomatic, the murmur is grade 2 or less, the history is unremarkable, and the rest of the physical exam is normal, then the murmur is likely benign in nature and may not require further evaluation. However, if there are positive findings in the history, on the examination, or the patient has cardiac symptoms, then further evaluation is probably warranted. If any doubt about whether a murmur is benign or pathologic, then further evaluation or referral is warranted.

Once a murmur is fully defined, one can use a basic algorithm to determine if further evaluation or referral is needed. Timing in the cardiac cycle is the first component to consider: determine if the murmur is systolic, diastolic, or continuous. If the murmur is systolic then determine if it is mid-systolic (crescendo-decrescendo, ejection type), early or late systolic, or holosystolic. Murmurs greater than or equal to grade 3, or early, late, or holosystolic should be referred to a pediatric cardiologist for evaluation (although, sometimes benign murmurs can be grade 3 if cardiac output is increased). If the murmur is mid-systolic and grade 2 or less in intensity, but the patient is symptomatic or there are other history or physical exam findings suggestive of cardiac disease, then the patient should be referred for evaluation. However, if the patient is asymptomatic and there are no other history or exam findings and the murmur is consistent with a benign murmur, no further workup is needed. A murmur heard only in diastole should be referred for evaluation. A continuous murmur consistent with either a venous hum or a mammary soufflé does not require further workup. But, if the continuous murmur is not consistent with one of the benign continuous murmurs, then further evaluation is warranted (❯ *Fig. 247.1*).

Patients with a cardiac murmur that is not clearly innocent should be referred to a pediatric cardiologist for evaluation. If the distance to a cardiologist is

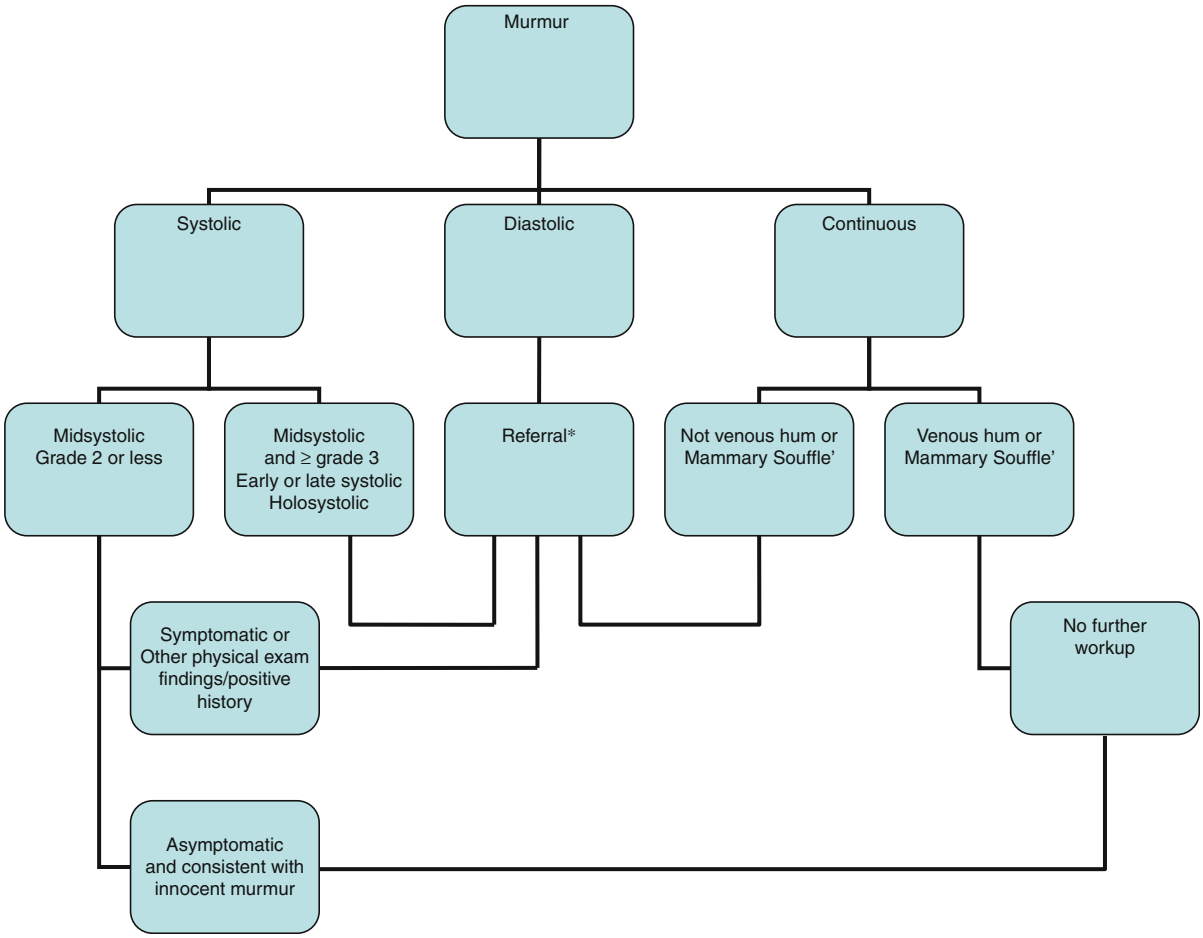

Figure 247.1
Murmur Algorithm. *Echocardiogram performed by telemedicine to a referral center may be appropriate if distance to a pediatric cardiologist is significant

significant, and tele-echocardiography is available, then performing an echocardiogram may be a reasonable alternative to a cardiology consult. Any echocardiogram on a pediatric patient is preferably done in a pediatric echocardiography laboratory and interpreted by a pediatric cardiologist. Patients with positive findings in their history or other findings on examination should be referred to a pediatric cardiologist.

Atrial Septal Defects

Definition

An atrial septal defect (ASD) is any deficiency in the atrial septum allowing communication between the right and left atria. An atrial septal defect is distinguished from a patent foramen ovale, which is not considered a pathologic finding and occurs due to inadequate fusion of the septum secundum to the septum primum. An atrial septal defect is one of the most common congenital heart anomalies, and can be found in 10–15% of patients with congenital heart disease**.** The foramen ovale is a normal interatrial shunt that is necessary in utero. As a result of increasing left atrial pressure after birth, the valve of the fossa ovalis is pushed against the limbus and is functionally closed. However, in 17–35% of people, the flap does not adequately close the fossa ovalis and a potential communication remains between the atria**.** A patent foramen ovale results from this inadequate closure. There are several types of atrial septal defects, and they are classified by their location relative to the fossa ovalis. A defect in the septum primum near the fossa ovalis is termed a secundum atrial septal defect because as a result of the deficiency, the ostium secundum appears enlarged.

Approximately 5–10% of ASDs are located superior and posterior to the fossa ovalis and are termed sinus venosus or superior vena cava type defects. With this type of interatrial communication, the defect is usually only bordered by atrial septal tissue at the anteroinferior border. The posterior border being the right atrial free wall and the superior border often being absent because of an overriding superior vena cava. Quite frequently this type of defect is associated with anomalous connection of the right pulmonary veins to either the superior vena cava or the right atrium.

A rarer defect is the coronary sinus ASD. Its location is inferior and anterior to the fossa ovalis and results from a defect in the wall of the coronary sinus as it passes the left atrium. It is usually associated with a persistent left superior vena cava that drains to the left atrium.

A final type of the interatrial communication is the primum ASD. The location of this type of defect is cephalad to the atrioventricular valves and is part of the spectrum of atrioventricular septal defects and thus will be discussed in a separate section.

Etiology

In general, ASDs occur sporadically; however, they are associated with some syndromes, namely, Holt-Oram which is characterized by ASDs and upper extremity anomalies. Although the genetic understanding of ASDs is far from complete, two gene mutations have been found to be associated with ASDs. *NKX2.5* and *GATA4* are two genes that have been shown to be linked to nonsyndromic congenital heart defects.

Epidemiology

The most common type of ASD is the secundum type and accounts for 6–10% of all cardiac anomalies. ASDs occur at a 2:1 ratio in females to males. ASDs have an incidence of one child per 1,500 live births.

Pathology/Pathophysiology

When an interatrial communication exists, a left-to-right shunting of blood will occur. The volume and direction of the blood flow is dependent on the size of the defect and the relative compliance of the ventricles. In early infancy the right ventricle is thickened and not very compliant, thus there is very little shunting across the ASD. However, within the first few weeks, left-to-right shunting occurs because the right ventricle becomes the more compliant ventricle, resulting in a lower right atrial pressure in comparison to the left atrial pressure. The left-to-right shunt can place a significant volume load on the right-sided cardiac structures, resulting in dilation of the right atrium and ventricle. If the right ventricular dilation is severe, the annuli of the tricuspid and pulmonary valves may also dilate and become insufficient. Pulmonary blood

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_248,

flow may be up to four times that of the systemic blood flow, producing elevated pulmonary artery oxygen saturations.

The pulmonary vascular bed is highly compliant and initially can handle the increased blood flow, as shown by the pulmonary resistance often being normal in the face of significant pulmonary blood flow. However, with chronic overload, the pulmonary vasculature undergoes microscopic change. Within the muscular pulmonary arteries, medial hypertrophy will begin to occur along with intimal proliferation. However, the permanent changes leading to pulmonary hypertension may not occur until the third or fourth decade of life. With unrestrictive ASDs, there is an increasing incidence of pulmonary hypertension with advancing age. There is also a strong female predilection to the development of pulmonary hypertension. Usually despite the increased pulmonary blood flow, the pulmonary artery pressure is within the normal range or only slightly above. Although it is extremely rare for pulmonary vascular obstructive disease to occur in patients with ASDs before their early 20's, there have been studies that have shown it may occur as early as 3 months old. These infants with pulmonary vascular obstructive disease and ASDs may have significant cyanosis and Eisenmenger syndrome.

Clinical Manifestations

The typical course of a secundum ASD during infancy is that it does not cause symptoms and often goes undiagnosed. With the typical left-to-right shunt across the atrial septum, there is a fixed and widely split S2 heart sound and a soft, systolic ejection murmur. The average age of diagnosis is 6 months. Rarely infants will present with congestive heart failure. It is poorly understood why these infants will be in heart failure as their hemodynamic findings on cardiac catheterization are not significantly different from infants not in heart failure. The usual clinical course is dependent on the amount of left-to-right shunting. If the shunting is only moderate, children will often remain asymptomatic. As the shunting increases, children may begin to complain of fatigue and dyspnea. Unlike ventricular septal defects, it is rare for children with ASDs to have growth failure. Because the signs and symptoms of ASDs may be subtle, adults may be diagnosed with the defect. Adults may present with atrial flutter or fibrillation.

Diagnosis

For a small-sized ASD, the electrocardiogram (ECG) is usually normal. The rhythm seen on the ECG is usually normal sinus. However, the rhythm may demonstrate a junctional or supraventricular tachycardic rhythm in a minority of patients, usually older in age. The QRS axis is often time normal, but may demonstrate right axis deviation if right ventricular hypertrophy is present. If right atrial enlargement occurs due to the left-to-right shunting, the P waves may exceed 3 mm. In older patients it is common to see a prolonged P–R interval due to the intra-atrial conduction delay causing first-degree atrioventricular block. An incomplete right bundle branch block with RSR' pattern is also characteristic and found in lead V1.

The chest radiograph usually shows varying degrees of cardiomegaly, depending on the amount of right atrial and right ventricular dilatation. The increased shunt flow causes the pulmonary vascular markings to be increased and the pulmonary arteries to appear engorged. As the pulmonary vascular resistance rises due to pulmonary vascular changes, the lung fields may become clear or oligemic and the main pulmonary artery will appear enlarged.

Transthoracic echocardiography with Doppler color flow can demonstrate the size and the location of the ASD. The atrial septum should be visualized from multiple planes to fully understand its location, size, and relation to other structures. Particular structures that should be noted in relation to the ASD include the superior and inferior vena cava, the pulmonary veins, and the coronary sinus. Color Doppler can demonstrate the direction of shunting across the ASD. The typical flow pattern across the defect is left to right, usually beginning in mid-systole and decreases in velocity and volume until early diastole. It is with early diastole that atrial contraction occurs and this accentuates the left-to-right shunting. Pulse Doppler echocardiography can demonstrate the flow pattern. Right atrial and right ventricular dilatation can be seen by echocardiography as evidence of the left-to-right shunting. While transthoracic echocardiography is usually sufficient in the pediatric population, transesophageal echocardiography is the usual diagnostic method in older patients.

Cardiac catheterization is usually not a needed diagnostic modality. However, in patients where there is concern regarding associated anomalies, particularly those involving the pulmonary veins, or questions regarding the pulmonary pressure or resistance, a cardiac catheterization may be required. The degree of shunting, the Qp:Qs ratio, can be calculated. If the defect is large in size, the pressures will be equal between the left and right atria. Due to the increased flow through the right side of the heart, the right ventricular pressure will be increased. The

pulmonary artery pressure is usually normal or only slightly elevated; however, there is a subset of patients that show a moderate increase in the pulmonary artery pressure. The measuring of the pulmonary vascular resistance becomes critical in patients with concern for pulmonary vascular obstructive disease to assure operability. If the pulmonary vascular resistance is elevated, 100% oxygen or nitric oxide can be given to assess reversibility. Cardiac catheterization will be discussed further in the treatment section, as percutaneous closure is often the first choice of treatment.

Differential Diagnosis

A large ASD may create a significant left-to-right shunt, but can usually be differentiated from other lesions by echocardiography. The defect is normally well visualized by echocardiography and can be differentiated from VSDs and atrioventricular septal defects (AVSD) by the location of the defect. In addition, there is usually more right atrial and ventricular dilation seen in ASDs than in VSDs and AVSDs due to the timing in the cardiac cycle and location of the shunt. The murmur of an ASD can be differentiated from these defects because a VSD and an AVSD usually have a holosystolic murmur while the murmur of an ASD is most commonly a soft, systolic ejection murmur. Another common finding seen with an ASD is the fixed splitting of the S2. A fixed, split S2 may also be found in other lesions such as pulmonary stenosis or partial anomalous pulmonary venous return. The pulmonary stenosis murmur will often be more harsh than that of the ASD. Both of these lesions should be easily differentiated by echocardiography.

Treatment

Prior to the use of interventional catheter procedures to close the ASD, surgical repair was the treatment of choice for any ASD of appreciable size, usually corresponding to a Qp:Qs ratio greater than 1.5:1. Because it is rare that clinical symptoms will occur in childhood from an ASD, the repair is often deferred until the age of 3–5 years old. After this age, there is no advantage in delaying repair. If symptoms of congestive heart failure are developing, or there is concern for pulmonary vascular disease, then the timing for treatment may necessitate intervening at an earlier age. Surgical closure is considered to be a safe and technically easy operation for secundum ASDs as well as sinus venosus defects. The surgical approach for closure of the ASD is typically through a median sternotomy.

Over the last 30 years, a transcatheter approach for ASD closure has become common and results are quite good with the continued advance of ASD occluder devices. In 2001, the Amplatzer septal occluder became the first FDA-approved device for transcatheter closure of ASDs. While the results are typically good for transcatheter closure, there is a slight risk of device erosion and thrombus from this type of procedure. The advantages of a transcatheter approach compared to surgical intervention include faster recovery time, less invasive than open heart with avoidance of cardiopulmonary bypass, and more cosmetically appealing due to the absence of a median sternotomy scar. Limitations of a catheter-based approach include the location and size of the ASD: the septal occluder requires a circumferential rim of septal tissue in order to achieve stable deployment. If the defect is too large or in a peripheral position on the septum, device closure is less suitable.

Prognosis

The natural history of ASDs is usually benign except for those that allow a large left-to-right shunt or are associated with other cardiac defects. Spontaneous closure of small- to medium-sized defects is also quite common. In a study performed by Radzik et al**,** all ASDs less than 3 mm in diameter had closed spontaneously prior to 9 months of age, 87% of those between 3 and 5 mm, 80% of those 5–8 mm, and none of those with defects larger than 8 mm. Other studies have shown that the rate of closure decreases significantly after the age of 3, thus it is often best to wait until this age before embarking on treatment to see if the defect closes spontaneously. As outlined above, it is rare for children to experience symptoms related to an ASD. The severity of symptoms and the likelihood of permanent pulmonary vascular damage increases with age. While congestive heart failure is extremely rare in infants with ASDs, this is a much more common finding in a patient over the age of 40 years. The most debilitating sequelae of an untreated ASD remains pulmonary vascular obstructive disease (PVOD). PVOD occurs in 5–10% of patients with untreated ASDs and has a female predilection. It is rare for PVOD to occur before the age of 20 years. In addition, atrial arrhythmias occur with increasing frequency in those with untreated ASDs. The incidence has been found to be as high as 52% in those over 60 years of age with an untreated ASD.

Ventricular Septal Defects

Definition/Classification

A ventricular septal defect (VSD) is any opening in the septum separating the right and left ventricles that allows communication between them. Excluding bicuspid aortic valve, the ventricular septal defect is the most common form of congenital heart disease. VSDs may be single or multiple. The defects are normally classified by their location in the interventricular septum.

The most common type of VSD is the perimembranous defect. The membranous septum is a relatively small area and is between the anterior and posterior divisions of the septal band and between the outlet and trabecular septum. Perimembranous defects may also be termed infracristal VSDs. The membranous septum is normally divided by the septal leaflet of the tricuspid valve and minor anomalies of the tricuspid valve may occur with perimembranous defects. There can be varying amounts of anterior malalignment between the anterior ventricular septum and the infundibular septum causing the aorta to override the septal defect. A less common occurrence is posterior malalignment which can cause obstruction along the left ventricular outflow tract. Although it is rare, a perimembranous septal defect can cause a left ventricular-to-right atrial shunt if the septal commissure of the tricuspid valve is disrupted.

Outlet defects, which have multiple other synonyms including supracristal, infundibular, conal, or subpulmonary, occur below the pulmonary valve. The right coronary cusp of the aortic valve may prolapse through an outlet defect which can cause aortic insufficiency.

The inlet septum is located posterior and inferior to the membranous septum and beneath the septal leaflet of the tricuspid valve. Occasionally associated with this type of defect is straddling of either the mitral or tricuspid valve.

The final type of VSD is termed the muscular type, found in the muscular septum. Muscular VSDs are often multiple and may be found anywhere in the muscular septum, but most commonly are seen at the apex. The defects may be difficult to visualize from the right ventricle due to the overlying trabeculations, making surgical closure more difficult. The muscular defects are often small and hemodynamically insignificant, many of which close on their own. When the defects are multiple, they often coalesce to form a single defect on the left ventricular side of the interventricular septum.

Etiology

Although no single gene has been identified to be the cause for VSDs, *NKX2.5* and *GATA4* are two genes that have been shown to be linked to nonsyndromic congenital heart defects. However, the concordance rate for identical twins is only 10% and suggests that VSDs are more likely due to random errors in development. The risk of a mother with a VSD to have an offspring with a congenital heart defect is 2–4%.

Epidemiology

An isolated VSD accounts for 20% of patients with congenital heart disease. It is thought that VSDs may be underdiagnosed due to spontaneous closure. Most recently, it was found that VSDs occur at an incidence as high as 5–50 per 1,000 newborns. There is a slight female preponderance.

Pathology/Pathophysiology

After birth, a left-to-right shunt across the VSD will begin to develop. The primary determinant of the blood flow across the defect is the size of the defect and the pulmonary vascular resistance (PVR). If the defect is small or medium in size, the dimension of the defect limits the amount of blood that shunts between the ventricles. The pressure gradient between the left and right ventricles determines the directionality of blood flow in these smaller VSDs. If the defect is larger then there is no restriction to flow across the defect. In these larger defects, the shunt is determined by the relative resistances of the systemic and pulmonary vascular bed. Thus, any condition that increases the systemic vascular resistance, such as a coarctation, will increase the left-to-right shunt. Likewise, any condition that obstructs right ventricular outflow, such as pulmonary stenosis, will decrease the shunt.

In the immediate postnatal period, PVR is high and there is little to no intracardiac shunting. The PVR begins to decrease and reaches near adult levels within 2 weeks, continuing to decline over the first few months of life. With the coincident drop in the PVR, the left-to-right shunting across a large VSD is accentuated and delays the rate of PVR decline. The increasing blood flow through the pulmonary vascular bed will lead to pulmonary overcirculation. In the setting of a large VSD, the pressure is equalized between the left and right ventricles, as well as the great arteries. Because of the elevated right

ventricular pressure, the right ventricle does not undergo its normal involution to a thin-walled, crescent-shaped ventricle. Instead, it remains thick walled to compensate for the increased pulmonary pressure. The left ventricle faces a volume overload because not only is blood being ejected out the left ventricular outflow tract, but the left ventricle also must eject blood through the VSD into the pulmonary circulation. The left ventricle will begin to dilate in the face of the excessive pulmonary venous return. Due to the marked increase in pulmonary circulation, the child will begin to develop congestive heart failure, normally between 2 and 8 weeks of age.

As in other lesions allowing increased pulmonary blood flow, the excessive flow can cause vessel injury to the pulmonary circulation. An unrepaired VSD may lead to chronic injury of the vessels, signaling pulmonary vascular obstructive disease.

Small- and moderate-sized VSDs will offer some resistance to flow. In these smaller types, there is normally a small shunt, and the workload is not increased in the ventricles. In addition there is the absence of an increase in the PVR. In moderate-sized defects, the shunt may be large enough to cause pulmonary overload with resultant dilation of the left atrium and left ventricle, but it is very rare to have an increase in PVR. Smaller VSDs may close spontaneously, usually by 6 months of age. Muscular-type defects are the most common to close spontaneously (by muscular septal growth) followed by perimembranous defects.

Clinical Manifestations

In infants with *small VSDs*, a murmur is often able to be auscultated by the 2 week newborn check-up, but may be heard as early as the first few days of life. The murmur becomes more evident as the PVR falls over the first weeks of life. Smaller defects usually do not cause hemodynamic effect. Infants with small VSDs should be able to take oral feeds without distress and should grow appropriately.

Upon examination, a high-pitched, holosystolic murmur is normally able to be auscultated, usually at the left lower sternal border. The murmur may be associated with a thrill. The murmur may encompass the second heart sound and slightly extend past it. If the defect is an outlet VSD, the murmur is often best heard at the upper left sternal border, due to the ejection of blood into the right ventricular outflow tract. Occasionally small, muscular VSDs will end in mid-systole during ventricular contraction due to VSD impingement of flow by the muscular septal tissue. Although there is blood flow across the defect during diastole, it is a small amount and is not turbulent, thus the lack of a diastolic component of the murmur.

The clinical presentation may vary widely for infants with *moderate- to large-sized VSDs*. If the PVR drops quickly and the defect is large, symptoms may be seen as early as 2 weeks of age. Symptoms include signs of congestive heart failure (tachypnea, diaphoresis with feeds, and poor weight gain). Cardiomegaly and hepatomegaly will often become evident by 2 months of age in those infants with signs of heart failure. Symptoms are often worsened during times of a respiratory illness, and this is a frequent cause for presentation. The tachypnea and signs of respiratory distress usually herald the development of pulmonary edema.

The murmur associated with moderate or large VSDs is holosystolic and best heard along the left sternal border. A thrill is often associated with the murmur. Frequently, a third heart sound can be auscultated as well as diastolic rumble when the pulmonary blood flow is twice that of the systemic blood flow. In moderate-sized VSDs, the second heart sound is usually widely split and varies only slightly with respiration. In large VSDs, the pulmonary component of S2 is loud and splitting is usually narrow but perceptible. A faint diastolic murmur, typically termed a diastolic rumble, heard at the apex often signifies relative mitral stenosis due to increased flow through the left heart.

Children with elevated PVR will be protected from the increased pulmonary blood flow, but lack of symptoms may disguise the worsening pulmonary vascular disease. In infants, transient episodes of cyanosis can be seen; however, if cyanosis persists, this may signify either an anatomic (e.g., right ventricular outflow tract obstruction) or a physiologic (e.g., elevated PVR) mechanism for reduced pulmonary blood flow. A large, unrepaired VSD may lead to episodes of cyanosis as the child enters adolescence and young adulthood, owing to the worsening pulmonary vascular disease. A holosystolic murmur is often auscultated in these patients, but is instead due to tricuspid valve insufficiency, a consequence of elevated right ventricular pressures. The second heart sound is loud, and normally single. This condition is termed Eisenmenger's complex. The pulmonary vascular damage that has occurred by this stage is irreversible and the patient is inoperable due to the elevated PVR.

Diagnosis

An electrocardiogram (ECG) is usually normal in patients with a small VSD. Occasionally there will be an rsR'

pattern in V1 or V4R. In moderate-sized defects that are associated with larger left-to-right shunts, evidence of left or biventricular hypertrophy will be seen on the ECG. Increases in right ventricular pressure may be judged by an increasing amplitude of R' in lead V4R. In patients with large VSDs, the axis may be deviated to the left due to the left ventricular hypertrophy. As pulmonary blood flow increases and the left atrium becomes dilated, the P waves may become wide and biphasic, best seen in leads I and V6.

The chest radiograph usually shows a normal heart size and pulmonary vascularity in children with a small VSD. A chest radiograph will show cardiomegaly, increased pulmonary vascular markings, and increased size of main pulmonary artery by 2–3 months in those children with moderate to large-sized VSDs. In those that develop Eisenmenger syndrome, there will be prominence of the main pulmonary artery and the proximal pulmonary tree, but the pulmonary vasculature distally will have decreased markings.

Echocardiography will allow the cardiologist to define the location, size, and number of defects in the ventricular septum. Color flow Doppler across the defect will demonstrate the direction of the shunting. By echocardiography, the left atrium and left ventricle can be assessed for changes in dimension that may occur with the increased pulmonary blood flow. With VSDs that are identified during infancy, serial echocardiograms may be used to document the change in size of the VSD. Smaller, muscular and perimembranous VSDs may grow smaller or close spontaneously. Aside from gaining information about the VSD, other associated abnormalities may also be identified by echocardiography. These include overriding aorta in the case of the perimembranous defect, straddling atrioventricular valves, pulmonary outflow tract obstruction, and aortic or pulmonary insufficiency.

Normally, echocardiography is sufficient to diagnose VSDs. When echocardiography data is not satisfactory, a cardiac catheterization may be indicated. Cardiac catheterization is especially useful in infants with evidence of elevated PVR and only a small or moderate-sized defect. A right heart cardiac catheterization can be performed and will give an accurate measurement of the right ventricular and pulmonary artery pressures, and PVR. Patients with pulmonary hypertension may not be amenable to surgical repair, thus it is very important in those patients with elevated PVR that they demonstrate reversibility with 100% oxygen or nitric oxide before proceeding.

Differential Diagnosis

In the case of an isolated VSD, the diagnosis may be confused for those other cardiac lesions that cause a significant left-to-right shunt. Atrioventricular septal defects often have a large left-to-right shunt, but are normally able to be differentiated by echocardiography. Another cardiac lesion that may be associated with a large left to right shunt with little or no cyanosis is that of double-outlet right ventricle (DORV). Truncus arteriosus is associated with increased pulmonary blood flow and may not have signs of cyanosis. By auscultation, the S2 is single and often has a click associated with the truncal valve. Echocardiography will easily distinguish this from an isolated VSD.

Treatment

Small VSDs usually do not cause hemodynamic significance and thus do not require medical or surgical treatment. As per the most recent subacute bacterial endocarditis (SBE) prophylaxis guidelines, no prophylaxis is required prior to procedures.

As stated in the Clinical Manifestations section, the symptoms normally associated with moderate or large VSDs are those consistent with congestive heart failure. Even the child where the VSD is likely to necessitate surgical management, a trial of medical management is first initiated. Symptoms are related to pulmonary overcirculation, thus diuretics are the first line of medical therapy. This will help to decrease pulmonary flow, but does have ill effects on electrolytes, most commonly hypokalemia and hypochloremia. If hypokalemia persists, spironolactone may be added for potassium sparing effect. If additional therapy is required for medical management, systemic afterload reduction with an ACE inhibitor is the next choice. Afterload reduction aids in decreasing the systemic vascular resistance as well as decreasing the systemic stimulation associated with the state of congestive heart failure. If symptoms of heart failure persist despite diuresis and afterload reduction, Digoxin may be added. Infants with moderate and large VSDs often have poor growth and will have weight and height plateau. Caloric supplementation is necessary when poor growth occurs. If the infant is unable to take the needed calories orally, a nasogastric tube may be required. With the application of medical therapy, most infants will show clinical improvement. In addition, the VSD may close or become smaller during infancy. However, with a decrease in symptoms, the clinician must be mindful to assure that the

improvement is not due to the PVR increasing or hypertrophy of the right ventricular outflow tract resulting in a reduced left-to-right shunt.

For many infants, the trial of medical therapy is only a bridge to surgical management, allowing symptomatic improvement and weight gain until VSD repair. During infancy, those with symptoms of congestive heart failure not able to be medically managed will require surgical therapy to close the VSD. Children with large defects and shunts of greater than 2:1 are normally repaired prior to 2 years of age, but can be repaired sooner if there is evidence of rising pulmonary pressures. If infants have an outlet-type VSD, the aortic valve is monitored to detect aortic insufficiency.

Children with small VSDs and shunts that are below a Qp:Qs of 1.5:1 typically do not require surgical intervention. A slightly increased risk for endocarditis does remain in those with unrepaired VSDs.

Closure of VSDs by a percutaneous transcatheter approach using a device is less established than device closure of ASDs. This technique appears to be most useful for muscular or residual VSDs. However, further studies are still needed to assess safety and long-term results.

Prognosis

Long-term survival is quite good for isolated VSDs. Patients with large defects normally require medical management and surgical repair. If the defect is only moderate in size, medical management may bridge them to spontaneous closure. Mortality due to VSD is rare, but may be due to associated pulmonary infections or the development of elevated PVR. If surgical repair is undertaken before the age of 2, it is rare to develop pulmonary vascular disease. However, if surgery is not performed before this age, as many as 25% of patients will develop pulmonary vascular disease. This is further evidence that surgical repair between 6 and 12 months should be undertaken in those infants with elevated pulmonary artery pressure. Typically after surgical repair, results are very favorable in terms of activity, growth, and development. Early repair has been shown to be associated with regression of left ventricular dilation and hypertrophy and improved cardiac contractility. Following surgery, care must be taken to monitor for signs of pulmonary hypertension, sinus node or atrioventricular node dysfunction resulting in conduction abnormalities, or aortic insufficiency. These are all rare but documented consequences observed in patients with surgical repair of VSDs.

Patients with small VSDs have an excellent prognosis. Many of these defects will close spontaneously in the first 2 years of life. These patients may be followed infrequently for detection of defect closure and observation for rare complications.

Atrioventricular Septal Defects

Definition

Atrioventricular septal defects (AVSD) are a group of defects that are comprised of a deficiency of the atrial and ventricular septum as well as abnormalities of the atrioventricular (AV) valves. Other common names for this collection of pathology includes endocardial cushion defect or atrioventricular canal defect. AVSDs can be further categorized depending on the defect of the ventricular septum. A partial AVSD is comprised of a primum ASD and typically has two distinct atrioventricular valves: the tricuspid and the mitral. In a partial AVSD the mitral valve will be cleft in the anterior leaflet. The mitral valve also has abnormal attachments to the ventricular septum and may cause left ventricular outflow tract obstruction because of anterior displacement. A complete AVSD will likewise have a primum ASD, but it will be contiguous with an inlet-type VSD. Unlike the partial AVSD with two distinct AV valves, the complete AVSD has a common AV valve with a single annulus. Although the AV valve has a single valve annulus, there may be two distinct valve orifices within the common AV valve. When this occurs, the defect is commonly referred to as an intermediate AVSD. The tissue comprising the AV valve itself has a wide range of variability, ranging from normal-appearing tissue to severely dysplastic leading to significant incompetence. Embryologically, the endocardial cushions give rise to the inferior portion of the atrial septum, the inlet portion of the ventricular septum, and the septal leaflets of both AV valves. Thus, the abnormal or deficient growth in this area produces the defect, and essentially amounts to a hole in the middle of the heart.

Etiology

AVSD is commonly associated with Down syndrome. Children that have Down syndrome are found to have congenital heart disease 40–45% of the time. Of these children that are found to have congenital heart disease, approximately 40% of them will have an AVSD. Most commonly, the type of AVSD is the complete form.

Other syndromes that are associated with AVSD include heterotaxy syndromes as well as Ellis-van Crevald syndrome. Nearly 14% of women with repaired AVSD who have children risk passing along a congenital heart defect trait, usually AVSD or tetralogy of Fallot.

Epidemiology

AVSD has an estimated occurrence of 0.19 in 1,000 live births and does not show any gender predilection. In relation to congenital heart disease, AVSD accounts for 4–5% of all disease.

Pathophysiology/Pathology

There are two separate annuli in partial AVSD and the mitral and tricuspid valves have the same septal insertion level due apical displacement of the mitral annulus. Because of this displacement, an interatrial communication is established through the primum ASD. The primum ASD is usually large and located anteroinferiorly to the fossa ovalis. As described in the section detailing ASDs, this type of lesion is not amenable to transcatheter closure. Because of the apical displacement of the mitral annulus the distance between the apex and the aortic annulus is greater than the distance between the apex and the mitral annulus and is a possible etiology of left ventricular outflow tract obstruction. The anterior leaflet is usually cleft in a partial AVSD. The cleft of the mitral valve in AVSD is directed toward the mid-portion of the ventricular septum. There is commonly a regurgitant jet through the cleft in the mitral valve and over time the mitral leaflets may become dysplastic and thickened.

As described in the section on ASDs, the shunt flow through the primum ASD of a partial AVSD is determined by the relative compliance of the ventricles unless the defect is such a small size that it restricts flow itself. A left-to-right shunt through the atrial communication may cause right ventricular dilation and displace the interventricular septum into the left ventricle. Over time, if there is persistent right ventricular volume overload, the right ventricle (RV) may have decreased systolic function. With increasing RV dysfunction, the RV compliance decreases and the shunt ratio may decrease. The recovery of the RV is often dependent on the timing of repair of the primum ASD. In cases of pulmonary hypertension, the shunt ratio may decrease, but there is still a high volume of shunting. Shunting from right-to-left may cause mild cyanosis and is a herald that the defect may no longer be correctable.

In a partial AVSD, there may be significant right atrial dilation due to increased volume from the shunt across the primum ASD. However, an additional factor is the cleft in the mitral valve. As described earlier, the cleft in a partial AVSD is unique in that it is located in the anterior leaflet and the regurgitant jet is directed at the interatrial septum.

In the complete form of AVSD, the septal defect extends to the interventricular septum, differentiating it from the partial form. In addition, there is a common AV valve rather than two separate AV valves. The left-sided papillary muscles are often rotated in an abnormal orientation, and combined with the anterolateral muscle bundle can create progressive left ventricular outflow tract obstruction. The common AV valve may not relate equally to both ventricles and one ventricle, usually the morphologic left ventricle, may become hypoplastic. This type of AVSD will be discussed further in the chapter on "❯ Single Ventricle Physiology." A frequent problem with the common AV valve is regurgitation. As with the cleft mitral valve in partial AVSD, these valve leaflets often become thickened. In complete AVSD, there is left-to-right shunting at both the atrial level as well as the ventricular. The ventricular level shunting occurs during ventricular systole and can lead to RV dysfunction and elevated pulmonary artery pressure. To combat the torrential pulmonary blood flow, PVR will rise and may remain elevated. Eventually the histologic changes that occur in the pulmonary vascular bed with the raising of PVR are permanent and prevent its return to normal levels even after surgical correction. Cases are typically considered to be inoperable when the PVR reaches markedly elevated (and fixed) levels; fortunately this is extremely rare in the current era.

Clinical Manifestations

Patients with partial AVSD are often asymptomatic through childhood. However, in cases where there is moderate to severe mitral regurgitation associated with the primum ASD, symptoms of excessive pulmonary blood flow such as tachypnea and poor weight gain may be evident during childhood. As many as one in five patients with partial AVSD and severe mitral regurgitation have symptoms of pulmonary overcirculation, dyspnea, or atrial arrhythmias during infancy. Compared to patients with secundum-type ASDs, patients with primum defects are more likely to have symptoms at an earlier age and at a more severe level. As with the secundum ASD, a primum ASD may be suspected during physical examination due to a systolic ejection murmur at the pulmonary position

and a second heart sound that is fixed and widely split. If the mitral regurgitation is severe, a holosystolic murmur may be heard at the apex position.

Symptoms due to excessive pulmonary blood flow will almost always occur during early infancy in complete AVSD. Most common are tachypnea and failure to thrive. If a patient is known to have complete AVSD and symptoms are not developing, that should be concerning for the premature development of pulmonary vascular obstructive disease. Further demonstration of the need for early repair of complete AVSD comes from a study showing that a 1-year-old child with an unrepaired AVSD has only a 15% chance of living until 5 years. The rapid progression to pulmonary vascular disease often occurs earlier in patients with Down syndrome, sometimes as early as 2 months of age. In the absence of elevated PVR, it is unusual to have oxygen desaturation. The excessive pulmonary blood flow will cause an accentuation of S2 and a systolic murmur at the pulmonary position on physical examination. A holosystolic murmur will be present if there is significant ventricular level shunting or AV valve regurgitation.

Diagnosis

A common finding on electrocardiogram is a superior or northwest QRS axis, most commonly between –90° and −120°. This altering of the axis is due to the displacement posteriorly of the atrioventricular node. Another common feature is prolongation of the P−R interval (first degree atrioventricular block). Greater than 50% of patients will display signs of right atrial enlargement. Right ventricular hypertrophy is frequently seen, and there is often some variation of the rsR' in the right precordial leads.

A chest radiograph will often show right atrial enlargement, with a mild to moderate degree of cardiomegaly. The pulmonary vascular markings will often be prominent. If the PVR remains elevated, the lung markings become clearer.

Echocardiography is the standard method for diagnosis of both the partial and complete form. Specific features of interest during the echocardiogram include the size of the atrial defect, the amount of regurgitation through either the cleft mitral valve or the common AV valve, and associated defects. In complete AVSD, it is important to examine the relationship of the common AV valve to the ventricles and if the inflow is asymmetric. In complete AVSD, the location and amount of ventricular level shunting should be identified. An evaluation of the left ventricular outflow tract should be undertaken.

Cardiac catheterization does not have a prominent role in the diagnosis or treatment of AVSD. A catheterization may be undertaken if there are questions regarding the PVR and thus the feasibility of repair.

Differential Diagnosis

In a partial AVSD, the primum ASD can usually be differentiated by echocardiography from other types of ASDs. The primum defects compared to the secundum-type defects will usually cause symptoms at an earlier age. In cases of common AVSD with unbalanced ventricles, associated lesions are often seen, including double inlet left ventricle, double outlet right ventricle, or heterotaxy syndrome. Unbalanced AVSD will be discussed further in the chapter on "Single Ventricle."

Treatment

Patients with partial AVSD are often asymptomatic in childhood. When diagnosed, the indications for repair are similar to those for other types of ASDs. When children do become symptomatic from AVSD, it is usually due to the excessive pulmonary blood flow. In these cases, diuretics and afterload reduction are initiated. Digoxin is also occasionally used in cases of symptomatic partial AVSD. A primum ASD will not close spontaneously, and surgical repair is recommended when patients fail medical management or approach school age, just as in other types of ASDs. The goals of surgical therapy are to close the atrial level shunt and to repair the left AV valve to assure competence. The repair of partial AVSD carries a low risk, with hospital death of 3% or less. Poor prognostic factors related to the repair include cyanosis at time of surgery, failure to thrive, and moderate to severe left AV valve regurgitation. Reoperation is required 11% of the time, most commonly for residual mitral valve stenosis or regurgitation.

Unlike partial AVSD, the diagnosis of complete AVSD is usually made in infancy because most patients are symptomatic. As the PVR falls, substantial left-to-right shunting will ensue and symptoms will begin to develop. Diuretics are initiated for the excessive pulmonary blood flow, and if the common AV valve regurgitation is significant, afterload reduction has been shown to be effective. Growth failure is common among these infants and increasing caloric density is quite common along with gavage feeds. When a contraindication to repair is present (prematurity, noncardiac disease complicating cardiac

surgery, respiratory infection), a pulmonary artery banding may be necessary to decrease the pulmonary blood flow.

Patients with Down syndrome and AVSD often present a unique problem. They are more likely to have complete AVSD than the partial type. Additionally, they are also more likely to have associate defects such as tetralogy of Fallot. It has been shown that patients with Down syndrome have a higher PVR than those without Down syndrome. With this knowledge, a lack of symptoms cannot be looked at as reassuring, but instead should be concerning that the PVR remains elevated. Unlike partial AVSD repair that is typically undertaken at early school age, the repair for complete AVSD must be performed prior to the development of irreversible pulmonary changes. Typically the repair is done before the infant reaches 6 months of age. The goal of repair is to close both the atrial and ventricular level shunts, as well as construct two separate AV valves. Risk factors for the surgical repair include early age of repair, preoperative heart failure class, and severity of AV valve regurgitation.

Prognosis

The long-term survival for partial AVSD is quite good. A Mayo Clinic study demonstrated 20- and 40-year survival of repaired partial AVSD to be 87% and 76%, respectively. Unrepaired partial AVSD has a course quite similar to unrepaired secundum-type ASD. Pulmonary vascular disease increases with each decade of life. If combined with moderate to severe mitral regurgitation, the likelihood of symptoms increases. Atrial dilation from the shunt can cause atrial arrhythmias later in life and is occasionally the presenting symptom. Risk of reoperation is 11% and more likely in those with severe mitral regurgitation. Rarely, a pacemaker is required postoperatively for bradyarrhythmias.

Complete AVSD that goes unrepaired has a grim prognosis due to torrential pulmonary blood flow. One study has shown that the mortality is as high as 80% by 2 years of age in patients who are unrepaired. The pulmonary blood flow along with chamber dilation sets the stage for severe congestive heart failure, arrhythmias, endocarditis, or pulmonary infections. Nearly 90% of patients who reach the age of 1 year will have developed irreversible pulmonary vascular disease if unrepaired. Complete AVSDs are associated with a 17% risk of late reoperation during the first 20 years following surgical repair. As in partial AVSD, AV valve stenosis or regurgitation is the most common reason for reoperation, typically on the left side. Other causes for reoperation include residual ASDs or VSDs, as well as progressive left ventricular outflow tract obstruction. Unlike partial AVSD, repair for complete AVSD carries a higher risk for complete heart block and the subsequent need of a pacemaker.

Patent Ductus Arteriosus

Definition

A patent ductus arteriosus (PDA) is a persistent communication between the descending aorta distal to the left subclavian artery and the main pulmonary artery. The PDA is formed from the left sixth aortic arch and has a vital role in fetal physiology. The PDA will vary in length and is typically 10 mm in diameter in a full-term infant. Typically, there is functional closure of the ductus 10–15 h after birth in a full-term infant. Closure is usually complete by 3 weeks of life resulting in the fibrous ligamentum arteriosum. PDA closure is mediated by vasoactive substances and variations in the pH level, oxygen tension, and prostanoids.

In fetal circulation, the PDA exists to allow blood to bypass the pulmonary circulation. By 6 weeks of gestation, the PDA is large enough to handle the majority of right ventricular output. The PDA is necessary in fetal life to prevent wasted circulation through the high resistance pulmonary vascular bed and an increased workload on the developing right ventricle.

Etiology

Because the closure of the PDA is not completely understood, work continues in order to understand why the vessel may remain patent through infant life. It is known that any condition in which the arterial oxygen content is lowered or the circulating level of prostaglandin is raised will create an environment which may lead to delayed closure. Common etiologies for these scenarios include pulmonary disease at birth such as meconium aspiration, or high-altitude. One of the most recognized conditions associated with persistence of the PDA arises in the premature infant. It is well documented that in low-birth-weight premature infants, a PDA is found in 45% of those with a birth weight $<$1,750 g. A PDA is oftentimes associated with other congenital heart defects and will be discussed as such separately in other chapters.

Epidemiology

The incidence of a PDA is approximately 1 in 2,000–2,500 live births, and increases the greater the degree of prematurity. This incidence represents about 10% of all congenital heart defects. There is a 2:1 female-to-male predilection.

Pathology/Pathophysiology

In the fetal circulation, the purpose of the PDA is to allow blood from the right ventricle to bypass the high resistance pulmonary vascular bed. However, postnatally, the PDA begins to reverse direction as the PVR decreases allowing for increased blood flow into the pulmonary circulation. In addition to the respective resistances between the pulmonary and systemic vascular beds, the diameter and length of the PDA as well as the pressure difference between the aorta and pulmonary artery will determine the direction and amount of shunting. A small PDA will have a small amount of shunting and be restrictive due to its size. However, a large PDA will result in equal pulmonary artery and aortic pressures and the major determinant of shunt flow will be the respective resistances. As the PVR falls in infancy, the left-to-right shunt through the pulmonary vascular bed will increase, as will the pulmonary venous return to the left atrium. The increased volume returning to the left atrium will put a strain on the left ventricle due to the increased volume that it receives. In addition, if the PDA is large, the increased pressure that the right ventricle is pumping against requires an increase in systolic work and eventually may cause right-sided failure. Premature infants are unable to compensate for this increased volume load on the left ventricle as well as full-term infants or older children, and thus often have symptoms of failure at an earlier time period.

As with other left-to-right shunt lesions, an increase in the pulmonary blood flow can delay the typical postnatal pulmonary vascular changes. A small PDA has very little to no effect on the pulmonary arterial circulation. However with a large PDA, the pressure will equalize and the PVR may decrease at a slower rate and not reach its typical nadir. A moderate-sized PDA is more regulated by its size and the shunt flow may only mildly increase the pulmonary artery pressure. The increased volume return to the left atrium is usually well tolerated in these patients. Long-standing left-to-right shunts such as those found with a PDA will eventually cause a fixed elevation in the PVR due to the increased pulmonary blood flow. At that time the PDA will allow right-to-left shunting and right-sided heart failure often ensues. The positive effect of PDA closure would then be lost.

Clinical Manifestations

A small PDA has only a small left-to-right shunt and minimally affects pulmonary artery pressure. Left ventricular failure does not occur in these patients and attention is usually only raised due to the presence of a murmur in childhood.

In an infant with a moderate-sized defect, the shunt volume may be great enough to cause symptoms of congestive heart failure (CHF) such as tachypnea and failure to thrive. The symptoms often increase as the PVR is falling and usually reach their peak at 2–3 months of age. The shunt volume however may not be great enough such that as they grow older, mechanisms such as improved contractility allow for compensation to this increased volume. In this case, the infants actually begin to improve clinically after 3–4 months of age and may go undetected.

A large PDA present in an infant will cause symptoms, most notably growth failure and tachypnea, particularly with oral feeds. The increased pulmonary blood flow also makes these infants more prone to respiratory infections, often coinciding with presentation. Due to the excessive pulmonary blood flow in a large PDA, left ventricular failure may develop at an earlier age and resultant pulmonary edema may be evident early in infancy. If the PDA remains unrepaired, typically by 8–16 months of age the PVR will reach systemic levels and the left-to-right shunting will greatly decrease. If this occurs, symptoms related to the excessive blood flow such as the tachypnea and poor feeding will decrease. Changes become irreversible as early as 15 months of age. Because of pulmonary hypertension, shunting will be right to left and cyanosis will occur, at first with activity but later on a permanent basis.

Rare clinical complications of a PDA include vessel aneurysm and endarteritis. With more efficacious treatment, the occurrence of bacterial endarteritis has become increasingly rare in developed countries. The typical organisms include *Streptococcus viridans* and *Staphylococcus aureus*.

During examination of infants with a moderate- to large-sized PDA, the pulse will often be in a tachycardic range and the pulse pressure is widened. When palpating the peripheral pulses they are typically bounding. The classic murmur associated with a PDA is a continuous,

machinery murmur that is in a crescendo–decrescendo pattern and best heard at the upper left sternal border. The murmur is frequently associated with a thrill. If the PDA is small in size, only a systolic murmur may be present. Because of the increased volume load on the left ventricle, a hyperdynamic precordium is palpated. Due to the increased volume across the mitral valve, a diastolic rumble auscultated at the apex is common. In a patient with an unrepaired PDA, as the PVR begins to rise from the excessive pulmonary blood flow, the murmur will become present only in systole and eventually will disappear.

Diagnosis

The ECG in patients with small- to moderate-sized PDAs may be normal. The increased volume load on the left ventricle can cause evidence of left ventricular hypertrophy manifested by deep Q waves and tall R waves in leads II, III, aVF, and the left precordial leads. As the left atrium enlarges, the P wave will widen in leads II and V1. If pulmonary hypertension begins to develop, signs of right ventricular hypertrophy may become present such as tall R waves in the right precordial leads.

In a patient with a moderate- to large-sized PDA, a chest radiograph will show cardiomegaly with evidence of left atrial enlargement. The pulmonary vascular markings will be increased and pulmonary edema may be present.

Definitive diagnosis of the PDA can be made by two-dimensional echocardiography. Color Doppler through the PDA can demonstrate the direction and the timing of flow during the cardiac cycle. Evidence of left atrial and left ventricular enlargement and hypertrophy can be followed with echocardiography. It is important to look for associated cardiac defects.

Cardiac catheterization is not typically used in the diagnosis of PDA. However, as for other left-to-right shunt lesions, if the PDA is diagnosed later in infancy or there is concern for increased PVR, a cardiac catheterization may be necessary to directly measure pulmonary pressures and resistance to determine feasibility of closure. Oxygen saturations in the pulmonary artery compared to the right ventricle can also be used to estimate the size of the shunt. Angiography during the cardiac catheterization can also further define the anatomy of the PDA and its associated connections. This information is not required for the diagnosis but does aid in possible treatment measures that may be undertaken by catheterization.

Differential Diagnosis

Because of auscultation early in infancy of a continuous murmur, other possible diagnoses must be considered. A venous hum has a continuous murmur, but can be varied with head position and pressure on the neck. Arteriovenous communications and an anomalous origin of the left coronary artery from the pulmonary artery both have continuous murmurs. In the case of the arteriovenous communication, the murmur is usually more superficial. Absent pulmonary valve syndrome may give a "sawing wood" murmur that sounds continuous, but can usually be differentiated by the clinical condition and the enlarged bronchi on the chest radiograph. Perhaps most difficult to distinguish from PDA is the aortopulmonary window. The murmur is very difficult to differentiate from that of the PDA; cardiac imaging is necessary to aid in diagnosis.

Treatment

The treatment of a moderate- to large-sized PDA is similar to other cardiac lesions allowing excessive pulmonary blood flow. The risk of permanent pulmonary vascular disease, left-sided heart failure, growth failure, and persistent pulmonary infections are all reason for early treatment. Because the risk of surgical or transcatheter closure is low, there is not usually a need for sustained medical management prior to definitive treatment. This differs from the typical management of other left-to-right shunt lesions such as VSD or AVSD that are typically managed medically until the patient reaches an acceptable age for surgical treatment. Unlike premature infants, Indomethacin is ineffective for PDA closure in term infants and older children and should not be attempted.

Treatment by transcatheter device closure with occluding coils or duct occluders is now the treatment of choice for PDAs that are larger than 3 mm in diameter and patients that are older than a few months of age. The procedure has essentially no mortality and a low morbidity while being 97% successful. Associated risks of the transcatheter closure include device embolization or device-related hemolysis. In the rare case that this does occur, surgical closure of the PDA can be made more complicated. For infants less than 3 months of age or patients with large PDAs greater than 12 mm in diameter, surgery remains the treatment of choice. The approach is usually a lateral thoracotomy that allows ligation of the PDA. Like transcatheter treatment, surgical ligation carries minimal risk of morbidity and mortality. The

most common complications of surgical closure are recurrent laryngeal nerve palsy and chylothorax. Hospital course may be as short as 2 days with surgical treatment. A technique that remains limited but has shown encouraging results is that of thoracoscopic, minimally invasive surgical closure. Obvious benefits include avoidance of a thoracotomy scar and faster rate of recovery. However, critics argue that unexpected surgical bleeding could cause a very difficult situation to manage and gain control over.

Prognosis

The prognosis for the isolated PDA is quite good if recognized during infancy prior to permanent changes of the pulmonary vasculature. Like other left-to-right shunt lesions, if the PDA is moderate to large in size and left unrepaired, pulmonary vascular disease occurs and these changes can become permanent over time. The natural history of these patients is quite poor as closure of the PDA is contraindicated and right ventricular failure eventually occurs. Typically the risk of treatment either by surgery or transcatheter device is low and the success rate is quite high. Life expectancy is near normal in patients with an isolated PDA that is closed prior to the development of severe pulmonary vascular changes.

249 Cyanotic Heart Disease

Stephen P. Seslar

Overview

Definition

On the surface, defining cyanotic congenital heart disease seems simple. The word cyanosis originated from the Greek *kyanōsis* from *kyanos*, meaning dark blue color. Sir William Osler concisely conveys its medical definition as "diminished oxygenation of the blood corpuscles." The word "congenital" is defined as "existing at or dating from birth." So at its essence, cyanotic congenital heart disease is a birth defect affecting cardiovascular structure, resulting in decreased oxygenation of red blood cells. Thus, all forms of cyanotic congenital heart disease result in the delivery of deoxygenated red blood cells into the systemic circulation. A mnemonic known as the "five T's" can be helpful in remembering the common forms of cyanotic congenital heart disease: tetralogy of Fallot, transposition of the great vessels, truncus arteriosus, total anomalous pulmonary venous connection, and tricuspid atresia. This is an imperfect pneumonic, and conditions such as pulmonary atresia with intact ventricular septum are included in the broader heading of congenital hypoplastic right-heart lesions represented by tricuspid atresia. This chapter will review each of these conditions in detail, except tricuspid atresia which will be covered in the chapter entitled Chap. 251, "The Single Ventricle".

Classification

In general, cyanotic congenital heart disease can be classified based on morphologic and embryologic grounds or based on physiology. Practically speaking, a physiologic approach is more useful to the clinician because it more readily translates into the clinical picture. One of the more common physiologic classification schemes of cyanotic congenital heart disease is to divide lesions by the presence of "too much" or "too little" pulmonary blood flow. In reality, classifying cyanotic congenital heart disease is challenging due to the marked heterogeneity of the underlying disorders. For example, on the milder end of the spectrum of tetralogy of Fallot, affected individuals will not manifest cyanosis (i.e., "pink tetralogy"). The limitations notwithstanding these classification schemes provide an important framework for understanding cyanotic congenital heart disease.

Etiology

Our understanding of the etiology of cyanotic congenital heart disease is evolving but remains incomplete. The development of a heart defect likely represents a complex interplay between genetic, environmental, and flow dynamic factors. From a genetic perspective, about 20% of congenital heart defects can be attributed to chromosomal abnormalities (e.g., trisomy 21) and Mendelian syndromes (e.g., the 22q11 deletion/DiGeorge syndrome). The remaining cases, once considered "sporadic," are now thought to be, at least in part, due to non-Mendelian/nonchromosomal genetic variants (e.g., NKX2–5). These new discoveries suggest that the genetic contribution to congenital heart disease may have been significantly underestimated in the past. Epidemiology studies have also identified several environmental factors that play a role in the genesis of congenital heart disease, for example, the association between maternal gestational diabetes and conotruncal heart defects. Finally, while genetic and environmental factors reside metaphorically "upstream" in the development of congenital heart disease, the final morphologic outcome in congenital heart disease is often felt to be the result of altered flow dynamics in the developing embryo.

Epidemiology

The incidence of cyanotic congenital heart disease as a group is notably consistent across time and geography. In a recent publication that reviewed and analyzed 44 published studies in which there were at least 100 subjects with cardiac lesions, the incidence of cyanotic congenital heart disease was about 1 per 1,000 live births. The incidence of specific lesions will be discussed under the appropriate subsections presented below.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_249,

Pathology/Pathophysiology

The specific structural defects that comprise the various forms of cyanotic congenital heart disease are distinct and diverse. Each will be reviewed in detail under the appropriate subsections below. Cyanosis can be the result of the heart's inability to deliver blood flow to the pulmonary circuit due to obstruction to flow. Examples of this "too little" pulmonary blood flow physiology include tetralogy of Fallot and various forms of right-sided heart disease (e.g., pulmonary atresia). Alternatively, some forms of cyanotic congenital heart disease have normal or "too much" blood flow, for example, transposition of the great vessels. In these instances, though the total volume of blood flow through the pulmonary circuit may be normal or increased, the amount of *effective* pulmonary blood flow is severely diminished. In all cases, by definition, the structural defects associated with cyanotic congenital heart disease result in the delivery of deoxygenated blood from the heart to the systemic circulation.

Symptoms and Signs

Signs and symptoms specific to each defect will be discussed under the appropriate subheading below. Signs and symptoms of cyanotic congenital heart disease are variable as the underlying heart defects. Even the defining sign of cyanosis is only variably present and often may be difficult to recognize. Depending on the specific heart defect and the severity within a particular lesion and the status of the ductus arteriosus, infants may demonstrate signs of cyanosis, respiratory distress, murmur, and cardiogenic shock. In other instances, infants may have no signs or symptoms apart from mild cyanosis. As a group, patients with cyanotic congenital heart disease are more often diagnosed in the neonatal period prior to hospital discharge than are other forms of congenital heart disease. In addition to signs and symptoms specific to the cardiovascular system, congenital heart disease may also be identified as part of a recognizable pattern of malformation, for example, DiGeorge syndrome which has a characteristic facial phenotype.

Diagnosis

As with any condition, the diagnosis of cyanotic congenital heart disease begins with a careful history and physical exam. While historical elements, signs, and symptoms raise the index of suspicion for cyanotic congenital heart disease, additional testing is performed to confirm and specify the exact nature of the heart defect. The tests used in the diagnosis of cyanotic congenital heart disease are common to those used for all forms of congenital heart disease, though the test performance characteristics of specific modalities may vary based on the type of cardiac defect. Some of the common diagnostic testing modalities are reviewed here.

History and Physical Exam

Simple historical elements such as the age of the patient and chronicity of the presentation can give important clues as to the nature of the heart defect. For example, patients with D-transposition of the great vessels or obstructed total anomalous pulmonary venous connections are likely to present early in the newborn period with signs of cyanosis and clinical compromise. Conversely, tetralogy of Fallot may have a more indolent presentation depending on the severity of the lesion and the timing and completeness of ductus arteriosus closure. The maternal/gestational history should be mined for risk factors such as advanced maternal age, diabetes mellitus, fetal alcohol exposure, or other teratogenic drugs, prescribed or illicit. Family history of congenital heart disease or relevant inherited disorders (DiGeorge syndrome) in a first degree relative should be noted.

Essential physical exam findings are basic but critical in narrowing the differential diagnosis of the cyanotic infant. Cyanosis is detectable at oxygen saturations below 85% (unless anemia is present). Cyanosis may be central or peripheral, and it is important to distinguish between the two because peripheral cyanosis is clinically benign and not associated with congenital heart disease. Peripheral cyanosis is typically noted in the extremities and perioral regions. Importantly, peripheral cyanosis, unlike central cyanosis does not involve the oral mucosa. A rapid clinical assessment should be performed in which the patient's state of arousal, color, respiratory pattern, and perfusion are evaluated. This rapid assessment can set the stage for the urgency of the subsequent evaluation and treatment. The general appearance of the patient may provide clues to a clinical syndrome. For example, the craniofacial features of DiGeorge syndrome may suggest a conotruncal defect such as tetralogy of Fallot. The presence or absence of a murmur should be noted, though it may be present in normal anatomy (e.g., innocent murmurs, ductus arteriosus closure) and absent in complex congenital heart disease (e.g., D-transposition of the great vessels, pulmonary atresia with intact ventricular septum).

Pulse Oximetry

In a study of 38,429 newborn infants, a preductal and post-ductal oxygen saturation <95% or a pre- and post-ductal difference >3% had a 62% sensitivity and a 99.8% specificity for the detection of ductal dependent circulation in this population. While room-air pulse oximetry can be very useful ruling out the presence of cyanotic congenital heart disease, it is not specific to cardiac cyanosis when abnormal.

Hyperoxia Test

Central cyanosis can be the result of lung or heart disease or a combination of both. The response of pulmonary cyanosis to the administration of exogenous oxygen can be used to distinguish it from cyanosis due to a cardiac lesion. This "hyperoxia test" should be performed as follows. The cyanotic patient is provided 100% FiO_2 for 10 min. An arterial blood-gas analysis should then be performed. If the PaO_2 is >200 torr, a cardiac cause for the cyanosis is highly unlikely. Conversely, if the PaO_2 fails to rise above 70 torr (in the setting of a normal pCO_2), congenital heart disease is likely. Intermediate PaO_2 response to hyperoxia challenge is less likely cardiac in nature, but a cardiac etiology cannot be excluded. It is important to base the result on an arterial PaO_2 rather than oxygen saturation due to the possibility of a falsely negative test result when the latter measure is used.

Chest Radiography

In symptomatic infants, chest radiography can facilitate the diagnosis of congenital heart disease and help distinguish primary heart disease from lung disease. Some radiographic signs such as the "boot-shaped heart" for tetralogy of Fallot or the "snow-man" sign for total anomalous pulmonary venous connection can even aid in the diagnosis of a specific cardiac lesion. The chest radiogram can also aid in the physiologic assessment of pulmonary blood flow and thus aid in the clinical management. The utility of chest radiography in asymptomatic infants with murmurs is less clear.

Electrocardiography (ECG)

The electrocardiogram is an inexpensive, noninvasive test. Unfortunately, it is also insensitive and nonspecific in the diagnosis of cyanotic congenital heart disease. This is particularly true in newborns, where there is a natural predominance of right-sided forces. There are some specific instances where ECG findings might facilitate the diagnosis of cyanotic congenital heart disease. Left-heart predominance in a cyanotic infant should raise concern of pulmonary atresia or some other form of hypoplastic right-heart variant. The presence of right ventricular hypertrophy in the older infant or child might facilitate the diagnosis of a right-sided obstructive lesion such as tetralogy of Fallot or pulmonary stenosis. Importantly, a normal ECG does not rule out the presence of cyanotic congenital heart disease and should not provide false reassurance.

Plasma B-Type Natriuretic Peptide (BNP)

A recent prospective study found that in pediatric patients with nonspecific signs and symptoms of a heart disease, elevated plasma BNP had a positive predictive value of 91% for the detection of a significant cardiovascular abnormality in newborn infants (77% in older children). The authors concluded that BNP levels can be helpful in the timely recognition of significant cardiovascular disease in this population.

Echocardiography

Since the early part of the 1980s, echocardiography has been the diagnostic method of choice for essentially all forms of congenital heart disease. More recent technological improvements have strengthened the utility of this testing modality further. It is noninvasive, painless, and requires no radiation exposure. In most instances, the availability of echocardiography has completely supplanted the need for cardiac catheterization in the diagnosis of congenital heart disease. It should be remembered, however, like any testing modality, echocardiography is subject to the rules of Bayesian logic. That is, the pretest probability of disease, in part, determines the predictive value of the test. If time and resources permit, evaluation by pediatric cardiologist and review of the ancillary tests outlined above can improve the test's performance. Simply put, if you have an idea what you are looking for before you start, you are more apt to find it (or more effectively exclude its presence).

Cardiac Catheterization

As stated in the section above, echocardiography has largely supplanted cardiac catheterization in the diagnosis

of congenital heart disease. Occasionally, echocardiography may not be sufficient, and cardiac catheterization is used to better define the anatomy. Practically speaking, this usually involves defining a detailed feature of a more general diagnosis made by echocardiography. For example, angiography can be used to determine the number and distribution of aorto-pulmonary collaterals in patients with tetralogy of Fallot/pulmonary atresia or assess the coronary circulation in patients with pulmonary atresia with intact ventricular septum.

Differential Diagnosis

The differential diagnosis of cyanotic congenital heart disease includes peripheral cyanosis, cyanosis secondary to pulmonary disease, or problems with oxygen transport (e.g., methemoglobinemia). The distinction between peripheral and central cyanosis is usually apparent by physical exam. Rarely, pulse oximetry or arterial blood-gas analysis is required. Pulmonary cyanosis can be distinguished from cardiac by the hyperoxia test (see above), a normal cardiac exam and normal appearing heart on chest radiography. Echocardiography, as noted above, remains the gold standard for defining or excluding suspected cyanotic congenital heart disease.

Treatment

Once identified, the treatment of cyanotic congenital heart disease involves initial resuscitation, stabilization, consultation with a pediatric cardiologist, and (if necessary) transport to a center specializing in the care of these patients. In newborns, after discussion with a pediatric cardiologist, prostaglandin E1 infusion at dose of 0.05–1 μg/kg/min may be initiated. Following this, infants will need to be monitored for apnea, a common side effect of this medication. Laboratory analysis of the acid-base status and blood-gas analysis should be performed. Continuous pulse oximetry can be used for detecting acute changes in oxygenation and to monitor the effects of prostaglandin therapy on ductal patency. Once a specific diagnosis has been established, a consultation by a congenital heart disease surgeon is performed (in conjunction with a pediatric cardiologist) for discussion of surgical options and timing. Ultimately, most forms of cyanotic congenital heart disease will require surgical intervention in infancy for an optimal outcome. The timing, nature, and risks of the surgical procedures will, of course, vary by the specific lesion. These will be reviewed in detail under the specific subheadings below.

Prognosis

The natural (untreated) history of all forms of cyanotic congenital heart disease is grim. The modified natural history of cyanotic congenital heart disease is one the greatest success stories of modern medicine. Indeed for the first time earlier this century, estimates of the number of adults living with congenital heart disease exceeded those of infants and children. Unfortunately, although the mortality rates associated with various forms of congenital heart disease have dramatically improved, adults with congenital heart disease remain at risk for a variety of lesion specific and generic health issues related to their congenital heart disease. As one recent review aptly expressed this sentiment in its title: Congenital heart disease never goes away, even when it has been "treated."

Prevention

The laudable goal of preventing of congenital heart disease remains largely unrealized. The multifactorial etiology and broad clinical spectrum of these conditions makes the discovery of a "magic bullet" for prevention unlikely. There is increasing evidence that folate supplementation may play a role in preventing certain forms of congenital heart disease, though definitive data is still lacking. Good prenatal care and proper management of gestational diabetes are clearly important. Efforts to prevent the development or progression of congenital heart disease through fetal intervention have been reported, but these procedures remain experimental and have only been applied to selected lesions. Presently, perhaps the best we can hope for is that earlier detection and diagnosis through fetal echocardiography will reduce or prevent the negative consequences caused by a missed postnatal diagnosis.

Tetralogy of Fallot

Definition/Classification

The sentinel four features of this form of cyanotic congenital heart disease as originally written by Etienne-Louis Arthur Fallot in 1888 (and subsequently translated from French) are: (1) pulmonary artery stenosis, (2) ventricular septal communication, (3) rightward deviation of the

aorta's origin, and (4) right ventricular hypertrophy. It is important to recognize that although these features are present in the majority of patients with tetralogy of Fallot, there is marked variability in the range of severity, and that these differences have important implications regarding treatment and prognosis. Tetralogy of Fallot is one of the conotruncal cardiac malformations. This implies that the primary malformation occurs in the area of the ventricular outflow tracts and great vessels. Tetralogy of Fallot is the prototypical example of a cyanotic congenital heart disease with "too little" pulmonary blood flow.

Etiology

The precise etiology of Tetralogy of Fallot is unknown. Like other conotruncal defects, it is associated with DiGeorge syndrome, but the majority of cases appear to be non-syndromic. Abnormalities in neural crest migration have been implicated, but the responsible gene(s) involved and the mechanism by which these gene defects result in the development of tetralogy of Fallot have not been elucidated. Though the spectrum of cardiovascular malformations involves the four elements outlined above, the pathogenesis of these anomalies is thought to be the result of a single error in development: hypoplasia or underdevelopment of the sub-pulmonary infundibulum.

Epidemiology

The incidence of tetralogy of Fallot is approximately 0.421 per 1,000 live births and appears to be consistent over time and geography, though an excess incidence has been reported in Malta (0.64 per 1,000 live births). It is the most common of the cyanotic congenital heart defects and most often occurs as an isolated entity. The presence of extra-cardiac abnormalities in patients with tetralogy of Fallot increases the incidence of an associated syndrome and worsens the prognosis. In one population-based study, karyotype abnormalities were present in 13% and extra-cardiac malformations in 17% of the infants. The most common anomalies seen were Down syndrome, cleft palate, cleft lip and palate, and combined skeletal, gastrointestinal, and renal lesions (VACTERL association). In another study, 2% had associated DiGeorge syndrome.

Pathology/Pathophysiology

In the cyanotic forms of tetralogy of Fallot, there is too little pulmonary blood flow secondary to right ventricular outflow tract obstruction. As noted above, the fundamental cause of this obstruction is underdevelopment of the right ventricular outflow tract. There is a large ventricular septal defect that allows equalization of pressure between the left and right ventricles and, over time, right ventricular hypertrophy worsens. As the degree of right ventricular outflow obstruction increases, the ventricular septal defect allows shunting of deoxygenated blood from the right ventricle to the left ventricle where it mixes with oxygenated blood in varying proportions before being pumped into the systemic circulation (*Fig. 249.1*). This ratio is determined by relative resistance between the pulmonary and systemic vascular beds. The greater the right ventricular outflow obstruction, the higher the resistance to pulmonary blood flow and the more deoxygenated blood crosses into the systemic circulation. Without intervention, the degree of right ventricular outflow obstruction increases with time, resulting in increasing cyanosis.

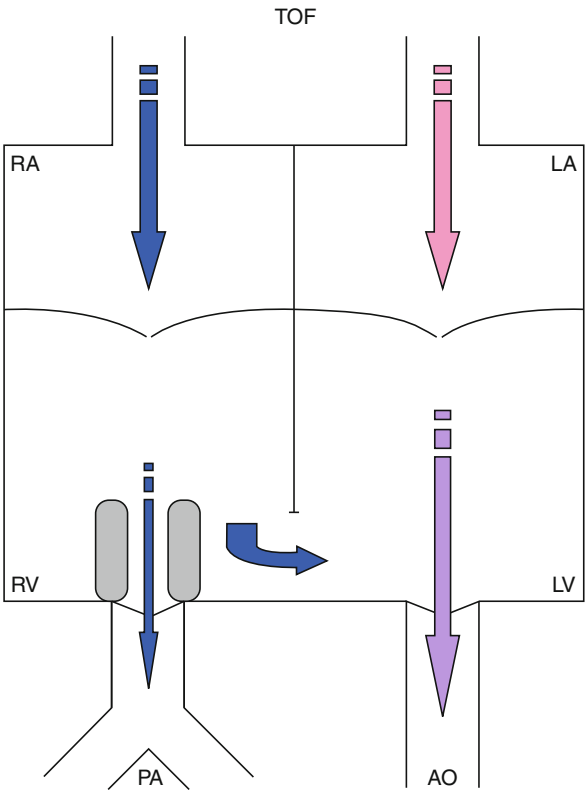

Figure 249.1
In tetralogy of Fallot, pulmonary blood flow is restricted, resulting in variable right to left shunting across the ventricular septal defect (*blue curved arrow*). *RA* right atrium, *RV* right ventricle, *LA* left atrium, *LV* left ventricle

Clinical Manifestations

The clinical manifestations of tetralogy of Fallot are determined by the degree of right ventricular outflow obstruction. Severe obstruction results in cyanosis typically recognized in the neonatal period. Tetralogy with more modest obstruction may be diagnosed secondary to the associated murmur with cyanosis being less evident. Patients with "pink" tetralogy of Fallot may develop symptoms of pulmonary overcirculation (e.g., tachypnea, failure to thrive).

One unique clinical manifestation of tetralogy of Fallot (or lesions of similar physiology) is the so-called hypercyanotic or "tet-spell." While there remains debate about the precise etiology of this clinical phenomenon, the net effect is a sudden and self-propagating imbalance between pulmonary and systemic vascular resistance that favors flow of deoxygenated blood across the ventricular septal defect into the systemic circulation, resulting in profound cyanosis and less commonly loss of consciousness, and even brain injury or death. Effective treatment measures are aimed at restoring balance between the systemic and pulmonary circulations by increasing systemic vascular resistance (knee to chest positioning, alpha receptor agonists) and lowering pulmonary vascular resistance (beta-blockers, morphine).

Figure 249.2
The diminutive size of the main pulmonary artery and the right ventricular hypertrophy contribute to create the "boot-shaped" heart appearance on chest X-ray in tetralogy of Fallot

Diagnosis

Physical exam demonstrates a murmur characteristic of pulmonary outflow obstruction (ejection type crescendo-decrescendo, best heard at the left upper sternal border). In most cases, the VSD is large and unrestrictive and does not contribute significantly to the murmur as there is equalization of pressure between the ventricles. The second heart sound is often single as the pulmonic valve component of the second heart sound is usually soft or inaudible. The presence of cyanosis is quite variable and, as discussed above, dependent on the degree of right ventricular outflow tract obstruction. Electrocardiographic findings may include right axis deviation and right ventricular hypertrophy. Given the natural right dominance of the newborn electrocardiograms, these findings may be less apparent in this setting. Chest X-ray may be normal but may also reveal the classic "boot-shaped" heart (*Fig. 249.2*). This appearance is created by a diminutive main pulmonary artery shadow and an upturning of the left ventricular apex, which is seen in the setting of right ventricular hypertrophy. Definitive diagnosis can be made by echocardiography which will identify the cardinal features of this disorder. Diagnosis can also be made by prenatal ultrasound (*Fig. 249.3*). Cardiac catheterization is reserved for select cases to better define specific details such as the integrity and adequacy of the pulmonary arteries and define the presence of aorta to pulmonary collaterals, particularly in the setting of complete or near atresia of the pulmonary valve. Catheterization can also be used to define the coronary anatomy, which can have important implications for surgical intervention.

Differential Diagnosis

The differential diagnosis of tetralogy of Fallot includes other forms of cyanotic congenital heart disease associated with a murmur, including isolated pulmonary stenosis and double outlet right ventricle with tetralogy-like physiology. For more detailed discussion of noncardiac differential diagnosis, see "Overview".

Treatment

The initial management of tetralogy of Fallot depends on the severity of the lesion and in particular the adequacy of pulmonary blood flow. In some cases, adequate pulmonary blood flow in the newborn period will require prostaglandin

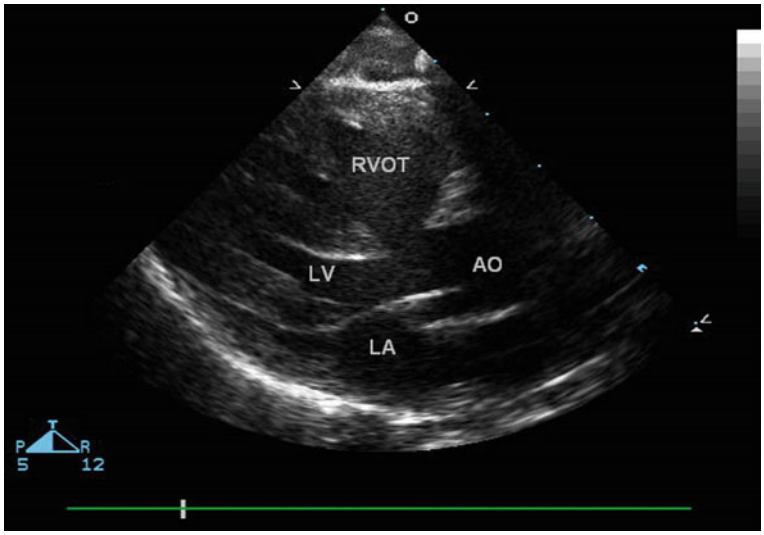

Figure 249.3
This still frame two-dimensional echocardiogram image demonstrates several of the salient features of tetralogy of Fallot, including the ventricular septal defect with the aorta overriding it, and the hypertrophied right ventricle. *LA* left atrium, *LV* left ventricle, *AO* aorta, *RVOT* right ventricular outflow tract

infusion to maintain patency of the ductus arteriosus. Surgical correction is necessary for optimal outcome. The timing of surgical repair and the use of a staged approach vary by institution, the severity of the lesion, and the size and age of the patient. In some centers, a complete repair is performed in the neonatal period. More commonly, complete repair is performed between 3 and 6 months of age. In a staged repair, the initial operation is performed to establish a reliable source of pulmonary blood flow, usually in the form of a shunt from the aorta to the pulmonary artery. Complete repair involves relief of right ventricular outflow obstruction and closure of the ventricular septal defect. When the pulmonary valve itself contributes significantly to the right ventricular outflow tract obstruction, a "transannular" patch-type repair is required which alleviates the obstruction but renders the valve incompetent. In some cases, an artificial connection between the right ventricle and pulmonary arteries is created using a conduit. If at all possible, the right ventricular outflow tract and pulmonary valves are preserved and a "valve-sparing" repair is performed.

Prognosis

The prognosis of unrepaired tetralogy of Fallot is poor. The modified prognosis of repaired tetralogy of Fallot varies with the severity of the underlying condition, the type of repair, patient age at the time of repair, and the presence of extra-cardiac anomalies. The overall 30 year actuarial survival rates of patients after repair of tetralogy of Fallot are impressive at 90%. Late death, when it occurs, is most often sudden. Less commonly, it may be due to congestive heart failure. Recent efforts have been directed at improving our understanding of who is at risk for late sudden death and how that risk can be modified. Perhaps the most important result of these efforts is understanding that the pulmonary valve insufficiency, which results from the transannular patch type of repair, is associated with late adverse clinical outcomes. In patients that demonstrate the adverse effects of long-standing pulmonary insufficiency, it is hoped that timely pulmonary valve replacement will reduce the associated risks, though this remains unproven.

Prevention

It is presently not possible to specifically prevent tetralogy of Fallot. Please see "Overview" of cyanotic congenital heart disease for a more general discussion of preventing congenital heart disease.

Transposition of the Great Vessels

Definition/Classification

Transposition of the great vessels is defined as ventriculoarterial discordance. This, simply stated, means that

the pulmonary trunk arises off of the morphologic left ventricle and the aorta arises off of the morphologic right ventricle. This malposition of the great vessels occurs in the setting of normal arrangements of the atria and ventricles. Often this form of transposition will be referred to as D-transposition (or D-TGA) in which the "D" is used to describe the abnormal relative positions between the aorta and main pulmonary artery. Transposition of the great arteries can be further classified as simple or complex based on the absence or presence of a coexisting congenital heart defects such as a ventricular septal defect, left ventricular outflow tract obstruction, aortic arch anomalies, and anomalous venous systemic connection. Discussion here will be focused on simple uncorrected transposition of the great vessels. Transposition, like tetralogy of Fallot, is classified as a conotruncal malformation. In contrast to tetralogy of Fallot, transposition represents a cyanotic congenital heart lesion with normal or "too much" pulmonary blood flow (see "Overview").

Etiology

The etiology of transposition of the great arteries is unknown. As stated above, transposition is a conotruncal malformation, but unlike truncus arteriosus and tetralogy of Fallot, its association with DiGeorge syndrome and 22q11 deletion is believed to be uncommon. More recently, case reports of micro-deletions in chromosome 22q11.2 in patients with transposition of the great vessels have been published. Though syndromic involvement is rare, a familial risk in transposition has been identified, again suggesting the involvement of non-Mendelian/nonchromosomal genetic variants in the etiology of this disorder. Fetal environmental factors such as maternal hormone imbalance have been suggested but are not widely accepted. The embryologic aberrancy that results in the transposition malformation is also uncertain. Like tetralogy of Fallot, defective conotruncal development is implicated. In transposition of the great vessels, some investigators believe there is failure of the normal balanced regression and enlargement of the tissue below the aortic and pulmonary valves, respectively. This results in abnormal anterior and rightward displacement of the aortic valve, placing it over the right ventricle and posterior leftward displacement of the pulmonary valve positioning it over the left ventricle. Research in the embryology of transposition is ongoing and is the topic of a number of reviews.

Epidemiology

The incidence of transposition of the great vessels is approximately 0.3 per 1,000 live births. It is present in approximately 4% (2–9%) of infants born with congenital heart disease. It is the most common cyanotic lesion diagnosed in the newborn period. There is a male predominance of unclear etiology.

Pathology/Pathophysiology

In transposition of the great vessels, the morphologic right atrium receives the oxygen depleted systemic venous return. This blue blood is passed through the tricuspid valve into the morphologic right ventricle from which it is pumped into the systemic circulation through the aorta. Oxygenated pulmonary venous return is conveyed from the morphologic left atrium through the mitral valve into the morphologic left ventricle where is it pumped into the pulmonary circulation via the pulmonary artery. In this way, the pulmonary and systemic circulations function in parallel rather than in series. In simple transposition of the great vessels, effective blood flow (oxygenated blood entering the systemic circulation, deoxygenated blood entering the pulmonary circulation) is that small portion of the total circulation that crosses the atrial septum, bronchopulmonary collaterals and, if present, the patent ductus arteriosus (*Fig. 249.4*). It is this mixing that allows survival in the postnatal state. So while total pulmonary blood flow in this lesion is not limited and over time is in excess, *effective* pulmonary blood flow (where deoxygenated blood in presented to the pulmonary circulation) is severely limited with obligatory cyanosis resulting.

Clinical Manifestations

Patients with simple transposition of the great vessels usually present in the first hours to days of life with cyanosis. Unless the cyanosis is profound, the infants may exhibit tachypnea but are typically not in distress. Infants are usually normal in size, and most infants appear otherwise normal. If the atrial septum is restrictive and/or the ductus arteriosus is small or closed, infants will be profoundly cyanotic and manifest the effects of severe oxygen deprivation to the tissues (hypoxemia, acidosis, lethargy, hypotonia). In these situations, urgent restoration of ductal patency and/or enlargement or creation of a patent foramen ovale may be lifesaving (see "Treatment").

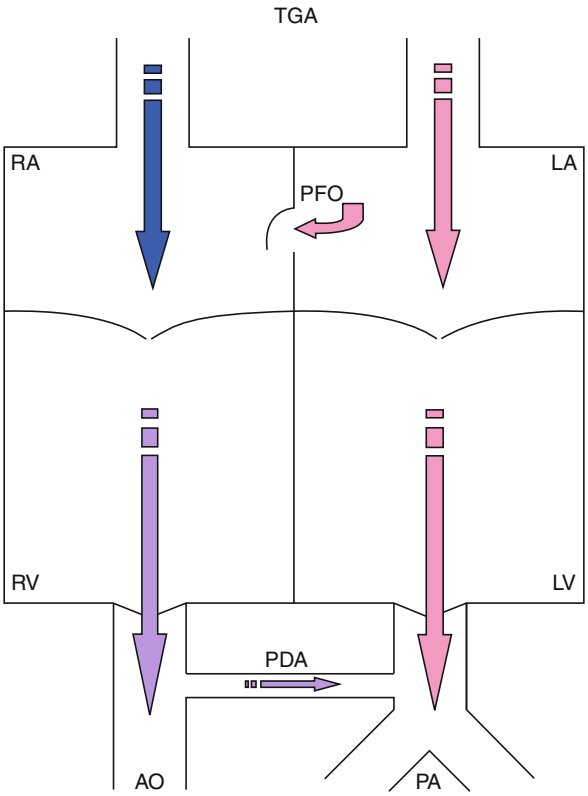

Figure 249.4
In transposition of the great vessels, effective pulmonary blood flow is severely limited (represented by PDA flow arrow). Oxygenated blood is delivered to the pulmonary circulation and deoxygenated blood is delivered to the systemic circulation. *RA* right atrium, *RV* right ventricle, *LA* left atrium, *LV* left ventricle, *PFO* patent foramen ovale, *PDA* patent ductus arteriosus

Diagnosis

Physical exam generally reveals evidence of central cyanosis. A murmur is not typical in simple transposition. Tachypnea without distress is common. Infants with an adequate atrial communication and/or patent ductus arteriosus may develop signs of congestive heart failure as pulmonary vascular resistance falls over the first few weeks of life. As stated above, the infant is usually non-dysmorphic. Electrocardiographic findings are nonspecific, especially in the newborn. Chest radiography is often normal in the first few days of life but may reveal the so-called egg on a string appearance due to the altered relationship of the great vessels and the resulting change in the mediastinal shadow (*Fig. 249.5*). Over time, as pulmonary vascular resistance and total pulmonary

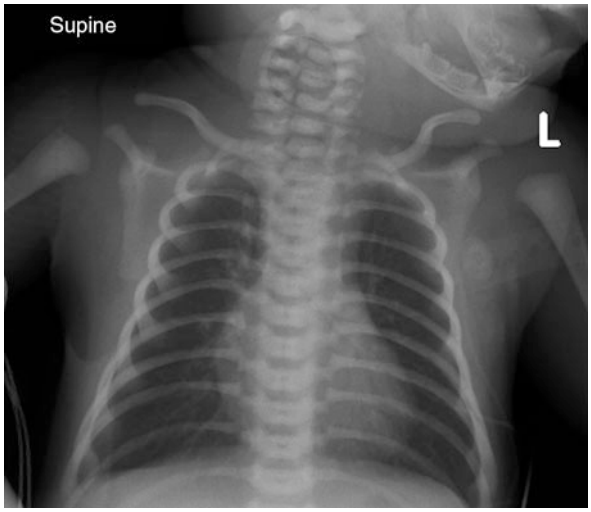

Figure 249.5
The superimposition of the aorta and pulmonary arteries creates a relatively narrow mediastinal shadow and results in an "egg on a string" appearance on chest X-ray in transposition of the great vessels

blood flow, the chest X-ray will show prominent pulmonary vascular markings and cardiomegaly. Echocardiography is the diagnostic modality of choice and can quickly and accurately make the diagnosis demonstrating the pulmonary artery arising from the left ventricle and the aorta from the right ventricle (*Fig. 249.6*). It also determines the status of the ductus arteriosus and foramen ovale. Echocardiography can also be used to guide percutaneous balloon atrial septostomy (BAS) (see "Treatment"). Echocardiography is also useful in delineating the coronary anatomy which can have important implications in the repair. Due to improved obstetric screening practices, transposition of the great vessels is increasingly diagnosed by prenatal echocardiography. Diagnostic cardiac catheterization is not typically performed in simple transposition unless the coronary anatomy is inadequately defined by echocardiography. In some centers, the BAS procedure is preferentially performed in the catheterization laboratory (see "Treatment").

Differential Diagnosis

The differential diagnosis of simple transposition includes other forms of cyanotic congenital heart disease that lack a murmur such as pulmonary atresia with intact ventricular septum or total anomalous pulmonary venous

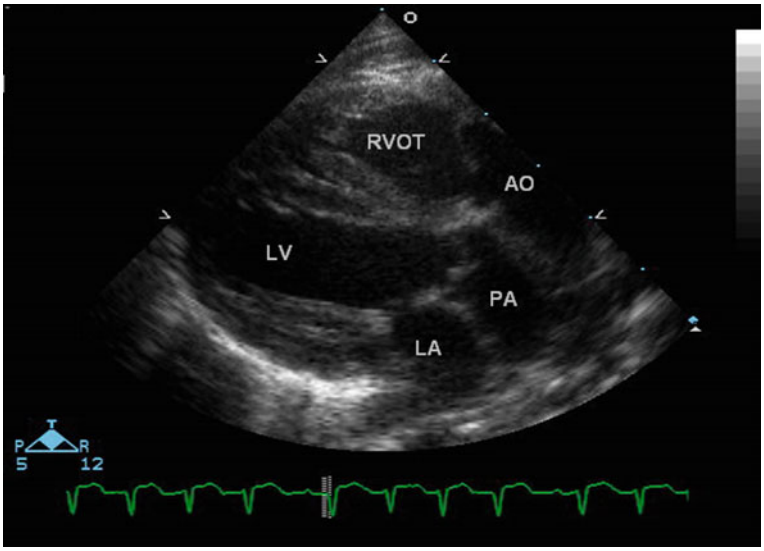

Figure 249.6
This still frame two-dimensional echocardiogram image demonstrates side-by-side great vessels – one of the echocardiographic hallmarks of transposition of the great vessels. *LA* left atrium, *LV* left ventricle, *AO* aorta, *RVOT* right ventricular outflow tract, *PA* pulmonary artery

connections. See "Overview" for discussion of noncardiac differential diagnoses.

Treatment

Initial treatment involves stabilization, correction of acidosis if present, and measures to improve effective pulmonary blood flow. The latter often involves enlarging the atrial level communication by performing a procedure known as the balloon atrial septostomy (BAS). This procedure, pioneered in the 1960s, involves placing a balloon tipped catheter through an existing but inadequate patent foramen ovale. Access to the systemic venous circulation is generally obtained through the umbilical or femoral vein. Once placed into the left atrium, the balloon is inflated with saline and pulled briskly through the patent foramen ovale with the intent to tear the relatively delicate portion of the atrial septum. Though still widely practiced, the safety of this technique has be called into question after a study demonstrated an increased incidence of silent cerebral emboli in infants having undergone BAS. Prostaglandin infusion is commonly used to restore or enhance ductal patency, though it can unfavorably alter tissue properties, rendering the tissue soft and friable and making its use unpopular with some congenital heart surgeons.

Definitive treatment of transposition of the great vessels requires a surgical intervention. Historically, surgical efforts for this condition involved an "*atrial* switch" procedure in which the atrial septum was removed and systemic venous return was baffled to the left ventricle. Pulmonary venous return was, in turn, routed to the right ventricle. Though this approach (often referred to using the eponyms "Senning" or "Mustard" procedure) restores pulmonary and systemic circulation in series, it leaves the right ventricle pumping to the systemic circulation and required extensive atrial reconstruction. Concerns over the adverse late sequela of the atrial switch approach led to a renewed interest in a more physiologic correction strategy: the arterial switch operation. This correction involves transecting the great vessels and reconnecting them to the appropriate ventricular chamber. It avoids the extensive atrial suture lines and baffle construction inherent in the atrial switch procedure and leaves the left ventricle pumping to the systemic circulation. Improved bypass and surgical technique made this strategy a reality in 1975 as first reported by Jatene and colleagues. Since this initial report, there have been a number of important modifications to the arterial switch procedure, and it has became the standard of care in the surgical treatment of transposition of the great vessels.

Prognosis

The prognosis of unrepaired transposition of the great arteries is dismal with >80% of individuals succumbing before their first birthday. The surgically modified natural history of transposition depends largely on the operative approach. Following an atrial switch type repair, the early and midterm prognosis is quite favorable, but there are a number of important late sequela, including arrhythmias, heart failure, and sudden death. Due to its relatively recent implementation as the treatment of choice for simple transposition of the great vessels, data on the long-term outcome of patients undergoing the arterial switch operation is limited. Short- and midterm results appear to be quite promising with relatively infrequent need for reoperation, minimal arrhythmia burden, and good quality of life. Despite these encouraging findings, long-term issues with risk of coronary artery disease and dysfunction of the neoaortic valve after the arterial switch operation will require ongoing assessment.

Prevention

Prevention of transposition of the great vessels is not currently possible. Perhaps the best that can be hoped for is that prenatal detection of transposition of the great arteries might prevent some of the early adverse outcomes associated with missed or late diagnosis, but detection rates remain low and impact on postnatal care remains unclear.

Truncus Arteriosus

Definition/Classification

The congenital heart lesion truncus arteriosus is another form of conotruncal abnormality defined by the presence of a single outlet vessel leaving the heart that supplies the systemic, coronary, and pulmonary circulations. A ventricular septal defect is invariably present and the common trunk overrides the ventricular septum. There should be no remnant of a pulmonary valve or main pulmonary artery connected to the heart. Two similar classification schemes have been described based on the arrangement of the pulmonary arteries arising off the aorta, but neither has significant impact on the basic pathophysiology.

Etiology

The etiology of truncus arteriosus is unknown. Approximately one-third of patients with truncus arteriosus will have a 22q11 deletion. Unlike transposition of the great vessels, syndromic involvement is fairly common with 32% of infants, with truncus arteriosus having multiple associated abnormalities (distinct from 22q11) according to one population-based study. Environmental factors contributing to the malformation of truncus arteriosus are not common, though some risk factors have been reported. There is a 6–12-fold increase in risk of truncus arteriosus in infants of a diabetic mother. Prenatal exposure to retinoic acid may also be a risk factor for the development of conotruncal malformations such as truncus arteriosus. The precise embryologic disturbance that results in truncus arteriosus is not known. At its most basic level, this perturbation of normal development involves the failure of the normal embryonic truncus arteriosus to partition into the pulmonary and aortic roots and associated semilunar valves. Also, since this process of septation contributes to the formation of the superior portion of the ventricular septum, the characteristic ventricular septal defect results. This topic is the subject of a detailed discussion and review.

Epidemiology

Truncus arteriosus is one of the rarer forms of cyanotic congenital heart disease with an estimated incidence of 0.1 per 1,000 live births. There is no gender predilection.

Pathology/Pathophysiology

In truncus arteriosus, the entire cardiac output is directed out of the heart through a common trunk which branches proximally to give off the coronary circulation followed by the pulmonary circulation, and finally the remainder of the systemic circulation in succession (Fig. 249.7). Because the pulmonary and systemic circulations occur in parallel, they are subject to competitive flow with the distribution of flow typically being determined by the relative resistances within each circuit. In the immediate newborn period, the pulmonary vascular resistance is high and the relative amount of pulmonary blood flow may be normal to only slightly increased. With the expected fall in pulmonary vascular resistance and increase in the systemic vascular resistance during parturition, the relative proportion of

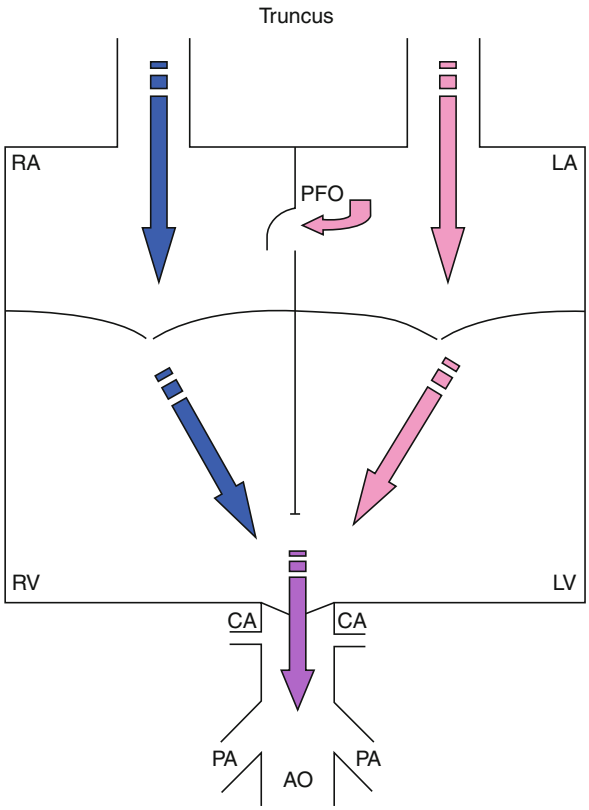

Figure 249.7
In truncus arteriosus, there is mixing of oxygenated and deoxygenated blood that exits the ventricular chambers via a common arterial trunk. *RA* right atrium, *RV* right ventricle, *LA* left atrium, *LV* left ventricle, *PFO* patent foramen ovale, *CA* coronary artery, *PA* pulmonary artery, *AO* aorta

pulmonary to systemic blood flow can increase rapidly. This can produce an inordinate work load on the newborn heart and lead to relatively early congestive heart failure, especially in conjunction with a regurgitant or stenotic truncal valve. Because the systemic and pulmonary circulations are in parallel, the oxygen saturations will rise as the proportion of pulmonary blood flow increases. Assuming unobstructed pulmonary arteries, the systemic blood pressure is transmitted to the pulmonary arterial bed. The increased flow and pressure is a recipe for pulmonary vascular disease, which can develop in as little as 6 months, if the lesion goes unrepaired.

Clinical Manifestations

Infants with truncus arteriosus are typically discovered in the first few weeks of life. In the first week of life, they may display mild cyanosis but otherwise appear well. Over the first couple of weeks, as pulmonary vascular resistance falls and the proportion of pulmonary to systemic blood flow increases, cyanosis improves, but signs and symptoms of congestive heart failure due to volume overload ensue, including tachypnea, increased work of breathing, excessive diaphoresis, and failure to thrive. The presence of significant truncal valve regurgitation will result in more rapid development of congestive heart failure and the associated symptoms.

Diagnosis

In the first weeks of life, physical examination of the infant with truncus arteriosus will reveal bounding pulses, a systolic flow murmur, and often a systolic ejection click created by the abnormal truncal valve, in addition to the signs and symptoms of congestive heart failure (outlined above). The precordial activity is increased. If the truncal valve is stenotic or regurgitant, a murmur will be present at birth, and this may lead to earlier diagnosis. Electrocardiography may show evidence of biventricular hypertrophy, though it may be normal in the first couple of days of life. Chest radiography at the time of presentation typically reveals cardiomegaly and increased pulmonary vascular markings. A right aortic arch (present in up to one-third of individuals with truncus arteriosus) in this setting should lead one to suspect truncus arteriosus. As with the other forms of cyanotic congenital heart disease, the diagnosis of truncus arteriosus is typically confirmed with echocardiography (*Fig. 249.8*). In most cases, accurate assessment of the pulmonary artery origins, the function of the truncal valve, coronary anatomy, and the continuity and sidedness of the aortic arch can be well established by echocardiography. Like other forms of congenital heart disease involving the conotruncus, prenatal diagnosis is also possible. Diagnostic cardiac catheterization is not typically performed for patients with truncus arteriosus unless the aortic arch, pulmonary artery, or coronary anatomy is inadequately defined by echocardiography. In the rare patient diagnosed beyond early infancy, cardiac catheterization can be performed to determine the pulmonary vascular resistance.

Differential Diagnosis

The differential diagnosis of truncus arteriosus includes other forms of congenital heart disease that produce mild cyanosis and congestive heart failure, including aorticopulmonary window, certain forms of double-outlet right ventricle, tetralogy of Fallot with pulmonary atresia, and certain forms of univentricular hearts.

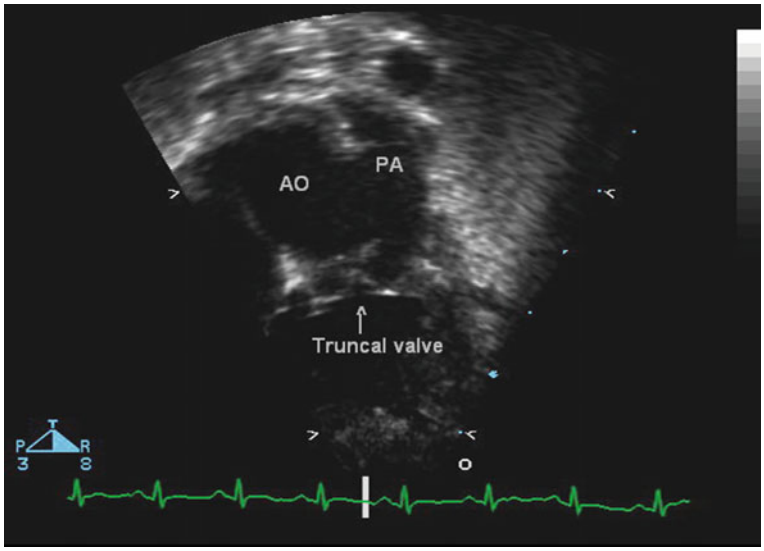

Figure 249.8
This still frame two-dimensional echocardiogram image demonstrates the proximal truncal root dividing into the aorta and pulmonary artery segments. *AO* aorta, *PA* pulmonary artery

Treatment

Though medical therapy, in the form of digoxin and diuretics, can be used to mitigate heart-failure symptoms in the short term, surgical therapy is required to avoid dismal outcome in these patients. In many centers, the surgical correction of truncus arteriosus is performed at the time of diagnosis, in the first few weeks of life. Some centers delay repair until 2–3 months of age if symptoms of heart failure can be managed with medical therapy. Surgical correction involves closure of the ventricular septal defect in such a way that the truncal valve is positioned over the left ventricle and removing the pulmonary arteries from the aorta and connecting them by way of a conduit to the right ventricle. The material used to fashion the conduit has evolved over the years. Typically, a cryopreserved allograft is used, but due to limited availability, effective alternatives have been found. Occasionally, due to stenosis, insufficiency, or both, the truncal valve will need to be repaired or replaced.

Prognosis

For patients with truncus arteriosus, prognosis in the modern era is dependent on the function of the truncal valve, continuity of the aortic arch, and the presence of extra-cardiac malformations. Prior to surgical repair, the prognosis for truncus arteriosus was dismal, with the majority of individuals diagnosed in infancy dying before their first birthday. With introduction and refinement, repair in the newborn period and young infancy is associated with very good short- and long-term survival. Due to the need for conduit replacement and progressive deterioration of the truncal valve, most individuals will require reoperation in childhood or adolescence.

Prevention

Prevention of truncus arteriosus is not currently possible. Please see "Overview" of cyanotic congenital heart disease for a more general discussion of preventing congenital heart disease.

Total Anomalous Pulmonary Venous Connection

Definition/Classification

Total anomalous pulmonary venous connection is defined as drainage of the entirety of pulmonary venous blood flow into the systemic venous circulation. The condition may be further classified as to the location of the anomalous connection: supracardiac (above the heart) or

infracardiac, or perhaps more importantly, by the presence or absence of pulmonary venous obstruction.

Etiology

The etiology of total anomalous pulmonary venous connection is not known. Familial cases have been reported, and more recently, a candidate gene was identified in a large family with non-syndromic total anomalous pulmonary venous connection, suggesting a genetic basis in some individuals. In some cases, total anomalous pulmonary venous connection occurs as part of a pattern of malformations, such as asplenia syndrome. Environmental factors such as maternal exposure to pesticides, paint, and lead in susceptible individuals may be a risk factor in the developing fetus for this condition. In most cases, total anomalous pulmonary venous connection appears to be a sporadic, non-syndromic isolated condition. The embryologic disturbance that results in total anomalous pulmonary venous connection is abnormal obliteration or atresia of the common pulmonary vein which results in failure of the pulmonary veins to connect properly to the left atrium.

Epidemiology

Total anomalous pulmonary venous connection is among the rarest of the conditions presented in this chapter with an estimated incidence of 0.09 per 1,000 live births. For reasons that are not known, Aboriginals from Manitoba and Ontario, Canada, have a significantly higher incidence (0.282 per 1,000 live births) of isolated total anomalous pulmonary venous connection.

Pathology/Pathophysiology

In total anomalous pulmonary venous connection, oxygenated blood returning from the lungs is routed into and mixes with deoxygenated systemic venous return. This admixture of systemic and pulmonary venous flow ultimately returns through normal anatomic channels to the right atrium. It is here that the circulation splits and runs in a parallel fashion with a portion crossing an ever-present atrial septal communication into the left atrium, where it will be passed to the left ventricle and subsequently provide the systemic cardiac output. The other portion of right atrial return will proceed to the right ventricle and be pumped into the pulmonary circulation

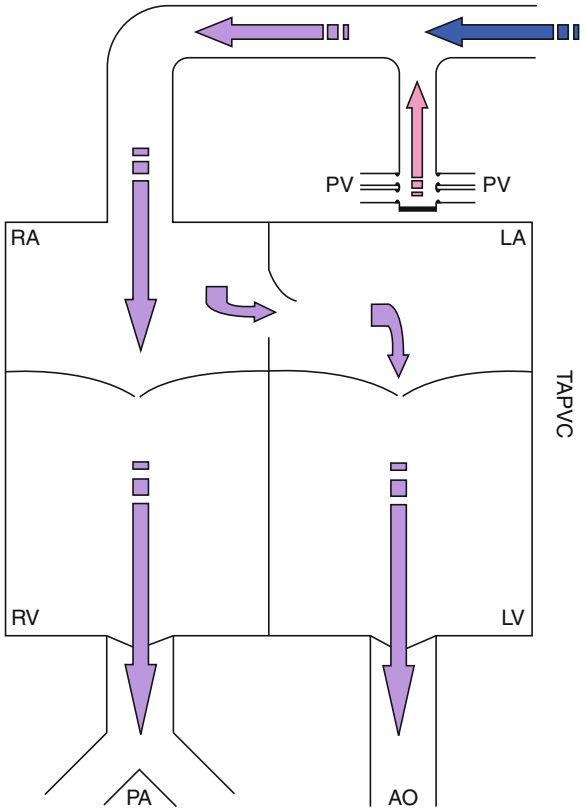

Figure 249.9
In total anomalous pulmonary venous connection, pulmonary blood flow fails to enter the left atrium but instead combines with systemic venous return in some manner, resulting in variably deoxygenated blood being ejected into the systemic circulation. The degree of cyanosis typically depends on the severity of pulmonary venous obstruction. *RA* right atrium, *RV* right ventricle, *LA* left atrium, *LV* left ventricle, *AO* aorta, *PA* pulmonary artery, *PV* pulmonary vein

(*Fig. 249.9*). The relative proportion of blood flow entering these two loops is dependent upon the relative resistance to flow in the two vascular beds. As noted below, the clinical presentation is largely determined by this factor. If there is obstruction to flow at any level in the pulmonary circulation (most commonly at the connection between the anomalous pulmonary veins and the systemic venous circulation), blood is shunted preferentially from the right atrium to the left atrium and into the systemic circulation, resulting in little pulmonary blood flow and therefore hypoxemia that is proportional to the degree of obstruction. In contrast, if the pulmonary venous connections are unobstructed, as the normal

newborn transition occurs, the pulmonary vascular resistance falls, and the proportion of pulmonary blood flow increases. In this scenario, there may be progressive pulmonary over-circulation and minimal hypoxemia. When the pulmonary venous connections to the systemic veins occur below the diaphragm, there is typically significant obstruction. In contrast, total anomalous pulmonary venous connections above the diaphragm are often unobstructed.

Clinical Manifestations

In obstructed total anomalous pulmonary venous connections, the affected infant is typically ill within the first couple of hours to days of life. The more severe the obstruction, the earlier symptoms develop. The symptoms are those of severe cyanosis, tachypnea, and respiratory distress. When the anomalous pulmonary veins are unobstructed, the presentation is usually delayed. Indeed, some cases have gone undetected until adulthood. In most cases, patients without obstruction present in the second to fourth month of life with signs of over-circulation and congestive heart failure, including failure to thrive and tachypnea.

Diagnosis

In obstructed anomalous pulmonary venous connections, the exam is notable for moderate to severe cyanosis at birth. Respiratory distress and hepatomegaly may appear within a few hours of life, although may be delayed if the ductus arteriosus remains patent. There may be a soft systolic murmur at the left lower sternal border, but often no murmur is present. The electrocardiogram typically will show right ventricular hypertrophy that may only be distinguishable from the typical RV dominance at a couple of days of age. On chest radiography, there may be evidence of pulmonary venous obstruction pattern characterized by a diffuse reticular appearance. The cardiac silhouette is typically normal is size. The echocardiogram is generally diagnostic (*Fig. 249.10*), though defining the precise pulmonary venous connections may

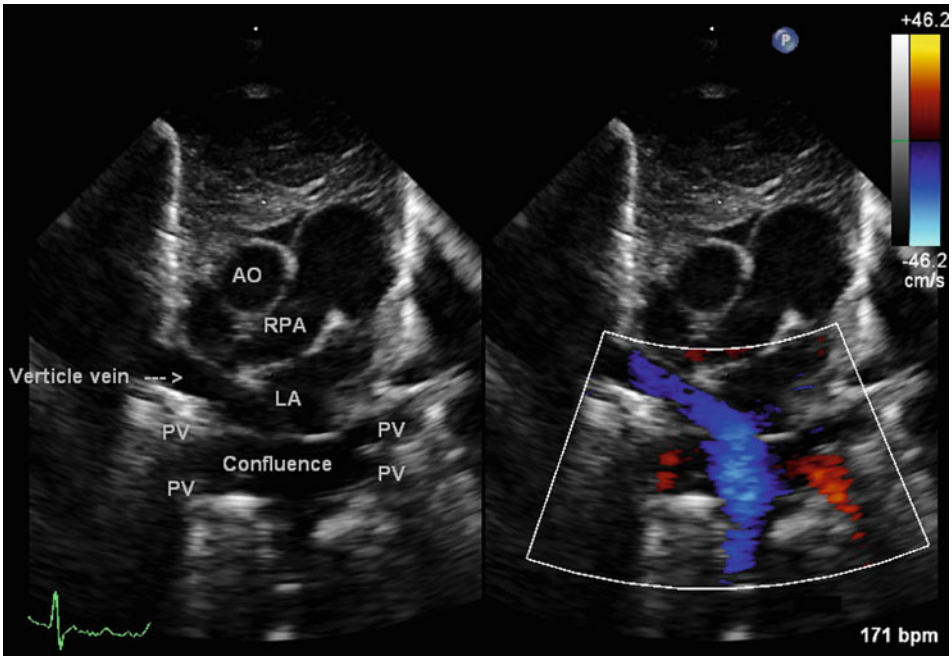

Figure 249.10

This is a still frame two-dimensional echocardiogram image with a simultaneously acquired Doppler color comparison image demonstrating four pulmonary veins entering a confluence behind and separate from the left atrium. A so-called vertical vein is seen exiting the confluence. This vertical vein will connect the pulmonary venous return to systemic venous return. *LA* left atrium, *PV* pulmonary vein, *AO* aorta, *RPA* right pulmonary artery

be difficult particularly in the setting of obstructed pulmonary veins and limited pulmonary blood flow. Historically, cardiac catheterization was performed to delineate the anatomy of the pulmonary veins. Unfortunately, cardiac catheterization carries significant risk in the ill neonate with total anomalous pulmonary venous return. More recently, other imaging techniques such as computed tomography (CT) have provided a noninvasive method for effectively defining the pulmonary venous connections when echocardiography is not sufficient.

Differential Diagnosis

The differential diagnosis of total anomalous pulmonary venous connection includes lung disease and persistent pulmonary hypertension of the newborn. Due to the associated significant cyanosis in the immediate newborn period, transposition of the great vessels can mimic the features of total anomalous pulmonary venous connection. Other congenital heart defects that can present in a similar fashion include hypoplastic left heart syndrome, though cyanosis is less prominent in this condition.

Treatment

Obstructed total anomalous pulmonary venous connection represents one of the few urgent surgical situations in the spectrum of congenital heart disease. There is a very limited role for medical management in the stabilization of the sickest infants in route to the operating room. Extracorporeal membrane oxygenation (ECMO) support has also been used in extreme cases to stabilize infants with severely obstructed anomalous venous connections prior to definitive surgical repair. Operative repair involves the reconnection of pulmonary venous return to the left atrium. The operative technique for repair of total anomalous pulmonary venous connection has evolved over the years due to the high risk of residual pulmonary vein obstruction at the repair site using traditional techniques. Toward this end, more recent surgical efforts have focused on minimizing manipulation of the pulmonary veins as much as possible using the so-called "sutureless" repair, a technique that continues to evolve.

Prognosis

The prognosis in total anomalous pulmonary venous connection is dependent upon the degree of pulmonary venous obstruction, the size of the intra-atrial communication, and the presence of associated cardiac malformations. In infants presenting shortly after birth due to obstruction, the outcome is dismal without surgical intervention. With time and improved operative techniques, the outcome of repaired total anomalous pulmonary venous connection is improving. In a recent retrospective study, the overall postoperative survival in a large single center cohort (with data collected from 1946 to 2005) was 68% at 1 year and 65% at 14 years. There was a marked improvement in operative outcomes in the modern era with a postoperative 5-year survival of 97% in patients undergoing repair since the year 2000. However, even with newer operative techniques and improved perioperative care, patients with obstructed total anomalous pulmonary venous connection requiring neonatal repair remain at high risk for mortality and need for reoperation. In addition, associated cardiac malformations, in particular, single ventricle physiology and heterotaxy are markers for poor outcome.

Prevention

Prevention of total anomalous pulmonary venous connection is not currently possible. Please see "Overview" of cyanotic congenital heart disease for a more general discussion of preventing congenital heart disease.

Pulmonary Atresia with Intact Ventricular Septum

Definition/Classification

This entity is defined by complete obstruction of the pulmonary valve. An "intact ventricular septum" is specified to distinguish this malformation from tetralogy of Fallot and related congenital heart lesions that have distinct developmental origins and physiologic properties. Attempts have been made to classify this disorder based on right ventricular size and morphology, but in practical terms, pulmonary atresia with intact ventricular septum represents a markedly heterogeneous spectrum of disease in terms of the development of the tricuspid valve and right ventricular cavity. The disorder ranges from a severe form of Ebstein's anomaly of the tricuspid valve with severe tricuspid insufficiency and cardiomegaly, to essentially isolated atresia of the pulmonary valve with otherwise normal right-heart development, to severe hypoplasia of the right ventricle and tricuspid valve. Perhaps the most important morphologic feature is the presence or absence

of right ventricular–dependent coronary circulation (see "Pathology/Pathophysiology" below).

Etiology

The etiology of pulmonary atresia with intact ventricular septum is not known. Syndromic involvement is rare, though there have been cases of pulmonary atresia with intact ventricular septum in patients with Down Syndrome. From an embryologic standpoint, pulmonary atresia intact ventricular septum is thought to occur *after* the development of the semilunar (pulmonary and aortic) valves. The process that results in obliteration of the previously formed pulmonary valve is not known. Infection and inflammation have been suggested but evidence is lacking. The degree of right ventricular hypoplasia appears to be determined by when in the developing embryo the valve becomes atretic. Not surprisingly, the earlier the disruption of normal fetal circulation, the more profound the effect on right-heart morphogenesis.

Epidemiology

Pulmonary atresia with intact ventricular septum may be the rarest of the congenital heart lesions discussed in this chapter with reported incidences ranging from 0.042 to 0.132 cases per 1,000 live births.

Pathology/Pathophysiology

In pulmonary atresia with intact ventricular septum, there is, by definition, no direct egress of blood from the pulmonary ventricle to the pulmonary arteries. Blood that enters the right ventricle must either return to the right atrium via tricuspid regurgitation or enter coronary-cameral fistulae that, if present, connect the right ventricle to the coronary circulation (*Fig. 249.11*). In most cases, the right ventricular chamber is hypoplastic to a variable extent, but in cases of an incompetent tricuspid valve (e.g., Ebstein's anomaly of the tricuspid valve), the right ventricular chamber may be normal in size or even enlarged. The development of coronary-cameral fistulae also appears to be dependent on the competency of the tricuspid valve and the pressure developed in the right ventricle. In certain situations, typically where the tricuspid valve is small and competent, the pressure in the right ventricle can exceed twice the systemic systolic blood pressure. This morphologic scenario is associated with the persistence of right ventricular sinusoids and fistulous connections to the coronary circulation. In some cases, these connections can result in abnormal coronary development, and the coronary blood flow becomes dependent on the fistulous connections from the right ventricle rather than from the aorta (i.e., right ventricular–dependent coronary circulation).

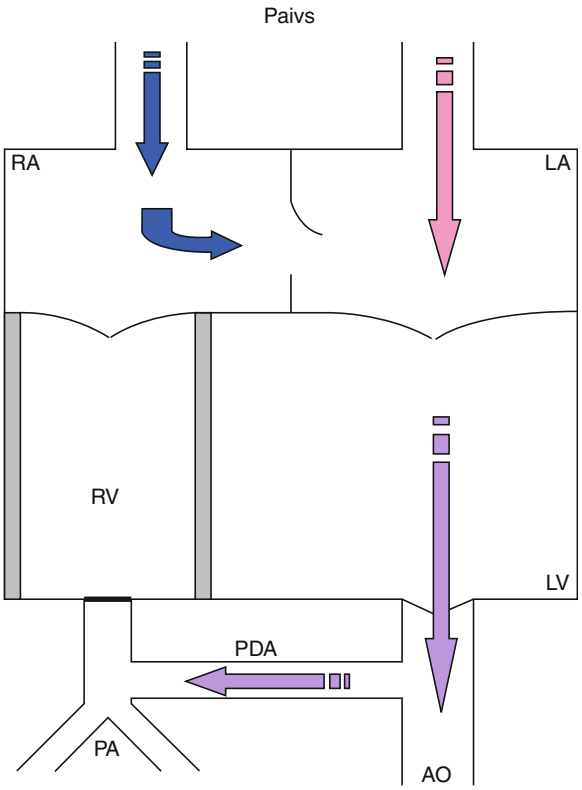

Figure 249.11
In pulmonary atresia with intact ventricular septum, pulmonary blood flow is not ejected from the right ventricle but instead is provided from systemic to pulmonary artery connections such as a patent ductus arteriosus. *RA* right atrium, *RV* right ventricle, *LA* left atrium, *LV* left ventricle, *PDA* patent ductus arteriosus

Deoxygenated systemic venous return (excluding the small amount that enters the coronary circulation from the right ventricle) must ultimately cross an ever-present atrial septal communication (usually a patent foramen ovale) and mix with oxygenated pulmonary venous return in the left atrium. From there, this admixture travels to the left ventricle where it is pumped to the systemic circulation. Pulmonary blood flow is supplied by a patent ductus arteriosus connecting the aorta to the pulmonary artery.

Clinical Manifestations

Infants with pulmonary atresia and intact ventricular septum usually appear well at birth with only minimal cyanosis. Cyanosis will generally worsen over the first 24–48 h and will become severe if the ductus arteriosus closes. Affected individuals are typically asymptomatic until severe hypoxemia develops.

Diagnosis

The typical examination of an infant with pulmonary atresia and intact ventricular septum is normal apart from mild cyanosis. There may be a systolic murmur of tricuspid insufficiency in the setting of a hypertensive right ventricle or a continuous murmur caused by a patent ductus arteriosus, but in most cases, a murmur is absent. As discussed above, syndromic involvement is uncommon, and most infants appear morphologically normal. Depending on the degree of right ventricular hypoplasia, the electrocardiogram shows evidence of left ventricular dominance uncharacteristic of a normal newborn EKG. In Ebstein's anomaly of the tricuspid valve, right atrial enlargement and/or preexcitation may be evident. There may be ST-T wave abnormalities if coronary circulation is altered. Chest radiography usually reveals a normal cardiac silhouette (except in the Ebstein's variant, in which case it may be markedly enlarged). Pulmonary vascular markings may appear normal or mildly diminished. As with the other forms of cyanotic congenital heart disease, echocardiography is diagnostic (*Fig. 249.12*) (and prenatal diagnosis through fetal echocardiography is possible). Unlike other forms of cyanotic congenital heart disease, however, cardiac catheterization plays an important diagnostic role for the detection and definition of coronary-cameral fistulae and diagnosis of important coronary structural abnormalities.

Differential Diagnosis

The differential diagnosis of pulmonary atresia with intact ventricular septum includes other forms of cyanotic congenital heart disease that lack a murmur such as transposition of the great arteries, obstructed total anomalous pulmonary venous connection, and single ventricle lesions such as tricuspid atresia.

Treatment

The initial management of the patient identified as having pulmonary atresia with intact ventricular septum centers on establishing and maintaining ductus arteriosus patency using prostaglandin E_1, as this ductal connection is the

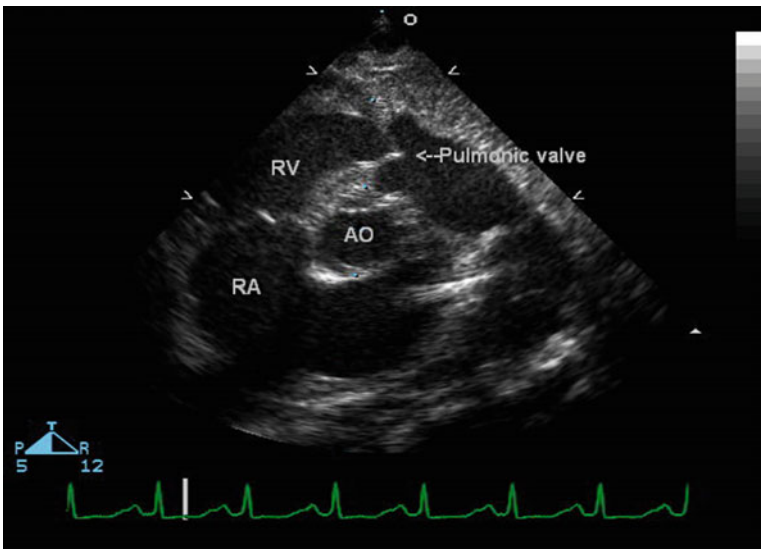

Figure 249.12
This still frame two-dimensional echocardiogram image demonstrates an atretic pulmonary valve that domes but does not open. *RA* right atrium, *RV* right ventricle, *AO* aorta

only source of pulmonary blood flow in these infants. The wide morphologic spectrum of pulmonary atresia with intact ventricular septum underscores the variability in the treatment approaches that follow. The choice of definitive treatment for pulmonary atresia with intact ventricular septum is fundamentally dependent upon the morphology and function of the tricuspid valve, the degree of right-heart hypoplasia and the presence of right ventricular–dependent coronary circulation. In patients without right ventricular–dependent coronary circulation, so-called decompression of the right ventricle through pulmonary valvotomy via surgical- or catheter-based techniques is part of the initial management. Depending on the size of the right ventricle, pulmonary blood flow may need to be augmented with a surgically created systemic to pulmonary artery shunt. In some cases, with adequately sized tricuspid valve and right ventricular growth, a two-ventricle circulation can result. In cases where the right ventricle remains inadequate for pumping the pulmonary cardiac output, patients may undergo surgical palliation in which the right ventricle is not utilized at all (i.e., complete cavopulmonary anastomosis or Fontan palliation) or is only partially utilized (i.e., "one-and-one-half ventricle" palliation) to support the pulmonary circulation. Cardiac transplantation has been suggested for infants with the most severe coronary abnormalities. The interested reader is referred to a recent comprehensive review of this complicated topic.

Prognosis

As with other forms of cyanotic congenital heart disease, prognosis is dismal without intervention. Because in the vast majority of cases pulmonary blood flow in this condition is dependent on ductal patency, most infants will die with spontaneous closure of the ductus arteriosus. With intervention, the prognosis is quite variable and not surprisingly correlates intimately with the underlying substrate and is improving over time. Despite improved perioperative care and surgical techniques, the prognosis of those at the severe ends of the spectrum (Ebstein's malformation of the tricuspid valve with severe tricuspid insufficiency and massive cardiomegaly on one side, or severe right ventricular hypoplasia with right ventricular–dependent coronary circulation on the other) remains relatively poor. In a recent retrospective analysis of a cohort of 210 patients managed in a single center, survival of patients born in the most recent birth cohort (between 1992 and 1998) had the best survival with 1-month, 1-year, and 5-year survival of 85%, 75%, and 67%, respectively (compared to 72%, 57%, and 48% of the group as a whole).

Prevention

In the true sense of the term, prevention of pulmonary atresia with intact ventricular septum is not currently possible. Small series have been reported in which fetal intervention has been attempted. Perforation and dilation of an atretic pulmonary valve in the fetus (after an initial learning curve) has shown some promising early results in altering the morphologic consequences of pulmonary atresia during fetal development and may be associated with improved right-heart growth and postnatal outcomes.

250 Obstructive Cardiac Lesions

Amy H. Schultz

Introduction

General Definition and Classification

Ordinarily, blood flows through the heart and blood vessels with great efficiency and without any significant pressure gradients across the valves or major blood vessels. Drops in pressure occur only across the resistance capillary beds. The obstructive cardiac lesions encompass any narrowing of the pathways to blood flow in the heart or major blood vessels such that a pressure gradient is generated as the blood traverses the circulation.

Obstructive lesions can be classified as congenital or acquired. The major cause of acquired valvular heart disease in childhood or young adulthood is rheumatic heart disease (Chap. 258, "Rheumatic Heart Disease/Acute Rheumatic Fever"). This chapter focuses primarily on congenital cardiac lesions.

Obstructive lesions can be classified by severity: mild, moderate, severe, or critical. The term "critical" generally refers to a lesion that is so severe that the circulation requires the ductus arteriosus to remain patent to assure stability. These lesions require intervention in the neonatal period.

Finally, in the case of obstruction in the region of the valves, the narrowing can be classified according to the level at which it occurs: the level of the valve itself ("valvular"), above the valve, below the valve, or at multiple levels. One confusing aspect of the nomenclature is in the terms "subvalvular" and "supravalvular." "Sub-" and "supra-" refer roughly to inferior and superior, respectively, such that, for example, a supravalvular mitral ring causes obstruction *proximal* to the valve (the left atrial side) as the blood flows, whereas supravalvular aortic stenosis causes obstruction *distal* to the aortic valve (in the proximal aorta), as the blood flows.

Right Heart Obstructive Lesions

Tricuspid Valve Stenosis and Atresia

The reader is referred to the chapter on *cyanotic heart disease* (Chap. 249, "Cyanotic Heart Disease"), sections on Tricuspid Atresia and Pulmonary Atresia with Intact Ventricular Septum.

Double-Chamber Right Ventricle

Definition and Classification

Double-chamber right ventricle is an entity in which abnormal muscle bundles create stenosis within the body of the right ventricle, subdividing the right ventricle into a high pressure inflow portion and low pressure outflow portion.

Etiology and Epidemiology

Anomalous muscle bundles form during development of the right ventricle. They are typically minimally obstructive in infancy, but become progressively obstructive over time. Frequently, a perimembranous ventricular septal defect and a subaortic membrane are also present. This is a relatively uncommon anomaly, occurring in a small percentage of cases of perimembranous ventricular septal defect and even less commonly as an isolated lesion.

Pathology

The anomalous muscle bundles usually run from the base of the ventricular septum, underneath the septal leaflet of the tricuspid valve, to the anterior wall of the right ventricle. There is associated right ventricular hypertrophy. If there is an associated ventricular septal defect, it can connect to either the low or high pressure chamber, but more commonly to the low pressure outflow portion of the right ventricle.

Pathophysiology

The inflow portion of the right ventricle is at high pressure, triggering the development of right ventricular hypertrophy. A mid-cavitary obstruction is present,

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_250,

leading to a significant pressure gradient between the high pressure inflow portion and the low pressure outflow portion of the right ventricle. The degree of obstruction is usually minimal in infancy and increases over time. If a ventricular septal defect is present, the magnitude and direction of shunting is determined by the size of the defect, which portion of the right ventricle it connects to, and the degree of obstruction.

Clinical Manifestations

In mild or moderate degrees of obstruction, patients are typically asymptomatic. Severe obstruction may lead to exercise intolerance or symptoms of right heart failure. Physical examination reveals a harsh systolic ejection murmur at the left lower and upper sternal borders, which may be associated with a thrill and palpable right ventricular impulse if obstruction is moderate to severe. Hepatomegaly and elevated jugular venous pulse may be present if the obstruction is severe enough to cause right heart failure. An associated ventricular septal defect may also generate a holosystolic murmur.

Diagnosis

ECG will demonstrate right ventricular hypertrophy if the obstruction is moderate to severe. Chest radiograph is likely to be normal unless a concomitant ventricular septal defect results in sufficient shunting to enlarge the heart size. Echocardiography can be used to make the diagnosis of double-chamber right ventricle by demonstrating the anomalous muscle bundles and the intracavitary gradient. Right ventricular hypertrophy may be apparent and any associated ventricular septal defect or subaortic membrane should also be documented.

Treatment

Double-chamber right ventricle is treated by surgical excision of the anomalous muscle bundles, usually via a ventriculotomy. An outflow tract patch may be required to alleviate all obstruction. Any associated ventricular septal defect or subaortic membrane is repaired at the same operation.

Prognosis

Surgical resection usually resolves the obstruction which should not recur. Long-term prognosis is excellent. Patients who have had such an operation via a ventriculotomy should be monitored for the development of ventricular arrhythmias.

Pulmonic Stenosis

Definition and Classification

Pulmonary valve stenosis is a narrowing at the level of the leaflets of the pulmonary valve. Supravalvar pulmonic stenosis is a narrowing at the level of the sinotubular junction of the pulmonary artery, just distal to the pulmonary valve. Pulmonic stenosis can be classified as mild, moderate, severe, or critical. Critical pulmonary valve stenosis presents in the neonatal period and requires patency of the ductus arteriosus to maintain adequate oxygenation. Criteria for assigning degrees of stenosis vary and are listed in *Table 250.1*. In the extreme, the pulmonary valve may be atretic; see the Chap. 249, "Cyanotic Heart Disease" for a review of Pulmonary Atresia with Intact Ventricular Septum.

Table 250.1
Various classification criteria for the severity of pulmonary stenosis

Source/indicator	Mild	Moderate	Severe
Natural history study:[a]			
• Peak systolic right ventricular to pulmonary artery pressure gradient (mmHg), at catheterization	<50	50–79	≥80
Bonow RO et al., Adult Valve Guidelines:[b]			
• Echocardiographic jet velocity (m/s)	<3 m/s	3–4 m/s	>4 m/s
• Echocardiographic peak instantaneous gradient (mmHg)	<36	36–60	>60 mmHg

[a]O'Fallon WM et al (1993) Second natural history study of congenital heart defects: materials and methods. Circulation 87(Suppl I):I4–I15
[b]Bonow RO et al (2006) ACC/AHA 2006 guidelines for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice. Circulation 114:e84–e231

Etiology and Epidemiology

Isolated pulmonary valve stenosis occurs in approximately 4 per 10,000 live births and is among the more common forms of congenital heart disease. The etiology of isolated pulmonary valve stenosis is not known. Dysplastic, thickened pulmonary valves are typically associated with Noonan syndrome. Supravalvar pulmonic stenosis is rare and often associated with a syndrome such as Noonan syndrome, Alagille syndrome, Williams syndrome, or congenital rubella syndrome; other cardiac malformations may coexist.

Pathology

Most commonly, pulmonary valve stenosis is a result of partial fusion of all three commissures of the pulmonary valve, with varying degrees of thickening of the leaflets. Bicuspid or unicuspid pulmonary valves can occur, more typically, as part of a more complex defect, such as tetralogy of Fallot. Significant thickening of all leaflets, without commissural fusion, occurs in a small percentage of patients, typically those with Noonan Syndrome. Secondary right ventricular hypertrophy, in proportion to the degree of stenosis, is present.

Supravalvar pulmonic stenosis is characterized by a narrowing at the sinotubular junction of the main pulmonary artery. There may also be associated thickening of the pulmonary valve leaflets.

Pathophysiology

Pulmonary stenosis creates a pressure gradient between the right ventricle and the pulmonary artery. The right ventricular systolic pressure is elevated in proportion to the degree of stenosis, inducing compensatory right ventricular hypertrophy. Cardiac output is maintained in all but critical degrees of stenosis, but the ability to augment cardiac output with exercise may be limited in moderate to severe stenosis. Right to left shunting across a patent foramen ovale or atrial septal defect may occur in moderate to severe pulmonary stenosis with associated prominent right ventricular hypertrophy.

In critical pulmonary valve stenosis, there is insufficient antegrade flow across the pulmonary valve. Some of the systemic venous return to the right atrium passes across the patent foramen ovale to the left atrium, maintaining systemic cardiac output, but resulting in cyanosis. Pathologic degrees of tricuspid regurgitation may be present due to the elevated right ventricular systolic pressure, which is often suprasystemic. The patent ductus arteriosus allows blood to pass from the aorta to the pulmonary artery to maintain a reasonable amount of pulmonary blood flow. If the ductus arteriosus constricts, the patient will become severely cyanotic.

Clinical Manifestations

Most patients with isolated pulmonary valve stenosis are asymptomatic and present with a murmur. Moderate to severe degrees of stenosis may lead to exertional dyspnea. Severe pulmonary stenosis may lead to cyanosis (if there is a concomitant atrial communication), exertional syncope, chest pain, and signs of right heart failure. The murmur is of a systolic ejection type, loudest at the left upper sternal border (pulmonic area) with radiation to the lung fields. The murmur becomes louder and harsher and peaks later as the degree of stenosis increases. An ejection click, which introduces the murmur, is noted in cases of valvar stenosis. The intensity of the click varies with respiration, softer in inspiration and louder in expiration. P_2 may be delayed, in proportion to the severity of the stenosis. In addition, P_2 becomes softer as the degree of obstruction increases. A palpable right ventricular impulse is present. A thrill may be palpable in the second or third left intercostal space in moderate or severe degrees of stenosis.

Neonates with critical pulmonary valve stenosis present with cyanosis and a harsh systolic ejection murmur. A separate systolic regurgitant murmur of tricuspid regurgitation may also be present. Signs of right heart failure (hepatomegaly) are also usually present.

Diagnosis

ECG demonstrates progressive degrees of right axis deviation and right ventricular hypertrophy in the setting of pulmonary valve stenosis. Chest radiographs frequently show a prominent main pulmonary artery segment due to post-stenotic dilation. Heart size is usually normal, except in severe pulmonary stenosis in which it is mildly enlarged. Decompensated severe pulmonary stenosis (with right heart failure) or critical pulmonary stenosis can demonstrate moderate to marked cardiomegaly.

Transthoracic echocardiography is the diagnostic gold standard. Careful attention must be paid to the views of the pulmonary valve and sinotubular junction to distinguish valvular from supravalvar stenosis. An estimate of the gradient can be obtained by Doppler techniques. Right

ventricular hypertrophy, in proportion to the severity of stenosis, will be apparent. The tricuspid valve function should be assessed. If mild or greater tricuspid regurgitation is present, the right ventricular systolic pressure can be estimated accurately.

Cardiac catheterization is usually reserved for situations in which echocardiography predicts that balloon valvuloplasty is indicated. Invasive hemodynamic assessment of pulmonary valve gradient is performed as part of this procedure.

Treatment

Intervention is indicated for symptomatic patients with pulmonary stenosis. Asymptomatic patients with moderate to severe pulmonary stenosis can undergo intervention electively. No intervention is necessary for mild pulmonary stenosis. Pulmonary valve stenosis may either progress or improve spontaneously in infancy, so some period of observation of patients with moderate pulmonary stenosis is indicated prior to intervention. A peak to peak gradient measured invasively in the cardiac catheterization laboratory atleast of 40–50 mmHg is typically considered an indication for intervention. Some practitioners may also employ an intervention threshold of right ventricular systolic pressure >75% of systemic blood pressure.

Balloon pulmonary valvuloplasty via cardiac catheterization has become the standard treatment for pulmonary valve stenosis, although it is generally not effective for supravalvular pulmonic stenosis (see Chap. 253, "Interventional Cardiology"). Inflation of the balloon either splits the fused commissures or results in a tear of the leaflet. Some degree of pulmonary valve insufficiency frequently results. Balloon valvuloplasty is highly efficacious, except in cases of dysplastic pulmonary valve with thickened leaflets but without significant commissural fusion. Supravalvar pulmonic stenosis and pulmonary valve stenosis due to dysplastic leaflets not responsive to balloon dilation are treated surgically. Thickened leaflets may be excised, and narrowing at the sinotubular junction is augmented with a patch.

Prognosis

Mild pulmonary stenosis has an excellent long-term prognosis without intervention. Outcomes after balloon pulmonary valvuloplasty are also very good. Early recurrence of significant obstruction occurs in 8–10% of patients and is often amenable to repeat balloon valvuloplasty. Late recurrence of pulmonary stenosis is rare (1–2%). Actuarial freedom from reintervention is 84% at 10 years. Some degree of pulmonary insufficiency occurs in 40–90% of patients and, to date, rarely requires intervention. However, as balloon pulmonary valvuloplasty was only introduced in 1982, further data needs to be collected as to the frequency of very late (decades) need for reintervention for pulmonary insufficiency. Endocarditis is rare in pulmonary stenosis.

Branch Pulmonary Artery Stenosis

Definition and Classification

Narrowing of the branch pulmonary arteries, also known as peripheral pulmonic stenosis (PPS), can be physiologic, which is common in newborns, or pathologic. Pathologic PPS typically occurs in association with specific syndromes which frequently include additional cardiac abnormalities.

Etiology and Epidemiology

Physiologic peripheral pulmonic stenosis occurs in about 5% of term newborns and a higher percentage of premature newborns. In the fetal circulation, a reduced amount of flow passes through the branch pulmonary arteries, as most of the flow from the main pulmonary artery is directed across the ductus arteriosus to the descending aorta. Postnatally, a relatively acute angle between the main and branch pulmonary arteries is present, and there is a size discrepancy between the relatively large main pulmonary artery and the smaller branch pulmonary arteries.

Pathologic branch pulmonary artery stenosis occurs in the setting of several different syndromes, listed in *Table 250.2*.

Pathology

In physiologic peripheral pulmonic stenosis, structures are fundamentally normal. The size discrepancy between the main and branch pulmonary arteries and the associated small pressure gradient typically resolve by 6 months of age. In pathologic forms, the branch pulmonary arteries may be diffusely hypoplastic or have multiple discrete stenoses. Discussion of the histopathologic findings in the various syndromes is beyond the scope of this chapter.

Table 250.2
Syndromes associated with pathologic branch pulmonary artery stenosis

Syndrome	Etiology	Incidence	Associated cardiovascular abnormalities
Congenital rubella syndrome	Maternal infection with rubella virus during pregnancy	US: 0–2 total cases reported per year Without vaccination program: 0.2–2:1,000 live births Effective vaccination programs exist in the Americas and Europe; Southeast Asia and Africa have little rubella vaccine coverage.	Patent ductus arteriosus Pulmonary valve stenosis Atrial septal defect Coarctation Systemic arterial stenoses More complex congenital heart disease
Alagille syndrome	JAG1 mutations (90%) Chromosome 20 microdeletion (7%) NOTCH2 mutation (rare)	1:20,000–1:70,000	Tetralogy of Fallot Ventricular septal defect Atrial septal defect Aortic stenosis Coarctation of the Aorta
Williams syndrome	Chromosome 7q11.2 microdeletion	1:7,500–1:20,000	Supravalvar aortic stenosis Supravalvar pulmonic stenosis Coarctation/arch hypoplasia
Elastin gene mutation (familial supravalvar aortic stenosis)	ELN mutation, loss of one functional copy	Unknown	Same as above for Williams syndrome
Noonan syndrome	Mutations in: PTPN11 (50%) SOS1 (20%) RAF1 (10–15%) KRAS (5%) Unknown (10–15%)	1:1,000–1:2,500	Pulmonary valve stenosis Hypertrophic cardiomyopathy Atrial septal defect Aortic valve stenosis Coarctation of the aorta
Cutis laxa	Mutation in one of several genes that are involved in assembly of elastic fibers including ELN and FBLN5.	Rare	Supravalvar aortic stenosis
Ehlers–Danlos syndrome	Mutations in multiple genes for different types of collagen or collagen-associated proteins	1:5,000	Mitral valve prolapse Coarctation of the aorta

Pathophysiology

Physiologic PPS imposes a nonsignificant pressure load on the right ventricle as the gradients are typically minimal. This mild degree of stenosis typically resolves spontaneously by 6 months of age.

In pathologic forms of branch pulmonary artery stenosis, the degree of stenosis is variable, ranging from mild to severe. In moderate to severe cases, significant pressure load is imposed on the right ventricle, resulting in compensatory hypertrophy. Right heart failure can result from severe cases.

Clinical Manifestations

Physiologic PPS is usually identified by a blowing systolic ejection murmur heard at the left upper sternal border, radiating to both axillae and the back. The remainder of the cardiac physical examination should be normal and there should be no history of cardiovascular symptoms.

Pathologic branch pulmonary artery stenosis will be asymptomatic if of mild degree. Moderate obstruction may affect exercise performance. Severe obstruction may lead to symptoms of right heart failure, dyspnea, or exercise intolerance. The physical examination reveals

a systolic ejection murmur in the pulmonic area, radiating to the back and axillae. If the obstruction is more severe, the murmur will be harsher and louder and may take on a continuous quality over the lung fields. The pulmonic component of the second heart sound (P_2) may be delayed, leading to wide splitting with normal to increased intensity of P_2. In the setting of right heart failure, hepatomegaly and elevation of the jugular venous pulse will be observed.

Diagnosis

Physiologic PPS can be diagnosed from birth up to about 6 months of age, but most typically in the first 3–4 months of life. Evidence of branch pulmonary artery stenosis persisting beyond 6 months of life should be considered pathologic.

The ECG is normal in physiologic PPS and mild degrees of pathologic stenosis, but typically demonstrates right ventricular hypertrophy in moderate to severe obstruction. A significant incidence of left axis deviation has been reported in congenital rubella syndrome and Noonan syndrome. Chest radiography is normal in physiologic PPS and mild to moderate degrees of pathologic stenosis. With severe branch pulmonary artery stenosis, some enlargement of the right atrium and right ventricle may be apparent.

Echocardiography in physiologic PPS typically identifies mild flow acceleration to 1.5–2.2 m/s in the proximal branch pulmonary arteries in the absence of any other cardiac abnormality. In pathologic branch pulmonary artery stenosis, the proximal portions of the branch pulmonary arteries can be measured and may be small for body surface area. Flow acceleration can be identified and may be greater in velocity than in physiologic PPS. In moderate to severe obstruction, right ventricular hypertrophy is observed. Right ventricular systolic pressure can be estimated from the velocity of the tricuspid regurgitation jet.

Treatment

Physiologic PPS requires no treatment and resolves spontaneously. Mild pathologic branch pulmonary artery stenosis does not require intervention. Moderate to severe degrees of branch pulmonary artery stenosis can be treated in the cardiac catheterization laboratory with balloon dilation and/or vascular stent implantation (see Chap. 253, "Interventional Cardiology"). Surgical augmentation of the main and proximal branch pulmonary arteries is possible up to the hilum of the lung.

Prognosis

Physiologic PPS resolves spontaneously, typically by 6 months of age. Pathologic branch pulmonary artery stenosis may either improve spontaneously with time (in the case of mild to moderate disease) or may be progressive (typically in the setting of severe disease). Severe progressive disease may lead to right heart failure and death.

Left Heart Obstructive Lesions

Cor Triatriatum

Definition and Classification

Cor triatriatum is a rare congenital anomaly in which the left atrium is partitioned into two chambers by a membrane. There is an orifice in the membrane of varying size. The more superior chamber receives the pulmonary veins. The left atrial appendage and the foramen ovale are inferior to the membrane.

Etiology and Epidemiology

During formation of the heart, the pulmonary veins connect to the heart by absorption of a common pulmonary vein into the left atrium. The anomaly of cor triatriatum is thought to result from incomplete absorption of the common pulmonary vein and is a rare entity.

Pathophysiology

Pulmonary venous blood returns from the lungs to the superior chamber and then passes through the orifice in the membrane to reach the inferior chamber. Depending on the size of the orifice relative to the size of the patient, varying degrees of obstruction result at the level of the membrane. The pressure in the pulmonary veins is elevated, and if the obstruction is severe, there may be secondary pulmonary arterial hypertension.

Clinical Manifestations

The more severe the obstruction, the earlier in life the lesion will present. If the obstruction is relatively mild, the patient may present in childhood or beyond with a diastolic inflow murmur at the apex or exercise intolerance. More severe obstruction will present with dyspnea and failure to thrive early in life. Physical examination may

reveal tachypnea, a diastolic inflow murmur over the apex, a loud single second heart sound indicative of pulmonary hypertension, and signs of heart failure including hepatomegaly. In the less severe forms with presentation at an older age, cor triatriatum needs to be distinguished primarily from mitral stenosis. In early infancy, the differential diagnosis of dyspnea and failure to thrive with signs of heart failure is wider and includes congenital mitral stenosis, coarctation of the aorta, hypoplastic left heart syndrome, cardiomyopathy, and total anomalous pulmonary venous return.

Diagnosis

The ECG may demonstrate right ventricular hypertrophy. Chest radiography may show evidence of pulmonary venous congestion and enlargement of the left atrium, pulmonary artery, and right heart chambers. Echocardiography provides visualization of the membrane and identification of the flow acceleration across the orifice of the membrane. The orifice can be measured. Parameters indicative of pulmonary hypertension can be assessed such as tricupsid and pulmonary regurgitation velocities for estimation of pulmonary artery pressure, ventricular septal position, and right ventricular wall thickness.

Treatment and Prognosis

Cor triatriatum is treated by surgical excision of the membrane. Surgery is usually very effective with complete or near-complete resolution of obstruction.

Mitral Stenosis

Definition and Classification

Mitral stenosis is a narrowing of the effective orifice of the mitral valve that results in obstruction to blood flow from the left atrium to the left ventricle. It can be classified as congenital or acquired. The major cause of acquired mitral stenosis is rheumatic heart disease (Chap. 258, "Rheumatic Heart Disease/Acute Rheumatic Fever").

Mitral stenosis can also be classified as mild, moderate, or severe on the basis of the mean gradient across the valve and the pulmonary artery systolic pressure (*Table 250.3*). In adults, mitral valve area is also utilized, but absolute cutoffs for mitral valve area are not useful in the pediatric population due to variation in patient size.

Table 250.3
Classification of severity of mitral stenosis, per adult valve guidelines (Bonow RO et al. (2006) ACC/AHA 2006 guidelines for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice. Circulation 114:e84–e231)

Indicator	Mild	Moderate	Severe
Mean gradient (mmHg)	<5	5–10	>10
Pulmonary artery systolic pressure (mmHg)	<30	30–50	>50
Valve area (cm^2)[a]	*>1.5*	*1.0–1.5*	*<1.0*

[a]Relevant to adult-sized patients

Etiology and Epidemiology

Isolated mitral valve stenosis is a rare anomaly. More frequently, congenital mitral stenosis is associated with other left heart obstructive lesions, including aortic stenosis and coarctation or aortic arch hypoplasia. There is increasing evidence that a variety of left heart obstructive lesions have a heritable basis. Shone's syndrome, as described in 1963, is a constellation of left-sided obstructive lesions, namely supravalvar mitral ring, parachute mitral valve, subaortic stenosis, and coarctation of the aorta.

Pathology

There are multiple different anatomic substrates for mitral stenosis in childhood, summarized in *Table 250.4*. Supravalvar mitral ring is a lesion in which fibrous tissue forms a ring on the left atrial side of the mitral valve, either just above or adherent to the mitral valve leaflets. Although this can occur as an isolated abnormality, most cases of supravalvar mitral ring are associated with an abnormal mitral valve or other left heart obstructive lesions. The mitral stenosis is usually progressive.

Congenital mitral stenosis usually comprises malformations of the leaflets, chordae, and papillary muscles. The leaflets are often thickened, and chordae may be thickened or shortened or insert into abnormal papillary muscles. The obstruction results not just from restriction at the level of the valve leaflets but also from decreased interchordal spaces. Two specific patterns of papillary muscle and chordae malformation have been noted: parachute mitral valve and arcade mitral valve. In parachute mitral valve, there is either only one papillary muscle or significant asymmetry of the papillary muscles, with one

Table 250.4
Etiologies of mitral stenosis in childhood

Congenital	**Supravalvar mitral ring**
	Valvular mitral stenosis
	– Annular hypoplasia
	– Leaflet abnormalities
	– Double orifice mitral valve
	Subvalvar mitral stenosis
	– Parachute mitral valve
	– Arcade mitral valve
	Multilevel obstruction
	Atrioventricular canal
	– Unbalance of the common atrioventricular valve toward the right ventricle
	– After repair of common atrioventricular canal
Degenerative	**Mucopolysaccaridoses**
Acquired	**Rheumatic mitral stenosis**

being much larger and receiving more chordae than the other. In arcade mitral valve, the chordae are shortened or absent and the leaflets may insert directly into abnormal papillary muscles or the ventricular wall.

In the case of atrioventricular canal, the common atrioventricular valve can be committed in a relatively equal fashion to both ventricles ("balanced") or may be more committed to one ventricle ("unbalanced"). If the valve is unbalanced toward the right ventricle, physiologic mitral stenosis may occur following septation of the valve at repair. Judgment is required on the part of the surgeon in deciding how to partition the common atrioventricular valve and to what degree to close the "cleft" in the left portion of the valve. The reader is also referred to the Chap. 248, "Left to Right Shunt Lesions".

One form of non-rheumatic-acquired mitral stenosis occurs in patients with mucopolysaccharidoses. Due to deposition of mucopolysaccharide in the mitral and aortic valve leaflets, the leaflets are thickened and have abnormal mobility; valvular stenosis and regurgitation can result.

Pathophysiology

Obstruction of flow across the mitral valve results in elevation of left atrial, pulmonary venous, and pulmonary arterial pressures. Elevated pulmonary venous pressures may result in pulmonary edema and reactive pulmonary arteriolar constriction. Elevated pulmonary arterial pressures increase the work on the right ventricle, leading to right ventricular hypertrophy and elevated right heart filling pressures. In the decompensated state, there is evidence of right heart failure.

Clinical Manifestations

Mitral stenosis presents with dyspnea, particularly in settings where the heart rate is increased and/or the cardiac output is augmented, both of which will magnify the gradient across the mitral valve. Such circumstances include exercise, emotional stress, fever, and atrial fibrillation. Infants are most likely to be symptomatic while feeding and may also present with failure to thrive.

Physical examination may reveal tachypnea, a loud pulmonic component of the second heart sound (P2) in the setting of pulmonary hypertension, and a diastolic rumble over the mitral area. An opening snap may be generated by limitation of leaflet opening in rheumatic mitral stenosis (Chap. 258, "Rheumatic Heart Disease/Acute Rheumatic Fever"). In mitral stenosis resulting in decompensated heart failure, rales and hepatomegaly or elevated jugular venous pressure may be apparent.

Diagnosis

ECG may demonstrate left atrial enlargement and right ventricular hypertrophy, depending on the severity of the obstruction. Chest radiographs will reveal left atrial enlargement and pulmonary venous congestion. Echocardiography can demonstrate abnormal movement of the mitral valve leaflets, abnormal chordal and papillary muscle structures, and abnormal flow characteristics. Severity of stenosis can be graded using mean transvalvular gradients derived from Doppler velocities, estimation of pulmonary artery pressure from tricuspid and pulmonary regurgitation velocities, and mitral valve area from planimetry (*Table 250.3*). Cardiac catheterization can be performed if more accurate assessment of hemodynamics is required.

Treatment and Prognosis

Diuretics may be helpful in ameliorating symptoms of mitral stenosis, but intervention to relieve obstruction is the more definitive approach in symptomatic patients with moderate or severe stenosis. Surgical excision is the treatment of choice for supravalvar mitral ring. In some instances, the valve may need to be replaced if the ring is adherent to the leaflets and removal is not possible without leaflet damage.

In the case of severe congenital mitral stenosis, transcatheter balloon dilation (balloon valvuloplasty) or surgical valvuloplasty or replacement can be performed. All approaches have a frequent need for reintervention when performed in small infants or children. Balloon valvuloplasty may not have long lasting results or may result in significant mitral regurgitation. Surgical valvuloplasty may not be durable, and replacement often results in obligate re-replacement as the child grows. There are long-term risks for endocarditis and atrial arrhythmias. Significant mortality is also noted in children with severe congenital mitral stenosis. Consequently, if significant congenital mitral stenosis is noted in association with other left heart obstructive lesions of moderate to severe degree, the option of single ventricle pallation is considered (see Chap. 251, "The Single Ventricle").

Subaortic Stenosis

Definition and Classification

Subaortic stenosis is an obstructive lesion localized to the left ventricular outflow tract, proximal to the aortic valve.

Etiology and Epidemiology

Subaortic stenosis is an uncommon lesion with several different anatomic substrates:

- Discrete fibrous subaortic membrane: this is the most common form. Frequently (~70% of cases) other cardiac anomalies are present, but this can also be seen in isolation.
- Tunnel-like subaortic stenosis.
- Posterior deviation of the infundibular portion of the ventricular septum, resulting in a ventricular septal defect and subaortic stenosis. This is often associated with coarctation of the aorta or interrupted aortic arch type B.
- Hypertrophic cardiomyopathy with obstruction resulting from a combination of a hypertrophied septum and abnormal movement of the anterior leaflet of the mitral valve (systolic anterior motion). Please see Cardiomyopathy for further discussion of hypertrophic cardiomyopathy.

Pathology

Discrete subaortic membranes are crescentic structures, typically extending from the membranous ventricular septum, posteriorly across the subaortic region to the mitral valve. Histology shows smooth muscle, fibrous, and fibroelastic layers covered by endothelium. Tunnel-like subaortic stenosis consists of a long segment fibromuscular obstruction.

Pathophysiology

Subaortic stenosis results in a pressure load on the left ventricle with secondary left ventricular hypertrophy. In addition, in the case of a subaortic membrane, the turbulent flow pattern of the blood after it traverses the membrane is thought to damage the aortic valve leaflets and can be associated with progressive aortic valve insufficiency.

Clinical Manifestations

Patients with a mild degree of obstruction are usually asymptomatic and present with a harsh systolic ejection murmur resulting from obstruction within the left ventricular outflow tract. A diastolic decrescendo murmur of aortic insufficiency may also be present. Moderate to severe subaortic stenosis may be manifest by exercise intolerance or exertional angina. Severe subaortic stenosis may lead to signs and symptoms of left-sided heart failure, exertional syncope, or sudden death.

Diagnosis

The ECG may demonstrate left ventricular hypertrophy if the obstruction is moderate or severe. Chest radiographs are generally not helpful. Echocardiography can visualize the nature of the obstruction, degree of left ventricular hypertrophy, and estimate the pressure gradient across the obstruction. Aortic insufficiency can be identified by color Doppler echocardiography. Cardiac catheterization can be performed if further quantification and localization of the gradient (subvalvar versus valvar) is needed.

Treatment and Prognosis

No specific therapy is recommended for mild degrees of obstruction unless significant aortic insufficiency develops in the case of a discrete subaortic membrane. A significant proportion of patients (~50%) may be stable for many years without progression of either obstruction or aortic insufficiency. For significant obstruction (peak to peak

gradient ≥40–50 mmHg) or progressive aortic insufficiency in the case of discrete subaortic membrane, surgical relief of obstruction is indicated, The surgery for a subaortic membrane consists of resection of the membrane and septal muscle; the latter is thought to reduce the relatively high risk of recurrence (~20%). For diffusely small outflow tracts, a Konno procedure can be performed in which the septum is incised inferior to the aortic valve, creating a ventricular septal defect which is patched, enlarging the outflow tract. Patients with subaortic stenosis are at risk for endocarditis.

Aortic Valve Stenosis

Definition and Classification

Aortic valve stenosis results from narrowing of the aortic valve, resulting in a pressure gradient between the left ventricle and the aorta. In childhood, congenital forms of aortic valve stenosis predominate; degenerative aortic stenosis is not seen. Rheumatic aortic stenosis is addressed in Chap. 258, "Rheumatic Heart Disease/ Acute Rheumatic Fever".

Aortic stenosis can be classified as mild, moderate, or severe (*Table 250.5*). In addition, the term "critical" is used to describe neonates who present with ductal dependency or hemodynamic instability due to aortic stenosis.

Etiology and Epidemiology

Bicuspid aortic valve disease is a common disorder, estimated to occur in approximately 1–2% of the population. The etiology is thought to be primarily genetic; studies indicate an autosomal dominant inheritance pattern with reduced penetrance. Bicuspid aortic valve occurs more commonly in males (male to female ratio>3:1) and is also seen commonly in Turner syndrome.

Pathology

The aortic valve normally consists of three leaflets. In the vast majority of cases of congenital aortic stenosis, there is fusion or partial fusion of one or two commissures such that the valve is functionally bicuspid or unicuspid. Unicuspid aortic valves are usually severely stenotic. Bicuspid aortic valve is now recognized to be associated with dilation of the ascending aorta, and this aspect of pathology requires monitoring as patients age, although it is rare to require intervention for a dilated ascending aorta in childhood.

Congenital aortic valve stenosis can much less commonly occur in trileaflet aortic valves whose leaflets are thickened. This pathology is associated with Noonan Syndrome.

Acquired aortic stenosis occurs in patients with mucopolysaccharidoses. Deposition of mucopolysaccharide in the mitral and aortic valve leaflets results in thickening and abnormal mobility; valvular stenosis and insufficiency can result.

Pathophysiology

It should be noted that many bicuspid aortic valves function normally in childhood, without significant stenosis or regurgitation. They are more prone to degeneration in adulthood than trileaflet aortic valves, at earlier ages.

Table 250.5
Various classification criteria for the severity of aortic stenosis

Source/indicator	Mild	Moderate	Severe
Natural history study:[a]			
• Peak systolic left ventricular to aortic pressure gradient (mmHg) at catheterization	<50	50–79	≥80
Bonow RO et al., Adult Valve Guidelines:[b]			
• Echocardiographic jet velocity (m/s)	<3.0	3.0–4.0	>4.0
• Echocardiographic mean gradient (mmHg)	<25	25–40	>40
• *Valve area (cm^2)*[c]	*>1.5*	*1.0–1.5*	*<1.0*
• Valve area index (cm^2/m^2)			<0.6

[b]Bonow RO et al. (2006) ACC/AHA 2006 guidelines for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice. *Circulation* 114:e84–e231
[c]Relevant to adult-sized patients

Aortic valve stenosis results in a pressure load to the left ventricle. With moderate or severe stenosis, left ventricular hypertrophy develops. Elevated left ventricular filling pressures may result. In critical aortic stenosis in the neonate, the severity of the stenosis results in left-sided congestive heart failure and may require perfusion of the body from the right heart via the ductus arteriosus to maintain adequate cardiac output.

Clinical Manifestations

A bicuspid aortic valve with no stenosis or insufficiency will cause no symptoms. A systolic ejection click is ausculated. Greater degrees of stenosis usually present with a harsh systolic ejection murmur, loudest at the right upper sternal border and radiating to the carotid arteries. A thrill may be palpable in the suprasternal notch. Patients with moderate or severe aortic stenosis will demonstrate limitations in exercise capacity. In severe stenosis with elevated left heart filling pressures, signs of left-sided heart failure may be present. Patients with severe stenosis may experience syncope or sudden cardiac death.

Critical aortic stenosis in the neonate may be first recognized by a murmur present from delivery or may present with cardiovascular collapse and respiratory distress within the first few days of life. Adequate cardiac output cannot be maintained without augmentation of the systemic output by the right heart via a patent ductus arteriosus.

Diagnosis

ECG demonstrates left ventricular hypertrophy if stenosis is moderate to severe. Chest radiography is generally unrevealing. Echocardiography is used to define aortic valve morphology and function, with Doppler derived estimates of transvalvular gradients. Left ventricular hypertrophy, if present, is evident. In critical aortic stenosis, the left ventricle is often dilated and dysfunctional.

Treatment and Prognosis

Neonates with critical aortic stenosis, as defined by symptoms rather than gradient, can be stabilized initially with infusion of prostaglandin E_1 and, if necessary, mechanical ventilation. Transcatheter balloon aortic valvuloplasty is then the treatment of choice. Surgical valvotomy is now rarely used. Repeat balloon valvuloplasty or eventual aortic valve replacement may be necessary in these patients.

Beyond the neonatal period, a peak gradient $\geq$ 50 mmHg in the catheterization laboratory is generally considered to justify intervention, particularly if accompanied by symptoms, abnormalities on an exercise test, or evidence of rapid progression. Several options are available: transcatheter balloon valvuloplasty, surgical valvotomy, and surgical valve replacement. Transcatheter balloon valvuloplasty is generally the initial approach, due to its less-invasive nature, unless contraindicated by the presence of significant aortic insufficiency. Surgical valvotomy is now rarely used.

Valve replacement can utilize either a bioprosthetic valve, a mechanical valve, a homograft (cadaver) valve, or the patient's own pulmonary valve (i.e., an autograft: the Ross procedure). Each approach has advantages and disadvantages. Bioprosthetic valves have a limited durability, which may be less in younger patients, and thus require re-replacement. Mechanical valves have a risk of thromboembolism and require long-term anticoagulation. Bioprosthetic and mechanical valves come only in sizes designed for adults, and thus it is generally not possible to place one in a small child. Homograft valves tend to calcify and degenerate relatively quickly. The Ross procedure creates two valve disease for the patient (the patient's pulmonary valve is replaced with a homograft) and the so-called neo-aortic valve may degenerate with time. Thus, it is the goal to delay valve replacement as long as possible, and choice of replacement valve has to be individualized to the situation. Surgical mortality is generally low with excellent long-term survival. Patients are at risk for endocarditis.

Aortic Valve Insufficiency (Regurgitation)

Definition and Classification

Any leakage of blood from the aorta into the left ventricle during diastole is termed "aortic valve insufficiency". The term "aortic valve regurgitation" refers to the same phenomenon. Aortic valve insufficiency may be caused by congenital abnormalities of the valve, secondary effects of other intracardiac abnormalities, rheumatic heart disease, or destruction of the valve by endocarditis. The degree of insufficiency can be classified as trivial, mild, moderate, or severe.

Etiology and Epidemiology

The primary cause of aortic valve insufficiency in childhood is bicuspid aortic valve disease. The reader is referred to the section on Aortic Valve Stenosis above for further

epidemiologic information on bicuspid aortic valves. Only 5% of bicuspid aortic valves were found to have significant (moderate or severe) aortic insufficiency at presentation in one large pediatric series. Aortic valve insufficiency also results from balloon aortic valvuloplasty performed for aortic stenosis.

Aortic valve insufficiency can also be caused by prolapse of one leaflet of the aortic valve into either a perimembranous or subpulmonic ventricular septal defect. A subaortic membrane can lead to secondary damage of the aortic valve with insufficiency.

Acquired aortic insufficiency occurs in patients with mucopolysaccharidoses. Deposition of mucopolysaccharide in the mitral and aortic valve leaflets results in thickening and abnormal mobility; valvular stenosis and insufficiency can result.

Pathology

For a discussion of the pathology of bicuspid aortic valve disease, see the Pathology section under Aortic Valve Stenosis, above. With moderate to severe aortic valve insufficiency, secondary dilation of the left ventricle with compensatory hypertrophy is observed.

Pathophysiology

During diastole, the aortic valve closes, but this does not prevent some quantity of blood from returning to the left ventricular cavity from the ascending aorta. If the degree of aortic insufficiency is moderate to severe, the left ventricle will dilate. Compensatory hypertrophy develops to normalize wall stress.

Clinical Manifestations

Patients with mild to moderate degrees of chronic aortic insufficiency are asymptomatic. Individuals with severe chronic aortic insufficiency can also be asymptomatic for extended periods of time. Eventually, however, exercise intolerance, dyspnea, or angina develops. It should be noted that acute onset of aortic insufficiency is less well tolerated due to abrupt rises in left ventricular filling pressures.

On physical examination, the apical impulse may be prominent and may be shifted laterally if there is significant left ventricular dilation. An ejection click is present in the case of bicuspid aortic valve disease. A_2 may be accentuated. The murmur of aortic insufficiency is a diastolic decrescendo murmur, loudest along the mid-left sternal border. It becomes louder and longer as the degree of aortic insufficiency progresses. An aortic ejection murmur may also be present due to the increased ejection volume or concomitant aortic valve stenosis. A presystolic Austin Flint murmur may be present at the apex due to the jet of aortic insufficiency striking the anterior leaflet of the mitral valve and thus affecting mitral inflow. In severe aortic insufficiency, the carotid and femoral pulses are noted to have a rapid rise and brisk collapse, known as "water hammer" or "pistol shot" pulses. The carotid pulses may be visibly prominent (Corrigan's sign) and flushing and blanching may be visible in the nailbeds (Quincke's pulses).

Diagnosis

ECG may demonstrate left ventricular hypertrophy in moderate or severe aortic insufficiency. Chest radiographs may show cardiomegaly and prominence of the ascending aorta if present. Echocardiography is indicated to confirm the presence of aortic insufficiency, as well as to assess its mechanism and severity. Measurement of the aortic root and ascending aorta should be performed due to the association between bicuspid aortic valve disease and dilation of the ascending aorta. Exercise testing can be used to assess exercise capacity and elicit symptoms if the history is unclear. Cardiac magnetic resonance imaging can quantify aortic regurgitant fraction, but is only routinely recommended if echocardiographic windows are poor. Similarly, cardiac catheterization is only recommended when noninvasive evaluation yields inconclusive or conflicting results.

Treatment and Prognosis

Most patients with isolated aortic insufficiency can be followed conservatively for long periods of time, often for decades. Progression of aortic insufficiency, in the absence of endocarditis, is typically slow. In a large pediatric series of patients with bicuspid aortic valves, after a mean follow-up without intervention or endocarditis of 14.4 years, relatively few patients progressed to moderate to severe aortic insufficiency. Sudden death is a rare complication of chronic severe aortic insufficiency ($<$0.2%/year).

Vasodilators including hydralazine, nifedipine, and ACE inhibitors have been used to reduce afterload, but there is no clear evidence that such therapy prolongs the compensated phase of aortic insufficiency. Thus, adult guidelines recommend use of vasodilators only for (1) short-term symptomatic relief and improvement in left ventricular function prior to surgical aortic valve

replacement in patients with left ventricular dysfunction and (2) symptomatic relief in patients not felt to be a candidate for aortic valve replacement.

Aortic valve surgery is indicated for (1) symptomatic individuals with severe aortic insufficiency and (2) for individuals with severe aortic insufficiency and evidence of decreased left ventricular systolic function, marked ventricular dilation, or rapidly progressive ventricular dilation out of proportion to somatic growth. Aortic valve repair techniques have been developed, although the durability of such repairs may be limited. For a discussion of aortic valve replacement and prosthesis choice in children, see the section on Treatment and Prognosis under Aortic Valve Stenosis above.

Patients with aortic cusp prolapse into a ventricular septal defect and associated aortic insufficiency are approached differently. Generally repair of the ventricular septal defect is recommended when the cusp prolapse is recognized, to prevent further deterioration of aortic valve function.

Supravalvar Aortic Stenosis

Definition and Classification

Supravalvar aortic stenosis is a narrowing at the sinotubular junction of the aorta, just distal to the aortic valve. It results in a pressure gradient between the left ventricle and the aorta. The severity of the narrowing can be classified as mild, moderate, or severe.

Etiology and Epidemiology

Supravalvar aortic stenosis can be caused by loss of one functional copy of the elastin gene. This can occur as part of Williams syndrome, which is caused by a chromosome 7q11.2 microdeletion, deleting multiple continguous genes, including the elastin gene, or as a single gene defect (familial supravalvar aortic stenosis). The incidence of Williams syndrome is approximately 1:7,500–1:20,000. It is not clear yet whether this mechanism explains all cases of supravalvar aortic stenosis or not.

Pathology

The supravalvar narrowing most commonly consists of an hourglass-shaped narrowing at the sinotubular junction of the aorta. Less commonly, there is diffuse hypoplasia of the arch starting at the level of the sinotubular junction. Histology shows a thickened and disorganized media of the aortic wall. There can be associated thickening of the aortic valve leaflets. The ostia of the coronary arteries may be stenotic or inflow into the coronary arteries can be limited by aortic valve tissue adherent to the supravalvar narrowing. Associated cardiac conditions may include diffuse arch hypoplasia, pulmonary valve stenosis, supravalvar pulmonic stenosis, or branch pulmonary artery stenosis.

Pathophysiology

Supravalvar aortic stenosis results in a pressure load to the left ventricle, similar to valvar aortic stenosis. Secondary left ventricular hypertrophy will develop in moderate to severe stenosis, in proportion to the degree of obstruction. Coronary artery ostial stenosis, if present, can lead to ischemic complications, including sudden death.

Clinical Manifestations

Mild degrees of obstruction are generally asymptomatic. Moderate to severe supravalvar aortic stenosis can lead to angina, exercise intolerance, or dyspnea on exertion. Sudden death can occur, particularly during or after procedures or exercise. On physical examination, facial features consistent with Williams syndrome may be present. A thrill may be palpable in the suprasternal notch or carotid arteries. Cardiac auscultation reveals a harsh systolic ejection murmur at the right upper sternal border, similar to valvar aortic stenosis. Ejection clicks are usually absent, but A_2 may be accentuated. Supravalvar aortic stenosis can result in elevated blood pressure readings in the right arm in the absence of arch obstruction or elevations of blood pressure in other extremities. This phenomenon is a manifestation of the Coanda effect, a more general principle of fluid dynamics that causes accelerated jets to adhere to surfaces, even as they curve. The jet in this case is eventually directed into the right subclavian artery.

Diagnosis

ECG may demonstrate left ventricular hypertrophy. Transthoracic echocardiography readily visualizes the area of narrowing, although careful attention may be necessary in some cases to distinguish valvar from supravalvar stenosis.

Estimates of the obstructive gradient can be obtained by Doppler echocardiography. Other associated cardiac lesions can also be assessed. Cardiac catheterization can more precisely define the gradient across the narrowing, and angiography can help identify coronary involvement.

Treatment

Mild degrees of stenosis do not require intervention. Surgical augmentation of the sinotubular junction is indicated for moderate to severe degrees of obstruction. Relief of coronary ostial stenosis, if present, is performed. In more complicated cases, other associated cardiac lesions may also be addressed.

Prognosis

The discrete form of supravalvar aortic stenosis has a better prognosis than the diffuse form, in which it may be difficult to relieve the obstruction without merely moving the level of obstruction farther distal along the aortic arch. Surgical relief of discrete supravalvar aortic stenosis has relatively low rates of mortality or need for reoperation. Residual valvar stenosis (due to thickened leaflets) and regurgitation may persist.

Aortic Arch Obstruction

Definition and Classification

Aortic arch obstruction can be separated into three main categories. Most common is coarctation of the aorta in which there is a relatively discrete narrowing of the aortic arch, typically just distal to the insertion of the left subclavian artery, opposite the former insertion of the ductus arteriosus ("juxtaductal"). The arch can also be more diffusely hypoplastic, involving not only the juxtaductal region but also the transverse arch. Finally, the aortic arch can be interrupted at one of several locations. In interrupted aortic arch type A, the interruption is distal to the left subclavian artery, in the same location as a juxtaductal coarctation; in type B, the interruption is between the origins of the left carotid artery and the left subclavian artery; in type C, the interruption is between the origins of the right and left carotid arteries.

Etiology and Epidemiology

Coarctation of the aorta has an incidence of approximately 4:10,000 live births. Coarctation of the aorta, aortic arch hypoplasia, and interrupted aortic arch type A are frequently associated with bicuspid aortic valve or other left-sided obstructive lesions. These left-sided lesions are increasingly being shown to have a genetic basis. Coarctation is also seen in Turner syndrome. Interrupted aortic arch type B, which is almost always associated with posterior malalignment ventricular septal defect, has a specific genetic etiology in approximately 35% of cases, namely microdeletion of chromosome 22q11 (DiGeorge Syndrome). Interrupted aortic arch type C is extremely rare.

Pathology

Inspection of a juxtaductal coarctation demonstrates a posterior shelf of tissue opposite the former insertion site of the ductus arteriosus, narrowing the lumen. This shelf may extend circumferentially around the vessel. In older children, significant arterial collaterals may develop connecting the proximal and distal segments of the aorta, derived typically from the intercostal arteries. Aortic histopathology may also show evidence of cystic medial necrosis.

Pathophysiology

Due to the obstruction within the aorta, there is hypertension proximal to the obstruction and a pressure load on the left ventricle. Distal to the obstruction, perfusion may be compromised. In critical coarctation and interrupted aortic arch, ductal closure results in inadequate perfusion to the lower body, including the abdominal viscera. Systemic acidosis ensues with risk for necrotizing enterocolitis, renal failure, hepatic infarction, and secondary myocardial dysfunction.

Clinical Manifestations

Critical coarctation or interrupted aortic arch presents in the neonatal period as the ductus closes with circulatory collapse or sudden death. These infants usually have a brief history of feeding poorly, irritability, or poor responsiveness, progressing to respiratory distress and/or seizures as they become acidotic. They typically present with tachypnea, an ashen appearance, poor perfusion, and poor pulses.

Some infants with severe coarctation present a bit later, at a few weeks of age, with symptoms and signs of left-sided congestive heart failure, such as poor feeding, poor weight gain, and tachypnea. These symptoms are a result of left ventricular dysfunction due to the pressure load imposed by the coarctation. Physical examination demonstrates poor femoral pulses as well as findings consistent with congestive heart failure.

In other individuals with coarctation, the physiology is compensated and may present in childhood with a murmur (usually continuous in the back), upper extremity hypertension, or diminished or absent femoral pulses. Leg claudication may be described.

Diagnosis

In long-standing coarctation, the ECG may reveal left ventricular hypertrophy, and the chest x-ray may demonstrate rib notching due to the compressive effect of engorged collateral vessels on the adjacent bony structures. Transthoracic echocardiography can accurately diagnose the range of aortic arch lesions. Occasionally CT or MR angiography or angiography at cardiac catheterization is used to supplement echocardiographic imaging. Karyotype should be considered in female patients with coarctation to evaluate for Turner Syndrome and 22q11 FISH testing is recommended for all patient with interrupted aortic arch type B.

Treatment

Neonates with identified moderate to severe coarctation or interrupted aortic arch are treated with prostaglandin E_1 infusion to maintain ductal patency and avoid circulatory collapse. The arch is then repaired surgically. Those who present with shock are stabilized with infusion of prostaglandin E_1 and supportive care which may include endotracheal intubation, correction of acidosis, inotropic infusions, and control of seizures. These neonates should not be fed enterally and should be evaluated for evidence of necrotizing enterocolitis. Evidence of hypoxic ischemic injury to the brain, kidneys, and liver should be sought. When the patient has recovered from this acute insult, the arch obstruction is addressed surgically.

For older children who present with coarctation, the obstruction can be addressed either surgically or via interventional catheterization (balloon dilation with or without stenting).

Prognosis

Without intervention, survival for patients with coarctation is significantly curtailed. Neonates presenting in shock will die without intervention. In a natural history study by Campbell of patients with coarctation who survived the first year of life, median survival was 31 years without intervention. Mortality was attributable to congestive heart failure, aortic rupture, bacterial endocarditis, and intracranial hemorrhage.

In contrast, survival for repaired coarctation is excellent, approximately 90% at 20 years. Five to ten percent of patients may have a residual gradient following repair or may develop recurrent coarctation following the repair. Hypertension also commonly develops late, in the absence of residual narrowing, and is more likely with later repair of coarctation, particularly after 9 or 10 years of age. Late complications can also include endocarditis, development of aneurysm at the repair site, or intracranial aneurysm.

251 The Single Ventricle

Nadine F. Choueiter · Mark B. Lewin

Definition

Single ventricle lesions are complex heart defects that result in one of the ventricles being hypoplastic or absent. The most common of these lesions are those that comprise the hypoplastic left heart syndrome (HLHS). Single ventricle lesions are divided into three categories based on the adequacy of pulmonary blood flow (PBF) and systemic blood flow (SBF).

- Lesions with unobstructed PBF and SBF
  - Double inlet left ventricle (DILV) with L-transposition of the great arteries
  - Double outlet right ventricle (DORV)
  - Unbalanced atrioventricular canal (AVC) with a dominant right ventricle
- Lesions with obstructed PBF
  - Tricuspid atresia
  - Pulmonary atresia with intact ventricular septum
  - Unbalanced AVC with a dominant left ventricle
  - D-transposition of the great arteries and pulmonary or subpulmonary stenosis
- Lesions with obstructed SBF
  - HLHS syndrome
  - Interrupted aortic arch with hypoplastic left ventricle
  - DORV with pulmonary or subpulmonary stenosis
  - D-transposition of the great arteries (D-TGA) with aortic or subaortic stenosis

Epidemiology

Depending on the study quoted and the lesions included in the definition of single ventricle, the incidence of single ventricle lesions is 1 in 5–10,000 live births in the United States. No sex predilection is noted.

Etiology

Etiology is still unknown. Single genes targeting alterations in mice have resulted in single ventricle lesions prenatally including Nkx2.5, dHAND, TGF b 2, Bop2, and Has2.

Pathophysiology

In single ventricle physiology the pulmonary and systemic circulations are in parallel rather than in series. When there is associated severe obstruction to pulmonary or systemic blood flow, the circulation is dependent on the patent ductus arteriosus and is thus termed "ductal-dependent circulation." The amount of PBF and SBF depends on the degree of obstruction and the vascular resistance in both circulations. There is complete mixing of systemic and pulmonary venous blood at the ventricular or atrial level. The degree of cyanosis is dependent on the amount of PBF.

In lesions with unobstructed PBF, the high pulmonary vascular resistance present at birth usually prevents symptomatic pulmonary overcirculation in the neonatal period. However as the pulmonary vascular resistance decreases over the first few weeks of life, pulmonary blood flow gradually increases and results in congestive heart failure.

The pulmonary vascular bed is protected from overcirculation in lesions with pulmonary or subpulmonary stenosis. The degree of pulmonary stenosis tends to increase with time and the patient becomes progressively more cyanotic.

In the presence of obstruction to SBF such as mitral atresia, aortic atresia, coarctation of the aorta, and hypoplastic or interrupted aortic arch, systemic perfusion is compromised leading to cardiogenic shock as the ductus arteriosus closes.

Clinical Manifestations

Most single ventricle lesions are diagnosed within the first few days to weeks of life. Neonates with pulmonary or subpulmonary stenosis are cyanotic and hypoxemic. A systolic ejection murmur will be noted on auscultation, a palpable thrill may be felt and the second heart sound is single. In cases of pulmonary atresia the systolic ejection murmur is not present. Instead a soft continuous murmur might be present secondary to the patent ductus arteriosus or aortopulmonary collateral vessels.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_251,

In the absence of significant pulmonary outflow obstruction, patients will exhibit signs of pulmonary overcirculation as the pulmonary vascular resistance drops. They will develop tachypnea, diaphoresis, poor feeding, and failure to thrive associated with congestive heart failure within the first 2–6 weeks of life. Symptoms of congestive heart failure might appear earlier in the presence of AV valve regurgitation, or left-sided obstruction. Irrespective of the presence of a mixing lesion, due to the presence of excessive pulmonary blood flow these patients may not appear grossly cyanotic. They may have a palpable thrill, soft systolic pulmonary murmur due to relative pulmonary stenosis, and a diastolic murmur due to relative AV valve stenosis. Hepatomegaly is detected in the presence of congestive heart failure. Right or left AV valve regurgitation results in a pansystolic murmur at the left mid-sternal border or the apex, respectively.

Patients with left-sided obstruction present with signs of poor peripheral perfusion and metabolic acidosis especially after closure of the ductus arteriosus. The second heart sound is single. A soft continuous murmur secondary to the patent ductus arteriosus might be present. Coarctation is detected by a diminished or delayed lower extremity pulse and/or discrepant blood pressures (in general the right arm blood pressure will be higher than the leg by at least 10 mmHg).

Diagnosis

In the era of fetal echocardiography 60% of patients with single ventricle lesions are diagnosed prenatally. The remaining patients are diagnosed postnatally based on the clinical findings discussed above. The following ancillary tests provide important information that helps diagnose patients with single ventricle lesions, distinguish between lesions with decreased or increased pulmonary blood flow, and determine the appropriate management options.

Chest Radiography

The chest x-ray (CXR) is particularly helpful in distinguishing between lesions that are associated with increased versus decreased pulmonary blood flow. In cases of unobstructed pulmonary blood flow, the cardiac silhouette is enlarged on CXR and the pulmonary vascularity is increased. Lesions associated with decreased pulmonary blood flow have a normal cardiac silhouette and decreased pulmonary vascular markings on CXR.

Echocardiography

The anatomy of single ventricle lesions is delineated in detail by two-dimensional echocardiography (*Fig. 251.1*). Echocardiography identifies:

Morphology of the dominant ventricular chamber
Location of the hypoplastic chamber
Presence of narrowing between the dominant ventricular chamber and the rudimentary chamber
Presence or absence of pulmonary stenosis
Presence or absence of aortic valve disease, arch hypoplasia, or coarctation
Location, commitment, and relationship of the great vessels (normally related or transposed)
Location and competency of the AV valves (single, straddling, or atretic valve)
Other associated defects (atrial septal defects)
Abnormalities of the systemic or pulmonary veins
Ventricular function

Doppler color flow mapping allows detection and quantification of AV valve regurgitation or semilunar valve insufficiency. Pulse wave Doppler identifies and quantifies the degree of stenosis.

The use of echocardiography in the management of infants with single ventricle lesions beyond the initial diagnosis will be discussed below.

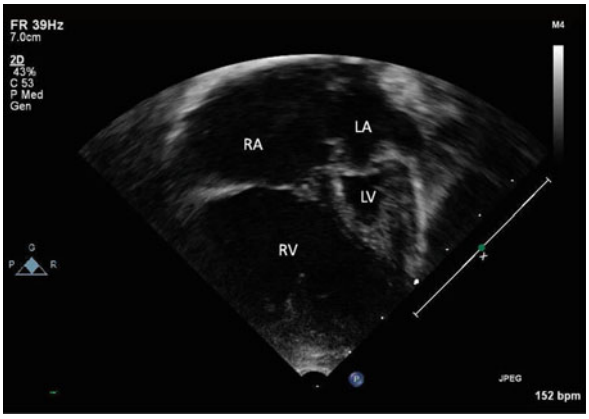

Figure 251.1
Two-dimensional echo apical four chamber view of a hypoplastic left heart syndrome. Large right ventricular and right atrial chamber. The left atrium and left ventricle are severely hypoplastic. *RA* right atrium, *LA* left atrium, *RV* right ventricle, *LV* left ventricle

Cardiac Catheterization

Given the detailed anatomy provided by echocardiography cardiac catheterization is reserved for patients with single ventricle lesions when:

- An anatomic or physiologic question is not answered with certainty by echocardiography.
- Intervention is required (such an atrial septostomy, stent implantation within the ductus arteriosus or pulmonary artery branch, coil occlusion of aortopulmonary collateral vessels, or systemic venovenous collaterals).
- There is the need for assessment of hemodynamics prior to second and third stage palliation surgery.

Electrocardiography (ECG)

The balance of forces between the left and right ventricle is shifted toward the dominant chamber. Right ventricular hypertrophy and right axis deviation are seen in on the ECG of patients with hypoplastic left ventricle. Similarly left ventricular hypertrophy is seen on the ECG of patients with a hypoplastic right ventricle. Left superior axis deviation, also known as northwest axis, is seen in patients with AVC lesions. ECG or other diagnostic tests are utilized when a rhythm disturbance is suspected. Atrial and ventricular arrhythmias as well as disturbances to atrioventricular conduction are common in this patient population.

Management

Neonatal/First Stage Palliation

Early neonatal survival is dependent on achieving a balanced circulation without excessive pulmonary blood flow, but with adequate flow to prevent severe cyanosis. Oxygen saturations are maintained between 75% and 85%. At these saturations pulmonary and systemic blood flow are balanced. Initial resuscitation includes maintaining or reestablishing the patency of the ductus arteriosus with prostaglandin E1 (PGE). It is important to provide a source of blood flow to the ductal-dependent circulation (pulmonary or systemic). A more permanent source of pulmonary or systemic blood flow is then achieved surgically (*Table 251.1*).

Table 251.1
Management of single ventricle lesions

Management of single ventricle lesions in the neonatal period depends on the adequacy of systemic and pulmonary blood flow. Beyond the neonatal period the goal is to separate the SBF and PBF by performing the Glenn/HF procedure at 2–5 months of age followed by the Fontan completion at 2–5 years of age

Single Ventricle Lesions with Unobstructed PBF and SBF

If well balanced at presentation, neonatal surgical intervention may not be necessary for patients in this category. The decrease in pulmonary vascular resistance with the concomitant increase in pulmonary blood flow within the first 6 weeks results in pulmonary overcirculation. In this case adequate regulation of pulmonary blood flow is achieved via banding of the pulmonary artery. This involves placing a ligature at the mid-portion of the main pulmonary artery such that artificial obstruction is created. The degree of restriction to pulmonary blood flow is guided by the oxygen saturation drop during the procedure. If the band is too loose the patient will have too much pulmonary blood flow; excessive constriction will result in cyanosis immediately or progressively as the child grows. Patients should be followed closely since they can outgrow the band, resulting in worsening cyanosis. Bands can also migrate after placement and either damage the pulmonary valve or obstruct the origins of the branch pulmonary arteries. The band is left in place until the patient is ready for the second stage palliation. At that time the band is removed. Banding remains a procedure with a surprisingly high mortality (typically as high as 10%). This is caused less by the procedure itself, and more commonly due to the difficulty in achieving the perfect balance of adequate pulmonary blood flow.

Single Ventricle Lesions with Obstructed PBF

Patients with single ventricle lesions associated with pulmonary outflow obstruction initially benefit from placement of either a prosthetic graft (3.5 mm) between a systemic artery and the pulmonary artery (modified Blalock–Taussig shunt: "m-BT shunt"), or a graft between the right ventricle (RV) and the pulmonary artery (RV to

pulmonary artery shunt). The ductus arteriosus is generally ligated during the same operation to avoid excessive pulmonary blood flow. Pulmonary blood flow is thus controlled by the size of the graft. m-BT shunt placement does not require cardiopulmonary bypass. The shunt is placed well proximal to the first branch of the pulmonary artery to decrease the potential for differential pulmonary artery growth and pulmonary artery distortion. In case of the RV-PA conduit, the long-term effects of a ventriculotomy to the right ventricle remains unknown. Placement of the RV-PA conduit requires cardiopulmonary bypass. Clotting of the m-BT shunt or the RV-PA conduit is a medical emergency addressed surgically or via balloon dilation/stenting in the cardiac catheterization lab due to the resultant development of severe and unrelenting cyanosis.

Single Ventricle Lesions with Obstructed SBF

Several modifications of the Norwood palliation for hypoplastic left heart syndrome (HLHS) have been used for patients with single ventricle lesions and aortic atresia, aortic arch hypoplasia, or subaortic obstruction. The main pulmonary artery is transected just below the bifurcation. The main pulmonary artery is then opened longitudinally and sewn to the ascending aorta. The aortoplasty is extended to distal to the area of obstruction or coarctation. An RV-PA conduit or a BT shunt is then placed to provide pulmonary blood flow. An atrial septostomy is performed to ensure adequate mixing of systemic and pulmonary venous blood at the atrial level. In patients with subaortic stenosis and distal arch obstruction, modifications of the Damus-Kaye-Stansel (DKS) procedure have been used to allow both great vessels to provide unobstructed flow to the systemic circulation. The semilunar roots, main pulmonary artery, and aorta are sewn together to provide unobstructed systemic blood flow. An atrial septectomy is performed if there is restriction to the left AV valve. Pulmonary blood flow is provided through a m-BT shunt or an RV-PA conduit. Both operations (the Norwood procedure or the DKS) require cardiopulmonary bypass (CPB) and in some centers deep hypothermic arrest (DHA). Patients are followed closely for aortic coarctation, shunt stenosis, decreased ventricular function, AV valve regurgitation, and arrhythmias.

Recently the "hybrid palliation" has been introduced as a less invasive alternative to the Norwood procedure. It consists of surgical bilateral pulmonary artery banding, combined with transcatheter balloon atrial septostomy and ductal stenting. It avoids the use of CPB which may be associated with adverse neurologic adverse events in the neonatal period. Experience with the hybrid procedure is limited but encouraging.

Palliative Surgeries Beyond the Neonatal Period

Second Stage Palliation/Cavopulmonary Anastomosis

Regardless of the type of neonatal surgical palliation, young infants with single ventricle lesions are still dependent on pulmonary blood flow from the ventricle. The single ventricle pumps to both the pulmonary and systemic circulation. This chronic work overload eventually leads to hypertrophy, dilatation, and failure of the single ventricle. The cavopulmonary anastomosis unloads the single ventricle and separates the pulmonary and systemic circulation. This is achieved by directing blood from the superior vena cava (SVC) to the pulmonary arteries through a surgically constructed anastomosis. It is performed in patients as young as 4–6 months of age when the pulmonary vascular resistance is low enough to allow passive pulmonary blood flow. The operation takes one of two forms:

- Bidirectional Glenn shunt (BDG): an end-to-side anastomosis of cephalic end the transected superior vena cava to the superior aspect of the right pulmonary artery
- Hemi Fontan (HF): an augmented side-to-side anastomosis between the back of the opened superior vena cava–right atrial junction and the anterior surface of the right pulmonary artery, with an intra-atrial patch placed to close the communication between the atrium and the pulmonary artery

The previously placed systemic to pulmonary artery shunt is taken down. The operation is performed off cardiopulmonary bypass. Major complications include obstruction of the cavopulmonary anastomosis leading to venous congestion, facial and upper extremity swelling, increased head circumference, and worsening cyanosis. Venovenous collaterals or pulmonary arterial venous malformations can form leading to worsening cyanosis.

Third Stage Palliation/Modified Fontan Operation

The relative size of the lower trunk and legs increases as infants grow into children. The ratio of IVC to SVC return

to the heart increases, resulting in increasing cyanosis following the cavopulmonary anastomosis. During the third stage blood from the inferior vena cava (IVC) is directed to the right pulmonary artery. This results in near normal arterial oxygen saturation since all of the systemic venous return (with the exception of flow from the coronary sinus) is directed to the pulmonary vascular bed before its return to the heart. The modified Fontan operation is generally performed in patients 2–5 years of age. It currently involves either a tunnel created within the lateral aspect of the right atrium (the "lateral tunnel") or an extracardiac conduit that directs IVC flow to the pulmonary artery. The extracardiac conduit is a (Gortex, homograft, or pericardial) tube graft interposed between the transected inferior vena cava and the underside of the right pulmonary artery (*Fig. 251.2*). There is still debate whether the extracardiac conduit approach is superior to the lateral tunnel. Approximately two thirds of Fontan operations in recent years have been performed using the extracardiac conduit approach (STS surgical database). In the early 1990s, fenestration of the Fontan was proposed as a new modification. This involves a small connection between the Fontan pathway and the right atrium. It is the physiologic equivalent of an atrial septal defect. If the pressure within the Fontan connection (systemic venous pressure) becomes too high, blood can "pop-off" and flow to the systemic circulation. While this right to left shunt will cause cyanosis, it does serve to maintain cardiac output in the event of adverse physiologic circumstances.

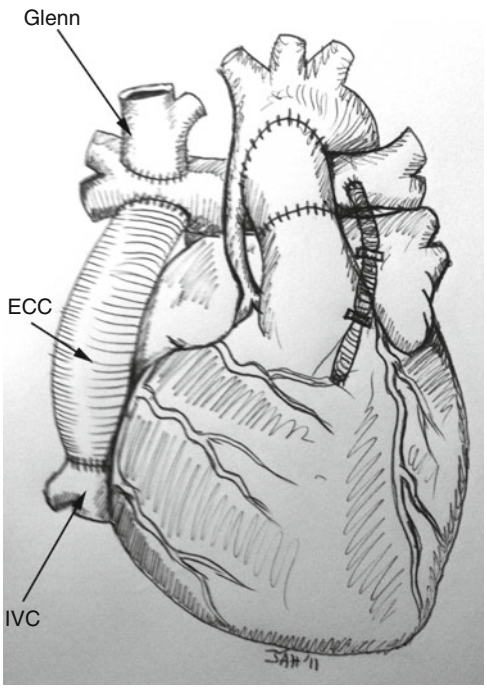

Figure 251.2
Fontan circulation. Courtesy of netterimages.com. Elsevier, INC

Major postoperative complications include pleural effusions, arrhythmias, thromboembolic events, and protein-losing enteropathy.

Pleural effusions are the most common problem after a modified Fontan operation. This has been reduced but not totally eliminated by the use of the Fontan fenestration. Many factors have been examined but the exact reason remains unknown. There is no good definitive treatment. Supportive treatment such as drainage of the effusion is recommended. It is important to maintain adequate fluid replacement and nutrition. If the effusion is chylous then the patient is switched to a fat-free diet or a formula rich in medium chain triglycerides (MCT).

Arrhythmias are common in both the immediate and in the late postoperative periods. These can occur in up to 50% of patients after a Fontan procedure depending on the type of Fontan and include sinus node dysfunction and atrial flutter/fibrillation. Arrhythmias in this population are thought to be secondary to surgical scarring and/or chronic atrial hypertension. Atrial arrhythmias can be managed medically or via ablation in the cardiac catheterization lab. Patients with bradyarrhythmias or sinus node dysfunction may need pacemaker implantation.

Multiple factors may contribute to the formation of thrombus including areas of sluggish flow in the Fontan circuit, atrial arrhythmias, as well as intrinsic or acquired abnormalities in hemostatic pathways. The emboli can occur in the pulmonary and systemic circulation. If a fenestration exists between the pulmonary and systemic sides of the heart, then a cerebral vascular accident or other signs of a paradoxical embolus can be seen. There is no consensus on whether or how to attempt thromboprophylaxis in Fontan patients. Some cardiologists use antiplatelet drugs and others prefer warfarin.

Protein-losing enteropathy (PLE) is an uncommon (3.7%) but dreaded complication of the Fontan operation occurring a median of 2.7 years after surgery and associated with a poor prognosis, with a 5-year mortality nearing 50%. The pathogenesis of PLE is poorly understood. Patients with PLE develop peripheral edema, ascites, and pleural effusions. Low serum albumin and fecal α1-antitrypsin concentration are reliable in identifying enteric protein loss. Management is geared toward therapeutic relief. Options include drainage of pleural and ascitic fluid, afterload reduction, diuresis, albumin

infusion, and a high protein/low fat diet. Various case reports have reported efficacy of oral steroids, heparin, spironolactone, and calcium infusion in the treatment of PLE. Heart transplantation is reserved for patients who have failed medical or surgical therapy.

Outcomes

Although the modified Fontan operation has improved the survival of patients with single ventricle physiology, it is a less than ideal hemodynamic outcome. Multiple studies looking at the results of the Fontan demonstrate a decrease in survival beyond 15 years after surgery. The survival rate and freedom from transplantation 15 years post-Fontan is 70–80%. Death usually is a result of comorbid conditions and complications mentioned above. The quality of life of patients after a Fontan is affected by a lower exercise performance as compared to subjects of the same age and gender. In addition Fontan patients are found to have a higher incidence of attention deficit disorder, learning disabilities, anxiety, and depression. The explanation for these cognitive, psychological, and psychiatric disturbances is likely multifactorial and is an area of active investigation.

252 Noninvasive Cardiovascular Imaging

Brian D. Soriano

Introduction

With recent advances in technology, initial diagnostic and physiologic assessments of cardiovascular structures can now be accomplished with noninvasive imaging techniques. The armamentarium available to the healthcare provider has expanded to the point that for a particular clinical question, multiple factors must be considered when choosing which modality will be most appropriate. This chapter aims to provide an overview of the various options available in clinical pediatrics, to guide the provider to determine which modality is best suited for their patient, and to recognize each modality's set of advantages and limitations. Metabolic and nuclear scintigraphy imaging will not be covered in this section, since both are more prevalent in adult cardiology and are infrequently employed in clinical pediatrics. Several citations are listed in the reference section for the interested reader.

In order to establish a framework and to better understand the nuances between noninvasive modalities, an overview of imaging terms follows.

Resolution

The ability to distinguish between two items, either visually by space, color, or even time. Resolution can be determined with quantitative means, such as the number of megapixels in a digital camera, or on a relative scale.

Contrast Resolution

Contrast resolution is the ability to distinguish between two points in space based on the differences in amount of light generated or reflected by the points. Low contrast is exemplified when one attempts to travel through dense fog or clouds (◉ *Fig. 252.1*). High contrast would be similar to seeing a black rabbit on a white background, or the moon in a pitch-black sky (◉ *Fig. 252.2*).

Spatial Resolution

Spatial resolution is the ability to distinguish two points in space (◉ *Figs. 252.3* and ◉ *252.4*). A microscope, for example, allows one to view items with high spatial resolution. An example of low spatial resolution is best illustrated during a football game where one is sitting in the highest of seats. At such distance, one cannot read individual letters on a player's jersey.

Temporal Resolution

Temporal resolution is the ability to detect differences in an object's position or appearance between two points in time. The football game analogy can be extended to help explain temporal resolution; the action of handling the ball may be so quick that one did not see how the ball was passed from one player to another – which reflects poor temporal resolution. If you are watching the game on a television and you see the replay in slow-motion, this is an example of high temporal resolution.

Gating

Technique used to reduce blurring of images (also called motion artifact) from patient movements. Acquiring images are timed, or "gated," to the item of motion such as an electrocardiogram tracing, or the breathing movements of the diaphragm.

Signal-to-Noise Ratio

Regardless of the type of imaging modality or its properties, if the image is thought to convey the clinical information that is required or expected, its quality or "signal" is thought to be adequate. A noisy image means that random perturbations in the image are

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_252,

Figure 252.1
Example of an image with poor contrast resolution. The fog makes it difficult to distinguish black from white

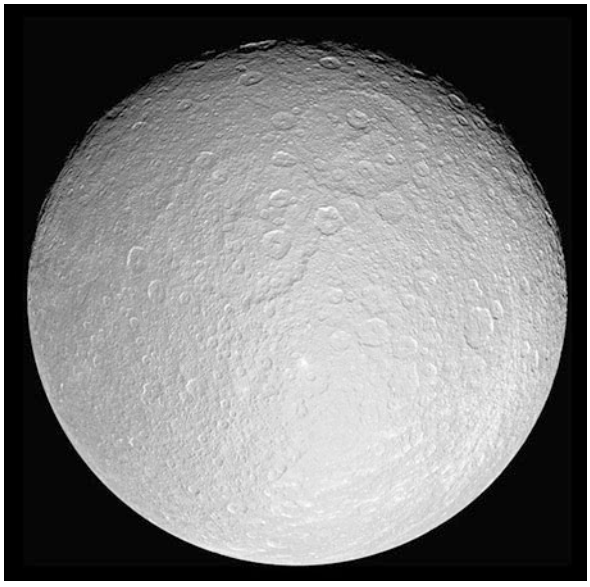

Figure 252.2
Example of an image with high-contrast resolution. The entire photograph is mostly black and white, with few grays

introduced, which can adversely affect the ability to use the images for clinical purposes. Such noise is the same as the static that can be seen on an analog television set (*Fig. 252.5*).

Overview of Modalities

Chest Radiography

The most venerable of noninvasive modalities: a chest radiograph is a 2-dimensional projection of all the structures of the thorax. Contrast is determined by the relative density of tissues, which allows one to identify various structures on a radiograph. Tissues such as bone absorb more of the x-ray energy than less dense tissues such as skin and lungs. Gross anatomic landmarks are readily identified and include the location of the cardiac apex, the sidedness of the aortic arch relative to the trachea, and the relative sizes of the cardiac chambers.

Compared to other noninvasive imaging modalities, when assessing cardiac structures and great vessels, the radiograph provides relatively few anatomic details. Nevertheless, it can provide important clues that would suggest the presence of significant structural heart disease. Vascular congestion and an enlarged heart can suggest left to right shunting such as an atrial septal defect. A cyanotic neonate with respiratory distress and a small heart silhouette can indicate total anomalous pulmonary venous connections. Prominent contours of the cardiac silhouette can also suggest pathologic conditions. If the silhouette bulges to the patient's right, for example, this finding can suggest right atrial enlargement.

Figure 252.3
Example of good (Fig. 252.3) versus poor (Fig. 252.4) spatial resolution. Notice how the coarse pixels of Fig. 252.4 prevent the ability to identify individual bricks of the tower

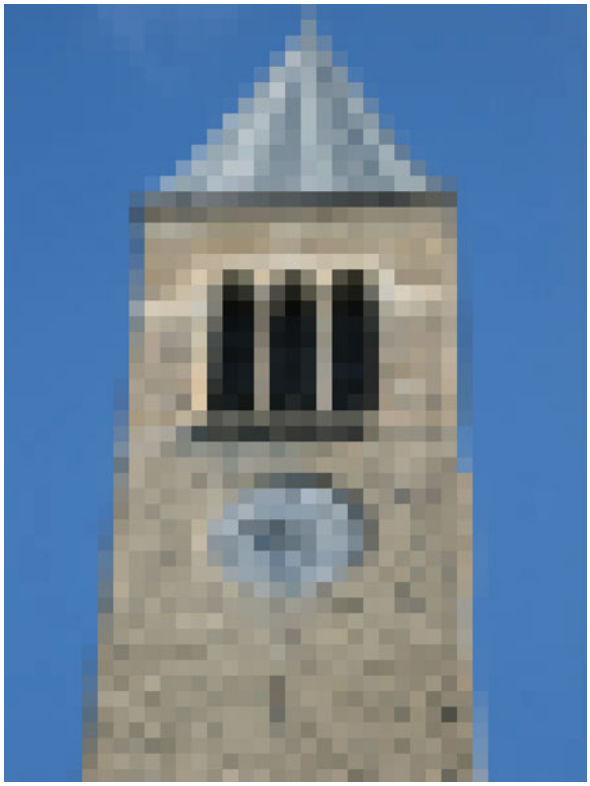

Figure 252.4

The chest radiograph's usefulness in accurately diagnosing or reliably excluding significant cardiac disease has been questioned. For example, the presence or absence of cardiomegaly by radiography has been used as a means to screen for congenital heart disease. In a series of pediatric ambulatory patients, Satou et al. determined the chest radiograph's ability to detect heart disease via cardiomegaly that yielded a high negative predictive value, but with a low positive predictive value. Because of the poor predictive value of chest radiography, in our practice, we do not routinely use radiography in ambulatory patients who are referred to rule out congenital heart disease.

Despite these limitations, radiography's nearly ubiquitous presence and quick acquisition make it an appropriate initial step to evaluate patients. This is especially pertinent when other modalities are not immediately available, or if the patient is critically ill.

Advantages of chest radiography:

- Easily accessible and widely available
- Provides a means to evaluate the cardiac silhouette and lung fields; helpful tool to evaluate for the presence of large vascular or intracardiac shunts
- Images are obtained rapidly

Disadvantages:

- Cannot rule out all congenital heart diseases
- Intracardiac anatomy such as valves and chambers cannot be delineated
- Ionizing radiation is used, though the dose is very small

Echocardiography

Echocardiography, also known as cardiac ultrasound, is the cornerstone of noninvasive cardiac imaging. In clinical pediatrics, a handheld transducer creates sound waves at a frequency that can range between 3 and 12 MHz,

Figure 252.5
Example of a noisy image. If there is more noise in the form of static, the tower would be more difficult to identify

which is well above the ability of human perception. After these inaudible sound waves propagate through the chest to the imaging area of interest, the sound waves reflect off the structure, creating an echo. The reflected sound waves are received by the handheld probe and the signals are digitally processed, yielding a corresponding picture.

While transthoracic echocardiography (TTE) is the most common means to evaluate the pediatric heart, other means of ultrasound imaging – some invasive – are available but are beyond the scope of this chapter. Such examples include intracardiac echocardiography which uses a special catheter-like transducer system, and intravascular ultrasound imaging. Fetal echocardiography is detailed in Chapter xx.

Given its ability to evaluate both anatomy and physiology, echocardiography is the most commonly used modality to diagnose congenital and acquired heart disease. In addition, serial evaluation is useful to follow patients with noncardiac diseases that may have an impact on the heart, such as systemic or pulmonary hypertension. Echocardiography may also be indicated in children with thromboembolic events, indwelling catheters and sepsis, or superior vena cava syndrome. Indications are outlined in ❯ *Table 252.1*. Pallor, acrocyanosis, and chest pain unrelated to exercise are not indications for echocardiography since cardiac pathology is rarely associated with these conditions.

Within echocardiography, several fundamental techniques exist that delineate both anatomy and physiology.

2-Dimensional Echocardiography

Using a variety of commercially available transducers and hardware, echocardiography can create a moving picture that helps evaluate cardiac structures and their function. Rapidly moving structures such as valve leaflet motion can be readily distinguished and carefully defined. Among the different means to image the heart, echocardiography usually has the best temporal resolution. For example, heart motion can be visualized at frame rates up to 200 Hz. To place this value in perspective, this is a temporal resolution that is up to ten times as rapid as a standard movie that plays at 24 Hz. This temporal resolution advantage diminishes in older, larger patients.

Doppler Echocardiography

When imaging moving objects, such as blood flowing through valves, reflected ultrasound can change frequencies, which is known as a Doppler shift. These changes remain inaudible, but are detectable by ultrasound machines, and can be used to evaluate for normal or pathologic flow through the heart.

Spectral Doppler displays the Doppler shift and intensity of ultrasound reflections as a function of time (❯ *Fig. 252.6*); in the clinical setting, this Doppler shift is used to measure velocities.

Color Doppler (❯ *Fig. 252.7*) evaluates these flows and can display a color-coded map to show what objects are moving toward the transducer (red) or away from the transducer (blue). Despite the colors that are displayed, Doppler cannot determine if the blood is oxygenated or deoxygenated.

Tissue Doppler focuses on the motion of the heart tissue rather than the blood, and is used to assess both systolic and diastolic functions.

While echocardiography cannot directly measure pressures within the heart and vessels, pressures can be

Tables 252.1
Indications for echocardiography, adapted from Lai et al

Signs or symptoms
• Central cyanosis*
• Hypoxemia
• Failure to thrive
• Exercise induced chest pain or syncope*
• Respiratory distress
• Murmurs
• Congestive heart failure
• Abnormal arterial pulses
• Cardiomegaly
• Arrhythmias
Indications even in the absence of cardiovascular signs or symptoms
• Certain syndromes known to be associated with congenital heart disease (For example: Turner syndrome, Down syndrome)
• Family history of inherited heart disease (e.g., hypertrophic cardiomyopathy)
• Extracardiac abnormalities that are known to be associated with congenital heart disease (e.g., congenital diaphragmatic hernia)
Abnormalities on other tests
• Fetal echocardiography or obstetric ultrasound
• Chest radiograph
• Electrocardiogram
• Chromosomal
Acquired heart diseases and noncardiac diseases
• Kawasaki disease
• Infective endocarditis
• Cardiomyopathies
• Rheumatic fever
• Systemic lupus erythematosus
• Myocarditis and pericarditis
• Human immunodeficiency virus (HIV) infection
• Exposure to cardiotoxic drugs
• Systemic hypertension
• Pulmonary hypertension

*Echocardiography is not recommended as the initial diagnostic test for pallor, acrocyanosis, or syncope not related with exercise

estimated based on Doppler-derived measurements of blood flow velocities. Using a simplified equation derived from Bernoulli, pressure (mmHg) = $4v^2$, where v is the velocity in m/s. While there are limitations to this derivation, it can be used to estimate pressure differences within the heart, especially in valve stenosis or in patients with tricuspid regurgitation.

In a commonly used indication, the previous equation is useful to determine if pulmonary hypertension is present. For example, if the tricuspid regurgitation jet velocity is measured to be 5 m/s, the predicted right ventricular systolic pressure will be at least 100 mmHg (*Fig. 252.8*). As long as there is no pulmonary stenosis which can confound the measurement, the pulmonary artery pressure will be as high as the right ventricular pressure.

3-Dimensional Echocardiography

Modern computing and processor speeds have advanced enough to the point that structures of the heart can be rendered in 3-dimensions, mitigating the need to mentally reconstruct 2-dimensional images. Valve anatomy can be shown to surgeons from their perspective, which is more challenging to perform with 2D alone. Several authors have advocated its use in imaging complex congenital heart disease. Ventricular volumes, especially of the geometrically complex right ventricle, can be more accurately measured than with 2D echocardiography.

Several limitations exist for echocardiography. The field of view for 2D ultrasound is relatively narrow, which prevents the ability to view all structures from a single location. When viewed on a display screen, echocardiogram images have a fan-shaped configuration, which reflects this narrow field. Because of this limitation, ultrasound requires multiple acoustic "windows" to examine the heart and to perform a complete evaluation (*Fig. 252.9*). Areas that have markedly different densities from their surrounding tissues, such as the interface between the lungs and the heart, prevent ultrasound from penetrating, which leads to inadequate ultrasound pictures. The same inadequacy exists in very large or obese patients, where transthoracic images can be poor. Compared to cardiac MRI, tissue contrast is relatively low in all types of echocardiography, making it difficult to distinguish areas of muscle from fat or from fibrous tissue. For example, when viewing intracardiac masses, it may be difficult to determine if the lesion is a thrombus or a tumor.

To circumvent some of the imaging limitations of transthoracic echocardiography, transesophageal echocardiography (TEE) can be employed. This technique utilizes a specialized ultrasound probe that can be

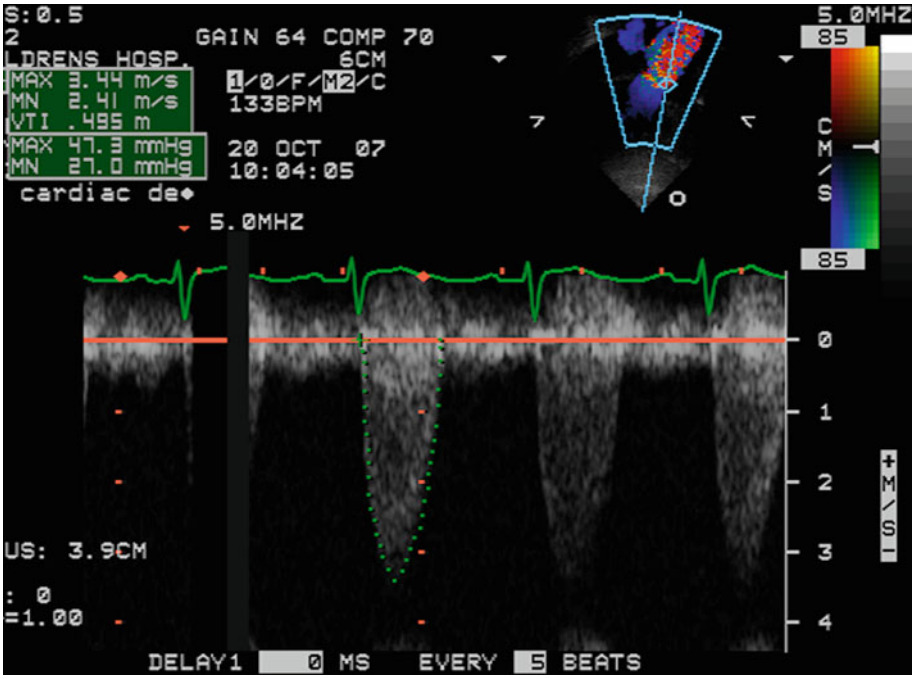

Figure 252.6
Spectral Doppler recording blood flow across the pulmonary valve. The x-axis represents time. The y-axis is velocity of blood flow in meters per second. In this patient, velocities across the valve are over 3 m/s consistent with pulmonary stenosis

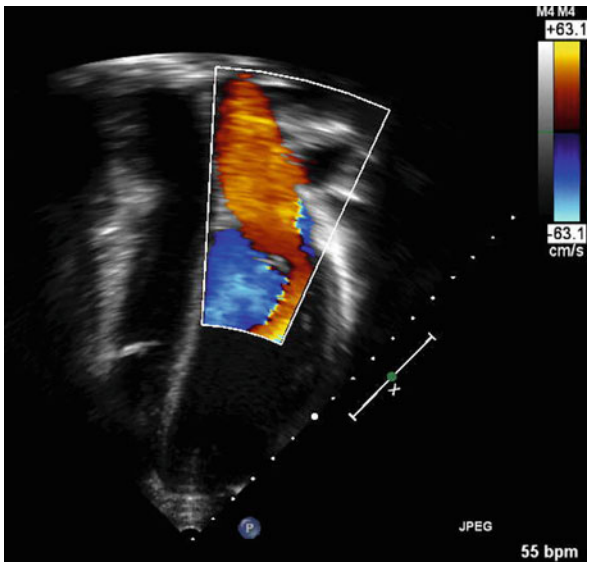

Figure 252.7
Color Doppler image of blood across the mitral valve. Typically, red and blue colors are used to represent flow (shown as gray patterns within the inner box)

passed through the mouth along the esophagus. Since the mid-esophagus is directly behind the heart, images of the heart are unobstructed. TEE still has its own drawbacks; it is the most noxious of the "noninvasive" imaging techniques and requires sedation. Superior mediastinal structures are not well seen, and TEE is contraindicated in esophageal diseases such as tracheoesophageal fistulas.

Advantages of echocardiography:

- Excellent temporal and spatial resolution
- No ionizing radiation
- Does not require confining patient positions
- Well studied and well evaluated. After radiography, it is the oldest and most established of all cardiac imaging techniques
- Can aid in the assessment of physiology and blood flow

Disadvantages:

- Small field of view, requiring multiple angles of imaging.
- Relatively less contrast resolution and signal-to-noise ratio.
- Detailed evaluation of cardiac structures can be hampered in active or morbidly obese patients.

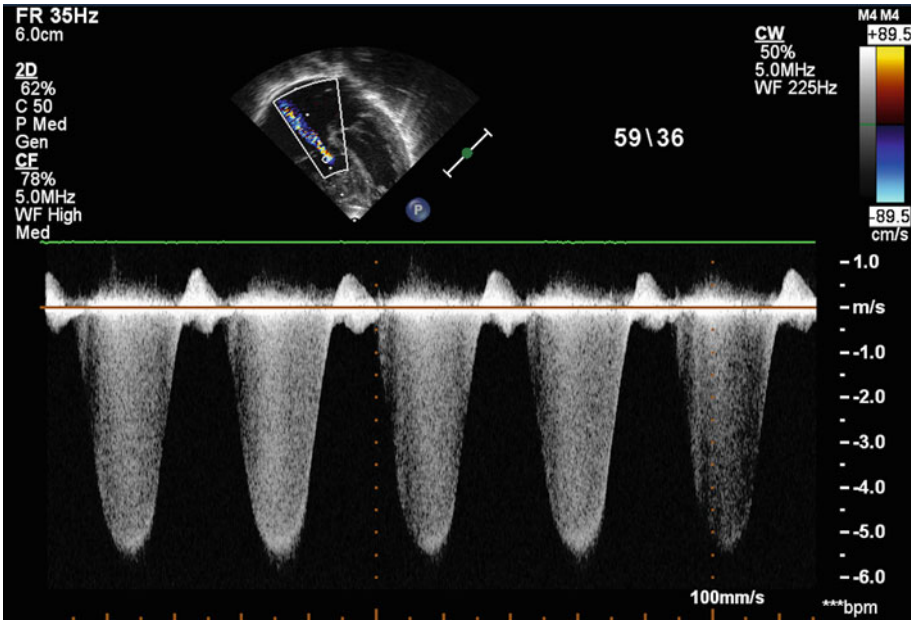

Figure 252.8
Determination of right ventricular pressure based on the tricuspid regurgitation jet. In this example, the velocity exceeds 5 m/s, which means the right ventricular systolic pressure is 100 mmHg

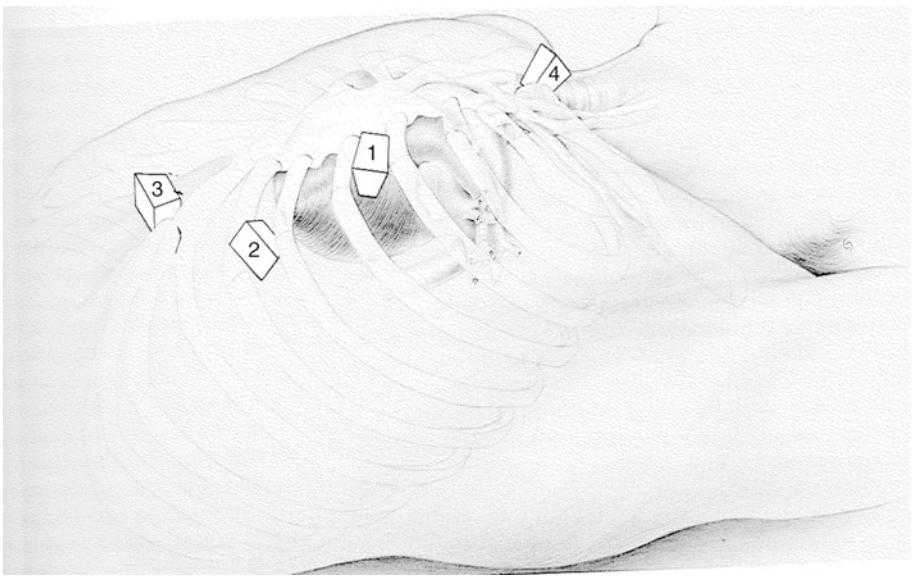

Figure 252.9
Acoustic windows for echocardiography, which shows where the ultrasound probe must be placed. 1 = parasternal, 2 = apical, 3 = subcostal, 4 = suprasternal. Due to ultrasound's small field of view, a full echocardiogram must utilize all windows so that the heart may be imaged from different angles (Figure reprinted with permission. From Sinder, *Echocardiography in Pediatric Heart Disease*, page 25, ©1997 Elsevier)

- Imaging of distal coronary artery anatomy is limited.
- Thoracic great arteries and veins are more difficult to view in larger patients.

Cardiac CT and CT Angiography

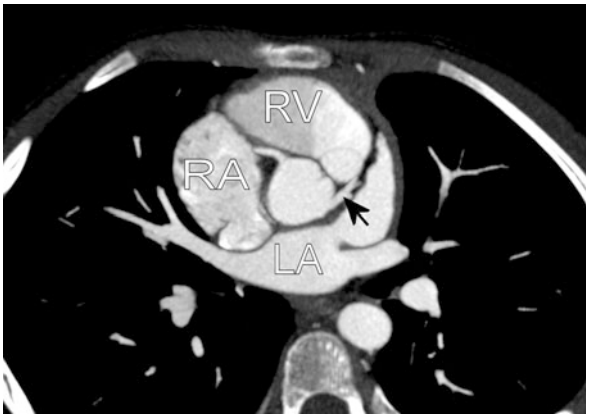
The adaptation of CT imaging in pediatrics has been fostered by rapid advances in hardware and software. Multidetector rows allow multiple simultaneous image acquisitions of the body. Some of the most recently developed scanners offer dual energy/x-ray sources which increases the speed and efficiency of image generation. Accompanied by strategies such as helical scanning, which allows the patient to literally glide through the scanner without staccato-like stops and starts, CT can produce high-quality and detailed images within seconds, which is a distinct advantage over the longer scan times of MRI and echocardiography. Electron beam CT uses a different means to create and direct x-ray energy; technical issues limit its clinical use and are not well documented in pediatrics. For interested readers, a more comprehensive review of cardiac CT advances is detailed by Flohr et al.

The spatial resolution of CT can be in the submilimeter range, which is finer than MRI or adult echocardiography. In larger pediatric patients, spatial resolution will be superior to echocardiography. This advantage over echocardiography is negated in infants and small children due to their smaller sizes and higher heart rates. CT has the additional advantage of evaluating lung parenchyma and airways. In patients with a suspicion for vascular rings, such as those who present with stridor or dysphagia, CT angiography of the chest can help confirm the diagnosis.

Although scan times are short and usually require only seconds for a complete evaluation, CT images of the heart may be blurred due to a combination of cardiac and respiratory motions. A restless patient would also create artifact if he or she cannot lie still in the scanner. Formally termed "motion artifacts," these problems manifest especially in pediatric patients, whose heart rates are faster than adults. Sometimes sedation is required, although it is used less frequently than with MRI.

To help reduce motion artifacts, a method called ECG gating can be employed. The end of diastole is a period of time within the cardiac cycle when the heart lies very still. On an electrocardiogram, this coincides with the time just before the QRS complex. When ECG gating is employed, the CT scanner obtains images only when cardiac motion has been minimized, producing sharp images of the heart itself (◉ *Figs. 252.10* and ◉ *252.11*). This technique would

◉ **Figure 252.10**
CT of the heart without gating. Notice how the intracardiac anatomy is blurred and difficult to discern. Though not shown here, imaging of the lung and great vessels would not be compromised by the lack of gating (Courtesy of Dr. Randy Otto)



◉ **Figure 252.11**
ECG-gated CT coronary angiography of the same patient. Compared to non-gated and blurry image, this image is crisper and without motion artifacts. The *dark arrow* shows the left coronary artery. RV = Right ventricle, RA = Right atrium, LA = left atrium (Courtesy of Dr. Randy Otto)

be required only if detailed CT evaluation of the coronary arteries or intracardiac structures is required. One disadvantage is that use of gating can increase the total dose of ionizing radiation. In addition, intravenous contrast is necessary to visualize vascular and intracardiac structures, but can be contraindicated in patients with renal insufficiency.

Despite attempts to minimize motion through ECG gating, an ongoing issue with pediatric imaging remains

within the CT hardware itself. The ring that houses and contains the x-ray energy source, and the detectors is called the gantry. In order to collect image information, this gantry must rotate in a 360° circle around the patient; one complete revolution can occur in as little as 0.3 s, but is not rapid enough to effectively obtain images when heart rates are over 65 beats per minute. While increasing gantry speed is theoretically possible, the sheer mass of the hardware within the gantry – which weighs over 1,000 kg – limits this possibility. While heart rate limitations are being overcome with newer, dual-source CT scanners, this technology is still being evaluated for pediatric cardiac applications.

CT imaging is also challenged by the delicate balance of two conflicting needs: minimizing radiation dose while maintaining adequate image quality. Lower doses of radiation can be achieved, but at the cost of increased image noise and a reduction in signal-to-noise ratio. Concerns of the long-term risks associated with ionizing radiation exposure have been raised, but there are constant efforts to reduce the total dose required to obtain a clinically meaningful cardiac CT.

Advantages of CT:

- Very rapid image acquisition, with a scan duration second only to chest radiography
- Wide field of view
- Excellent spatial resolution
- Allows visualization of airways and lung parenchyma
- Allows visualization of vascular structures within the entire thorax when intravenous contrast is used
- Distal coronary arteries can be visualized

Disadvantages:

- Ionizing radiation must be considered
- Poor temporal resolution
- Evaluation of intracardiac anatomy requires incremental doses of radiation
- Cannot reliably evaluate physiology, blood flow, or shunts
- Heart rates in a pediatric patient may limit image quality
- Renal insufficiency is a relative contraindication for intravenous contrast
- More costly study

Cardiac MRI and MR Angiography

Using gated fast imaging techniques, cardiac magnetic resonance imaging is one of the newest noninvasive imaging modalities, and provides the clinician with an additional tool for cardiac assessment. Images are created by taking advantage of electromagnetic properties of human tissue at an atomic level. A high-strength magnetic field, tens of thousands times the strength of the earth's magnetic field, aligns hydrogen atoms so that they are all parallel to each other. Using a precisely directed and carefully timed combination of radiofrequency pulses which create tiny alterations in the MRI's magnetic field, radiofrequency signals or "echoes" return from the heart, are collected by the scanner, and an image is constructed.

Cardiac MRI complements the information provided by more accessible noninvasive modalities such as radiography and echocardiography. It has a wide field of view, allowing one to view structures within the entire thorax and sometimes even the whole body. The temporal resolution is fine enough that – similar to echocardiography – the heart can be visualized in motion. Clinicians have the ability to evaluate ventricular function and flow in a quantitative as well as qualitative fashion. With this combination of abilities, both anatomy and physiology can be determined in a CMR examination.

One particular advantage of MRI over other modalities is its excellent tissue contrast. Even without the use of intravascular contrast agents such as gadolinium, tissues such as fat, muscle, and tendons can be readily distinguished. Intracardiac anatomy is well defined. Heart rates do not limit MRI imaging the same way they would for cardiac CT.

There are multiple applications of cardiac MRI in clinical pediatrics. For cardiac tumors, various sequences can be used to noninvasively predict the type of tumor to the point that MRI can be considered the first-line noninvasive study to determine tumor tissue characteristics. With gadolinium contrast agents, 3-dimensional reconstructions of the heart chambers and thoracic vasculature can be created (Fig. 252.12). The same contrast can help detect cardiac inflammation due to myocarditis, and scarring from infarctions, through a process called delayed enhancement.

The intracellular space of viable tissue "clears" gadolinium from the region while inflamed muscle tissue or scars tend to retain contrast for a longer period of time. Such retention leads to delayed enhancement of the tissue and may become a reliable prognostic indicator in congenital heart disease. In repaired tetralogy of Fallot, for example, presence of increased scarring – as manifested by delayed enhancement – has been associated with adverse outcomes in the adult population. Cardiac MRI has also been proposed as a screen for right ventricular abnormalities such as arrhythmogenic

Figure 252.12
MR angiogram of a double aortic arch, using 3D reconstruction techniques (Courtesy of Dr. Randy Otto)

right ventricular dysplasia. Though gadolinium contrast had been considered to be safe in patients with renal insufficiency, such thoughts have changed. Nephrogenic systemic fibrosis is a disorder that has recently been associated in renal failure patients who received higher doses of gadolinium and has led to more cautious use in this population.

While many diagnostic benefits exist with MRI, tradeoffs exist. Not all MRI centers will have the capability to image pediatric patients. As opposed to echocardiography where smaller patients will have better image quality (for both resolution and signal quality), the signal-to-noise ratio in infants and small children is typically worse with MRI. One additional drawback is the length of the study. The duration of time required for a full cardiac MRI can range from 30 min to over 1 h. Because a patient must lie still for the entire study, sedation is usually required for infants and young children. Finally, cardiac MRI may be a suboptimal test for the critically ill patient. The small space where the patient lies, coupled with a longer scan time can challenge assessment, monitoring, and medical intervention.

Advantages of cardiac MRI:

- No ionizing radiation
- Excellent contrast resolution, even without the use of intravenous agents
- Very good spatial resolution
- Allows detailed qualitative and quantitative evaluation of intracardiac anatomy, including proximal coronary arteries
- Wide field of view, allowing imaging of adult and obese patients
- Can evaluate and quantitate the physiology of blood flow and shunts
- Can noninvasively evaluate tissue characteristics

Disadvantages of cardiac MRI:

- Requires a regular cardiac rhythm. Arrhythmias can create artifacts.
- Loud environment. Potentially claustrophobic for some individuals.
- Long scan durations, ranging from 30 min to over 1 h.
- Distal coronary artery anatomy is difficult to see.
- May require sedation or anesthesia in smaller patients.
- Ferromagnetic materials such as pacemakers or some metal implants are contraindications for MRI.
- Small intracardiac shunts may not always be detectable.
- Not as readily available.
- More costly study.

Guidelines for Incorporating Noninvasive Cardiac Imaging

The relative strengths and weaknesses of each modality are outlined in *Table 252.2*. In a patient with known or suspected cardiac pathology, consultation with a specialist in pediatric cardiology should always be considered. If such expertise is not readily accessible, the following are suggestions to help guide the clinician. When there is an initial suspicion of cardiac pathology in the history or physical examination, electrocardiography, chest radiography, and echocardiography are first-line choices for evaluation.

In addition to the advantages and disadvantages outlined above, local practices and availability of expertise will modify the next appropriate choices. Transesophageal echocardiography is an option if transthoracic echocardiography is unable to visualize structures of interest. If coronary artery anatomy is a concern, cardiac catheterization can be considered. If only anatomic and not hemodynamic information is needed, alternatives to catheterization include cardiac CT or CT angiography. This is especially helpful if evaluation of the airways or lung parenchyma is required. Cardiac MRI is most useful in patients where CT intravenous contrast is contraindicated, if the clinician wants to

Table 252.2

The relative strengths and weaknesses of each modality are compared; "++++" indicates a relative strength, while "+" suggests a feature that is less useful

	Echocardiography	MRI	CT	Chest radiography
Spatial resolution	+++ ++++(infants and small children)	++	+++	++++
Temporal resolution	++++	+++	+	None
Contrast resolution	++	++++	+++	++
Duration of test	Medium: 20–45 min	Long: 30 min to over 1 h	Short: seconds to minutes	Seconds
Airway and lung parenchyma visualization	No	Large airways only	++++	+++
Physiology/ Blood flow	++++	+++	+	+
Pericardium visualization	++	++++	+++	+
Field of view	++	++++	++++	+++
Cost	Moderate	Highest	High	Low
Sedation	Infrequent/ideally needed in toddlers	Usually in infants/young children	Infrequent	Never
Ionizing radiation	No	No	Yes	Yes

avoid ionizing radiation, or if echocardiography could not determine the relevant anatomy or physiology. If required, quantitative assessment of intracardiac shunts, vasculature, or chamber volumes can be determined by MRI.

253 Interventional Cardiology

Troy A. Johnston

Introduction

The field of pediatric interventional cardiology has evolved rapidly over the last several decades. Cardiac catheterization, originally a diagnostic modality, is now primarily therapeutic. The first intervention, balloon atrial septostomy, was described by Rashkind and Miller in 1966. Since then, innovative thinking paired with technological advances has exponentially increased the number of catheterization therapies with each decade.

Interventional therapy is now an acceptable alternate treatment for many forms of congenital heart disease. Elegant devices are available to close atrial septal defects, muscular ventricular septal defects, and patent ductus arteriosus. Balloon angioplasty with and without stenting is used to treat pulmonary arterial stenosis and coarctation of the aorta. More recent developments include the percutaneous placement of semilunar valves, fetal interventions, and hybrid procedures wherein the interventional cardiologist works with the pediatric cardiac surgeon simultaneously.

The increased complexity and number of interventional techniques require highly specialized equipment and skills. Operators with advanced training coupled with sufficient case volume are key components in achieving acceptable results. Several initiatives are now underway to provide better quantification of outcomes. The use of multicenter studies for investigational therapies and outcome research will continue to improve the therapeutic options for a complex patient population.

Balloon Atrial Septostomy

Balloon atrial septostomy is performed by passing a balloon-tipped catheter through either the superior or inferior vena cava into the left atrium. Fluoroscopic or echocardiographic guidance is used. The catheter is passed from the right into the left atrium usually through a patent foramen ovale. The balloon is then inflated and forcefully pulled into the right atrium. This action tears the atrial septum, increasing the size of the intra-atrial communication.

Balloon atrial septostomy was first described as a palliative measure for infants with transposition of the great arteries. The increased size of the atrial communication allows for improved intracardiac mixing of the systemic and pulmonary venous blood. This increases the systemic arterial saturation. Alternatively, it may be used to relieve atrial septal restriction in other forms of complex congenital heart disease. Infants with hypoplastic left heart syndrome may have an inadequate outlet from the left atrium if the patent foramen ovale is too small. Balloon atrial septostomy can be used to palliate these infants until more definitive enlargement of the atrial communication is carried out at the time of surgery.

Balloon atrial septostomy is a safe and effective procedure when performed by experienced operators. Complications, although rare, include avulsion of the pulmonary veins or inferior vena cava and injury to atrioventricular valves.

Patients outside the neonatal period have a thicker atrial septum that is more resistant to balloon atrial septostomy. Standard balloon atrial septostomy is usually inadequate. Often there is no communication between the atria. Access to the left atrium may require transseptal needle puncture. This technique uses a long needle positioned from the femoral vein. After successful puncture, the communication can be enlarged using alternative techniques such as blade septostomy, static balloon dilation, or implantation of balloon-expandable stents. Indications for atrial septal defect creation or enlargement in an older patient include left atrial outlet obstruction or patients with severe pulmonary hypertension. The right-to-left shunt can improve cardiac output at the expense of decreased systemic arterial saturation. Risks to the more complex techniques include cardiac perforation, stent embolization, and increased risk of air embolism.

Balloon Valvuloplasty

The utilization of static balloon dilation to manage valve stenosis began in the early 1980s. Initially it was utilized to treat pulmonary valve stenosis and subsequently aortic valve stenosis. Mitral valvuloplasty for rheumatic mitral

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_253,

stenosis has proven effective. It also may have utility in the management of select patients with congenital mitral and tricuspid valve stenosis.

After hemodynamic measurements are obtained, the stenotic valve is crossed with a guide wire. The pulmonary valve is crossed in a prograde fashion. The aortic valve may be crossed retrograde from the aortic root, or prograde utilizing an existing atrial communication or performing a transseptal puncture. After gaining a stable wire position, a balloon-tipped catheter is advanced over the wire and positioned across the stenotic valve. The diameter of the balloon is selected as a ratio of the valve annulus. The ratio is usually less than 100% for aortic valvuloplasty, while a larger balloon to annulus ratio can be used for the pulmonary valve. The balloon is inflated with dilute contrast. When successful, the balloon tears the valve leaflets improving the valve orifice. A successful dilation usually increases the degree of valve insufficiency to some degree. This is assessed, along with hemodynamics after dilation.

Multiple studies have shown the safety and efficacy of balloon valvuloplasty with results similar to surgical intervention. The major long-term complication is clinically significant valve regurgitation. Primarily this has been a concern for the aortic valve. The use of smaller balloons for aortic valvuloplasty has been associated with less insufficiency. Other complications include annulus disruption, vascular injury, and arrhythmias. Embolization of either air or thrombus is a serious complication of dilation of the left-sided valves. Valvuloplasty of either semilunar valve may be associated with damage to the associated atrioventricular valve. Careful attention to wire placement and balloon position minimizes the risk of inadvertent tricuspid or mitral valve regurgitation.

Balloon Angioplasty and Stent Placement

Balloon dilation is most often utilized to treat congenital or postoperative pulmonary artery stenosis. It is also a treatment option for coarctation of the aorta and less frequently venous obstruction. Initially a hemodynamic and angiographic evaluation is performed. The site to be treated is crossed with a catheter and a stiff guide wire is positioned with the tip distal to the obstruction. The stiff wire is then used to position a balloon-tipped catheter in the vessel so that the tubular balloon straddles the obstruction. Static balloon dilation is then carried out. The balloon inflation pressure required is often much higher than that for valvuloplasty. Effective dilation is associated with disruption of the intima or even the media of the vessel wall. After dilation, the balloon catheter is removed and repeat hemodynamic and angiographic assessments are performed.

Vascular stenosis can be very resistant to balloon dilation. If a stenotic vessel is not dilated sufficiently during balloon inflation, favorable results may be achieved with the use of cutting balloons. These balloons have primarily been used for distal pulmonary artery stenosis. The balloon has multiple small metal blades attached to the outside of the balloon parallel to the balloon shaft which serve to circumferentially pierce the intimal layer of the vessel and thus relieve the obstructive process.

Endovascular stents are effective to treat lesions that are very compliant (*Fig. 253.1*). The vessel can be stretched to an acceptable diameter during balloon angioplasty, but recoils as soon as the balloon is deflated. The rigid metal wire mesh stent provides structural support allowing the vessel to stay open. The stents are delivered on balloon catheters and used to treat pulmonary, aortic, and venous stenosis. They are best utilized in children whose vessels are large enough to accommodate stents with the capacity for enlargement to sizes appropriate for adults. The large model stents can be serially dilated to account for somatic growth (*Fig. 253.1*).

Balloon angioplasty with or without stent implantation can be a safe and effective therapy for vascular stenosis. Complications include intimal disruption, aneurysm formation, and vessel rupture. Even temporary occlusion of blood flow can lead to hemodynamic deterioration in fragile patients. Stents are often more technically challenging to deploy. They carry the additional risks of embolization and fracture.

Patent Ductus Arteriosus Closure

Outside the neonatal period, transcatheter closure of the patent ductus arteriosus has replaced surgical intervention. Closure using stainless steel coils was first described in the early 1990s. The technique involves positioning a coil, now usually platinum, with a portion in the pulmonary artery and the majority within the ductus arteriosus. The larger the ductus the more coils are required for complete closure. Alternative devices have been developed that have made closure of larger ducts feasible. The Amplatzer Duct Occluder is a wire mesh device that is well suited for the larger ductus. It is usually deployed using femoral venous access. It is attached to a delivery cable that allows for device positioning and assessment prior to release. It is relatively easy to reposition or even remove the device and replace with a more

The superior and inferior margins of the stent are marked by *arrows*. The narrowest diameter is significantly improved

appropriate sized device. This greatly improves the safety and efficacy of the procedure.

The availability of multiple closure devices has limited surgical intervention to very small children, particularly premature infants. Complications from device closure include device migration, air or thrombus embolization, and infection.

Atrial Septal Defect Closure

Transcatheter device closure has become a safe and effective alternative to surgery for the majority of patients with secundum atrial septal defects. Multiple devices have been developed since the first transcatheter occlusion in the mid-1970s. Currently, the Amplatzer septal occluder and the Helex septal occluder are the only devices with FDA approval for atrial septal defect closure. Both devices consist of wire frames with two disks joined in the center. The devices are positioned with one disk in the left atrium and one in the right atrium. The disks are larger than the defect, which anchors the device in position across the defect. After appropriate echocardiographic imaging of the atrial septum, the defect is usually further sized by placing a compliant balloon in the defect and inflating until there is no flow seen through the defect. After sizing, the device is delivered through a long sheath positioned in the left atrium. The left side of the device is deployed in the left atrium and then the device is pulled into contact with the atrial septum. The right disk is then deployed by retracting the long sheath. If performed properly, the device is seated across the atrial septum with one disk on either side of the septum. If the device is in appropriate position, it is then released by unscrewing the delivery cable (*Fig. 253.2*).

Successful device placement can be achieved in centrally located defects that are not overly large. Devices are placed with echocardiographic and fluoroscopic guidance. Echocardiography allows for visualization of the device and its relation to other intracardiac structures. If the defect location is not central or the defect is very large, the device may interfere with mitral valve function, or pulmonary or systemic venous return. Both devices are designed so that they can be positioned within the heart prior to release from the delivery system. If echocardiography reveals any potential problems, the device can be removed by drawing the device back into the delivery catheter.

Appropriate device size selection is important to reduce the risk of device embolization. An inadequately sized device may embolize to the systemic or pulmonary

circulation. Embolization, if not immediate, occurs within the first hours after placement. Often embolized devices are retrieved percutaneously; however, surgical removal maybe required. Additional complications of percutaneous atrial septal defect closure include air or thrombus embolism, infection, stroke, and arrhythmias. A 6-month course of aspirin at an antiplatelet dose is used to reduce the risk of thrombus formation.

Ventricular Septal Device Closure

Defects in the muscular portion of the ventricular septum can be closed using transcatheter techniques. Currently, the Amplatzer muscular occluder and the Cardioseal are approved for this use in the United States. The Amplatzer device is a woven mesh device that has two disks separated by a wider waist than the Amplatzer atrial septal device. The Cardioseal was originally designed for atrial septal defect closure and consists of two wire frame–supported disks joined in the center. Both devices are deployed so that one disk is on the left side of the ventricular septum and the other on the right. Appropriate device placement requires that the device not interfere with atrioventricular or semilunar valve function. Device placement is usually accomplished using venous access. The long sheath is placed from the right ventricle into the left and therefore the left disk of the device is deployed first followed by the right. A combination of echocardiographic and fluoroscopic guidance is usually used during closure.

Although similar to atrial septal defect closure, the need to cross the tricuspid valve with stiff wires and sheaths combined with a more complex catheter course leads to the potential for more hemodynamic instability during this procedure. The occurrence of intraprocedural ventricular tachyarrhythmias and heart block may occur. Complications also include device migration, air or thrombus embolization, and infection.

Percutaneous Pulmonary Valve Replacement

A large number of patients with repaired congenital heart disease, such as tetralogy of Fallot, will have surgical placement of a tissue valve in the pulmonary position as a treatment for pulmonary regurgitation. These valves have a limited duration of function with the need for eventual replacement for failure due to progressive regurgitation, stenosis, or a combination of both. Previously, these patients would require multiple surgical valve replacements during their lifetimes (*Fig 253.3*).

Transcutaneous pulmonary valve replacement is now an alternative to surgical intervention in select patients. Currently in the United States, the Melody valve has received FDA approval and the Sapien valve is in clinical trial. The Melody valve consists of a small segment of bovine jugular vein containing a venous valve. The Sapien valve utilizes bovine pericardial tissue to construct a valve. Both valves are attached to the inner surface of a balloon-expandable stent. The apparatus can be compressed onto a balloon catheter that allows introduction through the systemic veins in older children and adults. Both femoral and internal jugular approaches have been used. Although technically challenging, this procedure can be performed safely by an experienced operator. Prior to valve placement the anatomy must be carefully assessed, particularly the landing zone for valve placement. It must not be too large to accommodate the valves, both of which have a limited maximum diameter. Additionally, the relationship of the coronary artery position to the conduit must be assessed. The inflated valve could potentially compress a coronary artery if it is in close proximity.

The short-term results of percutaneous pulmonary valve placement appear favorable. Longer-term data, including freedom from reintervention, is not yet available. Complications of the procedure include vascular rupture and device migration.

Hybrid Procedures

Cooperation between interventional cardiologist and cardiac surgeon to facilitate interventions has led to an increasing number of hybrid procedures. Loosely defined, a hybrid procedure is any one that requires the skill set of the surgeon and the interventional cardiologist. Commonly, the surgeon provides access via a sternotomy

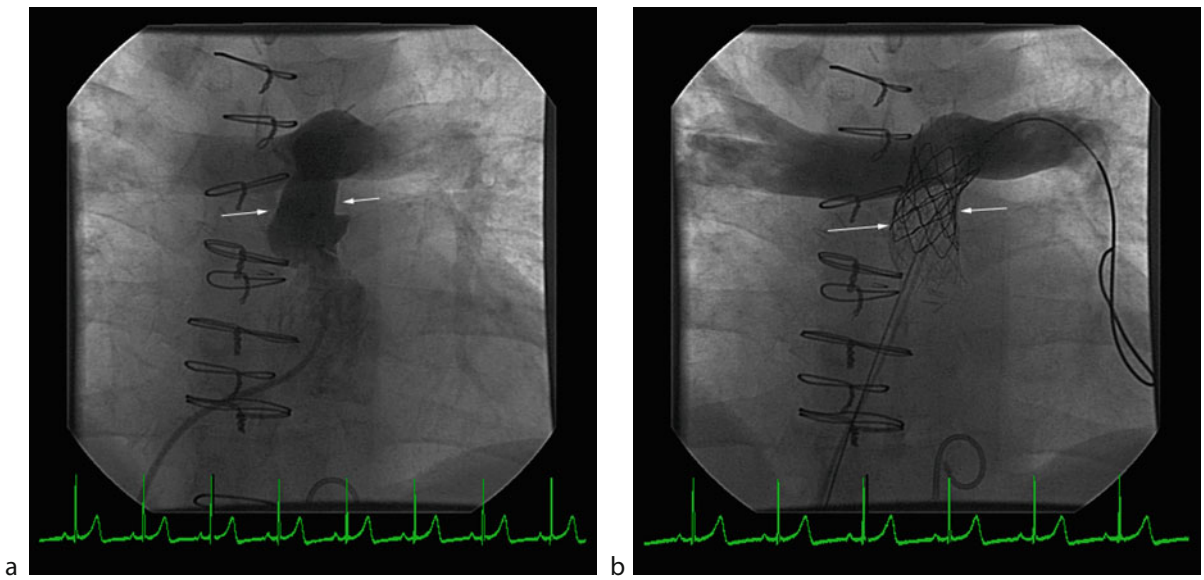

Figure 253.3

(a) Frontal projection of a pulmonary artery angiogram in a patient with tetralogy of Fallot who previously underwent placement of a valved conduit in the pulmonary position. There is stenosis and regurgitaiton of the conduit valve. The mid portion of the conduit is marked by *arrows*. (b) Frontal projection of a pulmonary artery angiogram in the same patient after Melody valve placement. The dark metal struts of the stent (*arrows*) are easily seen. The conduit stenosis is improved and there is no evidence of pulmonary regurgitation

thereby allowing vascular access directly into a vessel or even the heart. Occasionally, percutaneous procedures in small children are difficult or even impossible. By providing direct access through an open chest, the technical challenges inherent to small vessels and complex catheter courses are minimized. One example is perventricular placement of a muscular ventricular closure device. A sternotomy provides direct access to the heart through the free wall of the right ventricle. Needle puncture of the external wall of the right ventricle is used to introduce a wire into the right ventricle through the ventricular septal defect into the left ventricle. The wire is used to introduce a short sheath into the left ventricle through which an appropriate device can be deployed. Transesophageal echocardiographic guidance is used. This technique avoids the need for cardiopulmonary bypass and is an alternative to an often very difficult surgical procedure.

A hybrid approach has also been used as a first stage palliation for patients with hypoplastic left heart syndrome. In this procedure, the interventional cardiologist performs a balloon atrial septostomy providing unobstructed pulmonary venous return. Additionally, the cardiologist stents the patent ductus arteriosus. This provides unobstructed systemic blood flow without the need for prostaglandin infusion. The surgeon places bilateral pulmonary artery bands to prevent pulmonary over circulation. Multiple reports have shown that this technique can be performed safely. In most centers, it has not replaced the traditional surgical approach to patients with hypoplastic left heart syndrome. It may be a valuable alternative for the management of select high-risk neonates.

Fetal Procedures

The role of fetal intervention as a treatment for congenital heart disease remains unclear. It has been proposed as an option for progressive cardiac disease with poor prognosis. Several centers have shown that fetal cardiac intervention is technically possible. The majority of reported interventions have occurred in infants with severe aortic valve stenosis. Fetal critical aortic valve stenosis may progress to hypoplastic left heart syndrome. The rationale for performing fetal balloon aortic valvuloplasty is ultimately to achieve a two-ventricle circulation. The same rationale applies to the use of balloon pulmonary valvuloplasty in patients with pulmonary valve atresia with intact septum. Current work hopefully will clarify the utility of fetal cardiac intervention.

Introduction

Congenital heart surgery is a relatively young and constantly evolving discipline. The last 20 years have brought about rapid developments in the technologic realm as well as a more thorough understanding of both the anatomy and pathophysiology of congenital heart disease, leading to the improved care of children and adults with congenital heart defects.

One of the most important advancements was the introduction of cardiopulmonary bypass (CPB), which was used for the first time successfully to close an atrial septal defect by Dr. John Gibbon, Jr. on May 6, 1953. CPB allowed surgeons to empty the blood within the heart, stop it from beating if necessary, open any intracardiac chamber, and carry out reparative procedures in a controlled, unhurried manner. A simple CPB circuit includes: a pump, an arterial inflow into the patient, a venous outflow from the patient, a venous reservoir to collect and "store" the venous blood, an oxygenator to oxygenate the venous blood, filters to remove debris or air from the circuit, a heater/cooler to alter the temperature of the blood (or perfusate), and appropriate sized tubing. Although CPB makes heart surgery possible, infants and children provide important challenges in the use of CPB. First, repair of complex congenital heart defects often requires the use of hypothermia, complete arrest of the circulation, or very low flow rates. Second, the large disparity between the CPB circuit size and the patient requires excessive priming volumes that hemodilute important blood components. Postoperative care following congenital heart surgery, therefore, is often directed both at mitigating the deleterious effects of the intraoperative perfusion strategy as well as addressing the anatomic and physiologic aspects of the repair.

Concomitant advancements in the preoperative and postoperative care of patients with congenital heart disease have paralleled the intraoperative innovations.

These new advancements created a paradigm shift in the field of pediatric heart surgery. The traditional strategy of initial palliation followed by definitive correction at a later age, which had pervaded the thinking of most surgeons, began to evolve to one emphasizing early repair, even in the tiniest patients. Furthermore, some of the defects that were virtually uniformly fatal (such as hypoplastic left-heart syndrome) now can be successfully treated with aggressive forms of staged palliation, resulting in outstanding survival for many of these children.

Because the goal in most cases of congenital heart disease (CHD) is now early repair, as opposed to subdividing lesions into cyanotic or noncyanotic lesions, a more useful classification scheme divides particular defects into three categories based on the feasibility of achieving this goal: (1) defects that have no reasonable palliation and for which repair is the only option; (2) defects for which repair is not possible and for which palliation is the only option; and (3) defects that can either be repaired or palliated in infancy. It bears mentioning that all defects in the second category are those in which the appropriate anatomic components either are not present, as in hypoplastic left-heart syndrome, or cannot be created from existing structures. One obvious caveat is that the aforementioned classification scheme is certainly not absolute nor static. The vast morphologic heterogeneity that can manifest even within the same diagnostic subgroup mandates an *individualized* and creative approach to every patient.

Defects Where Repair Is the Only or Best Option

Atrial Septal Defect

An atrial septal defect (ASD), as discussed in previous chapters, is defined as an opening in the interatrial septum that enables the mixing of blood from the systemic venous and pulmonary venous circulations.

ASDs that are not amenable to percutaneous closure can be repaired in a facile manner using standard CPB techniques through a midline sternotomy approach. Because the surgery is usually relatively straightforward, systemic cooling is usually limited to 34°C. The heart is arrested with the infusion of a high potassium solution called cardioplegia into the coronary arteries, through a needle inserted into the ascending aorta. Arrest of the

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_254,

heart greatly facilitates the conduct of surgery and prevents the ejection of air into the systemic circulation, but does require the application of an aortic cross-clamp, which renders the coronaries ischemic. Myocardial protection can be improved during periods of coronary ischemia by intermittent (usually every 20 min) infusion of blood cardioplegia into the coronaries, topical and systemic cooling to decrease the metabolic demands of the heart, and by adequate venting of the heart to prevent distension. Closure of ostium secundum defects is accomplished either by primary repair or by insertion of a patch which is sutured to the rim of the defect. Our preference is patch closure using autologous pericardium, which can be "fixed" in glutaraldehyde. The fixation gives the pericardium, which is usually thin, some tensile strength. Although the decision of whether patch closure is necessary can theoretically be determined by the size and shape of the defect as well as by the quality of the edges, most surgeons will utilize a patch to decrease tension on the suture line.

Traditional surgical closure is well established, with a low complication rate and a mortality rate approaching zero.

Left Ventricular Outflow Tract Obstruction

Left ventricular outflow tract obstruction (LVOTO) can be generally subdivided into obstruction beneath the aortic valve (subvalvar aortic stenosis), obstruction at the valve level (valvar aortic stenosis), and obstruction above the valvar level, (supravalvar aortic stenosis). In many instances, these conditions coexist, and therefore, surgical relief of LVOTO may encompass more than one of the techniques described below in concert. The first decision that must be made in the neonate with critical left ventricular outflow tract obstruction is whether the patient is a candidate for biventricular or univentricular repair. Very rarely, if catheter-based therapy is not an option, relief of valvular aortic stenosis in infants and children can be accomplished with surgical valvotomy using standard techniques of CPB and direct exposure to the aortic valve. Cardioplegic arrest, if required, is administered using special catheters that are placed directly into the coronary ostia.

Should aortic valve replacement be required, the surgical therapy is dependent on the size of the aortic annulus, and whether concomitant obstruction exists at the subvalvar or supravalvar level. If the annulus is adequate, then a simple valve replacement using standard CPB and cardioplegic arrest is undertaken. If the annulus is too small to allow a prosthesis appropriate for the patient's body size (i.e., avoiding patient-prosthesis mismatch), an annulus enlarging procedure such as a Konno aortoventriculoplasty may be required. A Konno procedure essentially involves incising the aortic annulus within the left and right coronary commissure. The incision is carried onto the right ventricle. The conal septum is then resected, creating a ventricular septal defect, which can be closed with a patch. Many surgeons previously avoided aortic valve replacement for aortic stenosis in early childhood because the more commonly used mechanical valves would be outgrown and require replacement later, and the obligatory anticoagulation for mechanical valves resulted in a substantial risk for complications. In addition, mechanical valves have an important incidence of bacterial endocarditis or perivalvular leak requiring reintervention.

Given that repair of isolated discrete subaortic stenosis can be done with low rates of morbidity and mortality, some surgeons advocate repair in all cases of discrete subaortic stenosis to avoid progression of stenosis and the development of aortic insufficiency, though more recent data demonstrates that subaortic resection should be delayed until the LV gradient exceeds 30 mmHg, since most children with an initial LV gradient < 30 mmHg have quiescent disease. For discrete subaortic stenosis, the operation involves standard CPB and cardioplegic arrest without the need for systemic cooling below 34°C. The aorta is opened and the valve is inspected in that subaortic obstruction may coexist with valvar aortic stenosis. If the valve function and morphology appear reasonable, the membrane below the valve is excised. Often a portion of left ventricular muscle is resected along with the membrane, termed a myectomy, to completely relieve the obstruction. Diffuse AS is a more complex lesion and often requires aortoventriculoplasty as previously described. Results are generally excellent, with operative mortality less than 5%.

Supravalvar aortic stenosis also can be subdivided into discrete and diffuse types. The localized form of supravalvular aortic stenosis is treated by creating an inverted Y-shaped aortotomy across the area of stenosis, straddling the right coronary artery. The obstructing shelf is then excised and a pantaloon-shaped patch is used to close the incision. The diffuse form of supravalvular stenosis is more variable, and the particular operative approach must be tailored to each specific patient's anatomy. In general, either an aortic endarterectomy with patch augmentation can be performed, or if the narrowing extends past the aorta arch, a prosthetic graft can be placed between the ascending and descending aorta. Operative results for discrete supravalvular aortic stenosis are

generally good, with a hospital mortality of less than 1% and an actuarial survival rate exceeding 90% at 20 years. In contrast, however, the diffuse form is more hazardous to repair, and carried a mortality of 15% in a recent series.

Patent Ductus Arteriosus

The presence of a persistent patent ductus arteriosus is sufficient indication for closure because of the increased mortality and risk of endocarditis. In older patients with pulmonary hypertension, closure may not improve symptoms and is associated with much higher mortality.

Surgical approach employs a posterior lateral thoracotomy in the fourth or fifth intercostal space on the side of the aorta (generally the left). The lung is then retracted anteriorly. The ductus is ligated with a surgical clip or permanent suture.

In premature infants, the surgical mortality is very low, although the overall hospital death rate is significant as a consequence of other complications of prematurity. In older infants and children, mortality is less than 1%. Bleeding, chylothorax, vocal cord paralysis, and the need for reoperation occur infrequently.

Aortic Coarctation

The routine management of hemodynamically significant COA in all age groups has traditionally been surgical. Transcatheter repairs are used with increasing frequency in older patients and those with re-coarctation following surgical repair. Balloon dilatation of native coarctation in neonates has been recently utilized with only transient relief of obstruction. The initial question that must be answered prior to repair is whether the surgery should be performed using a left thoracotomy, which is typical, or a median sternotomy. Generally, if there is a question about transverse arch hypoplasia or other concomitant intracardiac lesions, a median sternotomy should be elected. The most common surgical techniques in current use are resection with end-to-end anastomosis or extended end-to-end anastomosis, taking care to remove all residual ductal tissue. Extended end-to-end anastomosis may also allow the surgeon to treat transverse arch hypoplasia which is commonly encountered in infants with aortic coarctation. An extended end-to-end or simple end-to-end repair usually does not require CPB. For the extended end-to-end repair, occasionally cerebral perfusion using a catheter placed into the innominate artery may be required in cases where both the left common carotid and left subclavian arteries are occluded and there is an incomplete Circle of Willis. The aorta above and below the narrowed segment is widely mobilized, and partial-occluding clamps are utilized to isolate enough aortic wall to fashion an anastomosis along the entire undersurface of the arch. In the simple end-to-end technique, the ascending and descending aorta are simply sutured together. The subclavian flap aortoplasty is another repair, though is used less frequently in the modern era because of the risk of late aneurysm formation and possible underdevelopment of the left upper extremity. In this method, the left subclavian artery is transected and brought down over the coarcted segment as a vascularized patch. The main benefit of these techniques is that they do not involve the use of prosthetic materials, and evidence suggests that extended end-to-end anastomosis may promote arch growth, especially in infants with the smallest initial aortic arch diameters.

Despite the benefits, however, extended end-to-end anastomosis may not be feasible when there is a long segment of coarctation or in the presence of previous surgery, because sufficient mobilization of the aorta above and below the lesion may not be possible. In this instance, prosthetic materials, such as a patch aortoplasty, in which a prosthetic patch is used to enlarge the coarcted segment, or an interposition tube graft must be employed.

The most common complications after COA repair are late restenosis and aneurysm formation at the repair site. Aneurysm formation is particularly common after patch aortoplasty when using Dacron material. In a large series of 891 patients, aneurysms occurred in 5.4% of the total, with 89% occurring in the group who received Dacron-patch aortoplasty, and only 8% in those who received resection with primary end-to-end anastomosis. A further complication, although uncommon, is lower-body paralysis resulting from ischemic spinal cord injury during the repair.

Truncus Arteriosus

Truncus arteriosus was first managed with pulmonary artery banding as described by Armer and colleagues in 1961. However, this technique led to only marginal improvements in 1-year survival rates because ventricular failure inevitably occurred. In 1967, complete repair was accomplished by McGoon and his associates based on the experimental work of Rastelli, who introduced the idea that an extracardiac valved conduit could be used to restore ventricular-to-pulmonary artery continuity. Over

the next 20 years, improved survival rates led to uniform adoption of complete repair even in the youngest and smallest infants.

Surgical correction entails the use of CPB and cardioplegic arrest. Repair is completed by separation of the pulmonary arteries from the aorta, closure of the aortic defect (occasionally with a patch) to minimize coronary flow complications, placement of a valved cryopreserved allograft or jugular venous valved conduit (Contegra) to reconstruct the right ventricular outflow tract, and ventricular septal defect closure. Important branch pulmonary arterial stenosis should be repaired at the time of complete repair, and can usually be accomplished with longitudinal allograft patch arterioplasty. Severe truncal valve insufficiency occasionally requires truncal valve repair, if feasible, or valve replacement. The results of complete repair of truncus have steadily improved. Severe truncal regurgitation, interrupted aortic arch, coexistent coronary anomalies, chromosomal or genetic anomalies, and age younger than 100 days are risk factors associated with perioperative death and poor outcome.

Total Anomalous Pulmonary Venous Connection (TAPVC)

Operative correction of TAPVC requires anastomosis of the common pulmonary venous channel to the left atrium, obliteration of the anomalous venous connection, and closure of the atrial septal defect.

All types of TAPVC are approached through a median sternotomy, and many surgeons use deep hypothermic circulatory arrest (DHCA) in order to achieve an accurate and widely patent anastomosis. DHCA requires systemic perfusion cooling, using the CPB circuit, of the patient over at least 20 min, to a core body temperature of 18°C. Once that core temperature is reached, the head is packed in ice, systemic steroids are often administered, and the perfusion through the CPB pump is stopped. Many surgeons use a catheter placed into the innominate artery with isolation of the other arch vessels, to allow perfusion to the brain during DHCA, termed selective antegrade cerebral perfusion. Once the circulation is arrested, the blood from the patient is drained into the venous reservoir, and the cannulae are removed from the body. Though there have been no definitive studies performed, most surgeons agree that a period of 40 min of DHCA is safe. Once the repair is completed, CPB is resumed, and the patient is slowly rewarmed to normothermia.

The technique for supracardiac TAPVC includes early division of the vertical vein; retraction of the aorta and the superior vena cava laterally to expose the posterior aspect of the left atrium and the pulmonary venous confluence; and a side-to-side anastomosis between a long, horizontal biatrial incision and a longitudinal incision within the pulmonary venous confluence. The ASD can then be closed with an autologous pericardial or synthetic patch.

Repair of infracardiac TAPVC entails ligation of the vertical vein at the diaphragm, followed by construction of a proximal, patulous longitudinal venotomy. This repair is usually performed by "rolling" the heart toward the left, thus exposing the left atrium where it usually overlies the descending vertical vein.

Cautious perioperative management of these infants is crucial because episodes of pulmonary hypertension can occur within the first 48 h, which contribute significantly to mortality following repair.

Results of TAPVC in infancy have markedly improved in recent years, with an operative mortality of 5% or less in some series. This improvement is probably multifactorial, mainly as a consequence of early noninvasive diagnosis and aggressive perioperative management. The routine use of echocardiography; improvements in myocardial protection with specific attention to the right ventricle; creation of a large, tension-free anastomosis with maximal use of the venous confluence and atrial tissue; careful geometric alignment of the pulmonary venous sinus with the body of the left atrium avoiding tension and rotation of the pulmonary veins; and prevention of pulmonary hypertensive events have likely played a major role in reducing operative mortality. The importance of risk factors for early mortality, such as venous obstruction at presentation, urgency of operative repair, and infradiaphragmatic anatomic type, has been debated.

The most significant postoperative complication of TAPVC repair is pulmonary venous obstruction, which occurs 9–11% of the time, regardless of the surgical technique employed. Mortality varies between 30% and 45%, and alternative catheter interventions do not offer definitive solutions.

Defects Requiring Palliation

Tricuspid Atresia

The treatment for tricuspid atresia in the earlier era of palliation was aimed at correcting the defect in the pulmonary circulation. That is, patients with too much pulmonary flow received a pulmonary band, and those with insufficient flow received a systemic-to-pulmonary artery shunt. Systemic-to-pulmonary artery shunts, or

Blalock-Taussig (B-T) shunts, were first applied to patients with tricuspid atresia in the 1940s and 1950s. Likewise pulmonary artery banding was applied to patients with tricuspid atresia and congestive failure in 1957. However, despite the initial relief of either cyanosis or congestive heart failure, long-term mortality was high, as the single ventricle was left unprotected from either volume or pressure overload.

The issues surrounding the approach to palliative surgery are discussed in Chap. 251, "The Single Ventricle". Recognizing the inadequacies of the initial repairs, Glenn described the first successful cavopulmonary anastomosis, an end-to-side right pulmonary artery (RPA)-to-superior vena cava (SVC) shunt in 1958, and later modified this to allow flow to both pulmonary arteries. This end-to-side RPA-to-SVC anastomosis was known as the bidirectional Glenn, and is the second stage to final Fontan repair in widespread use today. The Fontan repair was a major advancement in the treatment of congenital heart disease, as it essentially bypassed the right heart, and allowed separation of the pulmonary and systemic circulations. Multiple modifications of the initial repair, as described by Fontan in 1971, were performed over the next 20 years. One of the most important was the description by deLeval and colleagues of the creation of an interatrial lateral tunnel that allowed the inferior vena caval blood to be channeled exclusively to the superior vena cava. A total cavopulmonary connection could then be accomplished by dividing the SVC and suturing the superior portion to the upper side of the right pulmonary artery and the inferior end to the augmented undersurface of the right pulmonary artery. Pulmonary flow then occurs passively, in a laminar fashion, driven by the central venous pressure. This repair became known as the modified Fontan operation.

Another important modification, the fenestrated Fontan repair, a residual 20–30% right-to-left shunt is either created or left unrepaired at the time of cavopulmonary connection to help sustain systemic output in the face of transient elevations in the PVR postoperatively.

The last notable variation on the original Fontan repair uses an extracardiac prosthetic tube graft, usually 20 mm in diameter, as the conduit directing inferior vena cava (IVC) blood to the pulmonary arteries. This technique has the advantages of decreasing atrial geometric alterations by avoiding intra-atrial suture lines, and improving flow dynamics in the systemic venous pathway by maximizing laminar flow. The extracardiac Fontan operation can be completed without the use of cardiopulmonary bypass in selected cases, which may further improve outcomes. One potential disadvantage of the extracardiac Fontan is that it delays performance of the Fontan in order to allow placement of a conduit of sufficient size. Despite these innovative approaches, the current strategy for operative management still relies on the idea of palliation. Patients are approached in a staged manner, to maximize their physiologic state so that they will survive to undergo a Fontan operation. The therapeutic strategy must begin in the neonatal period and should be directed toward reducing the patient's subsequent risk factors for a Fontan procedure. Accordingly, small systemic-pulmonary artery shunts, which are usually performed through a median sternotomy, should be constructed for palliation of ductal-dependent univentricular physiology. This can easily be replaced with a bidirectional Glenn shunt or hemi-Fontan operation at 6 months of life. In non-ductal-dependent univentricular physiology, the infant can be managed medically until primary construction of a bidirectional cavopulmonary anastomosis becomes feasible.

The Fontan is usually performed when the child is between 2 and 4 years of age, and it is generally successful if the infant was staged properly, with a protected single ventricle, and there is adequate PA growth. The PVR should be below 4 Woods Units, and the ejection fraction should be more than 45% to ensure success. Fenestration of the atrial baffle may be helpful in patients with high PA pressures because their PVR may preclude adequate postoperative cardiac output.

Recent reports of the Fontan procedure for tricuspid atresia have been encouraging, with an overall survival of 86% and an operative mortality of 2%. The main complications following repair are atrial arrhythmias, particularly atrial flutter; conduit obstruction requiring reoperation; protein-losing enteropathy; and decreased exercise tolerance.

A recent prospective multi-institutional study from the Congenital Heart Surgeons Society reported the outcomes of 150 neonates with tricuspid atresia and normally related great vessels. Five-year survival was 86%, and by the age of 2 years, 89% had undergone cavopulmonary anastomosis, and 75% of those surviving cavopulmonary anastomosis underwent Fontan operation within 3 years.

Hypoplastic Left-Heart Syndrome

In 1983, Norwood and colleagues described a two-stage palliative surgical procedure for relief of HLHS that was later modified to the currently used three-stage method of palliation. Stage 1 palliation, also known as the modified Norwood procedure, bypasses the left ventricle by creating a single outflow vessel, the neoaorta, which arises from the right ventricle.

The current technique of arch reconstruction involves completion of a connection between the pulmonary root, the native ascending aorta, and a piece of pulmonary homograft used to augment the diminutive native aorta. There are several modifications of this anastomosis, most notably the Damus-Kaye-Stansel (DKS) anastomosis, which involves dividing both the aorta and the pulmonary artery at the sinotubular junction. The proximal aorta is anastomosed to the proximal pulmonary artery creating a "double-barreled" outlet from the heart. This outlet is anastomosed to the distal aorta, which can be augmented with homograft material if there is an associated coarctation. At the completion of arch reconstruction, a 3.5- or 4-mm shunt is placed from the innominate artery to the right pulmonary artery. The interatrial septum is then widely excised, thereby creating a large interatrial communication and preventing pulmonary venous hypertension.

The postoperative management of infants following stage 1 palliation is complex because favorable outcomes depend on establishing a delicate balance between pulmonary and systemic perfusion. Recent literature suggests that these infants require adequate postoperative cardiac output in order to supply both the pulmonary and the systemic circulations and that the use of oximetric catheters to monitor SVO_2 aids clinicians in both the selection of inotropic agents and in ventilatory management. Recent introduction of a modification that includes arch reconstruction and placement of the shunt between the right ventricle and the pulmonary artery (Sano shunt) diminishes the diastolic flow created by the classical aortopulmonary shunt and may augment coronary perfusion, resulting in improved postoperative cardiac function. A recent prospective, randomized, multi-institutional trial sponsored by the NIH, the systemic ventricle reconstruction (SVR) trial, evaluated neonates having either a modified Blalock-Taussig shunt versus a Sano shunt. The SVR trial showed higher 12-month transplant-free survival in the Sano shunt group, but a higher incidence of unintended reinterventions and complications. Longer follow-up data is currently being collected in this cohort.

Although surgical palliation with the Norwood procedure is still the mainstay of therapy for infants with HLHS, a combined surgical and percutaneous option (Hybrid procedure), which consists of bilateral pulmonary artery banding and placement of a ductus arteriosus stent, has emerged as a promising alternative that obviates the need for cardiopulmonary bypass in the fragile neonatal period. The hybrid procedure can also be used as a bridge to heart transplantation in those infants with severe atrioventricular valve regurgitation or otherwise unsuitable single-ventricle anatomy.

Following stage 1 palliation, the second surgical procedure is the creation of a bidirectional cavopulmonary shunt or Hemi-Fontan as discussed previously, generally at 3–6 months of life when the PVR has decreased to normal levels. Not all patients with HLHS require this three-stage palliative repair. Some infants afflicted with a milder form of HLHS, recently described as hypoplastic left-heart complex (HLHC), have aortic or mitral hypoplasia without intrinsic valve stenosis and antegrade flow in the ascending aorta. In this group, a two-ventricle repair can be achieved with reasonable outcome. Tchervenkov recently published the results with 12 patients with HLHC who underwent biventricular repair at a mean age of 7 days. The operative technique consisted of a pulmonary homograft patch aortoplasty of the aortic arch and ascending aorta and closure of the interatrial and interventricular communications. The left heart was capable of sustaining systemic perfusion in 92% of patients, and early mortality was 15.4%.

Although the Norwood procedure is the most widely performed initial operation for HLHS, transplantation can be used as a first-line therapy and may be preferred when anatomic or physiologic considerations exist that preclude a favorable outcome with palliative repair. Significant tricuspid regurgitation, intractable pulmonary artery hypertension, severe arrhythmias, or progressive right ventricular failure are cases where cardiac replacement may be advantageous. Widespread adaptation of transplantation as first-line treatment for HLHS has been limited by improved Norwood survival rates and by limited organ availability. Organ availability should be considered prior to electing transplantation, as 24% of infants died awaiting transplantation in the largest series to date.

Outcomes for HLHS are still significantly worse than those for other complex cardiac defects. However, with improvements in perioperative care and modifications in surgical technique, the survival following the Norwood procedure now exceeds 80% in experienced centers. The outcome for low-birth-weight infants has improved, but low weight still remains a major predictor of adverse survival, especially when accompanied by additional cardiac defects, such as systemic outflow obstruction or extracardiac anomalies.

Defects That May Be Palliated or Repaired

Transposition of the Great Arteries

The surgical treatment of transposition has evolved from the initial atrial switch operations (Senning and Mustard

operations), which afforded a physiologic correction, to an anatomic repair, the arterial switch operation, described by Jatene in 1975. Following median sternotomy and standard CPB, the arterial switch procedure involves division of the aorta and the pulmonary artery, mobilization of the coronary arteries and creation of coronary "buttons," posterior translocation of the aorta (LeCompte maneuver), proper alignment and anastomosis of the coronary arteries on the neoaorta, and placement of a pantaloon-shaped autologous pericardial patch to reconstruct the neopulmonary artery defect.

The most important consideration is the timing of surgical repair, because arterial switch should be performed within 2 weeks after birth, before the left ventricle loses its ability to pump against systemic pressure. Neonates with a concomitant ventricular septal defect have a pressurized LV, and therefore the timeframe prior to surgery may be more plastic, though, generally, early repair is indicated. In patients presenting later than 2 weeks, the left ventricle can be re-trained with preliminary pulmonary artery banding and aortopulmonary shunt followed by definitive repair. Alternatively, the unprepared left ventricle can be supported following arterial switch with a mechanical assist device for a few days while it recovers ability to manage systemic pressures. Echocardiography can be used to assess left ventricular performance and guide operative planning in these circumstances.

The subset of patients who present with D-TGA complicated by left ventricular outflow tract obstruction (LVOTO) and VSD may not be suitable for an arterial switch operation. The Rastelli operation, first performed in 1968, uses placement of an intracardiac baffle to direct left ventricular blood to the aorta and an extracardiac valved conduit to establish continuity between the right ventricle and the pulmonary artery, which has led to successful outcomes in these complex patients. Another option for this challenging subset of patients is the Nikaidoh procedure, in which the aortic root is mobilized and translocated posteriorly. The hypoplastic pulmonary annulus is incised onto the conal septum, which is also resected. The aortic root is sewn to the posterior portion of the opened pulmonary annulus, and the VSD is closed with a patch that is then sewn to the anterior portion of the aortic root. Reconstruction of the right ventricular outflow tract has been variable, with some surgeons favoring the use of an outflow patch, a valved patch, or a conduit.

For patients with D-TGA, IVS, and VSD, the arterial switch operation provides excellent long-term results with a mortality rate of less than 5%. Operative risk is increased when unfavorable coronary anatomic configurations are present, or when augmentation of the aortic arch is required. The most common complication is supravalvular pulmonary stenosis, occurring 10% of the time, which may require reoperation.

Tetralogy of Fallot (TOF)

John Deanfield said "... long follow-up inevitably means surgery in an earlier era: More recent surgery, at a younger age, with better preoperative, operative, and postoperative care, will improve long-term results. Data from the former (earlier) era will be overly pessimistic." This statement is particularly pertinent as surgical correction of TOF has evolved from a staged approach of antecedent palliation in infancy followed by intracardiac repair to primary repair during the first few months of life without prior palliative surgery.

However, systemic-to-pulmonary shunts, generally a B-T shunt, may still be preferred with an unstable neonate younger than 4 months of age, when an extracardiac conduit is required because of an anomalous left anterior descending coronary artery, or when pulmonary atresia, significant branch pulmonary artery hypoplasia, or severe noncardiac anomalies coexist with TOF.

Traditionally, TOF was repaired through a right ventriculotomy, providing excellent exposure for closure of the VSD and relief of the RVOT obstruction, but concerns that the resultant scar would significantly impair right ventricular function or lead to lethal arrhythmias led to the development of a transatrial approach. Transatrial repair, except in cases when the presence of diffuse RVOT hypoplasia requires insertion of a transannular patch, is now being increasingly advocated by many, although its superiority has not been conclusively demonstrated.

The operative technique involves the use of CPB with cardioplegic arrest and moderate hypothermia. All existing systemic-to-pulmonary arterial shunts, as well as the ductus arteriosus, are ligated. A right atriotomy is then made, and the anatomies of the VSD and the RVOT are assessed by retracting the tricuspid valve. The outflow tract obstruction is relieved by resecting the offending portion of the infundibular septum as well as any muscle trabeculations. If necessary, a pulmonary valvotomy or, alternatively, a longitudinal incision in the main pulmonary artery can be performed to improve exposure. Patch closure of the VSD is then accomplished, taking care when placing sutures along the posteroinferior portion to avoid the conduction system.

Operative mortality for primary repair of TOF in infancy is less than 5% in most series. Previously reported risk factors such as transannular patch insertion or younger age at time of repair have been eliminated secondary to improved intraoperative and postoperative care.

A major complication of repaired TOF is the development of pulmonary insufficiency, which subjects the RV to the adverse effects of acute and chronic volume overload (see Chap. 115, "Cyanotic Congenital Heart Disease"). This is especially problematic if residual lesions such as a VSD or peripheral pulmonary stenosis exist. Pulmonary valve regurgitation after repair of TOF is relatively well tolerated in the short term, partly because the hypertrophied right ventricle usually adapts to the altered hemodynamic load. The detrimental effects of chronic pulmonary valve regurgitation are, however, numerous, and include progressive right ventricular dilatation and failure, tricuspid valve regurgitation, exercise intolerance, arrhythmia, and sudden death.

When significant deterioration of ventricular function occurs, insertion of a pulmonary valve may be required, although this is rarely necessary in infants. Unfortunately, there are no universal criteria establishing the timing of pulmonary valve replacement, though dilation of the right ventricle, prolongation of the QRS duration beyond 180 ms, important atrial arrhythmias, or impaired ventricular function are widely used.

Ventricular Septal Defect

Repair of isolated VSDs requires the use of CPB with moderate hypothermia and cardioplegic arrest. The right atrial approach is preferable for most defects, except apical muscular defects, which often require a left ventriculotomy for adequate exposure. Supracristal defects may alternatively be exposed via a longitudinal incision in the pulmonary artery or a longitudinal incision in the right ventricle below the pulmonary valve. Regardless of the type of defect present, a right atrial approach can be used initially to inspect the anatomy, as this may be abandoned should it offer inadequate exposure for repair. After careful inspection of the heart for any associated malformations, a patch repair is employed, taking care to avoid the conduction system. Routine use of intraoperative transesophageal echocardiography should be used to assess for any residual defects.

Multiple or "Swiss-cheese" VSDs represent a special case, and many cannot be repaired during infancy. In those patients in whom definitive VSD closure cannot be accomplished, temporary placement of a pulmonary artery band can be employed to control pulmonary flow. This allows time for spontaneous closure of many of the smaller defects, thus simplifying surgical repair. Some centers, however, have advocated early definitive repair of the Swiss-cheese septum, by using oversize patches, fibrin glue, and combined intraoperative device closure, as well as techniques to complete the repair transatrially. At the University of California at San Francisco, 69% of patients with multiple VSDs underwent single-stage correction, and the repaired group had improved outcome as compared to the palliated group.

Even in very small infants, closure of VSDs can be safely performed with hospital mortality near 0%. The main risk factor remains the presence of other associated lesions, especially when present in symptomatic neonates with large VSDs.

Atrioventricular Canal Defects

The management of patients with AV canal defects can be especially challenging. Timing of operation is individualized, not only to the intracardiac anatomy, but also to chromosomal defects, such as Down's syndrome. Babies with Down's syndrome have a predilection for the persistence of high PVR. Those patients with partial defects can be electively repaired between 2 and 5 years of age, whereas complete AV canal defects should be repaired within the first year of life to prevent irreversible changes in the pulmonary circulation. Complete repair in infancy should be accomplished, with palliative procedures such as pulmonary artery banding reserved for only those infants with other complex lesions, or who are too ill to tolerate CPB.

The operative technique involves use of either continuous hypothermic CPB or, for small infants, DHCA. Through a median sternotomy, the heart is initially approached through an oblique right atriotomy, and the anatomy is carefully observed. In the case of a partial AV canal, the cleft in the mitral valve is repaired with interrupted sutures and the atrial septal defect is closed with an autologous pericardial patch. Complete AV canal defects are repaired by either a one-patch or two-patch repair. Details of the repair vary according to center, involving patch closure of the VSD, separating the common AV valve into tricuspid and mitral components, suspending the neovalves from the top of the VSD patch, and closing the ASD.

Partial AV canal defects have an excellent outcome, with a mortality rate of 0–2% in most series. Complete AV canal defects are associated with a poorer prognosis, with an operative mortality of 3–13%.

The most frequently encountered postoperative problems are complete heart block (1–2%), right bundle-branch block (22%), arrhythmias (11%), right ventricular outflow tract obstruction (11%), and progressive mitral regurgitation (13–24%). The increasing use of intraoperative transesophageal echocardiography may positively influence outcomes, as the adequacy of repair can be assessed and treated without need for subsequent reoperation.

Introduction

Disorders of cardiac rhythm can occur at any age, from the fetus to adult. The spectrum of arrhythmias ranges from transient phenomena to recurrent arrhythmias. Simple and isolated rhythm abnormalities such as isolated premature atrial complexes may be more bothersome to the care provider than to the patient, but persistent and life-threatening rhythms may require emergent treatment and intervention. While most children with cardiac arrhythmias may have structurally normal hearts, there is certainly an increased incidence of rhythm disorders in children with congenital heart disease. In addition, these patients may be more susceptible to morbidity or mortality than their counterparts with normal hearts. Management of arrhythmias in childhood depends on the expectations of the arrhythmia itself. This may range from expectant management to medical therapy to urgent intervention.

Components of the Normal Cardiac Conduction System

Sinus Node

The sinus node resides at the junction between the superior vena cava and the right atrium. The tissue is histologically distinct from atrial tissue and has no contractile components. Studies have demonstrated that the nodal tissue extends from the junction along the lateral wall of the right atrium. Impulses generated by automatic action potential behavior activate the adjacent atrial myocardium which then propagates by cell-to-cell activation to the additional atrial myocytes.

Atrioventricular (AV) Node

The atrioventricular node is located near the atrioventricular junction between the right atrium and the right ventricle. More well-defined than the sinus node, the compact atrioventricular node is located along the interatrial septum just anterior to the tricuspid valve. Action potential impulses propagating across the atrial myocardium reach the compact AV node. Conduction velocity is slowed in the AV node before it enters the specialized conduction fibers of the His-Purkinje tract.

His-Purkinje System

In the normal heart, the atria and the ventricles are electrically isolated from one another by the atrioventricular rings (mitral and tricuspid annuli). The penetrating bundle of His is usually the only conducting tissue to traverse the atrioventricular rings to the ventricles. The bundle is electrically well insulated from the interventricular septum until it gives off branches. The first branch from the His bundle leads to activation of the septum. The bundle then bifurcates into distinct right and left bundle branches. The left bundle branch itself is separated into anterior and posterior fascicles. At the terminus of each of the bundle branches, the specialized conduction tract divides into an array of short Purkinje fibers which respectively insert onto the ventricular myocardium. When conduction follows the normal conduction system, the ventricles are activated in an electrically synchronized manner that results in mechanically efficient ventricular contraction.

The Electrocardiogram and Normal Cardiac Conduction

Cardiac rhythm that begins in the sinus node and conducts normally to the ventricles is considered sinus rhythm. The rate of normal sinus rhythm and the normal conduction intervals vary significantly from infancy through childhood. The impulse generated sweeps from the sinus node across the right and left atria. On a normal electrocardiogram, this is evident by P waves that are upright in lead I, lead II, and lead aVF. There is typically an isoelectric pause following the P wave, as conduction enters the AV node and specialized conduction system, as there is no depolarizing signal from either the AV node or the His-Purkinje system. This interval, from the onset of the P wave to the onset of ventricular activation, is

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_255,

measured as the PR interval. When the ventricles are depolarized, this is manifest as the QRS complex. When ventricular activation occurs in a normal and organized fashion, the QRS complex duration (measured from the onset of the Q wave to the completion of the S wave) is fairly narrow. The ST segment is the period of generally isoelectric time before the onset of the T wave. The T wave represents the repolarization phase of the ventricular mass. The QT interval is the measurement between the onset of the Q wave to the end of the T wave. This can be difficult to measure, as the end of the T wave is often indistinct. The T wave in lead II is traditionally used for this measurement, although the T wave may be more distinct in other leads as well. There will occasionally be a distinct U wave following a T wave. Sometimes this is even fused with the downslope of the T wave (in which case it is often referred to as the TU wave). The U wave has little clinical significance (although it can become prominent during extremes of metabolic derangements, such as in severe hypokalemia or hypothermia). It is not measured as part of the T wave for the QT measurement unless it is at least 50% the height of the T wave. Abnormalities of the depolarization sequence will affect the repolarization sequence as well. Thus, if a patient has an abnormal QRS complex, the QT measurement will often be abnormal. The T wave in leads V1 and V2 are upright at birth, but typically become inverted by the first week of life. The T wave inversion persists until preadolescence or adolescence, when it returns to the upright adult configuration.

Abnormal Atrioventricular Conduction

When the normal sequence of atrioventricular conduction is disturbed, the cardiac rhythm may become irregular. However, many of these electrocardiographic manifestations will only be evident on the electrocardiogram itself and might not be appreciated by physical examination alone. Forms of atrioventricular block can occur with anything that interrupts or impedes conduction through the atrioventricular conduction axis from the AV node through the His-Purkinje system, whether this is intrinsic (due to parasympathetic stimulation) or an acquired problem.

First-Degree Atrioventricular Block

First-degree atrioventricular block describes any conduction delay that prolongs atrioventricular conduction beyond the normal range. However, conduction remains intact and the usual 1:1 atrioventricular association persists. The normal PR interval is up to 140 ms in the first 3 months, to 160 ms until 6 years of age, and up to 180 ms until age 15. First-degree atrioventricular block may be a normal variant or may be caused by factors that increase conduction time through the AV node. Elevated resting vagal tone can be seen in highly trained athletes, and often results in first-degree atrioventricular block on the resting ECG. More pathologic conditions, such as rheumatic fever or neonatal lupus syndrome or lyme disease, may also prolong the PR interval. However, except in cases where the PR interval is extremely prolonged, there is usually no outward manifestation of first-degree atrioventricular block and the physical examination is otherwise unchanged.

Second-Degree Atrioventricular Block

Second-degree atrioventricular block is ascribed when there is incomplete conduction from atrium to ventricle. This can manifest as an occasionally skipped beat on physical examination. Mobitz type I, also known as Wenckebach conduction, describes a pattern wherein the atrioventricular conduction becomes gradually delayed with each successive beat. The PR interval becomes progressively prolonged, and after a number of beats (usually two or three, although this could certainly be longer) there is loss of atrioventricular conduction for a single beat. On the subsequent beat, the PR is normalized and the sequence of prolongation begins again. A Wenckebach pattern can be seen on the electrocardiogram of otherwise normal and healthy young athletes, and is a reflection of increased resting vagal tone.

In Mobitz II conduction block, the PR does not prolong and there is loss of conduction after a stereotyped number of beats. Whereas Wenckebach phenomenon is a common finding that has no pathologic implications, Mobitz II conduction block is always abnormal. The etiology of Mobitz II conduction block does not appear to be due to impairment within AV node, but rather it is loss of conduction in the His bundle or below. Mobitz II conduction block is very rare in pediatrics, as it is usually a sign of a diseased conduction system. Patients with Mobitz II conduction block should be evaluated by electrophysiology study and may require permanent pacemaker implantation; patients with Mobitz I Wenckebach pattern would not require a pacemaker.

Third-Degree (Complete) Atrioventricular Block

Third-degree atrioventricular block occurs when there is complete lack of conduction between the atria and

ventricles. Often, the ventricles and thus cardiac output are supported by an escape mechanism of some form, either a junctional or ventricular escape rhythm (see below). Complete atrioventricular block can be congenital or acquired. Congenital complete atrioventricular block is most commonly associated with maternal lupus. While in severe situations the fetus or neonate may show signs of severe distress and congestive heart failure (manifested by the fetus as hydrops), many patients with congenital complete atrioventricular block may be entirely asymptomatic for many years, provided their escape rate is acceptable. Acquired heart block may occur in the setting of infection, as in the case of Chagas disease or Lyme disease. Severe rheumatic heart disease or myocarditis can also result in complete heart block. Though less common in the current surgical era, heart block can occur following cardiac surgery that involves the interventricular septum in approximately 1–3% of cases.

Bundle Branch Block

A bundle branch block occurs when conduction down the His-Purkinje axis has been interrupted along either the right or the left bundle branch. A right bundle branch block is characterized by an RSR′ pattern in V1 (sometimes described as "rabbit ears") and a broad S wave in leads I and V6 (*Fig. 255.1a*). A left bundle branch has a deep S wave in V1 and a monophasic and notched R wave in leads I and V6 (*Fig. 255.1b*). Often, a bundle branch block (particularly a left bundle branch block) indicates some type of pathology. Right bundle branch block is found in up to 23–29% of patients following surgery for congenital heart disease. Bundle branch block can be seen in the setting of a normal heart, in particular in the setting of the condition called the "athlete's heart." Due to high resting vagal tone, highly conditioned athletes can have a number of conduction abnormities, often first- and second-degree atrioventricular block or bundle branch blocks. These mild electrocardiographic abnormalities are typically normalized during even mild activity.

Functional bundle branch block "aberrancy" can be seen under certain circumstances. Aberrant conduction is seen after the onset of a rapid supraventricular rhythm. It can also be seen in very irregular rhythms such as atrial fibrillation. Functional bundle branch block is a transient phenomenon and resolves when the conditions return to normal. In contrast, permanent bundle branch block (as is seen following cardiac surgery) does not resolve.

Ventricular Preexcitation (Wolff–Parkinson–White Pattern)

Ventricular preexcitation occurs when ventricular myocardium is activated abnormally, usually through an abnormal conduction tract. The finding of preexcitation

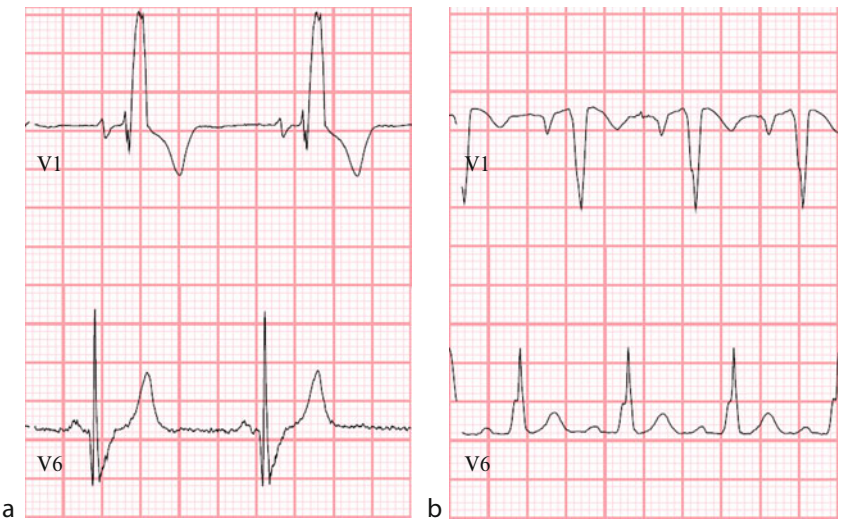

Figure 255.1
(a) Right bundle branch pattern with RSR′ pattern in V1 and wide slurred S wave in V6. (b) Left bundle branch pattern with deep S wave in V1 and tall notched R wave in V6

is indicative of the presence of an "accessory pathway." Typically, these bypass tracts bridge the electrical insulation of the atrioventricular groove, resulting in an anomalous atrioventricular electrical connection. Other variants exist, such as the accessory pathway arising from the AV node (nodo-ventricular pathway) or the His-Purkinje conduction axis (fasciculo-ventricular pathway), although these variants are very rare.

There are three classic electrocardiographic findings that define ventricular preexcitation: (1) widened QRS complex, (2) shortened PR interval, and (3) slurring delta wave (*Fig. 255.1*). The finding of Wolff–Parkinson–White pattern implies the presence of an accessory pathway capable of causing arrhythmias (see below). In most of these examples, the bypass tract does not imply the absence of normal conduction. Rather, it represents the combination of conduction through the abnormal pathway in addition to (or fused with) conduction through the normal His-Purkinje conduction pathways.

Premature Beats

Premature Atrial Complexes

Isolated atrial ectopy is common in childhood. There is no ethnic difference in the amount of presence of ectopy. It can be seen during fetal monitoring, and can be seen in up to one in four normal newborns; however, in the vast majority of the time, this resolves within the first few months of life.

Premature atrial complex occur when there is early depolarization of the atria from an ectopic focus that is different from the sinus node. This is diagnosed by identifying P waves that have a difference axis and appearance than the normal sinus P waves. Most of the time, the P waves will be very different in appearance and easily distinguished from normal sinus beats. However, on occasion premature beats may originate from the right atrium around, but separate from, the sinus node; these may be more difficult to distinguish from normal.

Atrial ectopy is typically conducted normally, meaning that there is a normal-appearing QRS complex that follows the premature atrial complex. The PR interval measured is usually different than normal, which is more a reflection of the atrial depolarization originating from an abnormal location rather than indicating a defect in atrioventricular conduction. Following the premature atrial complex is a normal-appearing QRS complex. Aberrant conduction can occur when the atrial premature beat occurs fairly early after the preceding beat. An aberrantly conducted QRS complex has the appearance of a bundle branch block or may just be slightly wider than the normal QRS complex. Aberrantly conducted premature atrial complexes are often mistaken for premature ventricular complexes due to their wider appearance, but are easily recognized by the presence of a preceding P wave. Premature atrial complexes can also have blocked atrioventricular conduction if they occur early enough after a preceding beat. While this is more pronounced in conditions where there is impaired atrioventricular conduction, it is still commonly seen in the presence of normal atrioventricular conduction and is simply a reflection of the impulse reaching the distal conduction system at a time when it or the ventricular myocardium is still refractory to depolarization. Blocked premature atrial complexes have an ectopic P wave that has no QRS complex following. Often, there will be a pause following the ectopic P wave before the next normally conducted sinus return beat (*Fig. 255.2*).

Premature Ventricular Complexes

Isolated ventricular ectopy is common in neonates and children as well. Ventricular ectopic beats can be distinguished from atrial ectopic beats as the QRS complex is often very wide and the T wave is often in an opposite axis to that of the normal QRS-T complex. There will be no P wave preceding the premature QRS complex. In isolation, ventricular ectopy has no pathologic implication in a child who has no clinical signs or symptoms to suggest any cardiac pathology.

Benign ventricular ectopy occurs in many school-aged children and adolescents. In the setting of a structurally and functionally normal heart, this generally has no clinical implications. Recent data have suggested that significantly elevated ectopy burdens can lead to ventricular dysfunction, but in most cases this does not require any treatment unless symptomatic. Most adolescents with benign ventricular ectopy are largely asymptomatic, even with relatively high ectopy burdens. Frequently, the ectopy will be suppressed by increased sinus rates. However, the absence of this feature does not have any predictive significance. In certain situations, patients may be exquisitely aware of their ventricular ectopy, which when frequent can be highly distracting. Any medication that diminishes spontaneous automaticity will usually decrease ventricular ectopy. Beta blockers and calcium channel blockers are commonly used to this end.

Bradycardic Rhythms

Sinus Bradycardia

The rate of the sinus node depends upon several factors. There are sympathetic and parasympathetic inputs to this area that influence the rate of automatic discharge from these cells. Sinus bradycardia describes the condition when the rate of impulses from the sinus node is slower than the typical range. This depends on the age of the patient, as the heart rate ranges vary considerably through infancy and childhood. Sinus bradycardia is generally distinguished from other slow atrial rhythms by the presence of a sinus P wave (see above).

Sinus bradycardia can be seen as a consequence of several conditions. It can be a late sequela after certain surgeries for congenital heart disease (such as for tetralogy of Fallot, transposition of the great arteries, or single-ventricle Fontan palliation). Sinus bradycardia may also occur as pharmacologic effect of certain drugs, in particular medications that affect automaticity, such as beta blockers or calcium channel blockers. Metabolic conditions such as hypothyroidism can result in sinus bradycardia.

Sinus bradycardia does not require treatment unless the patient is symptomatic. This is ambiguously defined; however, some symptoms that might fit would include fatigue, exercise intolerance, dizziness, near-syncope, or syncope. Management of sinus bradycardia is directed toward treating any underlying cause. Any offending medication or metabolic abnormality should be removed or corrected. Even in premature infants with frequent episodes of sinus bradycardia, including asystole, the problem is usually self-limited and rarely requires treatment. When symptomatic sinus bradycardia is expected to be more permanent, however, permanent pacemaker implantation may be required (see below).

Junctional Bradycardia

The region of the atrioventricular (AV) junction comprises the AV node and the His bundle. This exhibits automatic behavior in a fashion similar to the sinoatrial

node. Though poorly characterized, cells from the AV junction can originate action potentials that are then conducted from that point normally to the myocardium. The result is a normal-appearing (typically narrow) QRS complex. There will generally be no preceding P wave before the QRS complex. Sometimes P waves will be visible, but not in association with the junctional QRS complexes; although the P waves can also be seen superimposed upon the QRS complex when the atrium is activated simultaneously with the ventricles. When there is no atrial rhythm (e.g., sinus rhythm) to conduct, the AV junction automaticity becomes evident. This is known as a junctional escape rhythm and is usually at a much slower rate than is associated with sinus rhythm. Typical rates are between 45 and 55 beats per minute. However, when sinus nodal activity is faster and exceeds the junctional escape rate, normally conducted sinus rhythm is present (*Fig. 255.3*).

Junctional escape rhythm also occurs in association with complete (third-degree) atrioventricular block. In this setting, the rate of sinus P waves is usually normal for age, but none are conducted through the AV node. The junctional escape rate continues independently of the sinus rhythm. The rhythm of the atria and the ventricles are thus dissociated.

Supraventricular Arrhythmias

Sinus Tachycardia

Sinus tachycardia occurs when the rate of sinus node firing is greater than the upper limits of normal resting heart rate for age. The P wave morphology is typically normal, which differentiates this supraventricular rhythm from other forms of supraventricular tachycardia (see below). Common causes include increased catecholamine states, pain, anxiety, fever, intravascular dehydration, hyperthyroidism, and anemia. Treatment of sinus tachycardia is directed toward identifying and removing the cause of the drive for tachycardia.

The syndrome of inappropriate sinus tachycardia is an uncommon condition in which the average resting rates are faster than the normal range for age. In addition, normal activities that would typically result in mild sinus node acceleration, cause rapid acceleration that is fairly

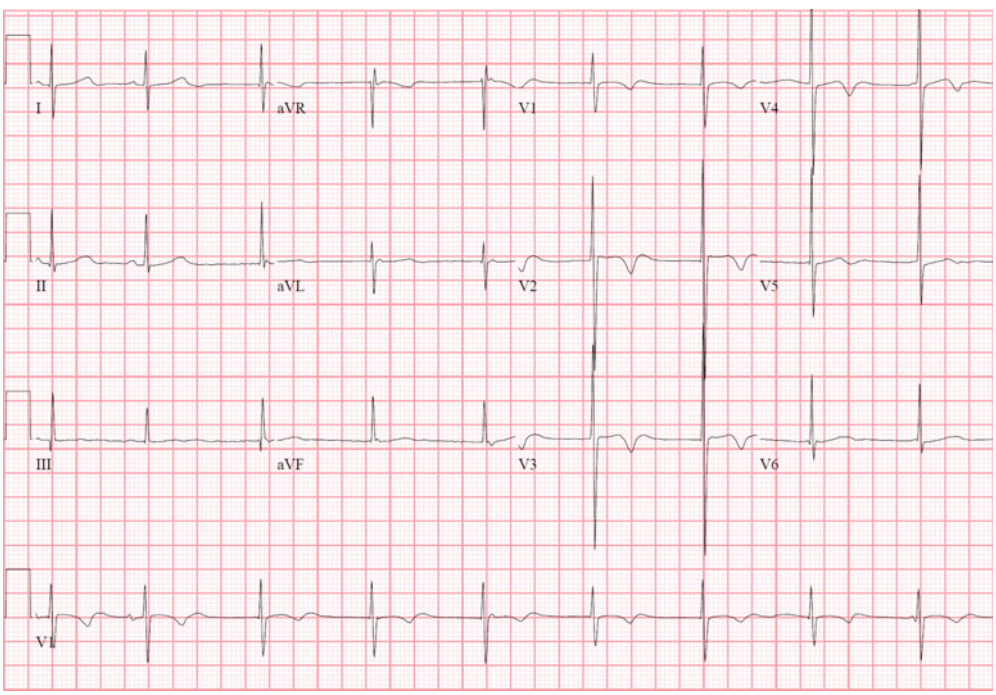

Figure 255.3
Junctional escape rhythm. After the first two sinus beats, there is severe sinus bradycardia with junctional escape rhythm at a rate of 62

symptomatic for the patient. Inappropriate sinus tachycardia is distinguished from other causes of sinus tachycardia by the nearly permanent nature of the arrhythmia, but care must be made to avoid making this diagnosis when there is a treatable cause of sinus tachycardia. This arrhythmia is rare in childhood, and is seen more commonly beginning in the second and third decades of life. Females are affected more often than males. When appropriately diagnosed, this condition is treated with drugs that diminish automaticity, namely, beta blockers or calcium channel blockers. In rare cases of highly symptomatic inappropriate sinus tachycardia that is recalcitrant to medical therapy, catheter-based modification of the sinus node may be used, although this is rarely required in children.

Supraventricular Tachycardia

The term "supraventricular tachycardia" encompasses a spectrum of arrhythmias that result in a rapid rhythm that involves the atria, hence the rhythm is supraventricular, or above the ventricles. These are most commonly divided into reciprocating arrhythmias such as accessory pathway-mediated tachycardia and atrioventricular nodal reentry tachycardia, and the automatic tachyarrhythmias such as atrial ectopic tachycardia and junctional tachycardia. As a group, these arrhythmias are relatively common in childhood. It is estimated that as many as 1 in 250 children will experience supraventricular tachycardia. When supraventricular tachycardia often occurs in an otherwise normal child, it may be highly symptomatic, but in most cases it is entirely benign. These arrhythmias may exact a significant impact on quality of life for the child, their family, and their community, which can influence the decisions regarding management. The exact mechanism of the supraventricular tachycardia may not be entirely obvious upon first presentation, but an accurate diagnosis is important for appropriate treatment.

Accessory Pathway-Mediated Tachycardia

Supraventricular tachycardia that utilizes an accessory pathway as the source of arrhythmia is the most common form of supraventricular tachycardia in childhood, but represents a smaller percentage of arrhythmia mechanism as the child ages. An accessory pathway provides the ability for electrical conduction to occur in an abnormal fashion. Normally, the penetrating fibers of the His bundle are the only mode of conduction across the insulating atrioventricular rings. However, when an accessory pathway bridges this barrier, a potential circuit exists. When conditions are appropriate, electrical impulses not only conduct normally to the ventricles through the His-Purkinje system, but may then conduct retrograde over the accessory pathway back to the atria. If not in their refractory periods, the atria, AV node, and His-Purkinje system conduct the electrical impulse back through to the ventricles, resulting in a rapid repetitive rhythm called atrioventricular reciprocating tachycardia. Heart rates can range between 180 and 250 beats per minute, and typically at a very fixed rate. So called "retrograde" P waves may be visible following the QRS complex, as evidence of the conduction time between activation of the ventricles, passage through the accessory pathway, and subsequent reactivation of the atria.

Most patients are aware of the sensation of rapid heart rate, or palpitations, but may show no other outward signs of the arrhythmia. Dizziness and lightheadedness are common, but not necessary; frank syncope is very rare. Pallor, diaphoresis, and respiratory pattern changes may be present. In the smaller infant there may be no symptoms at all, which can often delay the diagnosis. While this is usually diagnosed at the onset of symptoms, delayed recognition of supraventricular tachycardia is a cause of decreased ventricular function called tachycardia-induced cardiomyopathy, and can possibly lead to cardiovascular collapse.

When an accessory pathway only conducts retrograde, it is called a concealed accessory pathway. That is to say that it is not evident during normal sinus rhythm conditions, and is only active during reciprocating tachycardia. A manifest accessory pathway is one whose presence is obvious during normal sinus rhythm. These are pathways that cause the preexcitation of the Wolff–Parkinson–White pattern (see above). Manifest pathways usually conduct bidirectionally; anterograde conduction results in preexcitation on resting electrocardiogram, and retrograde conduction results in reciprocating tachycardia (*Fig. 255.4*).

Accessory pathways are felt to be embryologic remnants. Histological studies have demonstrated that numerous potential electrical connections exist in the developing heart of chick and human embryos. As fetal development proceeds, most of these excess connections regress as the atrioventricular rings form from the endocardial cushion tissue, with the most notable exception being the penetrating bundle of His. The prevalence of accessory pathways is impossible to know, although it is estimated that 1:1,000 persons have an accessory connection. Most connections are concealed, and therefore

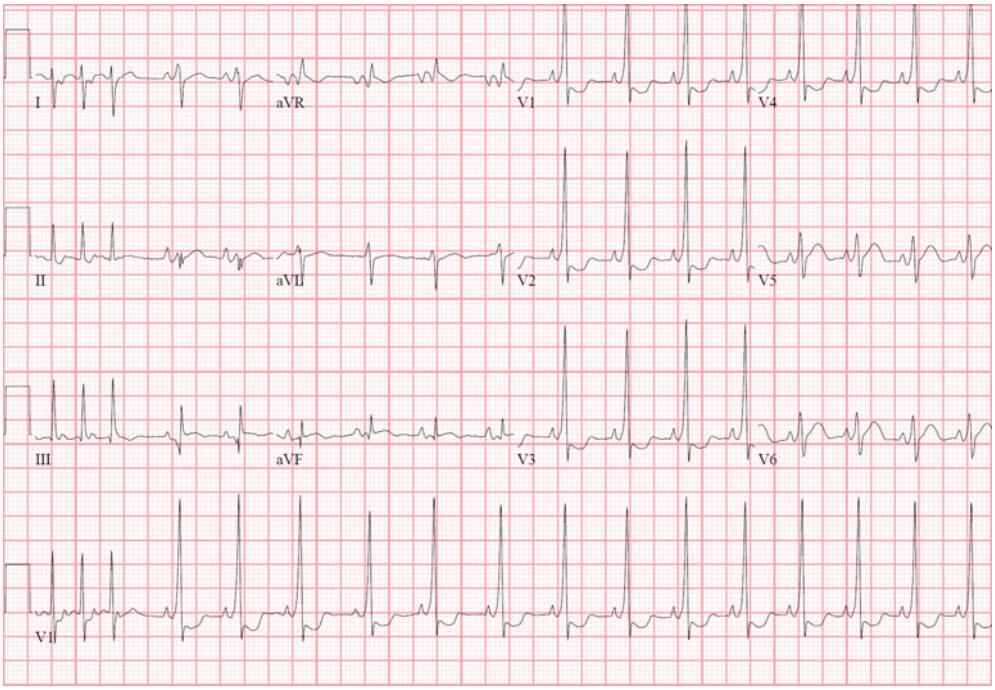

Figure 255.4
Supraventricular tachycardia. Spontaneous termination of SVT followed by sinus rhythm with Wolff–Parkinson–White pattern. Note the widened QRS, short PR, and slurred upstroke delta wave during preexcited rhythm

cannot be diagnosed by regular means unless a person has reciprocating tachycardia and undergoes invasive electrophysiologic testing (see below).

Atrioventricular Nodal Reentry Tachycardia

Another common reciprocating supraventricular tachycardia is atrioventricular nodal reentry tachycardia (AVNRT). With this arrhythmia, the circuit of tachycardia is contained entirely within the AV node itself and its inputs. The requisite for AVNRT is the presence of separate tracts within the AV node, called "fast" and "slow" pathways. This "dual AV nodal physiology" is usually only evident during invasive electrophysiologic testing. AVNRT is very rare in young children, becoming more common in school age and adolescents as well as adults. It is suspected that "dual AV nodal physiology" develops with age and while commonly found in adults is less prevalent in children.

Heart rates during AVNRT are similar to that found in accessory pathway-mediated tachycardia, generally between 180 and 240, although it is occasionally much slower. Palpitations are reported by patients experiencing AVNRT, and the signs and symptoms are similar to other reciprocating tachycardia. As with accessory pathway-mediated tachycardia, the QRS complex is narrow unless rate-related aberrant conduction is present. Generally, as the atria and ventricles are activated simultaneously and P waves are not readily visible, as they are superimposed upon the much higher amplitude QRS complexes. A small R′ can sometimes be seen during tachycardia only. As this is not present during normal sinus rhythm, this "pseudo-RSR′ pattern" is suggestive of this tachycardia, although not entirely pathognomonic.

As with other reciprocating tachycardias, the recurrence of AVNRT can be reduced using nodal blocking drugs. Beta blockers, digoxin, or calcium channel blockers are commonly used alone or in combination. Intravenous adenosine administration can be very successful in acutely terminating the tachycardia. Direct current cardioversion will often terminate the tachycardia, but is usually not necessary. Invasive electrophysiology study with catheter ablation may also be offered in centers where such procedures are provided.

Atrial Ectopic Tachycardia

Less common, but still well represented among pediatric supraventricular arrhythmias is atrial ectopic tachycardia

(AET). This is also known by other monikers such as ectopic atrial tachycardia or focal atrial tachycardia. In contrast to the reciprocating arrhythmias, AET is not caused by a bypass tract. Rather, this arrhythmia is caused by a focus of cells in the atria that have automatic properties (such as the sinus node) that exceeds the rate of the sinus node. The result is paroxysmal bursts of tachycardia; although prolonged and even incessant tachycardia can also be seen. These are frequently catecholamine sensitive, with increased symptoms experienced during times of activity or excitement. Heart rates during tachycardia can be variable, from 120 to over 300 beats per minute. Indeed, this heart rate variability is one of the distinguishing features from reciprocating tachycardias. In addition, the tachycardia accelerates ("warm-up") and decelerates ("cooldown") at the onset and termination. On electrocardiogram, atrial ectopic tachycardia is distinguished from sinus tachycardia by the morphology of the P wave. As the origin of atrial activity is not from the sinus node, the P waves are usually abnormal in appearance, often strongly inverted in the inferior leads (II, III, and aVF) and the anterior precordial (V1 and V2) leads. The P wave morphology on surface ECG can sometimes be used to predict the origin of tachycardia. Most of the time, the ectopic P waves can be demonstrated to be conducted with a normal QRS complex. Second-degree AV block may be observed, with the atrial rhythm continuing unabated despite inconsistent AV conduction (*Fig. 255.5*).

Correct identification of this arrhythmia is important to its appropriate treatment. Purely nodal blocking drugs will have little to no effect on this arrhythmia. Intravenous adenosine administration might demonstrate atrioventricular block with continuation of the atrial arrhythmia, although numerous studies have demonstrated that adenosine can terminate this arrhythmia, if only transiently. Direct current cardioversion is generally unsuccessful in terminating this arrhythmia. Given its automatic nature, cardioversion may temporarily cause the arrhythmia to cease, only to have it reinitiate promptly afterward. For medical management, drugs that diminish automaticity such as beta blockers, calcium blockers, sodium channel blockers are most likely to have an effect. In the long term, medical therapy is generally not successful in controlling this arrhythmia, especially in the setting of concurrent palliated or repaired congenital heart disease. The outlook for patients with AET is variable. Those who have the onset of tachycardia during infancy have a higher likelihood of spontaneous regression of the

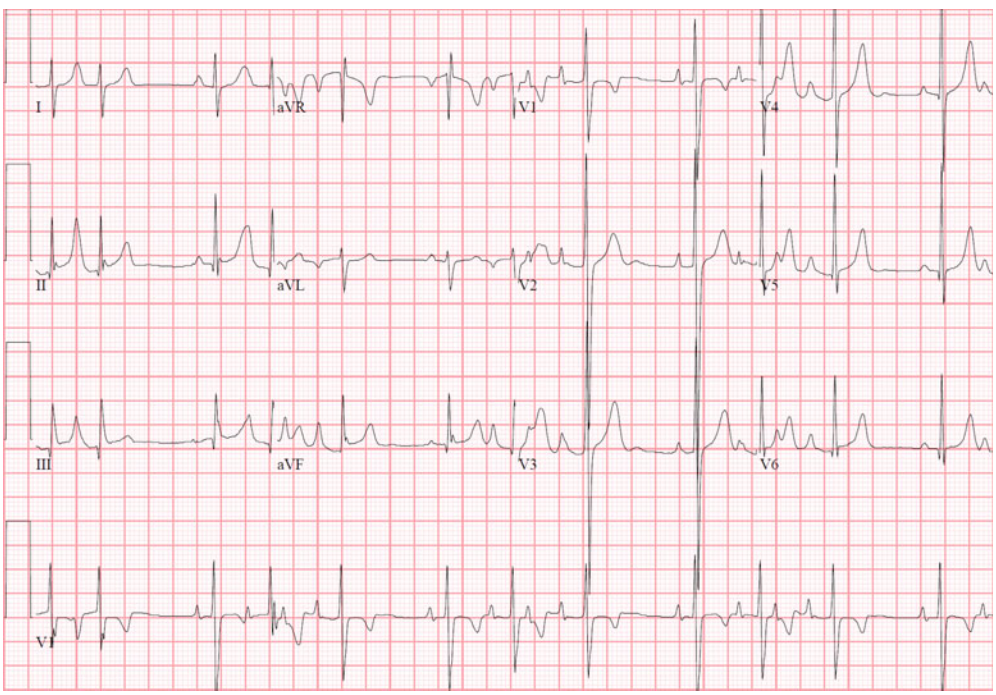

Figure 255.5
Atrial tachycardia. Bursts of atrial tachycardia in a patient presenting with myocarditis

arrhythmia than in those who develop their arrhythmia when older. For patients with recurrent atrial tachycardia, catheter ablation is also a therapeutic option with a high success rate.

Junctional Ectopic Tachycardia

Another automatic supraventricular arrhythmia seen in the pediatric population is junctional ectopic tachycardia (JET). This can be either acquired or congenital. The acquired form typically occurs in 3–10% of patients following cardiopulmonary bypass for congenital cardiac surgeries. While generally self-limited, this can become a significant management problem in a severely compromised postoperative patient. The congenital form is quite rare. In both of these types, the QRS complex is narrow, but usually not preceded by a P wave of any sort; ventriculo-atrial dissociation is present. P waves may be visible but do not precede the QRS complexes in any regular pattern. As an automatic arrhythmia, junctional tachycardia demonstrates the same "warm-up" and "cool-down" behavior as seen in automatic atrial tachycardia. Rates in tachycardia may vary between 170 and 210 beats per minute. Junctional rhythms that are not as fast as JET rates are often described as "accelerated junctional rhythm" and do not necessarily require treatment. At faster rates, the ventriculo-atrial dissociation can result in decreased cardiac output.

Junctional tachycardia is typically seen in an intensive care setting. Treatment includes cooling measures, temporary pacing, medical therapy, or extracorporeal support. JET does not usually respond to the types of antiarrhythmic medications used in other forms of supraventricular tachycardia. Procainamide, sotalol, and amiodarone are commonly utilized. Paroxysmal forms can be seen and may be treated medically, but also may be approached by catheter ablation in selected cases.

Atrial Flutter/Neonatal Flutter

Under certain conditions, a reentrant rhythm circuit can occur entirely within the atria themselves, that is, entirely independent of conduction to the ventricles. This is known as atrial flutter. While atrial flutter is commonly seen in adult, it is relatively rare in the child with a structurally normal heart. When present in the setting of either palliated or repaired congenital heart disease, it is referred to as "intra-atrial reentry tachycardia." During atrial flutter, the atria contract at a rapid rate, anywhere from 250 to well above 300 beats per minute. The atrioventricular node cannot generally conduct at this rate, but will conduct every second (2:1) or third (3:1) impulse; younger patients may conduct every atrial beat (1:1), resulting in a very rapid ventricular rate. On electrocardiogram, characteristic sawtooth "flutter waves" may be seen, particularly in leads II and III. These flutter waves persist at a consistent rate, regardless of the ventricular QRS rate. Administration of nodal blocking medications, in particular intravenous adenosine, can be diagnostic by blocking AV nodal conduction, while the flutter waves continue without interruption.

Atrial flutter can be seen not uncommonly in the late-term fetus and perinatal infant. This is known as fetal or neonatal flutter. In the fetus, brisk AV nodal conduction often results in rapid (1:1) ventricular rate. When undetected and untreated, this can result in congestive heart failure, which manifests as hydrops fetalis. Diagnosis may be difficult as it is unusual to be able to actually obtain a rhythm recording or electrocardiogram. A fetal echocardiogram may be able to demonstrate the rapidly contracting atria. Treatment of fetal flutter may be difficult due to the buffered nature of the fetus within the amniotic sac. Antiarrhythmic medications may be given through the mother, although high maternal doses are often required to achieve adequate transplacental levels within the fetus. For neonates who experience atrial flutter, direct current cardioversion is highly successful in terminating the arrhythmia, with a low rate of recurrence.

Ventricular Arrhythmias

Arrhythmias that predominantly involve the ventricles are known as ventricular tachycardias. Ventricular tachycardia takes many forms, ranging from a benign paroxysmal palpitations to a life-threatening arrhythmia. Early and accurate diagnosis is essential to differentiate between these ends of the spectrum. In general, ventricular tachycardias have a wide QRS complex with rates greater than 120–150 beats per minute. There are several diagnostic features of ventricular tachycardia. (1) Ventriculo-atrial dissociation. The ventricular rate usually exceeds the sino-atrial rate, and more QRS complexes than P waves may be seen on electrocardiogram. (2) Sinus capture beats. When appropriately timed P waves occur, they will conduct normally and be followed by a normal QRS-T complex. (3) Fusion beats. Sometimes, normally conducted QRS complexes will be superimposed by the wide QRS complex of the tachycardia. The result is an "in-between" QRS

complex that is neither wide nor narrow. (4) Wide QRS complex. This is not a necessity for ventricular tachycardia, as some forms of ventricular tachycardia have a relatively narrow QRS complex and can be mistaken for supraventricular tachycardia.

Accelerated Ventricular Rhythm (Accelerated Idioventricular Rhythm)

When the intrinsic ventricular automaticity is enhanced, an accelerated (idio)ventricular rhythm (AIVR) may be observed. This is often due to intrinsic catecholamine states, metabolic or electrolyte disturbances, or other conditions which may lead to increased myocardial automaticity. The QRS morphology is typically wide, differentiating this from other forms of increased automaticity such as accelerated junctional rhythm. The rate in AIVR may only slightly exceed the normal sinus rate or occasionally may be as fast as 120–150 beats per minute. This is generally very well tolerated hemodynamically, except in the extremely compromised child. AIVR can occur in normal individuals and does not portend any more significant arrhythmias. Diagnosis is made by identifying a wide QRS complex rhythm with rates slightly elevated above the patient's resting normal; with the ventricular rate exceeding the atrial rate, generally with ventriculoatrial dissociation. Treatment is directed by symptoms, although most patients are entirely asymptomatic. Drugs which decrease automaticity, such as beta blockers or calcium channel blockers, may decrease the presence of AIVR, but the rhythm itself is usually more bothersome to caregivers than to the patients themselves.

Monomorphic Ventricular Tachycardia

This form of ventricular tachycardia is most commonly due to increased automaticity from a locus within either the right or left ventricles, usually originating in either the right ventricular outflow tract or left ventricular outflow tracts. In the setting of a child with a structurally and functionally normal heart, it is considered benign. The tachycardia rate can range between 150 and 200, and often occurs in short bursts and volleys, although persistent forms can be seen. This is a wide QRS tachycardia typically with an inferior axis (positive QRS complex in lead aVF). Unless associated with other structural or functional heart disease, this does not progress to any more dangerous form of ventricular tachycardia and is treated on a symptomatic basis. As with the automatic supraventricular arrhythmias, medications that diminish myocardial automaticity are the primary medical therapies. Beta blockers and calcium channel blockers are commonly used, although numerous other antiarrhythmic medications have been used with good success. For patients with frequent recurrent episodes, invasive electrophysiology testing with catheter ablation is commonly utilized as well.

Another form of monomorphic ventricular tachycardia encountered in the pediatric population is known as "verapamil-sensitive ventricular tachycardia." As the moniker suggests, this form of arrhythmia is exquisitely sensitive to calcium channel blocker medications, which are the primary form of therapy. This is generally a paroxysmal arrhythmia, often having a very abrupt onset during activity. The tachycardia is a wide QRS complex with rates ranging between 150 and 200. The hallmark electrocardiogram of this arrhythmia is a right bundle branch pattern with a superior frontal plane axis (the QRS complex is negative in lead aVF). Given the relatively slow rates, this is typically very well tolerated, although some patients may have frequent and incessant tachycardia. Acute treatment with intravenous calcium channel blockers followed by oral therapy is indicated. Cardioversion may be used, but is rarely necessary. For those with frequent recurrent episodes, catheter ablation is also an option with good success rates.

Polymorphic Ventricular Tachycardia

In contrast to the stability monomorphic ventricular tachycardia, polymorphic ventricular tachycardia is a much more disorganized and a potentially life-threatening ventricular arrhythmia. It is an associated symptom of many forms of primary arrhythmia diseases, particularly those associated with sudden arrhythmic death. Like other forms of ventricular arrhythmias, this is diagnosed by identifying a rapid wide QRS complex tachycardia on rhythm recording. However, the QRS morphology varies widely from beat to beat, indicative of the generally disordered ventricular depolarizations underlying this arrhythmia. Cardiac output is severely reduced. If self-limited, this rapidly results in loss of consciousness and syncope. If sustained, sudden cardiac death can ensue. A particular variant of polymorphic ventricular tachycardia is known as *torsades de pointes*. Literally, "twisting about a point," the amplitude and axis of the QRS morphology rotates and undulates until eventually degenerating into a more chaotic ventricular fibrillation. It is the characteristic arrhythmia associated with Long QT Syndrome and other sudden arrhythmia death syndromes.

Ventricular Fibrillation

Ventricular fibrillation is an extremely rapid and chaotic ventricular rhythm. It is the final and the ultimate cause of death for many cardiac diseases. The electrocardiogram demonstrates a very fine and rapid disorganized rhythm with no recognizable P waves or QRS complexes. This can be caused by respiratory arrest, severe metabolic derangement, acidosis, or a primary cardiac cause. In rare instances, some people experience spontaneous and self-limited ventricular fibrillation. The cause of this idiopathic ventricular fibrillation is not well understood. Treatment is via immediate direct current defibrillation, either by external or internal defibrillator. Delay to defibrillation therapy rapidly results in brain and other end organ insult, and ultimately death.

Primary Arrhythmia Syndromes

There are several conditions that deserve separate mention. These are the primary arrhythmia syndromes in which arrhythmias are usually the sole symptom, usually without any other associated cardiac or systemic disease.

Wolff–Parkinson–White Syndrome

As has been described above, the Wolff–Parkinson–White syndrome involves the presence of preexcitation pattern on electrocardiogram in association with either palpitations or syncope. This is the result of an accessory pathway bypass tract that causes activation of the ventricles in addition to the normal His-Purkinje activation system. The degree of preexcitation depends largely on the location of the accessory pathway (or pathways) itself, and very little to do with the morbidity associated with this condition. As described previously, these accessory conduction pathways are embryologic remnants and have a prevalence that is estimated to be approximately 1 in 1,000 persons.

The characteristic arrhythmia associated with Wolff–Parkinson–White syndrome is a narrow QRS complex tachycardia mediated by the accessory pathway, called atrioventricular reciprocating tachycardia. During this supraventricular arrhythmia, conduction occurs in a normal antegrade fashion over the His-Purkinje system, resulting in a normal narrow QRS complex. Conduction then passes in a retrograde fashion over the accessory pathway to the atria, after which conduction enters the atrioventricular node and the His-Purkinje system in a repetitive fashion. Patients will experience paroxysmal episodes of rapid heart rate, causing palpitations. Some will have dizziness and chest discomfort; frank syncope during supraventricular tachycardia is rare.

Patients with Wolff–Parkinson–White have an increased risk of other atrial arrhythmias, particularly atrial fibrillation. During rapid atrial arrhythmias, electrical activation over the atria can bypass the atrioventricular node and His-Purkinje system entirely, resulting in extremely rapid conduction to the ventricles, and can lead to ventricular tachycardia or ventricular fibrillation. As a result, there is also an increased incidence of sudden cardiac arrest in those with preexcitation; sometimes this can be the first and sole symptom of this condition. The incidence of sudden death in Wolff–Parkinson–White syndrome is approximately 0.1–0.5% per patient year. The risk factors that have been proposed are numerous, but there is no single feature that adequately characterizes the high-risk patient. Noninvasive strategies to identify patients at greatest risk have been utilized through the years, but particularly in children, these have failed to provide a reliable means of risk stratification. In many centers, the gold standard has become invasive electrophysiology testing for risk stratification with catheter ablation when appropriate, once patients are felt to be appropriate candidates for the procedure.

Long QT Syndrome

The Long QT Syndrome is a family of disorders in which one of the myocardial ion channels (typically one of the potassium or sodium channels) is altered, resulting in prolongation of the cardiomyocyte action potential. The net result is lengthening of the QT interval on electrocardiogram. Patients with LQTS may be entirely asymptomatic, but have a predisposition toward syncope, seizures, ventricular arrhythmias (particularly polymorphic ventricular tachycardia), and sudden cardiac arrest. Formerly considered to be divided into autosomal dominant (Romano-Ward syndrome) and autosomal recessive (Jervell-Lange-Neilsen syndrome, or JLNS) forms, this distinction is now felt to be less clear. Patients with JLNS are homozygous for mutations in one of the myocardial potassium channels that is also expressed in the middle ear, resulting in congenital sensorineural deafness. The overall prevalence of LQTS in the general population is approximately 1:2,500, with JLNS being much less common. In most situations, the absolute QT measurement does not have much clinical significance. Formulae for normalizing this value for heart rate are used, with Bazett's

equation being the most widely used. This equation gives a correct QT interval (QTc) that is equal to the QT measurement divided by the square root of the preceding R–R interval (in seconds). While newborn infants may have resting QTc of up to 480, the upper limits of normal are 460 for a normal female and 450 for a normal male (*Fig. 255.6*).

The risk factors that characterize high-risk LQTS patients remains an active area of research. Certain combinations of specific mutation, resting QTc length, sex of the patient appear to be most useful in predicting risk of cardiac events, although this is far from a perfect method. Some countries (for example, Italy and Japan) have instituted nationwide electrocardiographic screening of newborns, school-aged children, and atheletes in an effort to diminish the incidence of sudden cardiac arrest in otherwise unrecognized and otherwise healthy children and young adults.

The primary therapy for most patients with LQTS is medical therapy with beta blockers and activity restrictions from highly competitive athletics. Selected patients who have either survived cardiac arrest or are felt to be at excessive risk for sudden cardiac death may have an internal defibrillator implanted. Genetic information is becoming helpful in guiding management as there appear to be distinct genotype–phenotype relationships in LQTS not present in other similar types of conditions, however specific genotypic-specific therapies are not yet available.

Brugada Syndrome

The Brugada syndrome is another primary electrical disease characterized by distinctive electrocardiographic changes. Specifically, there is significant ST segment elevation in the anterior (V1 and V2) precordial leads with associated T wave inversions. As with LQTS, the heart is structurally normal in Brugada syndrome. The actual prevalence is difficult to assess, but it is estimated to affect 1–5 per 10,000, but is much more common in Southeast Asian populations. Patients can experience palpitations, ventricular arrhythmias, and syncope. Sudden cardiac death, particularly during sleep, is an unpredictable outcome although this is a rare event in childhood. Genetic testing can identify a sodium channel mutation in approximately 20% of patients with Brugada syndrome. There are no known drugs that have been identified to diminish the symptoms or the risk of life-threatening arrhythmias

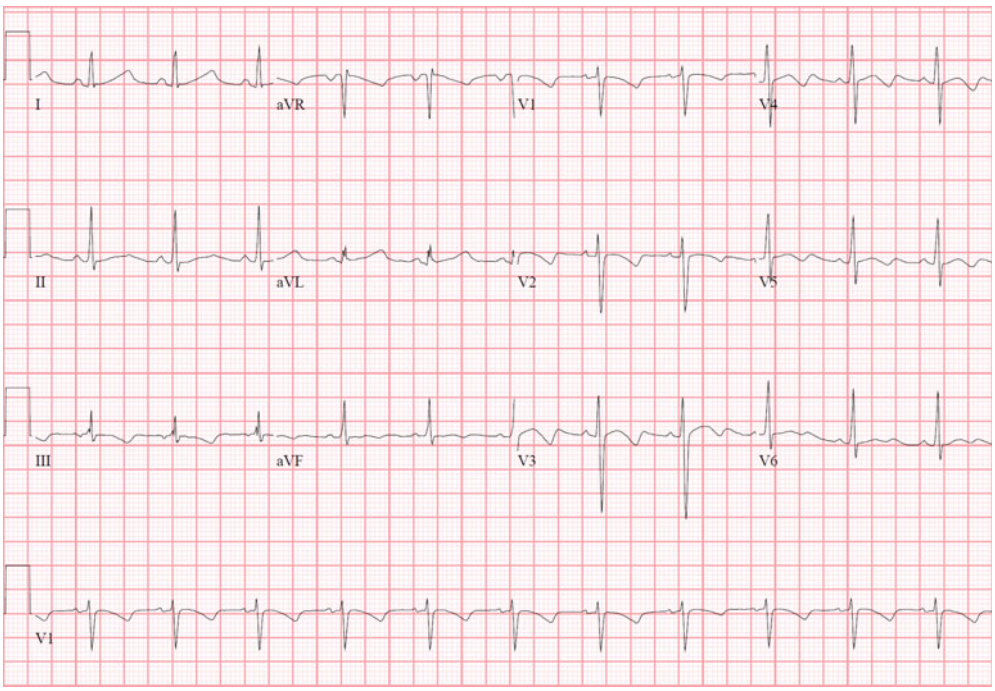

Figure 255.6
Long QT syndrome. Long broad T waves in patient diagnosed after surviving cardiac arrest. Characteristic T wave notching across precordial leads V2–V6 are seen

in Brugada syndrome. Implantable defibrillators have been demonstrated to improve survival in this group, although appropriate patient selection is controversial.

Implantable Arrhythmia Devices

Pacemakers

For patients in whom bradycardia is an irreversible and symptomatic problem, implantable pacemaker therapy may be indicated. By means of leads attached to the heart, a pacemaker can sense either atrial or ventricular activity, and provide electrical activation to either the atria or ventricles when necessary to improve heart rate. This may involve pacing the atrium (atrial pacemaker), pacing the ventricle (ventricular pacemaker), or both (dual chamber pacemaker). Pacemakers can be implanted in a pectoral position, with the leads connecting it to the heart running in a transvenous route to the endocardial surface. In some patients, the device may be placed in an epicardial location, with the leads sewn to the epicardial surface, and the pacemaker generator placed in an adjacent location, often within the abdomen.

Defibrillators

Some patients have a significantly elevated risk of experiencing a lethal ventricular arrhythmia, either because they have already survived a cardiac arrest at least once before or they are felt to have a substantial risk from underlying structural or primary electrical disease, an implantable defibrillator may be used. Implantable cardioverter-defibrillators (ICDs) are implanted in much the same way that implantable pacemakers are. They also have nearly all of the same functionality; that is to say that they can provide pacing to the attached atrium or ventricle when necessary. However, a primary distinction is that an ICD can also detect tachycardic events, primarily ventricular tachycardia and ventricular fibrillation, and have the capacity to deliver a defibrillation shock to terminate the arrhythmia.

Electrophysiology Study and Catheter Ablation

Certain arrhythmias may be amenable to invasive investigation in the electrophysiology laboratory, and potentially to utilize catheter ablation to provide a cure for the arrhythmia. This requires the placement of several multielectrode catheters within the heart via a transvenous approach. By delivering pacing sequences and analyzing the electrical response, specific arrhythmias and rhythm responses can be elicited. The specific timing of activation of the atria, AV node, His-Purkinje system, and ventricles is measured. The presence or absence of accessory pathway conduction can be demonstrated. And the exact mechanism of a child's arrhythmia can be determined. When deemed appropriate, catheter ablation is performed. This utilizes maneuverable catheters that are positioned directly upon the arrhythmia substrate, whether it is an accessory pathway, anomalous conduction tracts of the AV node, or an ectopic arrhythmia focus. Energy is delivered in the form of radiofrequency (heat) or cryoablation (cold) to destroy the arrhythmia targets, while leaving the rest of the myocardium intact. Initially developed in the 1980s, transcatheter ablation has become a highly successful modality for treatment of a number of arrhythmias. In children, the success rate is quite high, and is commonly conducted in centers that perform this procedure.

256 Sudden Cardiac Death and Preparticipation Sports Screening

Domenico Corrado · Federico Migliore · Alessandro Zorzi · Cristina Basso · Gaetano Thiene

Definition

Sudden cardiac death is usually defined as unexpected death occurring instantaneously or within 1 h of the onset of symptoms or collapse as a result of natural causes in someone without a previously recognized cardiovascular abnormality.

Etiology

Risk of Sudden Death

Sudden cardiac death in an athlete usually occurs either during (80%) or immediately after (20%) physical exercise, suggesting that participation in competitive sports activity increases the likelihood of cardiac arrest. The risk benefit ratio of physical exercise differs between adults and young competitive athletes. This may be explained by the different nature of cardiovascular substrates underlying sport-related sudden death in the two age-groups (*Table 256.1*).

Atherosclerotic coronary artery disease is the most common cause of sudden death in adults and elderly exercising subjects. Epidemiologic studies support the concept that habitual sport activity may offer protection over the long-term against cardiovascular events. Regular exercise prevents development and progression of atherosclerotic coronary artery disease by favorable effects on lipid metabolism and weight reduction, and enhances both coronary artery plaque and myocardial electrical stability.

Unlike older athletes, a broad spectrum of cardiovascular substrates (including congenital and inherited heart disorders) may underlie sudden death in young competitive athletes (age $\leq$35 years). An Italian prospective study demonstrated that adolescent and young adults involved in sports activity have 2.8 greater risk of sudden cardiovascular death (SCD) than their nonathletic counterparts (*Fig. 256.1*). However, sports is not itself the cause of the enhanced mortality, since it triggers cardiac arrest in those athletes who are affected by cardiovascular conditions which predispose to life-threatening ventricular arrhythmias during physical exercise. This reinforces the need for systematic evaluation of adolescent and young individuals embarking in sports activity in order to identify those with potentially lethal cardiovascular diseases and protect them against the increased risk of sudden death.

Causes of Sudden Death

The vast majority of young competitive athletes who die suddenly have underlying structural heart diseases, which provide a substrate for ventricular tachycardia/fibrillation leading to cardiac arrest. As reported in *Table 256.1*, cardiomyopathies have been consistently implicated as the leading cause of sports-related cardiac arrest in younger athletes. Hypertrophic cardiomyopathy (HCM) has been reported to account for more than one third of fatal cases in the USA and arrhythmogenic right ventricular cardiomyopathy/dysplasia (ARVC/D) for approximately one fourth in the Veneto Region of Italy. Other cardiovascular substrates for sports-related sudden death in the young include premature atherosclerotic coronary artery disease, congenital coronary anomalies, myocarditis, dilated cardiomyopathy, mitral valve prolapse, conduction system diseases, and Wolff–Parkinson–White (WPW) syndrome.

HCM: This is a genetically determined heart muscle disease, which is characterized by a hypertrophied, nondilated left ventricle in the absence of cardiac or systemic diseases capable of producing hypertrophy. Characteristic morphologic and functional cardiac abnormalities include either symmetric or asymmetric (i.e., with disproportionate septal thickening) LV hypertrophy (*Fig. 256.2a*), and reduction in LV chamber size with increased myocardial stiffness, which may critically impair diastolic LV and intramural coronary blood filling. Dynamic LV outflow tract obstruction is also demonstrable at rest or with exercise in a large proportion of patients. The histopathologic hallmark of HCM is myocardial disarray with widespread, bizarre, and disordered

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_256,

arrangement of myocytes usually associated with interstitial and/or replacement-type fibrosis (Fig. 256.2b). Myocardial fibrosis is an acquired phenomenon, in part related to abnormalities of the intramural coronary arteries which show dysplasia of the tunica media with luminal narrowing ("small vessel disease").

HCM has been implicated as the principal cause of sudden death during sports in the USA. Cardiac arrest has been attributed to ventricular fibrillation, which is triggered by the interaction between adrenergic stimulation, such that occurring during physical exercise, and the underlying, electrically unstable cardiomyopathic substrate. The observation of acquired myocardial damage, either acute or in the form of large septal scars, supports the hypothesis that myocardial ischemia intervenes in the natural history of the disease and contributes to the arrhythmogenicity.

ECG abnormalities such as an increased QRS voltage, pathologic "q" waves, and repolarization changes have been reported in up to 95% of patients with hypertrophic cardiomiopathy. This explains why preparticipation ECG screening of young competitive athletes in Italy has allowed successful identification and mortality reduction of athletes with HCM.

ARVC/D: This is an inherited heart muscle disorder that is characterized pathologically by fibro-fatty replacement of RV myocardium. The most frequent clinical manifestations consist of ECG depolarization/repolarization changes mostly localized to right precordial leads, global and/or regional morphologic and functional alterations of the right ventricle, and arrhythmias of RV origin which can lead to sudden death, especially during physical exercise. The propensity for sudden arrhythmic death during physical activity is linked to both hemodynamic and neurohumoral factors. Physical exercise may acutely increase RV afterload and cavity enlargement, which in turn, may elicit ventricular arrhythmias by stretching the diseased RV musculature. Alternatively, the hypothesis of "denervation supersensitivity" of the right ventricle to catecholamines has been advanced. Finally, in a subgroup of patients with familial ARVC/D (ARVD2), a cardiac ryanodine receptor (RYR2) missense mutation has been

Table 256.1

(a) Short axis view of the heart showing massive left ventricular hypertrophy and a large scar in the posteroseptal region; (b) corresponding panoramic histologic section showing intraseptal replacement-type fibrosis. Trichrome Heidenhain, original magnification ×3 (Modified from Basso C, Thiene G, Corrado D, Buja GF, Melacini P, Nava A (2000) Hypertrophic cardiomyopathy: pathologic evidence of ischemic damage in young sudden death victims. Hum Pathol 31:988–998)

identified. Such a genetic defect leads to abnormal calcium release from the sarcoplasmic reticulum during effort, which, in turn, induces ventricular arrhythmias due to afterdepolarizations and triggered activity.

The heart of young competitive athletes dying suddenly from ARVC/D demonstrates global RV dilatation and aneurysms of posterobasal, apical, and outflow tract regions, which are potential sources of life-threatening ventricular arrhythmias (*Fig. 256.3*). These pathologic features of the right ventricle allow differential diagnosis with training-induced right ventricular changes ("athlete's heart"), usually consisting of RV enlargement without regional abnormalities.

ARVC/D has been reported to be the leading cause of sports-related sudden death in the Veneto Region of northeastern Italy. The most likely explanation of this finding is that systematic preparticipation screening of young competitive athletes has changed the natural prevalence of cardiovascular causes of sports-related sudden death. In Italy, most sudden deaths due to HCM have been prevented by identification and disqualification of the affected athletes at preparticipation screening. Therefore, other cardiovascular conditions such as ARVC/D have come to account for a greater proportion of all sudden death in Italian athletes.

Early identification of athletes with ARVC/D plays a crucial role in the prevention of sudden death during sport. The disease should be suspected in the presence of inverted T waves in right precordial leads. In this regard, more than 80% of athletes who died from ARVC/D had repolarization ECG changes. In the past, affected athletes had not been identified at preparticipation screening because the disease was unrecognized clinically. More recently, with the increased awareness of the disease, more and more affected athletes are being detected by screening and protected from the risks of athletic competition.

Coronary artery disease: Premature coronary atherosclerosis is an important substrate for sudden death even in young competitive athletes ($\leq$35 years). In these young subjects, coronary artery disease exhibits distinctive characteristics in terms of a warning clinical prodrome and pathological features, such as extent, site, and morphology of obstructive atherosclerotic plaques. Young athletes dying from premature coronary artery disease usually do not have history of angina pectoris or previous myocardial infarction, and sudden death is often the first manifestation of the disease. Exercise testing may fail to show myocardial ischemia or arrhythmias. Fatal coronary atherosclerosis is more often a "single vessel disease" that characteristically affects the proximal left anterior descending coronary artery and is often due to fibrocellular plaques (i.e., fibrous plaques with intimal smooth muscle cell hyperplasia, so-called "accelerated atherosclerosis") and a preserved tunica media in absence of acute thrombosis. These morphological features have been suggested to underlie abnormal hypervasoreactivity, possibly culminating in cardiac arrest by vasospastic myocardial ischemia. Because of the scarcity of warning symptoms and the limitation of exercise testing, early

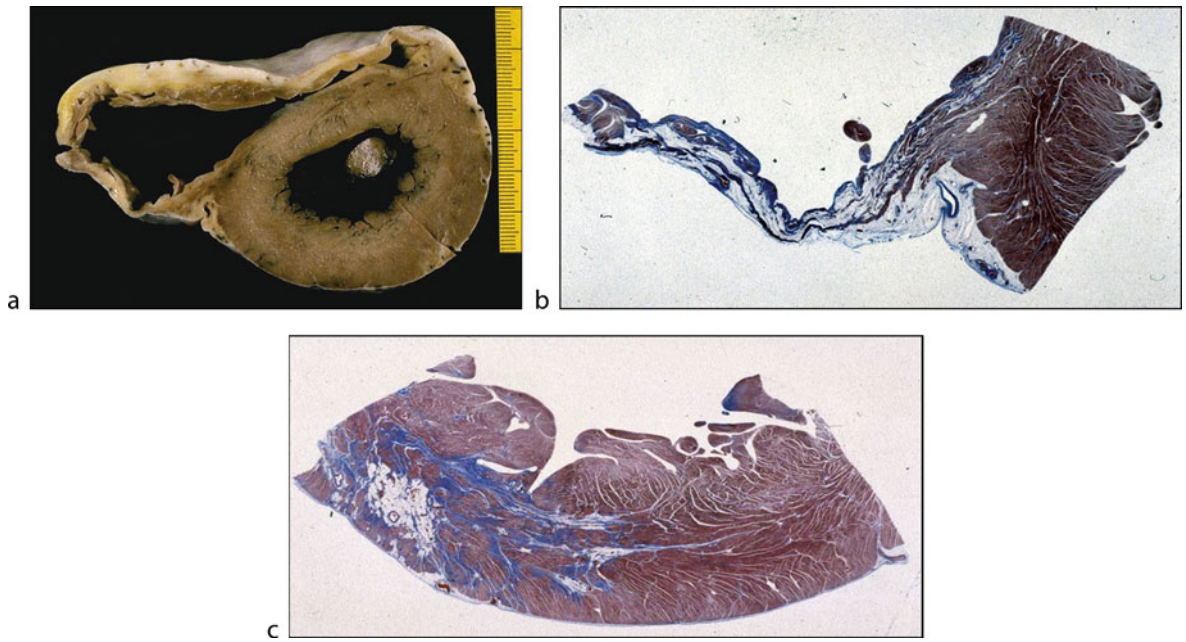

Figure 256.3

A 17-year-old soccer player who died suddenly from ARVC/D. (a) Cross section of the heart specimen with infundibular and inferior sub-tricuspid aneurysms; (b) panoramic histologic view of the aneurysm of the inferior region, showing wall thinning with fibro-fatty replacement. Azan stain, original magnification, × 2.5; (c) panoramic histologic view of the left ventricle showing a spot of fibro-fatty myocardial replacement. Azan stain, original magnification, ×2.5 (Modified from Basso C, Thiene G, Corrado D (1996) Arrhythmogenic right ventricular cardiomyopathy. Dysplasia, dystrophy, or myocarditis? Circulation 94:983–991)

identification of young athletes with premature coronary atherosclerosis at risk of ischemic cardiac arrest remains a challenge.

Congenital coronary artery anomaly: Anomalous origin of a coronary artery from the "wrong" coronary sinus is a congenital malformation with a silent clinical course, which may precipitate sudden and unexpected ischemic cardiac arrest in young competitive athletes. The most frequent anatomic findings consist of both (left and right) coronary arteries arising either from the right or the left coronary sinus. In both conditions, as the anomalous coronary vessel leaves the aorta, it adopts an acute angle with the aortic wall, and, thus, traverses between the aorta and the pulmonary trunk, often following an aortic intramural course, with a "slit-like" lumen (*Fig. 256.4*). Exercise-induced myocardial ischemia has been hypothesized to be caused by aortic root expansion which compresses the anomalous vessel against the pulmonary trunk, increases the acute angulation of the coronary take-off, and aggravates the "slit-like" shape of the lumen of the proximal intramural portion of the aberrant coronary vessel.

Myocarditis: Either in its acute or healed forms, myocarditis may provide a myocardial electrical substrate for ventricular arrhythmias and exercise-related sudden death. Life-threatening ventricular arrhythmias in athletes may also be the result of focal myocarditis, which is clinically silent and difficult to be detected by endomyocardial biopsy.

Other structural causes: Despite its high prevalence in the general population, mitral valve prolapse is a rare cause of sudden death in athletes. The pathogenesis of the sudden cardiac arrest remains unresolved. Fatal coronary embolism from atrial platelet deposits, and cardiac arrest due to malignant ventricular tachyarrhythmias attributed to "valve friction" have been advanced as possible mechanisms.

Ventricular preexcitation syndrome (WPW syndrome) or progressive cardiac conduction disease (Lenègre disease) may represent an uncommon substrate for exercise-related sudden death.

Spontaneous laceration or dissection of the ascending aorta with rupture into pericardial cavity and cardiac tamponade is a rare cause of fatal electromechanical

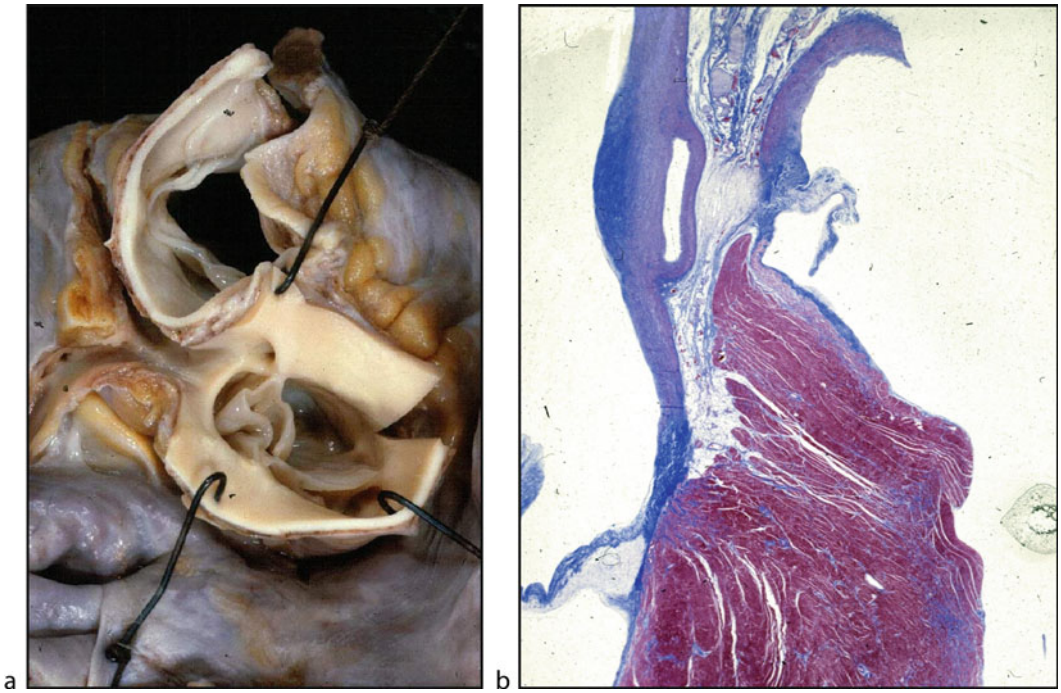

Figure 256.4

A 22-year-old soccer player who died suddenly from congenital coronary anomaly. (a) View of the aortic root showing the right coronary artery ostium arising from the left (wrong) coronary sinus; (b) histology of proximal right coronary artery, which appears to run within the aortic wall (intramural course), with a slit-like lumen (Azan Stain, original stain × 10) (Modified from Corrado D, Thiene G, Nava A, Pennelli N, Rossi L (1990) Sudden death in young competitive athletes: clinico-pathologic correlations in 22 cases. Am J Med 89:588–596)

dissociation during sports. The basic heart defect is an elastic fragmentation of the aortic tunica media with cystic medial necrosis that may rarely present as isolated histologic feature, but more frequently in association with isthmic coartation and/or bicuspid aortic valve, or in the setting of Marfan syndrome.

Nonstructural causes: Two to five percent of young people and athletes who die suddenly have no evidence of structural heart diseases, and the cause of their cardiac arrest is in all likelihood related to a primary electrical heart disease such as inherited cardiac ion channel defects (channelopathies) including long and short QT syndromes, Brugada syndrome, and cathecholaminergic polymorphic ventricular tachycardia.

Long QT syndrome is a genetic disorder characterized by prolonged ventricular repolarization (prolonged QTc interval) that predisposes to life-threatening ventricular arrhythmias such as torsade de pointes. The genetic background resides on defective genes encoding ion channels that regulate myocyte repolarization. According to molecular genetics, seven different variants (LQT1 to LQT7) of long QT syndrome are recognized. Different molecular mechanisms may explain differences seen in clinical manifestations. LQT1 patients are prone to syncope or cardiac arrest during physical exercise, mostly while swimming. On the contrary, LQT3 patients show a bradycardia-dependent QT prolongation, and they experience sudden death events at rest (while sleeping). LQT2 subjects are more susceptible during emotions and under acoustic stimuli.

Brugada syndrome is an inherited ion channel disease characterized by the peculiar ECG pattern consisting of right precordial "coved-type" ST-segment elevation (both spontaneous or induced by pharmacologic sodium channel blockade) in association with arrhythmia-related syncope/cardiac arrest, inducibility at programmed ventricular stimulation, or a familial history of sudden death. A cardiac sodium channel gene (SCN5A) mutation has been detected in up to 30% of Brugada syndrome cases. Ventricular fibrillation leading to sudden death usually occurs at rest and, in many cases, at night (during sleep) as a consequence of an increased vagal stimulation and/or

withdrawal of sympathetic activity. Enhanced adrenergic drive, such as occurs during sports activity, could have an inhibitory effect and theoretically reduce the risk of sudden death. On the other hand, the adaptation of the cardiac autonomic nervous system to systematic training, which results in increased resting vagal tone or during the post-exercise recovery period may enhance the propensity of athletes with Brugada syndrome to die at rest, during sleep, or immediately after effort.

Catecholaminergic ventricular tachycardia is an inherited ion channel disease characterized by exercise-induced polymorphic ventricular tachycardia (most often with the so-called bidirectional pattern) which can degenerate in ventricular fibrillation. Unlike long QT syndrome and Brugada syndrome, this condition is not associated with abnormalities of basal 12-lead ECG and remains unrecognized unless the athlete undergoes ECG stress testing. A genetically defective ryanodine receptor has been reported to account for an abnormal calcium release from the sarcoplasmic reticulum. Accordingly, the potential arrhythmogenic mechanism is triggered activity due to late afterdepolarizations, which are provoked by intracellular calcium overload and enhanced by adrenergic stimulation such as that during sports exercise.

Trauma-related sudden death: Blunt, non-penetrating, and often innocent appearing blows to the precordium may trigger ventricular fibrillation without structural injury to ribs, sternum, or heart itself (commotio cordis). Commotio cordis is most frequently caused by projectiles which are implements of the game and strike the chest at a broad range of velocities, such as hockey pucks, or by virtue of bodily collision, for example, a karate blow. Based on experimental and clinical observations, the mechanism by which ventricular fibrillation and sudden death occurs requires a blow directly over the heart, exquisitely timed to within a narrow 10–30 ms window just prior to the T-wave peak during the vulnerable phase of repolarization. Basic electrophysiologic mechanisms of commotio cordis are largely unresolved, although selective K^+_{ATP} channel activation appears to play a role.

Noncardiac causes: Rarely, sudden death may be caused by noncardiac conditions including bronchial asthma and rupture of a cerebral aneurysm.

Epidemiology of Sudden Death in the Athlete

The sudden and unexpected death of an athlete is always a powerful and tragic event, which devastates families, other competitors, institutions (high school, college, or professional organization), sports-medicine team, and the community. Sudden demise of an athlete has a tremendous impact on the media because it affects apparently healthy individuals who are regarded as the healthiest group in society and, often, as heroes. Instinctively, everyone wonders what intervention might have prevented the death.

The most common mechanism of cardiac arrest in young competitive athletes is abrupt ventricular fibrillation as a consequence of an underlying cardiovascular disease. The culprit disease often is clinically silent and unlikely to be suspected or diagnosed on the basis of spontaneous symptoms. Preparticipation screening of athletic population offers the potential to identify asymptomatic athletes at risk of sudden death during competitive sports.

This section will address efficacy, feasibility, and cost-effectiveness of preparticipation screening for detection of potentially lethal cardiovascular diseases and prevention of SCD.

Incidence of Sudden Death

The assessment of the precise frequency with which sudden death occurs in athletes is hampered by the retrospective nature of most analyses. The sudden death incidence is fortunately low and varies in the different athlete series reported in the literature. In apparently healthy adults (>35 years of age), joggers, or marathon racers, the estimated rate of sports-related fatalities ranges from 1:15,000 to 1:50,000. In comparison, a significantly lower incidence of fatal events has been reported in young competitive athletes (≤35 years of age). Van Camp et al. in a nationally based survey estimated the prevalence of sudden death in high-school and college athletes in the USA to be 0.4 per 100,000 athletes per year. Maron et al. showed the prevalence of cardiovascular sudden deaths in competitive high-school athletes (age 13–19 years, mean 16) from Minnesota to be 0.35 per 100,000 sports participations, and 0.46 per 100,000 individual participants per year (0.77 per 100,000 male athletes). A prospective population-based study in the Veneto Region of Italy reported an incidence of sudden death of 2.3 (2.62 in males and 1.07 in females) per 100,000 athletes per year from all causes, and of 2.1 per 100,000 athletes per year from cardiovascular diseases.

The risk of sudden death in athletes increases with age and is greater in men. This explains why mortality rates found in Italy are significantly higher than those reported in the USA. Compared with US high-school and college participants, the Italian athletic population includes

older athletes (age range 12–35 vs 12–24 years) and a significantly higher proportion of men (82% vs 65%).

The striking male predominance (male to female ratio up to 10:1) of sudden death in athletes has been related to the higher participation rate of male compared with female in competitive sports, as well as the more intensive training load and level of athletic achievement of males. Furthermore, male gender was reported to be an independent predictor of sports-related sudden death, most likely as a consequence of the greater prevalence and/or phenotypic expression in young males of cardiac diseases at risk of arrhythmic cardiac arrest, such as cardiomyopathies and premature coronary artery disease.

Prevention of Sudden Death by Preparticipation Screening

Preparticipation medical evaluation of athletic populations has the ability to identify asymptomatic athletes who have potentially lethal cardiovascular abnormalities and to protect them from the risk of sudden death during sports activity.

Screening Protocol in the USA and Italy

Preparticipation cardiovascular screening has traditionally been performed in the USA by means of history (personal and family) and physical examination without 12-lead ECG or other testing, which are requested largely at the discretion of the examining physician. This screening method has been recommended by the Sudden Death and Congenital Defects Committee of the American Heart Association on the assumption that 12-lead ECG is not cost-effective for screening large population of young athletes due to its low specificity. Such a screening strategy, however, has a limited power to detect potentially lethal cardiovascular abnormalities in young athletes. One retrospective analysis on 134 high-school and collegiate athletes who died suddenly showed that cardiovascular abnormalities were suspected by standard history and physical examination screening only in 3% of the examined athletes and, eventually, less than 1% received an accurate diagnosis.

The addition of 12-lead ECG offers the potential to enhance the sensitivity of the screening process for detection of cardiovascular diseases at risk for sudden death. Italy is the only country in the world where law mandates that every subject engaged in competitive sports activity must undergo a clinical evaluation to obtain eligibility before entering in competitive sports. A nationwide mass preparticipation screening program, essentially based on 12-lead ECG, has been the practice since 1982. The preparticipation evaluation involves nearly six million athletes of all ages annually, representing about 10% of the overall Italian population. A flow chart illustrating the Italian screening protocol is reported in *Fig. 256.5*. The initial cardiovascular evaluation consists of complete personal and family history, physical examination including blood pressure measurement, and 12-lead ECG. The athletic evaluation is performed by a physician with the specific training, medical skill, and cultural background to reliably identify clinical symptoms and signs associated with those cardiovascular diseases responsible for exercise-related sudden death. In Italy, physicians primarily responsible for preparticipation screening and eligibility for competitive sports attend postgraduate residency training programs in sports medicine (and sports cardiology) full time for 4 years. Such specialists work in sports medical centers specifically devoted to periodic evaluation of athletes. The screening starts at the beginning of competitive athletic activity that for the majority of sports disciplines corresponds to an athlete age of 12–14 years, and is repeated on a regular basis (every 1 or 2 years).

Medical history: The majority of conditions at risk of sudden death during sports are genetically determined diseases with an autosomal dominant pattern of inheritance, hence the importance of family history in identifying affected athletes. The family history is considered positive when close relative(s) had experienced a premature heart attack or sudden death (<55 years of age in males and <65 years in females), or in the presence of a family history of cardiomyopathy, Marfan syndrome, long QT syndrome, Brugada syndrome, severe arrhythmias, coronary artery disease, or other disabling cardiovascular diseases. The personal history is considered positive in cases of exertional chest pain or discomfort, syncope or near-syncope, irregular heartbeat or palpitations, and in the presence of shortness of breath or fatigue out of proportion to the degree of exertion.

Physical examination: Positive physical findings include musculoskeletal and ocular features suggestive of Marfan syndrome, diminished and delayed femoral artery pulses, mid-or end-systolic clicks, a second heart sound single or widely split and fixed with respiration, marked heart murmurs (any diastolic and systolic grade $\geq$ 2/6), irregular heart rhythm, and brachial blood pressure >140/90 mmHg (on >1 readings).

ECG: Twelve-lead ECG is considered positive in the presence of one or more of the findings reported in *Table 256.2*.

Subjects who have positive findings at basal evaluation are referred for additional testing, initially "noninvasive," such as echocardiography, 24 h ambulatory Holter

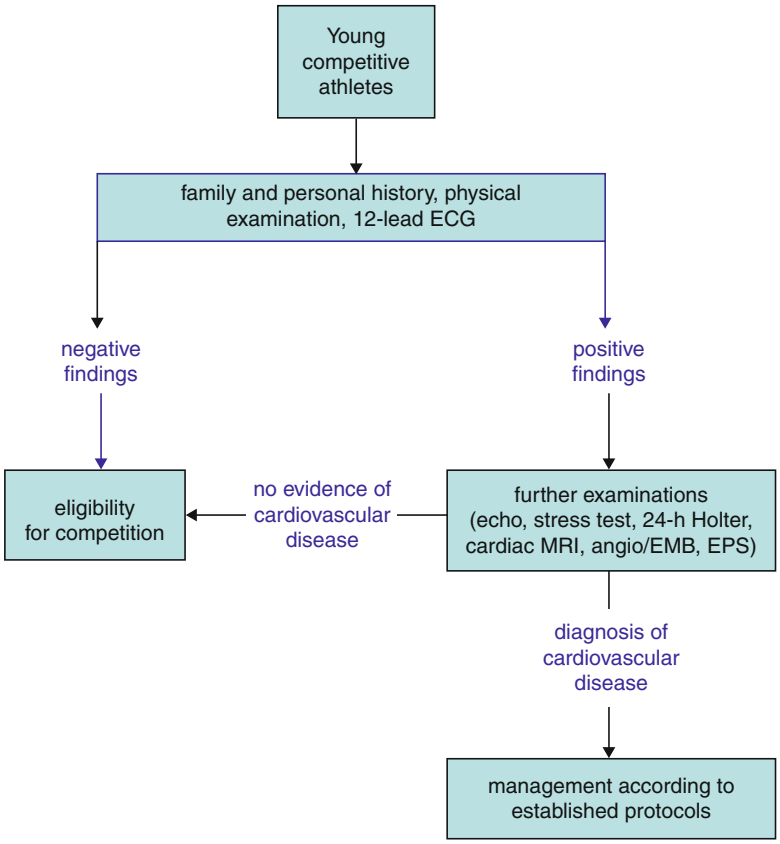

Figure 256.5

Flow chart of the Italian protocol of cardiovascular screening of young competitive athletes (see text for explanation). *Angio/EMB* contrast angiography/endomyocardial biopsy, *EPS* electrophysiologic study with programmed ventricular stimulation, *MRI* magnetic resonance (Corrado D, Basso C, Schiavon M, Pelliccia A, Thiene G (2008) Pre-participation screening of young competitive athletes for prevention of sudden cardiac death. J Am Coll Cardiol 52:1981–1989)

monitoring, and exercise testing. Alternatively or in uncertain cases, "invasive" tests such as contrast ventriculography (both right and left), coronary angiography, endomyocardial biopsy, and electrophysiologic study may be necessary in order to confirm or rule out the suspicion of heart disease. Finally, subjects recognized to be affected by cardiovascular conditions potentially responsible for sudden death in association with exercise and sport participation are managed according to the available recommendations for sports eligibility.

Time of Screening

ECG abnormalities and arrhythmic substrates of most inherited heart diseases at risk of sudden death in the young are age dependent and occur during adolescence or young adulthood. Preparticipation screening of children $\leq$12 years is expected to have a low sensitivity for detection of cardiomyopathies, cardiac ion channel diseases (except for long QT syndrome), and progressive cardiac conduction diseases that usually develop during the later period of life. It is noteworthy that a prospective study in the Veneto region of Italy demonstrated that sport-related sudden death is an exceptional event in individuals less than 12 years. Screening should be repeated on a regular basis at least every 2 years with the aim to timely identify delayed phenotypic manifestations, disease progression, or substrate worsening over the time.

Efficacy of Preparticipation Screening

HCM has been reported to be the leading cause of sudden death in young competitive athletes, accounting for up to 40% of athletic field deaths in the USA. Although

Table 256.2

ECG features of cardiac diseases detectable at preparticipation screening in a young competitive athlete

Disease	QTc interval	P wave	PR interval	QRS complex	ST interval	T wave	Arrhythmias
Hypertrophic cardiomyopathy	Normal	(left atrial enlargement)	Normal	Increased voltages in mid-/ left precordial leads; abnormal "q" waves[b] in inferior and/or lateral leads; (LAD, LBBB); (delta wave)	Down sloping (up sloping)	Inverted in mid-/ left precordial leads; (giant and negative in the "apical" variant)	(atrial fibrillation); (PVB); (VT)
Arrhythmogenic right ventricular cardiomyopathy/ dysplasia	Normal	Normal	Normal	Prolonged >110 ms in right precordial leads; epsilon wave in right precordial leads; reduced voltages ≤0.5 mV in frontal leads; (RBBB)	(up sloping in right precordial leads)	Inverted in right precordial leads	PVB with a LBBB pattern; (VT with a LBBB pattern)
Dilated cardiomyopathy	Normal	(left atrial enlargement)	(prolonged ≥0.21 s)	LBBB	Down sloping (up sloping)	Inverted in inferior and/or lateral leads	PVB; (VT)
Myocarditis	(prolonged)	Normal	Prolonged ≥0.21 s	(abnormal "q" waves)[b]	Down- or up sloping	Inverted in ≥2 leads	(atrial arrhythmias); (PVB); (2nd or 3rd degree AV block); (VT)
Long QT syndrome	prolonged >440 ms in males >460 ms in females	Normal	Normal	Normal	Normal	Bifid or biphasic in all leads	(PVB); (torsade de pointes)
Brugada syndrome	Normal	Normal	Prolonged ≥0.21 s	S1S2S3 pattern; (RBBB/LAD)	Up sloping "coved-type" in right precordial leads	Inverted in right precordial leads	(polymorphic VT); (atrial fibrillation) (sinus bradycardia)
Lenègre disease	Normal	Normal	Prolonged ≥0.21 s	RBBB; RBBB/LAD; LBBB	Normal	Secondary changes	(2nd or 3rd degree AV block)
Short QT syndrome	Shortened <300 ms	Normal	Normal	Normal	Normal	Normal	Atrial fibrillation (polymorphic VT);

Table 256.2 (Continued)

Disease	QTc interval	P wave	PR interval	QRS complex	ST interval	T wave	Arrhythmias
Preexcitation syndrome (WPW)	Normal	Normal	Shortened <0.12 s	Delta wave	Secondary changes	Secondary changes	Supraventricular tachycardia; (atrial fibrillation)
Coronary artery diseases[a]	(prolonged)	Normal	Normal	(abnormal "q" waves)[b]	(down- or up sloping)	Inverted in ≥2 leads	PVB; (VT)

[b]Abnormal "q" waves = ≥0.04 s in duration or ≥25% of the height of the ensuing R wave or QS pattern in two or more leads

echocardiography is the main diagnostic tool for recognition of HCM, it is expensive and impractical for screening a large athletic population. The Italian experience demonstrated that a protocol utilizing ECG in addition to history and physical examination successfully identifies HCM in the general population of young competitive athletes. Among 33,735 athletes undergoing preparticipation screening at the Center for Sport Medicine of Padova from 1979 to 1999, 22 (0.07%) showed definitive evidence, both clinical and echocardiographic, of HCM. An absolute value of screening sensitivity for HCM in young competitive athletes cannot be derived from this study because systematic echocardiographic data were not available. However, this 0.07% prevalence of HCM in the white athletic population of the Veneto Region of Italy that was evaluated by history, physical examination, and ECG is similar to that of 0.1% reported in young white individuals in the USA, assessed by echocardiography. This indicates that Italian screening essentially based on 12-lead ECG may be as sensitive as screening by echocardiography in detecting HCM in the young athletic population.

Twelve-lead ECG offers the potential to detect (or to raise clinical suspicion) lethal conditions (other than HCM) manifesting with ECG abnormalities, such as ARVC/D, dilated cardiomyopathy, long QT syndromes, Lenègre disease, Brugada syndrome, short QT syndrome, and WPW syndrome. Overall, these conditions (including HCM) account for up to two thirds of sudden deaths in young competitive athletes.

The possibility of detecting young competitive athletes with either premature coronary atherosclerosis or anomalous coronary artery is limited by the scarcity of baseline ECG signs of myocardial ischemia. However, we reported that approximately one fourth of young athletes who died from coronary artery diseases had warning symptoms and/or ECG abnormalities at preparticipation screening that could raise the suspicion of a cardiac disease.

Echocardiographic study in addition to the basal protocol does not seem to significantly improve efficacy of the preparticipation screening in identifying HCM. Pelliccia et al. did not identify any HCM by routine echocardiographic examination in 4,450 elite athletes previously cleared by ECG at preparticipation evaluation.

The Italian screening modality has proven to be more sensitive than the limited US protocol. Among the 22 Italian athletes (12 males and 2 females, aged 20 ± 4 years) who were identified and disqualified due to HCM, 18 (82%) had shown ECG changes at preparticipation evaluation that included repolarization abnormalities in 14 (87.5%), elevated QRS precordial voltages in 11 (69%), and abnormal Q waves in 5 (31%). Moreover, premature ventricular beats were recorded in 5 (23%). It is noteworthy that only 5 of these 22 athletes (23%) had had a positive family history, a cardiac murmur, or both at preparticipation evaluation. These findings indicate that the Italian screening modality including 12-lead ECG has a 77% greater power for detecting HCM than the protocol limited to history and physical examination recommended by the American Heart Association.

Mortality Reduction

It is noteworthy that none of the 22 young athletes with HCM who were identified in the Padua country

area by preparticipation athletic screening and disqualified from training and competition died during an average 8-year follow-up period. This favorable long-term outcome of former athletes with HCM was the result not only of restriction from competitive sports activity but also of the subsequent close follow-up and clinical management aimed to prevent sudden death. These findings suggest that preparticipation screening does not change merely the mode of death from exercise-related to exercise-unrelated, but reduces mortality from HCM.

A more recent time-trend analysis of the changes in incidence rates and causes of sudden death in young athletes aged 12–35 years in the Veneto region of Italy between 1979 and 2004 definitively demonstrated that preparticipation ECG screening is a life-saving strategy. According to this time-trend analysis, sudden-death mortality from any cardiovascular cause declined in Italian athletes sharply after the introduction of a nationwide screening program in 1982. During the study periods, there were 55 sudden cardiac deaths in screened athletes (1.9 deaths/100,000 person-years) and 265 deaths in unscreened nonathletes (0.79 deaths/100,000 person-years). The annual incidence of sudden cardiac death in athletes decreased by approximately 90%, from 3.6/100,000 person-years in 1979–1980 to 0.4/100,000 person-years in 2001–2004, whereas the incidence of SCD among the unscreened nonathletic population did not change significantly over that time (Fig. 256.6). The decline in the death rate started after mandatory screening was launched and persisted to the late screening period. Compared with the prescreening period (1979–1981), the relative risk of SCD was 44% lower in the early screening period (1982–1992) and 79% lower in the late screening period (1993–2004). Most of the reduced death rate was due to fewer cases of sudden cardiac death from cardiomyopathies. Over the same time interval, a parallel study examined trends in cardiovascular causes of disqualification from competitive sports in 42,386 athletes undergoing preparticipation screening at the Center for Sports Medicine in Padua. The decline of mortality from cardiomyopathies paralleled the concomitant increase in the number of athletes with cardiomyopathies (both HCM and ARVC/D) who were identified by preparticipation screening and disqualified from competitive sports.

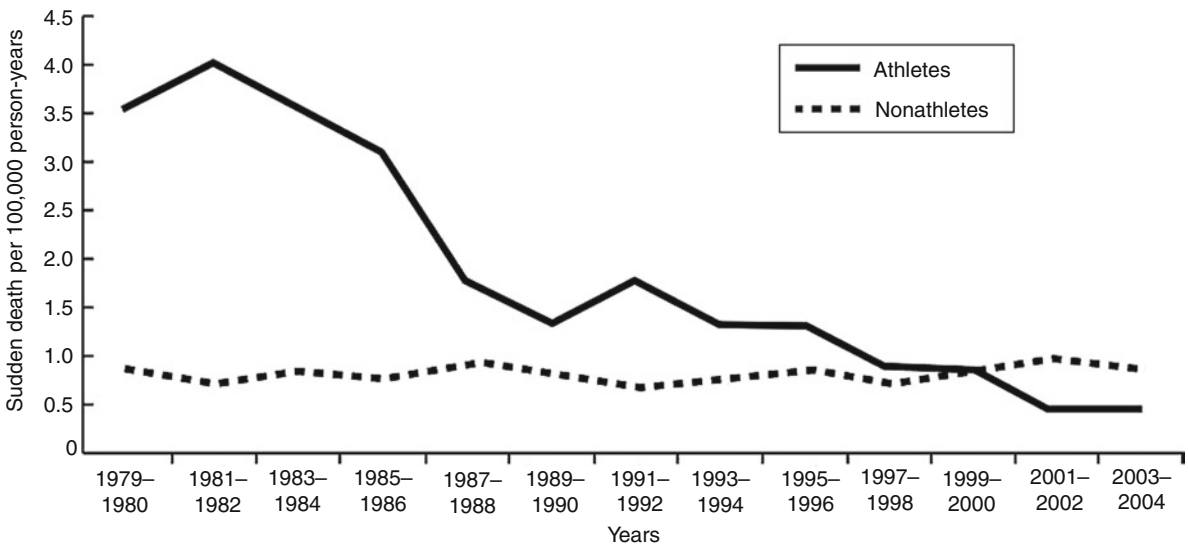

Figure 256.6

Annual incidence rates of SCD per 100,000 screened competitive athletes and unscreened nonathletes 12–35 years of age in the Veneto Region of Italy, from 1979 to 2004. During the study period (the nationwide preparticipation screening program was launched in 1982), the annual incidence of SCD declined by 89% in screened athletes (P for trend <0.001). In contrast, the incidence rate of SCD did not demonstrate consistent changes over time in unscreened nonathletes (Modified from Corrado D, Basso C, Pavei A, Michieli P, Schiavon M, Thiene G (2006) Trends in sudden cardiovascular death in young competitive athletes after implementation of a preparticipation screening program. JAMA 296:1593–1601)

Cost-Benefit Considerations

Screening of large athletic populations has a significant socioeconomic impact. Strategies for implementing the screening program depend on the particular socioeconomic and cultural background as well as on the specific medical systems in place in different countries. In Italy, screening is made feasible thanks to the National Health System, which is developed in terms of health care and prevention services, and to the limited costs of cardiovascular evaluation in the setting of a mass-program. The cost of performing a preparticipation cardiac history, physical examination, and ECG by qualified physicians has been estimated to be ≈30 Euro (approximately US $45) per athlete. The screening cost is covered by the athlete or by the athletic team, except for athletes younger than 18 years, for whom the expense is supported by the National Health System. Moreover, the cost of further evaluation of athletes with positive findings at first-line examination is smaller than expected on the basis of the *presumed* low specificity of athlete's ECG. The percentage of athletes requiring additional testing, mainly echocardiography, did not exceed 9%, with a modest proportional impact on cost.

Costs of infrastructure and training courses for preparticipation screening must also be taken into account in the calculation of the overall screening cost. Strategies for screening implementation should be in the hands of health-care policy makers and services providers, with their program development based on the specific national health and socioeconomic systems.

The young age of the screened athletic population and the genetic nature of the causes of SCD in this age-group profoundly impacts cost-benefit considerations. Unlike older patients with coronary artery diseases or heart failure, adolescents and young adults diagnosed with a genetic disease at risk of arrhythmic SCD will survive for many decades with normal or nearly normal life expectancy thanks to restriction from competition and prophylactic therapy against life-threatening arrhythmias. This large number of life-years saved influences cost-effectiveness analyses and explains why all reports on ECG screening of *young individuals* have provided cost estimates per year of life saved well below $ 50,000, which is the traditional threshold to consider a health intervention cost-effective. The benefit of preparticipation evaluation goes beyond the detection of index athletes with an inherited heart disease because it enables cascade screening of relatives and results in a multiplier effect for identifying other affected family members and thus saves additional lives.

257 Pulmonary Hypertension/ Eisenmenger Syndrome

Delphine Yung

Introduction

Pulmonary hypertension is an abnormal hemodynamic state not commonly seen in pediatrics. However, outcomes of children with this condition are generally poor if left untreated. Therefore, this chapter is focused on the approach to identifying the clinical forms of pulmonary hypertension that are most likely to be seen in children. The important concepts of treatment are discussed, but specific treatment regimens are not. Further reading for greater comprehension and consideration of consultation with a specialized center for pediatric pulmonary hypertension are encouraged.

Definition

Pulmonary Hypertension Hemodynamics

Pulmonary hypertension is defined as mean pulmonary artery pressure equal to or greater than 25 mmHg at rest by right heart catheterization. Abnormal elevation of pulmonary pressure is due to either increased flow through the pulmonary vessels or increased resistance in the pulmonary vessels.

$$\text{Pressure} = \text{Flow} \times \text{Resistance}$$

Increased flow through the pulmonary bed results from left-to-right shunts of congenital heart disease or other congenital malformations. Increased flow usually occurs in the setting of normal pulmonary vascular resistance. However, pulmonary vascular resistance can become abnormally elevated over time if the shunt is not repaired, causing the initial left-to-right shunt to eventually become a right-to-left shunt. The most severe and irreversible type of this condition is known as Eisenmenger syndrome. Pulmonary vascular resistance can also be elevated in other conditions such as congenital or acquired diseases of the pulmonary vessels, airways, and lungs. Elevation of pressure "downstream" from the lungs may result from pulmonary vein stenosis and heart valve or heart muscle disease, which can in turn cause elevated pulmonary pressure. The prognosis and treatment of pulmonary hypertension depends on identification of the etiology.

Normal Pulmonary Pressure by Age, Including Fetal

Normal changes in pulmonary arterial pressure, pulmonary blood flow, and pulmonary vascular resistance from fetal life to postnatal life are described in the Chap. 245, "Fetal Cardiology and Neonatal Transition". These changes are particularly important for the pediatrician to understand because disease states in the neonate may be due to alterations in these mechanisms. Expansion of the lung, and increase in oxygen concentration lead to a dramatic dilation of the pulmonary vessels immediately after birth. Further reduction in pulmonary vascular resistance takes place over the next 10–14 days as the relatively thick vascular smooth muscle layer of the fetal pulmonary arterioles regress to resemble the adult medial layer. Pulmonary vascular resistance fall to near adult levels about 6–8 weeks after birth, and continues to gradually fall with growth of both alveoli and pulmonary arterioles for the next 4–5 years (*Fig 257.1*).

Classification/Etiology

The clinical classification system has gone through a series of changes that reflects the understanding of pathological, pathophysiological, and therapeutic characteristics (*Table 257.1*). Since 2003, the term PPH "primary pulmonary hypertension" has been abandoned in favor of "pulmonary arterial hypertension" (PAH), and indicates that the disease is found in the precapillary vessels, differentiating it from other forms of pulmonary hypertension (PH). As information and evidence about pulmonary hypertension continues to grow, there will likely be more modifications in the future.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_257,

Epidemiology

The incidence and prevalence of most forms of pediatric pulmonary hypertension is unknown. All forms of pulmonary hypertension in the clinical classification (Table 257.1) have been described in children, but the most common are idiopathic/heritable, associated with congenital heart disease, and chronic lung disease of prematurity.

1. *Persistent Pulmonary Hypertension of the Newborn (PPHN)*: The incidence of PPHN is ~1–2 per 1,000 live births in the USA. Although PPHN has been classified as PAH, its unique natural history, treatment, and outcome should be discussed separately (Neonatology).
2. *Idiopathic PAH*: The best available data is from the French registry, which estimates the prevalence of PAH at 15 cases per million adults and idiopathic PAH at 5.9 cases per million adults.
3. *PAH associated with Congenital Heart Disease (CHD)*: The overall incidence of CHD is approximately 8 in 1,000 live births. Pulmonary hypertension is common in infants and children with congenital heart disease, and based on natural history studies, approximately 30% of all children born with CHD who do not undergo surgical repair will develop pulmonary vascular disease. However, data on pulmonary arterial hypertension and Eisenmenger syndrome in

Table 257.1
Updated clinical classification of pulmonary hypertension (Dana Point 2009)

1. Pulmonary arterial hypertension (PAH)
1.1. Idiopathic
1.2. Heritable
1.2.1. BMPR2
1.2.2. ALK1, endoglin (with or without hereditary hemorrhagic telangiectasia)
1.2.3. Unknown
1.3. Drugs and toxins induced
1.4. Associated with (APAH)
1.4.1. Connective tissue diseases
1.4.2. HIV infection
1.4.3. Portal hypertension
1.4.4. Congenital heart disease
1.4.5. Schistosomiasis
1.4.6. Chronic hemolytic anemia
1.5. Persistent pulmonary hypertension of the newborn
1′ Pulmonary veno-occlusive disease and/or pulmonary capillary hemangiomatosis
2. Pulmonary hypertension due to left heart disease
2.1. Systolic dysfunction
2.2. Diastolic dysfunction
2.3. Valvular disease
3. Pulmonary hypertension due to lung diseases and/or hypoxemia
3.1. Chronic obstructive pulmonary disease
3.2. Interstitial lung disease
3.3. Other pulmonary diseases with mixed restrictive and obstructive pattern
3.4. Sleep-disordered breathing
3.5. Alveolar hypoventilation disorders
3.6. Chronic exposure to high altitude
3.7. Developmental abnormalities
4. Chronic thromboembolic pulmonary hypertension
5. PH with unclear and/or multifactorial mechanisms
5.1. Hematological disorders: myeloproliferative disorders, splenectomy

Table 257.1 (Continued)

5.2. Systemic disorders: sarcoidosis, pulmonary Langerhans cell, histiocytosis, lymphangioleiomyomatosis, neurofibromatosis, vasculitis
5.3. Metabolic disorders: glycogen storage disease, Gaucher disease, thyroid disorders
5.4. Others: tumoral obstruction, fibrosing mediastinitis, chronic renal failure on dialysis

ALK-1 activin receptor-like kinase 1 gene, *APAH* associated pulmonary arterial hypertension, *BMPR2* bone morphogenetic protein receptor, type 2, *HIV* human immunodeficiency virus, *PAH* pulmonary arterial hypertension

the current era have only been reported in adults. One European study estimates that 6–28% of adults with CHD have PAH, and 3–7% have Eisenmenger syndrome; another estimate is that 1.6–12.5 cases per million adults with CHD in Europe have PAH, and 25–50% of these individuals are affected by Eisenmenger syndrome.

4. *PH associated with chronic lung disease of prematurity*: Chronic lung disease of prematurity develops in 10–15,000 newborns in the USA annually, and is also high worldwide. The exact incidence of pulmonary hypertension with chronic lung disease of prematurity is not known, but is associated with a significant increase in mortality.

Pathogenesis

1. *Right Heart Failure*: Elevated pressure in the pulmonary vessels creates increased work for the right ventricle. The right ventricle initially compensates for increased afterload by hypertrophy and dilation, but stroke volume and cardiac output eventually decrease over time, leading to right heart failure. The timing and degree of right ventricular decompensation varies widely among individuals, but the reasons for this are unknown. The function of the right ventricle is a major determinant of the functional status and prognosis in pulmonary hypertension. Therapy aimed at improving right ventricular function may improve functional status.
2. *Elevated Pulmonary Vascular Resistance (PVR)*: In PAH, elevated pulmonary pressure results from restricted flow through the pulmonary arterial vessels leading to a pathological increase in PVR. Increased PVR is predominantly due to a loss of vascular luminal cross section from vascular remodeling and vasoconstriction.
   (a) Remodeling of the small pulmonary arteries (called "resistance arteries" because they regulate regional blood flow in the lung) causes a fixed obstruction, which does not respond to acute vasodilator challenge. The mechanisms of vessel remodeling are endothelial dysfunction, excessive proliferation and decreased apoptosis in pulmonary artery smooth muscle cells (PASMC), abnormal activation of adventitia, thrombosis and inflammation. Endothelial damage can also be caused by shear stress due to increased pulmonary blood flow and increased pulmonary artery pressure of CHD or mechanical stress of lung disease.
   (b) Excessive vasoconstriction has been related to increased expression of potassium channels in the smooth muscle cells and endothelium leading to an overload of intracellular calcium. The increase in the vasomotor tone is reversible with acute vasodilator testing. Vasoconstriction can be a reflex response to stretch receptors in the left atrium and pulmonary veins in left heart disease and to hypoxia from lung disease.
3. *Cellular and Molecular Abnormalities and Targets for Therapy*: Knowledge of multifactorial disease pathways has led to the development of targets for therapy. These pathways are thought to be similar in children and adults.
   (a) There is an imbalance in the major arachidonic acid metabolites with a decrease in prostacyclin and increase in thromboxane A_2. Prostacyclin is a potent vasodilator, inhibits platelet activation, and has antiproliferative properties. Thromboxane A_2 is a potent vasoconstrictor and promotes platelet activation and proliferation. There are increased levels of endothelin-1, a potent vasoconstrictor and stimulator of pulmonary artery smooth muscle cell proliferation. Nitric oxide is a vasodilator and inhibitor of platelet activation and vascular smooth muscle cell proliferation. Decreased nitric oxide synthase has been observed in PAH patients. The nitric oxide second messenger cyclic guanosine monophosphate (cGMP) is inactivated by phosphodiesterase, especially the PDE-5 isoform found in large quantities in the lung.
   (b) Serotonin is a vasoconstrictor and promotes PASMC hypertrophy and hyperplasia, and there

are alterations in the serotonin transporter in patients with PAH. There is decreased vasoactive intestinal peptide, a vasodilator similar to prostacyclin. Mediators of inflammation such as platelet-derived growth factor (PDGF), vascular endothelial growth factor (VEGF), antiapoptotic protein survivin, and transcription factors HIF-1 alpha (hypoxia inducible factor-1 alpha) and NFAT (nuclear factor activating T lymphocytes) play a role in PAH. Drugs in trial for therapy include PDGF receptors antagonists, imatinib and sunitinib, and sorafenib, a VEGF antagonist.

4. Pulmonary vascular disease is being increasingly seen as a problem of angiogenesis. Evidence suggests that lung blood vessels, instead of passively forming alongside airways, actively promote normal alveolar growth during development and contribute to the maintenance of alveolar structures throughout life. These pathways clearly play an important role in pediatric diseases such as PPHN, chronic lung disease of prematurity, and CHD. Stem cells may also play important roles in angiogenesis and vascular remodeling, but their therapeutic value is unknown.
5. Pulmonary hypertension can also result from the passive backward transmission of pressure elevation in left heart disease, where the pulmonary pressure is additive to the elevated downstream pressure, but transpulmonary pressure gradient (TPG = mean PA pressure minus PCWp) and pulmonary vascular resistance is normal, (e.g., mean PA pressure and pulmonary capillary wedge pressure are elevated, but TPG is normal).
6. *Genetics*: The bone morphogenetic protein receptor type 2 (BMPR2) has been recognized in about 20% of cases of idiopathic PAH and more than 70% of familial or heritable PAH. BMPR2 belongs to the superfamily of transforming growth factor beta receptors that control vascular cell growth. Mutations in two other members of this superfamily, activin-like kinase-type 1 (ALK1) and endoglin (ENG) cause hereditary hemorrhagic telangiectasia and rarely also cause heritable PAH. Mutations are autosomal dominant with incomplete penetrance.

Pathology

1. The pathological findings of medial hypertrophy in the muscular and elastic pulmonary arteries, and dilation and intimal thickening of elastic pulmonary arteries are seen in all forms of pulmonary hypertension, regardless of etiology.
2. Pulmonary arterial hypertension is further characterized by lesions of the pre- and intra-acinar pulmonary arteries. Heath and Edwards, in their study of CHD, were the first to systematically describe and classify these lesions by severity, increasing in grade from 1 to 6. Less severe lesions, corresponding to Heath–Edwards grade 1–3, are usually diffuse, and may be considered more reversible. These lesions include isolated medial hypertrophy, medial hypertrophy and intimal thickening of concentric lamellar, eccentric, and concentric nonlaminar types. More severe complex lesions, corresponding to Heath–Edwards grade 4–6, may be focal and include plexiform lesions, dilation lesions, arteritis or inflammation, and thrombosis in situ (*Fig. 257.2*).
3. Adventitial thickening and proliferation is seen in persistent pulmonary hypertension of the newborn, but rarely in other causes of pulmonary arterial hypertension.
4. Pulmonary venous occlusive lesions and capillary proliferation and dilation may be patchy and should be assessed. These findings suggest pulmonary veno-occlusive disease or pulmonary capillary hemangiomatosis, two rare diseases that are being increasingly recognized as possibly overlapping with pulmonary arterial hypertension.
5. In pulmonary hypertension due to left heart disease in children, there is medial hypertrophy of the pulmonary arteries and also thickening or "arterialization" of the pulmonary veins, along with proliferation and dilation of lymphatics or lymphangiectasia, and interstitial edema.

Clinical Manifestations

Because pulmonary hypertension is rare, pediatricians unfortunately often do not recognize symptoms and signs of pulmonary hypertension until right heart failure becomes advanced.

Symptoms

Patients with pulmonary hypertension manifest signs and symptoms related to the degree of pulmonary artery pressure elevation and degree of right heart failure. Shortness of breath with exertion, or dyspnea, is a common symptom that can be mistaken for asthma. Other symptoms may include chest pain, dizziness, atrial arrhythmias, hemoptysis, and syncope. Syncope is due to the sudden

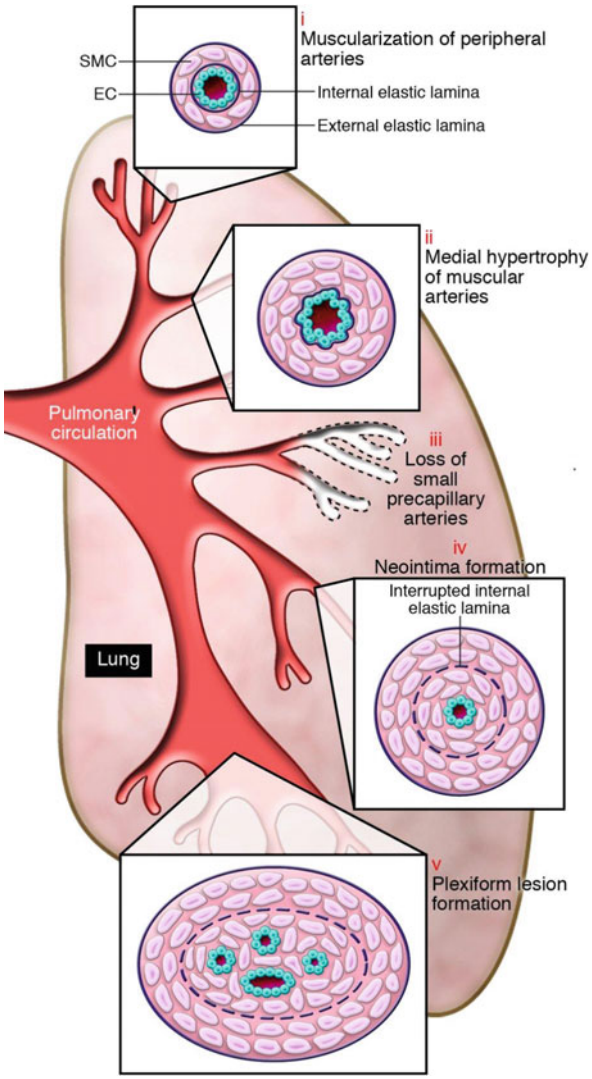

Figure 257.2
Pathobiology of PH. Schema illustrating the different vascular abnormalities compared with normal pulmonary circulation, associated with PH. This schema depicts the abnormalities throughout the pulmonary circulation, including (i) abnormal muscularization of distal precapillary arteries, (ii) medial hypertrophy (thickening) of large pulmonary muscular arteries, (iii) loss of precapillary arteries, (iv) neointimal formation, and (v) formation of plexiform lesions in these vessels

failure of right-sided cardiac output, and occurs in patients without a cardiac shunt (e.g., a patent foramen ovale) that can function as a "pop-off" to support systemic circulation. Syncope and subsequent hypoxic seizures may be misdiagnosed as a seizure disorder.

Signs

The signs of pulmonary hypertension on physical examination can be subtle and frequently missed. However, an increased RV impulse and a loud single second heart sound are usually present, and murmurs of tricuspid regurgitation, pulmonary ejection or pulmonary regurgitation can also be present. In more advanced disease, signs of right heart failure may be observed such as tachycardia, tachypnea, edema, hepatomegaly, and ascites. Cyanosis is not seen in pulmonary hypertension unless there is associated lung disease or a right-to-left cardiac shunt, as in classical Eisenmenger syndrome.

Diagnosis

When pulmonary hypertension is suspected, the goals are to confirm the diagnosis of pulmonary hypertension, and to identify associated diseases. Further classification into pulmonary arterial hypertension (Group 1) or other groups is imperative to develop an appropriate treatment plan. Because of the poor prognosis of the disease if left untreated, evaluation should be comprehensive and timely, and consideration should be given for referral to a specialized center for pediatric pulmonary hypertension.

Diagnostic Tests

(a) *EKG*: The electrocardiogram usually shows right axis deviation, right atrial enlargement, and right ventricular hypertrophy. Atrial arrhythmias can be seen.
(b) *CXR*: The chest x-ray may show right atrial and ventricular enlargement and large central pulmonary arteries (*Fig. 257.3*). The peripheral pulmonary vessels may appear hypovascular due to decreased pulmonary flow in the arterioles. The chest x-ray may also suggest the presence of lung disease.
(c) *Echocardiogram*: The echocardiogram is one of the most important screening tools in the assessment of pulmonary hypertension. The pulmonary pressure can be estimated by measuring tricuspid regurgitation jet velocity, although the tricuspid jet estimation can both overestimate and underestimate pressure. Patients in whom estimated RV systolic pressure is greater than half of systemic pressure, or greater than 40 mmHg, warrant further evaluation. Secondary signs of elevated right ventricular pressure should also be assessed, including right atrial enlargement,

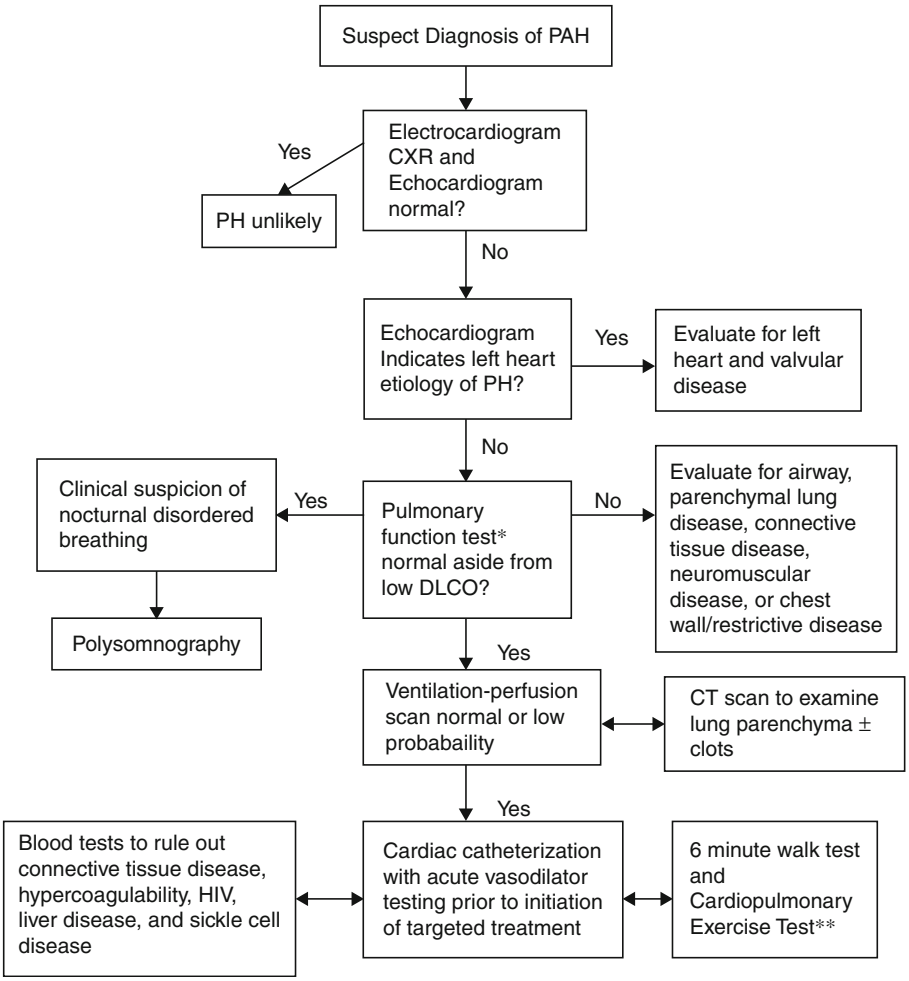

Figure 257.3
Pediatric pulmonary arterial hypertension diagnostic evaluation

right ventricular enlargement and hypertrophy, and interventricular septal wall flattening. Poor right ventricular function and pericardial effusion may accompany signs of right heart failure. The other main purpose of the echocardiogram is to rule out specific causes of pulmonary hypertension, including CHD, cardiomyopathies, and congenital or acquired valve defects. The presence of an interatrial shunt (e.g., patent foramen ovale) may need to be defined contrast echocardiography.

(d) *Pulmonary Function Testing*: PFTs may not be able to be performed by young children. However, it is important to evaluate ventilatory function, including total lung volume and diffusion capacity. Patients with moderate to severe abnormalities should be evaluated for possible underlying lung disease.

(e) *Nocturnal oximetry*: If obstructive sleep apnea is clinically suspected, then nocturnal oximetry is a useful screening test.

(f) *Radionuclide perfusion (V/Q) scan*: This study is important to exclude chronic thromboembolic pulmonary hypertension (Diagnosis group 4), and is more sensitive than the chest CT.

(g) *Chest CT*: The chest CT is valuable in determining the presence and extent of parenchymal lung disease (diagnosis group 3).

(h) *Right heart catheterization*: The right heart catheterization is the gold-standard procedure for measuring

and confirming elevation of pulmonary artery pressure. Performance of the right heart catheterization in children with suspected pulmonary hypertension requires expertise in pediatric anesthesia and in pediatric cardiology due to the significant risk associated with the procedure. Baseline measurements during catheterization should include saturations in all veins and arteries (with blood gases as appropriate) and cardiac chambers if a shunt is suspected. Pressures should be measured in the right atrium, right ventricle, pulmonary artery, pulmonary capillary wedge, systemic artery, and if appropriate, the left atrium and ventricle. Calculations should include cardiac index, pulmonary blood flow, pulmonary vascular resistance (PVR), and systemic vascular resistance (SVR), PVR:SVR ratio, and the presence of any cardiac shunts. Acute vasodilator testing, which is most commonly done with inhaled nitric oxide, is necessary to test for vascular reactivity and to guide treatment. Cardiac catheterization should differentiate pulmonary hypertension into the following hemodynamic definitions:

- *PH*: Pulmonary hypertension is defined as mean pulmonary artery pressure 25 mmHg or greater.
- *PAH*: Pulmonary arterial hypertension is further differentiated by the elevation of pulmonary vascular resistance above 2.5 or 3 Woods units * m^2.
- *Pulmonary venous hypertension*: Conversely, careful pressure measurements will be able to identify left-sided heart disease (diagnosis group 2) and elevation of pulmonary pressure that is passive (normal transpulmonary gradient, <10 mmHg), reflex (elevated transpulmonary gradient, >10 mmHg, that is reversible with acute vasodilator testing), or fixed.
- Pulmonary hypertension caused by increased pulmonary blood flow via intracardiac or extracardiac shunt.

Functional Assessment

Functional ability has been demonstrated in adults to be associated with worse outcome. In children, an assessment of functional ability or clinical assessment of right heart function/failure is important in determining optimal treatment course. The WHO functional classification in pulmonary hypertension was developed for adults, but can also be used as a guideline to assess children (Table 257.2).

Table 257.2
World Health Organization Functional classification in pulmonary hypertension (PH)

Class I	Patients with PH but without resulting limitation of physical activity. Ordinary physical activity does not cause undue dyspnea or fatigue, chest pain, or near syncope.
Class II	Patients with PH resulting in slight limitation of physical activity. Comfortable at rest; ordinary physical activity causes undue dyspnea or fatigue, chest pain, or near syncope.
Class III	Patients with PH resulting in marked limitation of physical activity. Comfortable at rest; less than ordinary activity causes undue dyspnea or fatigue, chest pain, or near syncope.
Class IV	Patients with PH with inability to carry out any physical activity without symptoms. These patients manifest signs of right heart failure. Dyspnea and/or fatigue may even be present at rest. Discomfort is increased by any physical activity.

(a) Objective and serial measurement of exercise and functional ability may be obtained in older children with the 6-min walk test and cardiopulmonary exercise test. Serial B-type natriuretic peptide BNP levels have also been described as a biomarker for disease severity.

Differential Diagnosis/Concomitant Diagnoses

1. At the outset of the evaluation, all etiologies (see Table 257.1) need to be considered.
2. In children, one of the more common causes of pulmonary hypertension is lung disease, due to a growing population of former premature infants who develop chronic lung disease or "new" bronchopulmonary dysplasia in the post-surfactant era. They are at risk of developing pulmonary hypertension despite treatment for the lung disease. Patients with developmental abnormalities of the lung, such as lung hypoplasia from congenital diaphragmatic hernia, are also at risk for developing PH.
3. Cardiac disease is also a common cause of pediatric pulmonary hypertension. Simple systemic to pulmonary shunt lesions probably account for most of the clinical classification group 1 associated congenital

heart disease. However, complex types of congenital heart disease may be considered a combination of diagnosis group 1 and group 2 (left heart disease). These include left-sided obstructive lesions (and forms of Shone's syndrome), hypoplastic left heart syndrome with restrictive atrial septum, and pulmonary vein stenosis. Cardiomyopathy with elevated left ventricular end diastolic pressure can also lead to pulmonary hypertension. A less common form of pulmonary hypertension occurs with high cardiac output states, such as large arterio-venous malformations or liver failure, due to initially high flow through the pulmonary vessels, and later by elevated left end diastolic pressure as heart failure develops.

4. Patients with pulmonary hypertension should be screened for a history compatible with sleep-disordered breathing or with nocturnal oximetry, followed by formal sleep polysomnography if indicated. Mild sleep apnea, can exacerbate pulmonary hypertension through pulmonary hypoxic vasoconstriction. Sleep apnea is rarely a sole cause of pulmonary hypertension. Treatments include tonsillectomy and adenoidectomy, supplement oxygen and/or positive airway pressure during sleep.
5. Infants with Down syndrome deserve special mention due to the frequency of multiple co-existing conditions that place them at higher risk for developing pulmonary hypertension. These conditions include poor airway tone leading to airway obstruction, gastroesophageal reflux and aspiration, and CHD.
6. Less common diagnoses that require workup include the possibility of a coagulopathic state, hypothyroidism, and connective tissue disease, as the treatment for these is specific. ANA is elevated in 40% of patients with idiopathic disease, and may not represent connective tissue disease. Hemoglobinopathies and HIV should be screened for in all appropriate populations. Pulmonary veno-occlusive disease and pulmonary capillary hemangiomatosis are two rare entities that are not well understood, but can be suspected by CT and confirmed by lung biopsy (*Table 257.3*).

Treatment

General Care

General care for the patient with pulmonary hypertension begins with identifying the etiology of pulmonary hypertension and all the potential exacerbating factors. Diagnoses of lung disease, coagulopathy, and connective tissue disorders need to be treated with input from a specialist in that area. The repair of CHD should be considered on an individual basis. Right heart failure will develop in untreated pulmonary hypertension, and recognition of the degree of right heart failure will guide treatment decisions.

(a) *Digoxin*: There is little data on the use of digoxin, but it is sometimes used in those patients with right heart failure and a low cardiac output and in patients with atrial arrhythmias.
(b) *Diuretics*: Diuretics are used to manage right ventricular volume overload, which is occasionally seen as hepatomegaly or peripheral edema.
(c) *Anticoagulation*: There is expert consensus to support the use of warfarin for anticoagulation titrated to an INR of 1.5–2.5.
(d) *Bronchodilator*: If there is evidence of mild obstructive airway disease that responds to bronchodilator therapy, bronchodilators may be trialed.
(e) *High altitude (including airplane flights)*: A general measure is to recommend relocation to lower altitude for patients chronically residing at altitudes greater than 2,500 m. Patients with oxygen saturations lower than 92% at rest should be considered for a recommendation of supplemental oxygen therapy with airplane flights.
(f) *Oxygen*: Hypoxia is not common in idiopathic pulmonary arterial hypertension. However, patients with associated lung and heart disease occasionally have oxygen saturations less than 92%. Hypoxic pulmonary vasoconstriction will exacerbate pulmonary hypertension and consideration should be given for treatment by oxygen to a saturation greater than 92%, and higher if appropriate for the specific diagnosis. However, patients with Eisenmenger syndrome do not usually benefit significantly from oxygen therapy.
(g) *Exercise*: Children usually self-limit. In the rare functional class I patient, more strenuous exercise may be considered after a formal cardiopulmonary exercise test.
(h) Immunizations should be given, especially for influenza, pneumococcus, and RSV Ig if indicated by age.

Specific Therapies

1. Children with idiopathic pulmonary arterial hypertension who respond to acute vasodilator testing in the catheterization laboratory with a significant decrease in pulmonary artery pressure to near normal levels have been successfully treated with calcium channel blocker therapy. A significantly greater proportion of children are acute responder compared to adults.
2. Specific pulmonary arterial vasodilators have been developed based on known mechanisms of action to treat pulmonary arterial hypertension. These have been studied in adults with pulmonary arterial hypertension. These classes of medications are prostacyclins (epoprostenol, treprostinil, iloprost, beraprost), endothelin receptor antagonists (bosentan, sitaxsentan, ambrisentan), and phosphodiesterase inhibitors (sildenafil, tadalafil). There is data on efficacy for epoprostenol and bosentan in children with IPAH and CHD. Guidelines for treatment are based on those for adults.
3. Polycythemia occurs in Eisenmenger patients because of chronic hypoxia, and phlebotomy may be considered in patients with symptoms of hyperviscosity. However, phlebotomy should only be undertaken in centers experienced with the procedure to prevent hemodynamic instability. Iron deficiency and microcytic anemia may also cause symptoms of hyperviscosity.
4. Patients who fail medical therapy and progress to severe heart failure may opt to undergo lung transplant or heart–lung transplant.
5. Atrial septostomy to create a pulmonary to systemic shunt has been shown to improve severe right heart failure and survival. More recently, creation of a Pott's shunt (right pulmonary artery to descending aorta shunt) has been described to improve severe right heart failure in patients with PAH associated with CHD and IPAH.

Prognosis

1. Estimated median survival of adults in the NIH registry was 2.8 years, with 1-, 3-, and 5-year survival rates of 68%, 48%, and 34%, respectively, whereas the mean untreated survival time for children was only 10 months after diagnosis. However, improved survival for children has been shown with epoprostenol, calcium channel blockers, and bosentan. Unfortunately, there is still no cure, so therapy is aimed at improving quality of life, functional status, and survival.
2. The survival for patients with Eisenmenger syndrome is better than that with IPAH. Despite early surgical repair of the congenital heart defect, some patients may go on to develop progressive pulmonary vascular disease for reasons that remain unclear.

Prevention

1. *CHD repair*: Natural history studies guide the timing of repair for VSD, PDA, and ASD to prevent risk of pulmonary vascular disease. The exact timing for these lesions and for more complex lesions is

case-specific and may require further evaluation by cardiac catheterization.

2. Pediatric patients who have a known risk for pulmonary hypertension can be screened at intervals and referred to for further evaluation and treatment if pulmonary hypertension is identified. These diagnoses include premature infants with chronic lung disease, sickle cell disease, scleroderma and other connective tissue disease, lung/liver transplant listing, severe sleep apnea, HIV and those at genetic risk.

258 Rheumatic Heart Disease/Acute Rheumatic Fever

Bruce G. Hardy

Rheumatic fever (RF) continues to be a major heath concern worldwide, especially in developing countries. It is a complex disease that is a result of an interaction between Group A streptococcus (GAS) and a susceptible host. Although rheumatic heart disease (RHD) is generally the most serious acute and chronic concern, RF also affects the joints, brain, and the skin. It remains the most common cause of acquired cardiac disease in children and adolescents worldwide.

Pathogenesis

Acute rheumatic fever follows an infection of Group A streptococcus (GAS), virtually always a pharyngeal infection. There have been a few reports of RF following GAS skin infection in areas of Australia, but this is unusual.

The risk of developing rheumatic fever following untreated GAS tonsillopharyngitis is approximately 1%. Virulence is dependent on the M protein, a surface protein of the bacterial wall, which carries specific epitopes. There are more than 80 specific serotypes, which lead to rheumatic fever. However, the reason why specific strains within a given serotype have increased RF virulence has not been determined. The causal strain of GAS adheres to the oral and pharyngeal cells and then releases a variety of degradation products that present antigenic determinants which cross-react with certain human tissues, particularly cardiac valve tissue and the myocardium.

The pathologic changes in the heart can be grouped in two phases. The first phase occurs in the first 2–3 weeks after a GAS infection, and consists of infiltration of T cells, B cells, and macrophages and is accompanied by interstitial edema and deposition of eosinophilic granular material. The second phase, that of proliferation, is prolonged, and may occur over months to years. The cardinal finding during this phase is the Aschoff nodule, with a central area of fibrinoid changes surrounded by and infiltrated by large multinucleated "owl eye" cells. It is the mitral valve that is most often affected by RF, often accompanied by aortic valve changes.

During acute RF, the mitral subvalvular structures are usually affected, with chordal elongation and annular dilation, causing mitral insufficiency. There are also changes in the mitral valve leaflets. In the early stages, echocardiography may demonstrate the initial changes of mitral valve leaflet restriction and thickening which exacerbates the mitral insufficiency. The later stages of chronic RF mitral valve disease are characterized by mitral leaflet shortening and rigidity, leaflet retraction, and chordal fusion and shortening. The later stages include both mitral insufficiency and mitral stenosis.

The aortic valve is affected less often than the mitral valve and virtually always occurs with mitral valve disease rather than as an isolated finding. In the acute phase of RF there may be aortic insufficiency, often with leaflet prolapse. In chronic RF, there may be leaflet thickening, fibrosis, and retraction of the leaflets leading to further aortic valve insufficiency.

Epidemiology

Worldwide, it is estimated that there are at least 282,000 new cases of RF and 233,000 deaths each year, most of these occurring in developing countries. This estimate may be quite low because of the difficulties in obtaining accurate surveillance data. The incidence in some areas may be as high as 500 per 100,000 people. The major determinants of rheumatic fever incidence and rheumatic heart disease are poverty, malnutrition, overcrowding, poor housing, and a shortage of health-care resources.

Although there has been a dramatic decline in the number of RF cases in developed countries, there has been a resurgence in various areas. In 1987, Veasy reported a significant number of new cases of RF in the Salt Lake City area of the USA. Although RF has usually been associated with poor socioeconomic status, in this study the affected children were predominantly from white (96%) middle-class families with above-average incomes and with ready access to medical care. In 1989, a survey of pediatric cardiologists in the USA suggested a five- to tenfold increase in the number of new RF cases compared to earlier years.

Prevention of Rheumatic Fever

Rheumatic fever could essentially be prevented if Group A streptococcal pharyngitis was diagnosed and treated. However, even in developed countries this is not possible. Patients with streptococcal pharyngitis do not all have diagnostic testing done, as it is difficult for families to differentiate streptococcal disease from viral infections. A study by Veasy in the Salt Lake, Utah area found that of 274 confirmed cases of RF, only 17% had sought medical attention for a sore throat. Also, streptococcal infections may be without concerning symptoms, yet may lead to RF. In developed countries, since RF is uncommon, families may not be aware of the need to diagnose and treat streptococcal infections.

The problem is much more severe in developing countries, where there is less availability of diagnostic tests, there are financial difficulties in obtaining care, and there may be inadequate patient awareness of the need to diagnose and treat strep pharyngitis to prevent RF. This is of particular importance in areas with a high prevalence of RF. Kathikeyan et al. recently published a special report in *Circulation* suggesting the use of clinical protocols to inexpensively indicate a high likelihood of strep pharyngitis, allowing for rapid treatment. The authors emphasize the advantage of rapid and efficient primary prevention of RF to avoid the long-term sequelae of chronic rheumatic fever. Primary prevention of RF is clearly favorable to secondary prophylaxis and this paradigm has been shown to be successful in Costa Rica and Cuba, almost eradicating RF with programs of primary prevention.

Diagnosis of Rheumatic Fever

The diagnosis of rheumatic fever remains a challenge, in part because there is no single set of definitive signs or tests, and in part because few clinicians care for many patients with rheumatic fever. In 1944, T. Duckett Jones, Research director of the House of Good Samaritan, in Boston, proposed a set of criteria that would guide physicians in the diagnosis of acute rheumatic fever. These criteria have undergone four major revisions, most recently in 1992, and were reviewed without new changes by an American Heart Association working group in 2002.

The Jones Criteria are meant to be guidelines, and are not meant to be a substitution for the careful judgment of clinicians. The criteria are divided into three groups: major features, minor features, and supportive evidence of a preceding Group A streptococcal infection, as detailed in *Tables 258.1* and *258.2*.

Table 258.1

Major criteria	Minor criteria
Carditis Polyarthritis Chorea Erythema marginatum Subcutaneous nodules	Clinical findings Fever Arthralgia Laboratory findings Elevated sedimentation rate Elevated C-reactive protein ECG finding Prolonged PR interval

Table 258.2

Supporting evidence for a preceding group A streptococcal (GAS) infection
Positive throat culture or rapid streptococcal antigen test
Elevated or rising streptococcal antibody titer

Criteria for the Diagnosis of Rheumatic Fever

Primary episode of rheumatic fever:

1. Two major criteria OR one major criteria and two minor criteria
2. Plus supportive evidence of a preceding Group A streptococcal infection

Rheumatic Fever recurrence in a patient without a history of rheumatic heart disease:

1. Two major criteria OR one major and two minor criteria
2. Plus supportive evidence of an antecedent Group A streptococcal infection

Rheumatic Fever recurrence in a patient with a history of rheumatic heart disease:

1. Two minor criteria
2. Plus supportive evidence of an antecedent Group A streptococcal infection

Chorea or indolent carditis:

1. There is no need for other criteria or evidence of an antecedent Group A streptococcal infection

Major Criteria

Carditis

Carditis is the most serious manifestation of acute rheumatic fever and is the only major manifestation that has long-term sequelae. In developing countries, rheumatic carditis continues to be the leading cause of acquired heart disease.

The criterion for carditis is met when a new murmur of mitral insufficiency and/or aortic insufficiency is evident. Frequent examinations may be necessary since the murmurs may change from day to day. Tachycardia is often an early sign of carditis, but is also present in most febrile and inflammatory diseases. Careful history and examination of patients is necessary to evaluate evidence of cardiac compromise.

Although the primary pathological concern in RF is valvular disease of the mitral and aortic valves, initially there may be a pancarditis with accompanying myocardial dysfunction, exacerbating the heart failure that is secondary to the valve dysfunction. However, troponin levels are not used to diagnose RF since the levels are variable and are not adequately specific or sensitive. Several studies have demonstrated a lack of elevated troponin levels in acute rheumatic fever, indicating the absence of myocardial necrosis in most cases.

The clinical presentation of carditis is quite variable, ranging from the asymptomatic patient with a murmur suggesting mitral insufficiency to the critically ill patient with cardiac failure. Carditis is an early finding, with 90% of those with carditis presenting in the first 2 weeks of the RF illness. If the cardiac involvement is mild, the valvular insufficiency may decrease or even resolve as the inflammatory process subsides. However, patients with moderate to severe carditis often develop chronic and progressive valvular disease.

The Jones criteria are based on auscultatory findings of mitral insufficiency and/or aortic insufficiency. Mitral insufficiency is the most common finding in RF carditis, and is present in approximately 90% of patients. The characteristic murmur of mitral insufficiency is a high-pitched regurgitant holosystolic murmur heard at the apex. The murmur is best heard at end-exhalation with the patient in the left lateral decubitus position. The murmur may be quite soft, even with acute severe mitral insufficiency. Aortic insufficiency is present in approximately 25% of patients with RF carditis, and usually occurs in combination with mitral insufficiency. Only about 5% of patients with RF have isolated aortic insufficiency. The murmur of acute aortic insufficiency is generally a soft early diastolic murmur that is heard at the mid-left sternal border with the patient at end-inhalation and leaning forward in a sitting position.

When mitral insufficiency is moderate to severe, left ventricular filling pressures rise with resultant pulmonary vascular engorgement and pulmonary edema. This is evident clinically as dyspnea, orthopnea, and paroxysmal nocturnal dyspnea. Secondary pulmonary hypertension may develop and right ventricular failure may ensue. If mitral insufficiency is mild, patients may be asymptomatic or symptoms may be limited to tachycardia, decreased exercise tolerance, and dyspnea with exertion.

Echocardiography

Although echocardiographic findings by themselves are not yet accepted as fulfilling the criteria for carditis, echocardiography is utilized routinely when available.

The Jones Criteria for the diagnosis of acute rheumatic fever were written long before the availability of echocardiography and there continues to be controversy concerning the specificity and sensitivity of echocardiography for the diagnosis of RF. Since many normal patients have a small amount of mitral and aortic insufficiency, there has been concern that echocardiography may result in the overdiagnosis of RF. On the other hand, echocardiography has the ability to evaluate abnormal mitral and aortic valves even when a murmur may be absent and is therefore more sensitive than auscultation. All patients with suspected RF should have an echocardiogram, and a physician knowledgeable about the specific changes that occur in RF should interpret the study. To differentiate pathologic from normal physiologic mitral and aortic insufficiency, the World Health Organization has recommended the following criteria: (a) color Doppler jet > 1 cm in length, (b) color Doppler jet evident in at least two imaging planes, (c) color Doppler jet mosaic with a velocity > 2.5 m/s, and (d) Doppler spectral tracing holosystolic for mitral insufficiency and holodiastolic for aortic insufficiency. These criteria have been validated by Minich et al. in 1997.

The current WHO recommendations are accepted in developed countries, but there has been concern that these criteria are not adequately sensitive for use in developing countries. A recently published study by Marijon et al. suggested the incorporation of echocardiographic morphologic criteria in addition to the Doppler criteria for the diagnosis of carditis secondary to RF. They studied 2,370 children in Mozambique, an area with a high prevalence of RF. The maximum sensitivity of the WHO

Table 258.3

Combined criteria
Doppler criteria
Any degree of valvular regurgitation seen in at least two planes
Associated with at least two morphological signs
Leaflet restriction
Subvalvular thickening
Valvular thickening

criteria was 25% and the maximal sensitivity of the combined criteria was 97%. They felt that the combined criteria are adequately specific since there are almost no other causes of valve thickening in children. The use of these more sensitive criteria may be useful, especially in developing countries, since diagnosis of the first episode of RF allows secondary prophylaxis, with the possibility of decreasing the risk of recurrent episodes of RF and decreasing the incidence of progressive valve disease.

The echocardiographic criteria suggested are summarized in *Table 258.3*.

Arthritis

Migratory polyarthritis is the most common of the major Jones criteria, occurring in 40–70% of cases. Unfortunately, it is also the least specific of the major criteria. The signs of arthritis may also occur in diseases such as Juvenile Rheumatoid Arthritis. The arthritis generally presents from 10 days to 5 weeks after the initial streptococcal infection. The large joints of the knees, ankles, elbows, and wrists are most commonly involved, and typically there is migration from one joint to another. Because of the migration, only one joint may appear to be involved at one time and serial examinations may be necessary. Although the arthritis is typically polyarticular, in some parts of the world, such as Australia's North Territory, monoarthritis may occur. It is important to differentiate true arthritis, a major criterion, from arthralgia, a minor criterion. The joints affected by arthritis are red, swollen, and are exquisitely tender. The joints affected by arthralgia are painful, but not red or swollen. Even with no treatment, the arthritis often resolves 3–4 weeks and is not associated with chronic abnormalities. There is usually such a dramatic response to aspirin therapy that lack of response within 2–3 days should prompt consideration of other etiologies.

There is an entity termed poststreptococcal reactive arthritis that differs from the typical polyarthritis of RF. It appears after a relatively short latent period of 7–10 days, is usually not migratory, is often persistent, and does not respond rapidly to aspirin therapy. This type of arthritis is not generally associated with RF, but there have been reports of patients that were thought to have this type of arthritis and subsequently developed the valvular changes of RF. Any patient with this form of arthritis should be evaluated carefully for other signs of RF.

Chorea

The word chorea is from a Greco-Latin word implying the act of dancing. In the sixteenth century, the term chorea was used by Paracelsus to describe the frenzied movements of religious fanatics who journeyed to the healing shrine of St. Vitus during the middle ages. Thus the term St Vitus dance, an older term for Sydenham's chorea. In the seventeenth century, the English physician Thomas Sydenham described the physical signs of chorea as a true medical entity, though the association of chorea with rheumatic fever was not noted until the nineteenth century.

Chorea occurs in approximately 10–30% of cases of RF. It presents much later than arthritis and carditis, with a latency period of 1–6 months. Because of the latency, patients may not remember an episode of pharyngitis, may not remember the signs or symptoms of arthritis or carditis, and the evidence of the streptococcal infection may not be present. For this reason, the diagnosis of RF may be made when chorea is evident even without other criteria or without evidence of a preceding streptococcal infection.

Patients with chorea have involuntary and purposeless movements, incoordination of muscular movements, and emotional lability. Mild cases may come to attention because of deteriorating school performance, irritability, poor attention span, and changes in coordination. The clinical manifestations of chorea are secondary to inflammatory changes in the basal ganglia, cerebral cortex, and the cerebellum.

Chorea and carditis coexist in approximately 50% of patients with RF. The cardiac involvement in patients with chorea tends to be mild initially, but even those with no cardiac abnormalities at the time of diagnosis of RF are at risk for progressive valvular disease.

Erythema Marginatum

The rash of erythema marginatum is uncommon in RF, only occurring in 5%. However, it is a helpful major criterion since it is quite specific. The rash rarely occurs as the sole

major criterion, but almost always is associated with carditis. The rash is evanescent and may be missed on a single examination. A hot bath often accentuates the rash. It presents as a bright pink/red papule that spreads with serpiginous borders and has central clearing. The borders are usually macular but may be papular and it does blanch with palpation. The rash is not pruritic and is not painful.

Subcutaneous Nodules

Subcutaneous nodules are quite uncommon in RF, occurring in less than 10% of cases. They are not a strong criterion for RF since they may also occur in rheumatoid arthritis and systemic lupus erythematosus. The nodules are usually on the extensor surfaces of the elbows, wrists, knees, ankles, and spinous processes of the back. They may also occur on the scalp. The nodules are generally 0.5–2 cm in diameter, firm, movable, and are not tender to palpation. Subcutaneous nodules rarely are the sole major criterion, and are almost always associated with carditis.

Minor Criteria

The minor criteria are supportive data, with low specificity.

Fever: Most patients are febrile in the early phase of RF, with temperatures ranging from 38°C to 39.5°C (100–103°F). The fevers resolve in 1–2 weeks even without treatment.

Arthralgias: Arthralgias defined as joint pain with no redness or swelling, usually involve the large joints. The pain may vary from mild to severe and the joint involvement may be migratory. Arthralgia cannot be used as a minor criterion if arthritis is used as a major criterion.

Acute-phase reactants: Most clinicians obtain both an erythrocyte sedimentation rate (ESR) and a C-reactive protein (CRP) level. Both are quite nonspecific and are elevated in most inflammatory processes.

Prolonged PR interval: This is a nonspecific criterion, but an ECG should be done on all patients with possible RF. It is not a specific finding since the PR interval is prolonged in one third of patients with a recent Group A streptococcal infection, regardless of whether RF develops.

Supportive Evidence of an Antecedant Group A Streptococcal Infection

Although a positive throat culture or a positive rapid antigen test is acceptable evidence of an antecedent infection, these tests do not rule out a carrier state instead of an acute infection. Elevated or rising antibody titers yield more reliable evidence of a recent infection. The most commonly measured antibody titers are antistreptolysin O (ASO) and antideoxyribonuclease B (anti-DNase B). When one is measured, 80–85% of patients with RF will have an elevated titer. When both are measured, over 90% will have elevation of at least one titer. Determination of a rising antibody titer may be more useful than a single antibody titer, especially if the initial titer is normal or only mildly elevated. The titers peak about 2–4 weeks after the infection.

Treatment of Acute Rheumatic Fever

The diagnosis of acute rheumatic fever should be substantiated before beginning anti-inflammatory therapy in order to avoid diagnostic confusion by the possible suppression of a variety of other inflammatory diseases. However, comfort measures should be initiated, and any signs of carditis should be treated early.

There are four goals in the initial therapy for RF:

1. Symptomatic relief
2. Eradication of group A beta-hemolytic streptococcus
3. Treatment of the manifestations of carditis, if present
4. Prophylaxis against subsequent infection with GAS, to prevent recurrent RF

Symptomatic Relief

Bed rest has been a mainstay of treatment for RF. In the 1940s, and 1950s patients were treated with bed rest for up to a year based on data that indicated this decreased the severity of carditis and fewer episodes of reactivation. Now, it is usually recommended that patients remain at bed rest or chair for 4–6 weeks, depending on the clinical course.

It is standard to treat patients with aspirin, usually starting at 80–100 mg/kg/day divided in four doses. Serum concentrations should be maintained in the range of 20–30 mg/dl. Aspirin is generally continued until the patient is asymptomatic and the acute-phase reactants have returned to normal.

The arthritis of RF is exquisitely responsive to salicylate therapy, and if there is no improvement after several days other diagnoses should be considered.

Carditis

The severity of carditis should be ascertained frequently, and should be treated aggressively with conventional

therapy for heart failure. Although patients with significant carditis are often treated with corticosteroids, studies have not shown any significant differences in outcome. Steroids have not been shown to improve the long-term outcome of carditis, but treatment with steroids is associated with a more rapid decrease in inflammation, fewer new murmurs, and an earlier disappearance of existing murmurs.

Eradication of Group A Streptococcus

Patients with acute RF should be treated with either 10 days of antibiotic or a single IM dose of antibiotic, even if there is no evidence of pharyngitis at the time of the diagnosis. These recommendations are summarized in Table 258.4.

Prevention of Recurrent Attacks of Rheumatic Fever (Secondary Prevention)

All individuals who have had acute RF are at high risk for a recurrence if they incur another GAS infection. A recurrent episode of RF may worsen any cardiac disease already present and it may cause new cardiac disease in those without carditis during their initial episode of RF. Because many infections with GAS are without symptoms, the most effective course is to institute a regimen of continuous antibacterial prophylaxis as well as treatment of new known acute GAS infections. The recommendations for secondary prevention of recurrent RF are summarized in Table 258.5.

Duration of Prophylaxis

The duration of prophylaxis is not well defined, and should be individualized. Patients at high risk for GSA, such as teachers, physicians, and nurses should be treated as long as they have this exposure. Most physicians suggest that prophylaxis should continue at least until the patient is a young adult, which usually is at least 10 years after acute RF. Guidelines published by the American Heart Association and endorsed by the American Academy of

Table 258.4
Primary prevention of rheumatic fever (RF) (treatment of streptococcal pharyngitis)

Agent	Dose	Mode	Duration
Penicillins		Oral	10 days
Penicillin V	Children ≤27 kg (60 lb): 250 mg 2–3 times daily		
	Children >27 kg (60 lb), adolescents and adults: 500 mg 2–3 times daily		
	OR		
Amoxicillin	50 mg/kg once daily (maximum 1 g)	Oral	10 days
	OR		
Benzathine penicillin G	600,000 units for children ≤27 kg (60 lb)	Intramuscular	Once
	1,200,00 units for patients >kg (60 lb)		
For patients allergic to penicillins:			
Narrow-spectrum cephalosporin[a]	Depends on the specific antibiotic	Oral	10 days
	OR		
Clindamycin	20 mg/kg/day, divided TID (max 1.8 g/day)	Oral	10 days
	OR		
Azithromycin	12 mg/kg once daily (maximum 500 mg)	Oral	5 days
	OR		
Clarithromycin	15 mg/kg divided BID (maximum 250 mg BID)	Oral	10 days

Table 258.5
Secondary prevention of recurrent rheumatic fever (secondary prevention)

Agent	Dose	Mode
Benzathine penicillin G	600,000 units for children ≤27 kg (60 lb)	Intramuscular
	1,200,00 units for patients >kg (60 lb)	
	Every 4 weeks[a]	
Penicillin V	250 mg twice daily	Oral
Sulfadiazine	0.5 g once daily for children ≤27 kg (60 lb)	Oral
	1.0 g once daily for patients >kg (60 lb)	
For patients allergic to penicillin and sulfadiazine		
Macrolide or azalide	Depends on the antibiotic used	Oral

[a]In high-risk situations, administration every 3 weeks is justified and recommended

Pediatrics are in *Table 258.6*. Many clinicians feel that all patients with valvular heart disease secondary to RF should remain on continuous prophylaxis throughout life.

Table 258.6
Duration of secondary rheumatic fever prophylaxis

Category	Duration after last episode of RF
RF with carditis and residual heart disease (persistent valvular disease)	10 years or until 40 years of age (whichever is longer), sometimes lifelong prophylaxis
RF with carditis but no residual heart disease (no valvular disease)	10 years or until 21 years of age (whichever is longer)
RF without carditis	5 years of until 21 years of age (whichever is longer)

Level of confidence: Only consensus of experts, case studies, or standard of care

Bacterial Endocarditis Prophylaxis

The AHA has recently published updated recommendations regarding the use of prophylactic antibiotics to prevent infective endocarditis. These guidelines no longer suggest prophylaxis for patients with a history of RF unless they have a prosthetic valve or prosthetic material used in valve repair. In this situation, it is advised to use an antibiotic other than a penicillin since oral α-hemolytic streptococci would likely have developed resistance to penicillin.

Chronic Rheumatic Heart Disease

Chronic rheumatic heart disease (RHD) remains the most serious complication following acute rheumatic fever worldwide, especially in developing countries. In children, the most common form of RHD is mitral insufficiency rather than mitral stenosis. Aortic insufficiency is less common, and almost always accompanies mitral insufficiency. The cause of the mitral insufficiency is usually shortening, retraction, and deformity of the leaflets and often accompanied by chordal shortening and fusion. These changes result in inadequate leaflet coaptation, allowing insufficiency. There may be secondary left ventricular dilation, which causes annular dilation and an alteration of the papillary muscle orientation allowing for further insufficiency of the mitral valve. Chronic mitral insufficiency causes left ventricular dilation and eventual left ventricular systolic and diastolic dysfunction. The elevated left ventricular end-diastolic pressure and the elevated left atrial pressure lead to dyspnea, especially with exertion, and decreased exercise tolerance.

Aortic insufficiency may accompany mitral insufficiency in the early years of RHD, and may increase the left ventricular dimensions and accelerate left ventricular dysfunction. Aortic insufficiency seldom occurs without associated mitral insufficiency.

Mitral stenosis may develop as early as the second decade of life secondary to leaflet thickening and retraction, fusion of the commissures, and chordal shortening. Eventually, the leaflets may calcify, further increasing the stenosis. In developed countries, mitral stenosis generally does not occur until 15–40 years after the initial occurrence of RF. Mitral stenosis occurs earlier in developing countries, probably because of multiple episodes of acute RF. The result of mitral stenosis is an elevation in left atrial

pressure with the development of dyspnea, decreased exercise tolerance, and pulmonary hypertension. The left atrial enlargement may lead to atrial flutter/fibrillation.

Aortic stenosis may accompany mitral stenosis and is generally a slowly evolving process. Over time, there may be the development of aortic valve thickening, fibrosis, calcification, and fusion of the commissures. Aortic valve insufficiency usually persists, and may even worsen as the leaflets become more thickened and rigid. Over time, left ventricular failure may ensue, as the aortic valve disease is additive to the mitral valve disease.

The treatment of the valvular changes in chronic RHD is related to the hemodynamic effects. Although patients may be treated medically for decades, many eventually need to have replacement of the mitral and/or aortic valves. Mitral stenosis is occasionally treated with dilation during a cardiac catheterization, though this may increase the insufficiency. Aortic stenosis is not generally amenable to dilation and valve replacement is the only effective treatment.

259 Secondary Cardiac Morbidities

Melanie D. Everitt · Lloyd Y. Tani

Case Presentation

A 12-year-old girl with type 1 diabetes mellitus (DM) for 5 years presents for a routine well-child visit. What is her risk of future cardiovascular events and what additional historical information, physical examination, and laboratory studies should be obtained?

Definition

Secondary cardiac morbidity is heart disease that develops as a result of other systemic disorders. This form of acquired heart disease can affect the coronary arteries, central vasculature, pericardium, myocardium, or the neural regulatory system of the heart depending upon the pathology of the primary disorder and the side effects of its treatment.

Etiology

While acquired heart disease in the overall pediatric population is relatively uncommon, secondary cardiac morbidity can develop from a variety of more common medical conditions in childhood. Examples of these childhood illnesses are listed in *Table 259.1*. Early diagnosis and treatment can affect the progression and severity of secondary heart disease. The key to timely diagnosis is in recognizing that these comorbidities exist, having awareness of the contributing factors, and being mindful that the signs and symptoms of cardiac involvement can mimic those of other more common childhood illnesses.

Epidemiology

Specific cardiac morbidity that can develop in the setting of other diseases includes early coronary artery disease (CAD), neuropathy, heart failure, cor pulmonale, pericardial effusions, arrhythmias, and systemic hypertension (HTN). Early arteriosclerosis is seen in the majority of the diseases discussed herein, with diabetes mellitus, chronic kidney disease, and chronic inflammatory illnesses of particular note. Based on the Third National Health and Nutrition Examination Survey (NHANES III), the prevalence of type 1 diabetes mellitus is 1.7/1000 and that of type 2 is 4.1/1000. By adulthood, over 40% of diabetics older than the age of 35 years have been diagnosed with cardiovascular disease. Children with chronic kidney disease are now surviving longer such that death due to secondary morbidity rather than renal failure is a growing concern. In autopsy series of children with end stage renal disease (ESRD), 50% or more had evidence of early arteriosclerosis. Regarding hospitalizations in children with ESRD, one-third of admissions are related to cardiovascular events.

Most prevalent of all the cardiac morbidities is systemic hypertension. The reported prevalence of systemic hypertension (HTN) in children ranges from 1% to 4% with an increasing prevalence of HTN paralleling the rise in childhood obesity. With respect to HTN secondary to other childhood illnesses, a secondary cause is more likely present in younger children compared to adolescence. Overall secondary HTN accounts for about 50% of childhood HTN. Disease-specific epidemiology is discussed in more detail below.

Pathology

Diabetes Mellitus

Diabetes mellitus (DM) is a well-known risk factor for the development of early and usually subclinical atherosclerosis in childhood and ischemic heart disease and heart failure later in life. HTN and dyslipidemia confer additional risk and frequently coexist in patients with type 2 DM. As the incidence of DM in children rises, pediatricians are poised to impact the future development of CAD and heart failure through the early recognition and treatment of CAD risk factors in conjunction with glycemic control.

A serious complication of DM that is under recognized but highly associated with mortality is cardiovascular autonomic dysfunction. Cardiac autonomic neuropathy (CAN) results from damage to the autonomic nerve fibers that innervate the heart and blood vessels. The clinical

Immune disorders
Systemic lupus erythematosus
Systemic juvenile rheumatoid arthritis
Systemic scleroderma

manifestations of CAN include resting tachycardia, exercise intolerance, orthostatic hypotension, and silent myocardial ischemia. Screening for CAN is recommended in patients with type 2 DM at the time of diagnosis and in patients with type 1 DM within 5 years of diagnosis. Assessment of heart rate variability to deep breathing, standing, and Valsalva maneuver as well as assessment of blood pressure (BP) response to standing and sustained handgrip are screening recommendations endorsed by the American Diabetes Association. Treatment of CAN involves intensification or reinforcement of glycemic control to slow progression of neural dysfunction as well as symptomatic relief of orthostatic hypotension by increasing fluid and salt intake and avoiding situations that provoke hypotension. The diagnosis of CAN warrants further testing for other forms of diabetic neuropathy.

Thyroid Disorders

Both hypothyroidism and hyperthyroidism yield alterations in cardiac function, heart rate, and vascular resistance. Cardiac manifestations of hyperthyroidism are tachycardia, including sinus tachycardia and supraventricular arrhythmias; systolic HTN related to increased contractility and cardiac output; and low diastolic pressure related to decreased vascular resistance, which is manifest as a widened pulse pressure. Left ventricular dysfunction and overt heart failure can occur but are uncommon. If present, a tachycardia-mediated cardiomyopathy related to the primary thyroid disorder is most likely. The cardiac function usually returns to normal once the hyperthyroidism is treated and/or the heart rate is controlled with beta-blockade. The cardiac manifestations of hypothyroidism include bradycardia and diastolic HTN related to increased vascular resistance, which is manifest as a narrowed pulse pressure. Cardiac dysfunction is rare in hypothyroidism. Pericardial effusions can develop but tend not to be hemodynamically compromising. The development of an effusion tends to correlate with disease severity and, when present, is usually associated with the non-pitting myxedema characteristic of hypothyroidism.

Cardiovascular signs and symptoms related to the effects of thyroid dysfunction may be the primary reason patients with thyroid disease seek medical attention. Patients may present with palpitations, diaphoresis, dyspnea, fatigue, and/or edema. In addition to clues provided by the clinical history and remainder of the examination, ancillary cardiac testing may point to the primary diagnosis of thyroid disease. An electrocardiogram will allow determination of the heart rhythm but may also show low voltages characteristic of hypothyroidism. A 24-h Holter monitor with excessive sinus tachycardia and limited heart rate variability is seen in hyperthyroidism. An enlarged cardiac silhouette on chest radiograph should prompt echocardiographic assessment of ventricular function or the presence of a pericardial effusion. Treatment of the thyroid disorder usually yields resolution of the cardiac morbidity.

Chronic Kidney Disease

The risk of death due to heart disease and the rate of hospitalizations for heart failure, CAD, and stroke are disproportionately higher in individuals with renal insufficiency as opposed to those without kidney disease. Proposed mechanisms for an association between kidney disease and heart disease include the presence of increased levels of inflammatory factors, abnormal Apo lipoprotein levels, elevated plasma homocysteine, disruption of calcium and phosphorus homeostasis, enhanced

coagulability, anemia, left ventricular hypertrophy (LVH), increased arterial calcification, endothelial dysfunction, and arterial stiffness. In pediatric patients with ESRD, approximately one-quarter of deaths is attributable to cardiovascular disease including pericardial disease, arrhythmias, left ventricular dysfunction, and CAD. A Dutch national study of ESRD diagnosed in childhood observed an age-specific all-cause mortality rate 30 times the expected mortality of the general population. Death from cardiovascular disease occurred at a mean age of 17.3 years with a median time between first renal replacement therapy and death of 3.7 years (0.1–25.9).

Even in children with mild degrees of renal insufficiency, cardiac structure and function may be affected early in the course of disease. The largest pediatric study to date to assess cardiac abnormalities in children with chronic renal insufficiency is a sub-study of the Effect of Strict Blood Pressure Control and ACE Inhibition on the Progression of Chronic Renal Insufficiency in PEdiatric Patients (ESCAPE) trial. One-third of the 156 patients examined had LVH and the presence of LVH was independent of BP elevation as assessed by ambulatory BP monitoring. Thus, while BP control is important in these patients, it does not appear to be the sole determinant of LVH in the setting of kidney disease. Subclinical systolic and/or diastolic dysfunction may also develop in children with renal insufficiency. Both can contribute to the reduced exercise capacity that is seen even early in the course of chronic kidney disease.

Renal Parenchymal and Renovascular Diseases

While essential HTN is common in the adolescent and adult, renal parenchymal and renovascular diseases constitute the majority of causes of HTN in the younger child. Renal parenchymal disease is identified as the cause in two-thirds of cases of secondary HTN in childhood. Renal parenchymal disease is most commonly due to reflux, obstruction, or chronic glomerulonephritis. Approximately 10% of cases of secondary HTN in childhood are attributed to renovascular disease. Renovascular disease produces HTN through reduced blood flow to one or both kidneys as occurs in renal artery stenosis, thrombosis, vasculitis, dissection related to trauma or aneurysm, abdominal radiation, or external compression.

Severe HTN related to renal disease can lead to ventricular dysfunction and congestive heart failure. When concurrent, the findings of left ventricular hypertrophy, diastolic dysfunction, and left atrial enlargement support HTN as the etiology of the ventricular dysfunction. In a retrospective review of 11 neonates diagnosed with neonatal cardiomyopathy and systemic HTN, 9 of the infants had HTN due to renovascular disease.

Cystic Fibrosis

A secondary manifestation of cystic fibrosis (CF) is cor pulmonale. Cor pulmonale is abnormal hypertrophy or dilation of the right ventricle that results from pulmonary HTN caused by disorders of lung function or structure. Given the severe pulmonary disease characteristic of cystic fibrosis (CF), it is not surprising that cor pulmonale is an associated cardiac morbidity. Intraluminal obstruction of the bronchi by mucus leads to hypoxemia. As the pulmonary disease and degree of hypoventilation progress, hypercarbia and respiratory acidosis ensue. Low alveolar oxygen tension, hypercarbia, and acidemia promote pulmonary vasoconstriction resulting in pulmonary HTN. Moreover, lung hyperexpansion due to air trapping may also raise the pulmonary vascular resistance. Nasal polyps that develop in the setting of CF can promote obstructive sleep apnea and worsen nighttime hypoxemia. During acute infections, the pulmonary HTN is exacerbated, but it is the chronic pressure overload that drives the development of right ventricular hypertrophy. Intrapulmonary shunts related to dilated bronchial arteries and the exaggerated changes in intrathoracic and intrabdominal pressures play a role in the volume overload and dilation of the right ventricle. Collectively, these derangements lead to right ventricular failure sooner in patients with chronic lung disease than in those with other degrees of right ventricular pressure overload.

Bronchopulmonary Dysplasia

Cor pulmonale as a result of pulmonary arterial hypertension (PAH) is an important cardiovascular comorbidity in the infant with bronchopulmonary dysplasia (BPD). The lung injury in BPD affects not only airspace development but also pulmonary vasculature development such that there are fewer capillaries and abnormal regulation of vascular reactivity. In a study of 42 premature infants with BPD and PAH, 43% had systemic or suprasystemic right ventricular pressures and these infants had a survival rate of only 37% at 1 year.

Systemic HTN is reported in approximately 10% of infants with BPD. Etiologies include altered neurohormonal regulation; increased catecholamine, angiotensin,

and antidiuretic hormone levels; the side effect of steroid or beta-agonist administration; and other morbidities of prematurity such as renovascular disease. Routine BP monitoring is recommended at least weekly for hospitalized infants and at each outpatient visit thereafter. Systemic HTN in infants with BPD is usually transient but responds well to pharmacologic therapy.

Sickle Cell Disease

Cardiac complications of sickle cell anemia (SCA) include diastolic dysfunction, myocardial infarction, exercise-induced ischemia, fatal arrhythmias, and cor pulmonale.

Cardiomegaly is a common finding on chest radiograph in individuals with SCA but is not usually indicative of reduced cardiac function. Increases in heart chamber size and ventricular wall thickness are seen in children with SCA beginning in the first year of life. The degree of cardiomegaly is inversely related to the hemoglobin level and directly related to age or duration of illness. The degree of cardiomegaly seen in patients with SCA tends to be greater than that seen in other patients with chronic anemia despite similar levels of hemoglobin.

Diastolic dysfunction in the absence of systolic dysfunction can occur due to the ventricular hypertrophy and myocardial ischemia that coexist in SCA. A study of 107 children with SCA found impaired diastolic function to be present in over half. The clinical significance of these findings in asymptomatic children is not known but in adults with SCA, diastolic dysfunction is an independent risk factor for death.

The true prevalence of myocardial ischemia is likely underreported in patients with SCA. A number of case reviews cite the occurrence of myocardial infarction in patients with SCA who have no other coronary risk factors, and studies involving asymptomatic children with SCA have frequently detected abnormalities consistent with ischemia by exercise testing and perfusion scanning. Mechanisms of ischemic injury are likely multifactorial including anemia, platelet thrombi, coronary vasospasm, hypoxemia, abnormal sickling in the microcirculation, and increased oxygen demand of the hypertrophied heart muscle. The signs and symptoms of myocardial ischemia in these patients are nonspecific and similar to those of sickle cell crisis or acute chest syndrome, likely resulting in underdiagnosis.

Cor pulmonale due to pulmonary HTN is a cardiac complication of SCA as well. Pulmonary HTN is present in approximately one-third of children with SCA even in the absence of acute illness. Moreover, by the time these patients reach adulthood, the presence of pulmonary HTN is a strong predictor of death. In the setting of severe acute chest syndrome, pulmonary HTN resulting in cor pulmonale and death can occur. The pathophysiology of pulmonary HTN in SCA includes microvascular insults related to sickling along with the vasoconstrictive effects of hypoxemia.

Thalassemia

Heart complications are the leading cause of mortality in thalassemia major. In these patients, severe anemia necessitating regular transfusion therapy develops as early as infancy. The increased iron load resulting from frequent red cell transfusions coupled with greater intestinal absorption of iron lead to iron deposition in the heart. Cardiomegaly related to isolated chamber enlargement may result solely from anemia as occurs in sickle cell disease, but patients with thalassemia major can develop an iron-induced cardiomyopathy. Decreased systolic function, impaired relaxation, pericarditis, or fatal arrhythmias can occur. The development and progression of cardiac involvement is related to the frequency of transfusions. Chelation therapy is essential to minimize iron overload and end-organ damage and has been reported to slowly reverse the damage in some cases.

Cancer

The development of cardiac dysfunction is a serious consequence of cancer treatment in childhood. Among chemotherapeutic agents, the anthracyclines are particularly cardiotoxic, but are also effective in the treatment of over half of all cancer cases in children. Thus, it is not surprising that 15% of all pediatric cardiomyopathies occur in patients treated for malignancy. While higher cumulative doses and longer time since therapy are associated with increased likelihood of myocardial dysfunction, the cardiotoxic effects can occur at lower doses and early in treatment. More commonly, myocardial dysfunction appears at a median of 10 years after cessation of anthracycline therapy. Presentations of cardiac involvement vary and include asymptomatic decline in ventricular function detected upon routine echocardiography, symptomatic congestive heart failure due to systolic and/or diastolic dysfunction, arrhythmia, myocarditis, pericarditis, acute coronary syndrome, and sudden death. The mechanisms implicated in injury involve the

accumulation of anthracyclines and metabolites in cardiac myocytes, the formation of toxic free radicals, and the release of cytokines and vasoactive amine. The end result is irreversible myocyte loss.

Radiation therapy also poses a risk of acute and chronic cardiac toxicity. Younger age at irradiation, higher cumulative dose to the chest, and exposure to other cardiotoxic agents increase the risk of cardiac morbidity. Pericarditis is the most common manifestation of radiation therapy and is seen in up to 20% of patients. Chronic pericarditis tends to develop within 10 years of treatment. Recurrent effusions or constrictive pericardial disease can occur with the need for surgical pericardiectomy in some cases. Acute pericarditis occurring within a few weeks after treatment is rare and usually resolves without the need to discontinue radiation treatment. Radiation can also induce microvascular insufficiency and myocardial ischemia leading to myocyte necrosis and interstitial fibrosis. This insult to the myocardium manifests as a restrictive cardiomyopathy with primarily diastolic dysfunction and pulmonary hypertension or as a dilated cardiomyopathy with systolic dysfunction.

Immune Disorders

A number of immunologic disorders are associated with cardiac involvement. Pericarditis with effusions, valvulitis, myocarditis, vasculitis, and conduction abnormalities or arrhythmias can be the presenting feature or develop in the course of disease. Secondary cardiac morbidity may develop from vasculitis or nephritis-related systemic HTN or from pulmonary HTN related to pulmonary veno-occlusive disease, pneumonitis, or pulmonary fibrosis. Systemic lupus erythematosus, systemic-onset juvenile rheumatoid arthritis, and systemic scleroderma are among the primary immunologic disorders of childhood with both direct and indirect effects on the cardiovascular system.

Therapies directed at the immune system and the primary disease are paramount. In some cases, the injury to the heart may be irreversible. Acute or chronic inflammation can lead to permanent valve injury or myocyte death with resultant scar formation, impairment of systolic or diastolic dysfunction, and a predisposition for ventricular arrhythmias.

Clinical Manifestations

The signs and symptoms of acquired heart disease secondary to systemic illnesses vary depending upon the primary disorder and its impact on the cardiovascular system. Diastolic dysfunction and/or systolic dysfunction may be quite advanced before signs or symptoms of heart failure are detected. Moreover, early findings may be dismissed as related to an exacerbation of the primary disease. Signs and symptoms that should alert one to possible cardiac disease are shown in *Table 259.2*.

Diagnosis

The diagnosis of cardiac comorbidities is dependent upon the awareness of potential cardiac disease and recognition of suspicious signs and symptoms. Electrocardiography and chest radiography may aid in detection or monitoring of heart disease, but in general, the value of these tests to screen for asymptomatic or early heart disease is limited. Electrocardiography allows determination of heart rhythm, but a normal ECG does not exclude the presence of right or left ventricular hypertrophy, chamber enlargement, pulmonary HTN, or CAD. Chest radiography may show cardiomegaly or pulmonary edema, but a normal chest radiograph does not equate to a structurally and functionally normal heart. In CF or BPD when the lungs are hyperinflated, cardiomegaly may not be apparent by chest radiograph until heart failure is advanced. However, serial studies may allow for the detection of incremental changes in the size of the cardiac silhouette.

Table 259.2
Symptoms and signs suggestive of secondary cardiac mordibity

Symptoms	Signs
Activity intolerance • Dyspnea on exertion • Fatigue • Poor feeding in an infant Chest pain Palpitations or irregular heart beat Syncope Orthopnea Abdominal complaints • Pain • Early satiety	Tachypnea Tachycardia/ bradycardia Hypertension/ Hypotension Abnormal breath sounds • Crackles • Rales Abnormal heart sounds • Murmur • Prominent S2 • Muffled heart sounds or rub • Gallop Jugular venous distension Hepatomegaly or ascites Edema

With respect to systemic HTN secondary to chronic disease or as an additional risk factor for heart disease, blood pressure should be assessed at each visit. Once a diagnosis of hypertension has been established, echocardiography should be performed to assess for end-organ effects. Measurement of left ventricular mass, systolic function, and diastolic function should be part of this echocardiographic examination. Echocardiography is useful not only in screening for end-organ remodeling but also in monitoring the efficacy of antihypertensive therapy. Ambulatory BP monitoring can aid in diagnosing "white coat HTN," investigating symptoms of hypotension while on antihypertensive medication, and monitoring response to treatment in patients with refractory HTN or persistent evidence of target organ damage despite apparent BP control.

Echocardiography is a useful noninvasive modality to assess for pulmonary HTN and secondary right heart changes. When tricuspid valve regurgitation and pulmonary valve regurgitation are present, Doppler interrogation can provide an estimation of right ventricular and pulmonary arterial pressures. The presence of right ventricular hypertrophy, right ventricular dysfunction, or abnormal configuration of the interventricular septum suggestive of elevated pulmonary artery pressures can also be identified by echocardiography. Cardiac catheterization, with direct measurement of pulmonary pressures, is the gold standard to evaluate the severity of pulmonary HTN and degree of vascular reactivity to potential therapeutic agents including oxygen, nitric oxide, and prostacyclin. Consultation with a cardiologist can guide the echocardiographic assessment and determine if more invasive testing such as cardiac catheterization is warranted.

With respect to children undergoing treatment for malignancies, specific screening guidelines to detect the cardiotoxic effects of chemotherapy and radiation have been developed by the Children's Oncology Group (COG). Patients undergoing treatment with anthracycline agents or radiation therapy should have baseline and serial electrocardiographic and echocardiographic screening. The frequency of long-term echocardiographic screening as recommended by COG varies based on age at first cardiotoxic therapy, cumulative dose of anthracycline, and the use and dose of radiation therapy. Children who were younger than 5 years old at the time of initial therapy and received any dose of radiation therapy combined with any dose of anthracycline should have an echocardiogram performed every year as part of long-term follow-up. Children who were at least 5 years of age at the time of first anthracycline dosing who received <200 mg/m2 and were not treated with radiation should have echocardiographic screening at 5-year intervals as long as left ventricular systolic function does not decrease on serial testing.

In general, a careful history and physical examination are valuable diagnostic tools, but routine screening ECG and chest radiograph have limited or no value. If cardiac complications are suspected on the basis of history, disease severity or chronicity, risk factors, symptoms, or signs, then referral to a cardiologist for individualized testing using echocardiography, exercise testing with measurement of functional capacity, cardiac MRI, 24-h Holter monitoring, event monitoring, and/or cardiac catheterization is prudent.

Differential Diagnosis

Not infrequently, the signs and symptoms of cardiac disease are nonspecific and can mimic an exacerbation of the primary medical illness. Additionally, the primary illness can obscure important signs indicative of cardiac disease. Such is the case in patients with CF or BPD who have lung hyperexpansion that obscures the auscultatory findings of a narrowly split or prominent second heart sound indicative of pulmonary HTN. Alternatively, the primary illness can yield signs or symptoms of heart disease that lead to undue concern and cardiac testing. For example, hepatic enlargement is a worrisome indicator of heart failure. However, a downwardly displaced liver related to lung hyperexpansion rather than an increased liver span can be mistaken for hepatomegaly. Thus, the differential diagnosis should be broad to include possible secondary morbidities. However, attention to a detailed history and physical examination with expert consultation when deemed necessary is important to avoid unnecessary testing.

Treatment

In some cases, treatment of the primary disorder results in complete resolution of the cardiac disease. Alternatively, medical therapy directed against the cardiovascular morbidity is necessary. *Table 259.3* outlines the general management approach to the patient with secondary cardiac disease including the assessment of additional risk factors.

With respect to HTN in children, blood pressure (BP) should be assessed routinely at clinical visits. HTN should be diagnosed according to published normals based on age, sex, and height. Dietary modification and exercise are

Table 259.3
Treatment approach to the patient with secondary cardiac disease

Risk assessment	Therapy
• Severity and chronicity of primary disorder • Ideal weight or body mass index • Impaired glucose tolerance • Dyslipidemia ▪ Low HDL ▪ Elevated Triglycerides ▪ Elevated LDL • Hypertension • Sedentary lifestyle • Tobacco use • Illicit drug use • Alcohol use • Family history of early CAD or death	• Optimize treatment and compliance with therapy of primary disorder • Dietary modification • Routine exercise • Supplemental oxygen • Lipid-lowering medications • Antihypertensive medications • Anti-congestive medications ▪ ACE inhibitor ▪ Beta-blocker ▪ Diuretic ▪ Digoxin • Cessation of smoking, alcohol use, and illicit drug use

recommended as initial treatment if the systolic or diastolic BP is consistently between the 90–95th percentiles for age, sex, and height. If the BP target is not reached within 6–12 months of lifestyle intervention, pharmacologic treatment is recommended. For systolic or diastolic BP consistently above the 95th percentile or BP >130/80 mmHg in an adolescent, medication should be initiated along with lifestyle intervention as soon as HTN is diagnosed. An angiotensin converting enzyme (ACE) inhibitor is the drug of choice in patients with DM with the goal BP <130/80 mmHg or less than 90th percentile for age, sex, and height, whichever is lower. The choice of antihypertensive for children with other medical conditions should be individualized based upon the etiology, renal function, and presence of interacting medications.

When pulmonary HTN is present, factors that contribute to elevated pulmonary artery pressures should be sought and treated if possible. Oxygen therapy has been shown to confer survival benefit in patients with COPD and hypoxemia (PaO_2 <55 mmHg), and this is extrapolated to CF. However, outcomes research specific to patients with CF is lacking. Supplemental oxygen is recommended for patients with daytime hypoxemia or with hypoxemia during sleep or exercise. Polysomnography is used to determine the presence and degree of nighttime hypoxemia and hypercarbia and to monitor the efficacy of supplemental oxygen. For infants with BPD and hypoxemia or pulmonary hypertension, long-term supplemental oxygen should be prescribed at levels to maintain normal saturations but to minimize the adverse effects of hyperoxia including retinopathy and further lung injury. The safety and efficacy of newer oral agents to treat pulmonary HTN have not been established in infants and may be contraindicated in the setting of liver dysfunction. There are no proven therapies for pulmonary HTN related to SCA, but supplemental oxygen for patients with hypoxemia or oxygen-responsive pulmonary HTN based on direct hemodynamic assessment in the catheterization laboratory is a reasonable first approach. Transfusion therapy also reduces pulmonary HTN in some patients, presumably by decreasing the incidence of vaso-occlusive crises, acute chest syndrome, and lung damage. Similarly, these therapies benefit patients who have myocardial ischemia as they promote oxygen delivery, increase oxygen-carrying capacity, reduce sickling in the microvasculature, and reduce the myocardial demands imposed by anemia.

Assessment and treatment of modifiable risk factors are valuable. If there is a family history of hypercholesterolemia or an early cardiovascular event, children over the age of 2 years old should have a fasting lipid profile. In children with diabetes, the profile is best performed once glycemic control has been achieved. In children without risk factors for CAD and with adequate control of their primary illness, initial lipid screening may be delayed until closer to adolescence, around the age of 10 years. If the lipid profile is abnormal, annual monitoring is recommended with therapy as appropriate. Glycemic control and lifestyle modifications are primary therapy. The addition of statin therapy should be considered in older children when LDL levels remain elevated despite glycemic control and lifestyle modification. If the lipid profile is normal, then screening should be repeated every 5 years.

For the treatment of systolic ventricular dysfunction, medicines with proven survival benefit in adults, such as ACE inhibitors, beta-blockers, and spironolactone, may be beneficial to children with systolic dysfunction. Additional anti-congestive therapies such as diuretics and digoxin are indicated for symptomatic heart failure. However, there is limited data regarding the efficacy of these therapies in children. A randomized trial of ACE inhibition in children with anthracycline-induced cardiomyopathy found no difference in any dimensions of health-related quality of life measures and no significant improvement in exercise function. With respect to the use of beta-blockers, anecdotal benefit has been reported in children, but a large randomized controlled trial in children with heart failure due to a variety of causes did not show a difference in clinical outcomes compared to placebo. Consultation with

a pediatric cardiologist is advised when medical therapy is deemed necessary, and monitoring for adverse effects of medications should be performed. Heart transplantation is an option for a select group of patients with intractable, symptomatic heart failure whose primary disease is well controlled and not expected to influence transplant outcome.

Prognosis

In some cases, the cardiac morbidity is reversible with early diagnosis and treatment of the primary disorder and/or the heart disease. However, cardiovascular events are an important cause of mortality in childhood and in adult survivors of childhood illness. One-quarter of deaths in children with ESRD are attributed to cardiovascular causes, and cardiovascular events are the leading cause of death in adults with ESRD. In patients with CF and overt heart failure, mortality approaches 75% at 1 year. Two-thirds of deaths in patients with thalassemia major are due to cardiac involvement. Among survivors of childhood cancers treated with cardiotoxic therapies, cardiovascular events are the leading nonmalignant cause of death. Specifically, mortality from anthracycline heart failure is reported as high as 20%. With respect to immune disorders, women with SLE have an incidence of myocardial infarction that is 50 times greater than of women without SLE. Thus, prevention, early diagnosis, and treatment of secondary cardiac morbidity may significantly impact the outcome of individual patients.

Prevention

The mainstay of prevention of cardiac disease due to chronic disease in childhood is treatment of the underlying disorder. Assessment for additional cardiovascular risk factors is imperative and should occur on a regular basis. These risk factors include obesity, HTN, dyslipidemia, glucose intolerance, smoking, illicit drug use, alcohol abuse, sedentary lifestyle, and family history of early CAD ($\leq$55 years of age in first-degree male relatives; $\leq$65 years of age in female relatives). Modification of risk factors through lifestyle changes including diet and exercise should be emphasized. If risk reduction goals cannot be met through lifestyle changes and/or intensification of therapy for the primary disorder, antihypertensive and/or lipid-lowering medications are indicated. Regarding the cardiotoxic effects of anthracycline exposure, dexrazone has been shown to be cardioprotective in women with metastatic breast cancer. Studies in children are ongoing.

Summary

A variety of secondary cardiac morbidities are associated with childhood illness. Overt disease may develop in childhood or progress over years to impact cardiovascular well-being in adulthood. The care of the child with chronic medical illness should be comprehensive with awareness of potential comorbidities, intensification of therapies directed toward the primary illness, identification and treatment of the cardiovascular disorder as indicated, and modification of contributing factors. Specific therapies to reduce cardiovascular risk or to treat manifest cardiac changes depend upon the underlying disease, comorbidities, age of the child, and physician as well as patient and family preference. Most therapeutic strategies are derived from trials performed in adults with limited data in children. Consultation with a pediatric cardiologist can guide diagnostic endeavors and medical therapy.

260 Adult Congenital Heart Disease

Michelle Gurvitz · Karen Stout

Introduction and Scope of the Problem

With advances in pediatric cardiology and cardiac surgery, over 85% of children with congenital heart disease (CHD) now survive to adulthood. Studies estimate that there are approximately one million adults with CHD in the US and that this rapidly growing adult population probably outnumbers the children with CHD (*Fig. 260.1*). Early mortality and multiple morbidities, however, continue to affect these adults as they age.

The adult with CHD brings special challenges to medical care, and managing the needs of these adults is not simply a continuation of that provided to children. The patients have the long-term sequelae of the congenital cardiac condition (native, palliated, or repaired) in addition to superimposed conditions of adulthood. Many adult cardiologists are unfamiliar with CHD and many pediatric cardiologists are unfamiliar with acquired conditions of adulthood. In addition, diagnostic testing may be more difficult as transthoracic echocardiographic (TTE) imaging can be limited with the larger body habitus of adults. Other imaging is often required such as magnetic resonance imaging (MRI), computed tomography (CT), or cardiac catheterization. There are recent guidelines for care published in Canada, Europe, and the United States to give guidance for general adult CHD management issues.

This chapter will outline the most common congenital heart conditions as they present and are managed in adulthood. As anatomy and physiology of the lesions were discussed in other chapters, this chapter will focus on complications and long-term outcomes for each CHD lesion. This chapter will also review common lifestyle issues as they relate to adults with CHD.

Atrial Septal Defects

Presentation

Atrial septal defects (ASDs) of all types may present for the first time in adulthood, either asymptomatic or symptomatic. Diagnosis of an ASD in an asymptomatic adult will most often result from findings that prompt an echocardiogram, such as a newly auscultated murmur or abnormalities seen on screening studies done for other reasons, such as a chest x-ray or ECG.

The typical presentation in adults will be related either to the effects of chronic right-sided volume load or to paradoxical embolus. The initial presentation of the right heart volume load by an ASD may range from subtle progressive exercise intolerance to atrial arrhythmias to right heart failure, though typically the presentation is one of dyspnea and palpitations. Atrial arrhythmias are typically related to right atrial and right ventricular dilation resulting from the volume load posed by the ASD. Systemic embolic events such as stroke or myocardial infarction may be the consequence of paradoxical emboli crossing from the right heart to the left through the ASD. Adults who underwent repair of a simple ASD in childhood are typically asymptomatic.

Complications

The complications of ASD are related to volume load on the right heart, and associated right heart dilation. If the right ventricular dilation is sufficient, concomitant tricuspid regurgitation may lead to additional volume load on the right heart. In some patients, there may be concomitant pulmonary hypertension. Pulmonary hypertension as a consequence of ASD is rarely severe but can complicate management if it is significant. Right heart failure is relatively uncommon as a new presentation, though in elderly adults with concomitant heart disease, the hemodynamic impact of the ASD may change sufficiently to precipitate overt heart failure symptoms.

Atrial flutter, atrial fibrillation, and sick sinus syndrome represent sequelae of right heart volume overload. The behavior of these rhythms will be typical for atrial flutter or fibrillation in adults, with rapid ventricular rates and thromboembolic complications, but the underlying substrate for the arrhythmia may be alleviated with repair of the ASD and improvement in right heart dilation.

In some patients with a sinus venosus defect or other rare ASDs such as a coronary sinus defect, hypoxia may be

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_260,

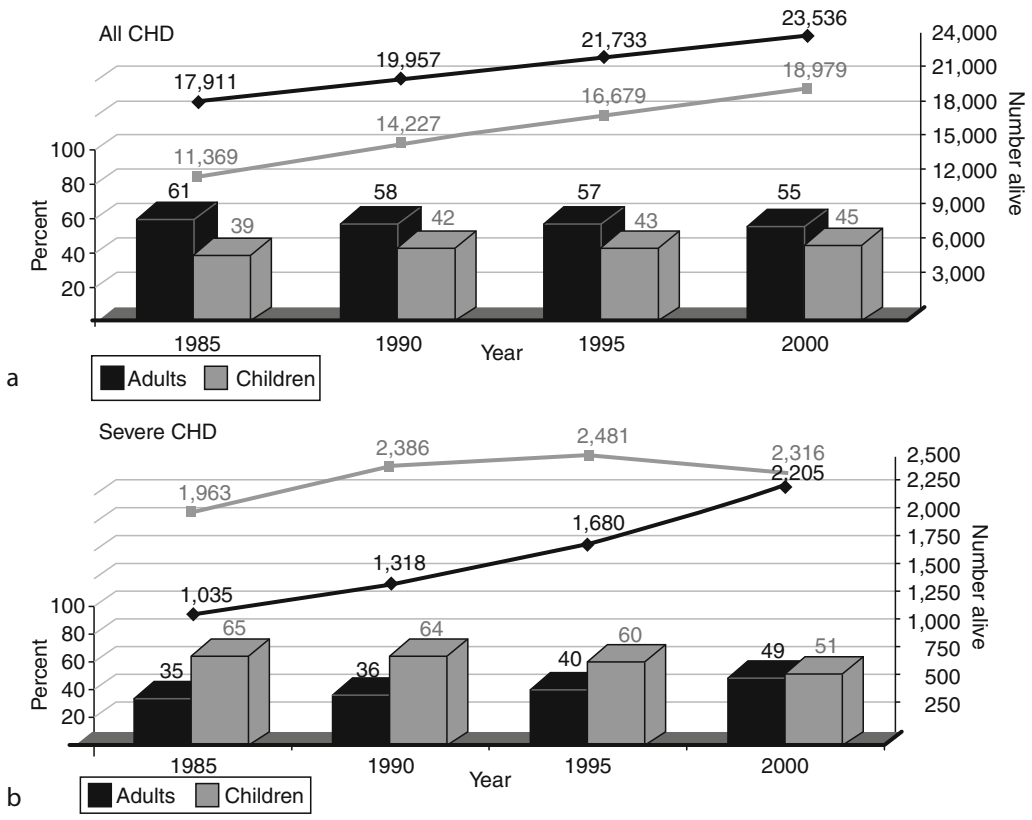

Figure 260.1
Numbers and proportion of adults and children with all CHD (a) and severe CHD (b) in 1985, 1990, and 2000 (From Marelli et al. (2007) J Am Coll Card)

a dominant part of the presentation. In patients who underwent repair of an ASD in childhood or adolescence, they are typically asymptomatic unless the right heart dilation or pulmonary hypertension did not resolve fully after repair. If repaired late, some patients may yet develop atrial arrhythmias or exercise intolerance, even though the volume load itself is alleviated.

Management

For those adults with ASD diagnosed in adulthood, if there is evidence of hemodynamic consequence of the ASD then closure should be considered. In adult patients with an enlarged right heart, a secundum ASD clearly large enough to account for right heart enlargement and no other complicating factors, percutaneous device closure in the cardiac catheterization laboratory is appropriate. However, in many cases the decision to close an ASD in an adult is often multifactorial and requires input from an ACHD center, especially if pulmonary hypertension is present.

After ASD closure, when residual conditions such as right heart enlargement, atrial arrhythmias or pulmonary hypertension persist, these patients should continue to have annual clinical follow-up.

Outcomes

In general, the outcomes for patients who underwent repair of a simple ASD in childhood are excellent. Catheter-based closure also provides excellent outcomes for those patients with secundum ASD with suitable anatomy.

The outcomes for patients with persistent pulmonary hypertension or other cardiac defects are generally determined by those abnormalities, and may not be as good as the outcomes for those patients with simple ASD. Atrial arrhythmias remain a potential concern, even after ASD closure.

Ventricular Septal Defect (VSD)

Presentation

The clinical presentation and treatment of a VSD at any age is dependent on the location and size of the defect and the pulmonary vascular resistance. In adulthood, patients with unrepaired, uncomplicated small VSDs present with a loud, harsh, blowing systolic murmur. Adults with unrepaired, large VSDs present with cyanosis, pulmonary hypertension, and complications of Eisenmenger syndrome (ES, see below). Adults with repaired VSDs should have no significant murmur and no symptoms; the only sign of prior disease is a sternotomy scar and a conduction delay on electrocardiogram (EKG). VSDs with complications present differently depending on the issue involved.

Complications

Large VSDs cause symptoms and cardiac enlargement in childhood. If there is no intervention, patients develop irreversible pulmonary vascular disease and ES. Small defects are well tolerated and patients do not show symptoms or cardiac enlargement. Moderate-sized defects may progress to develop some pulmonary vascular disease or chamber enlargement later in life and require close follow-up.

All unrepaired VSDs, and repaired defects with patch leaks, carry a risk of endocarditis; attention should be given to teeth, nail, and skin hygiene but antibiotic prophylaxis is no longer recommended by the American Heart Association except in cases of patch leaks or prior episodes of endocarditis. Adults with unrepaired small VSDs are also at risk for development of aortic valve prolapse or a double-chambered right ventricle. Either of these complications will often prompt surgical evaluation and intervention.

VSD repairs can be complicated by anatomic and arrhythmic findings. These include VSD patch leaks, sinus node dysfunction, heart block, or tachyarrhythmias.

Management

Adults with repaired or unrepaired VSDs require periodic adult CHD clinic follow-up including exam, electrocardiogram (EKG), and a TTE. Occasionally, further imaging such as MRI or transesophageal echocardiogram is needed. Surgical patients, who had repairs as children, may not have clinical impairment but do carry a risk of conduction abnormalities. A post-operative right bundle branch block is common (up to two thirds of patients), while first degree or higher grade heart block is much less common (<10%). Those with left-sided-chamber enlargement prior to repair may continue to have enlargement and possibly dysfunction depending on the age of repair and the ability of the ventricle to remodel.

Outcomes

Patients with VSDs typically have excellent long-term outcomes. According to the natural history studies, patients with small VSDs that are asymptomatic and acyanotic have very favorable outcomes and 25-year survival is ~96%. Even after surgical repair, the 25-year survival remains high at 89%. It is anticipated these patients will live long into adulthood but formal longer studies have not been performed.

Atrioventricular Septal Defect (Endocardial Cushion Defect)

This section discusses adults with complete or partial atrioventricular septal defects (AVSD) also known as atrioventricular canal or endocardial cushion defects.

Presentation

Patients born with a complete AVSD undergo repair in childhood or will present in adulthood with ES. Patients with partial AVSDs (typically primum ASD and cleft mitral valve) may present as children and have surgical repair at that time or may present unrepaired in adulthood. Patients with repairs present with normal exam findings or murmurs of post-operative defects including VSD patch leaks or residual atrioventricular (AV) valve abnormalities. Unrepaired adults may be asymptomatic and come to cardiology attention due to an abnormal EKG or chest x-ray, and/or a murmur and a wide split second heart sound, and/or symptoms including dyspnea on exertion or rapid heartbeats.

Complications

Those with a repaired AVSD or partial AVSD may have sequelae of the surgical repair. These include patch leaks in the atrial or ventricular septal patch, AV valve abnormalities, or left ventricular outflow tract (LVOT) obstruction. Residual AV valve regurgitation is the most common long-term complication and occurs in up to 18% of repairs. Surgical patients are also at risk for atrial arrhythmias and complete heart block.

Management

As adults, unrepaired partial AVSD patients are usually sent for surgical repair. Generally, repaired partial or complete AVSD patients are seen every 1–2 years for follow-up. TTE imaging and EKG surveillance are recommended at routine visits. Some patients require operations to repair or replace the AV valve (usually the left-sided one) or relieve LVOT obstruction. The valve repair surgery can be difficult and it is recommended that repeat surgery be performed by a surgeon experienced with adult CHD.

Outcomes

After repair of an AVSD, patients can expect to do well and lead active lifestyles. The complications of heart block or AV valve regurgitation requiring repeat surgery create worse outcomes for some patients. However, the outlook is improving as mortality following AV valve replacement has decreased from 30% prior to 1990 to <5% in more recent times.

Tetralogy of Fallot

Presentation

It is rare for adults to present with unrepaired or palliated tetralogy of Fallot (TOF). Reflecting the relatively early ability to perform a complete repair (VSD closure, alleviation of RVOT obstruction), TOF is the most common repaired cyanotic heart disease in adults. Adults with repaired TOF are often asymptomatic, but may present with arrhythmias, syncope, exercise intolerance, sudden death, or heart failure. As with most ACHD, arrhythmias are often markers of hemodynamic abnormalities.

Complications

The most common hemodynamically significant sequelae of TOF repair is pulmonary regurgitation. The repair of TOF often involves a transannular patch across the RVOT, resulting in significant pulmonary regurgitation. Right ventricular dilation will result, and though better tolerated than the initial RVOT obstruction and VSD, may result in significant problems in adulthood. Pulmonary regurgitation and right ventricular dilation are associated with atrial and ventricular arrhythmias, diminished exercise capacity, and heart failure. Some patients may also develop left ventricular dysfunction or aortic regurgitation. Aortic dilation may be progressive in a small subgroup of patients. Sudden death occurs in approximately 6% of patients followed for >20 years.

Management

Adults with TOF should be followed annually by an ACHD cardiologist. Echocardiography is the standard for evaluation, but MRI has evolved to be the standard for assessing RV size and function. Other modalities, such as ECG, exercise testing, ambulatory ECG, and catheterization, may have a role. Many adults with repaired TOF will require pulmonary valve replacement to alleviate the hemodynamic impact of pulmonary regurgitation. Bioprosthetic valves are used in this circumstance; these have a limited life span, hence patients may require multiple valve replacements during their life span. Therefore, decision making regarding the timing of pulmonary valve replacement is not simple. There are multiple indications for pulmonary valve replacement in adults with TOF, which are predicated on the availability of reliable imaging data (*Table 260.1*). A catheter-based option for valve replacement is available, but there is no long-term data on their durability.

Outcomes

Patients with repaired TOF may generally do well and survival is clearly superior to unrepaired tetralogy of Fallot. However, arrhythmias and heart failure may impair quality of life and may also result in significant morbidity and mortality. Current diagnosis and treatment recommendations are intending to minimize the risks associated with the residual hemodynamic lesions such as pulmonary regurgitation. The complexity of evaluation and decision making in adults with TOF is sufficiently

challenging that all adult patients with repaired TOF are recommended to be followed by ACHD cardiologists.

D-Transposition of the Great Arteries

D-Transposition of the great arteries (D-TGA) occurs when the aorta arises anteriorly and rightward from the right ventricle while the pulmonary artery arises posterior and leftward from the left ventricle. It can occur in isolation or with associated lesions such as a VSD or coarctation of the aorta. If unrepaired, it carries a mortality of up to 90% in infancy. The surgical repair of this lesion has evolved over the past 5 to 6 decades. The optimal current repair is the arterial switch procedure and is done in the first few weeks of life. The arterial switch operation began to gain acceptance in the 1980s. Prior to the arterial switch, patients underwent a surgery where atrial flow was redirected, either the Mustard or Senning procedure, so blood flow was physiologically corrected but remained anatomically abnormal. Surviving adults with D-TGA have usually undergone one of the above operations; presentation, complications, management, and follow-up are directly related to the type of surgical intervention.

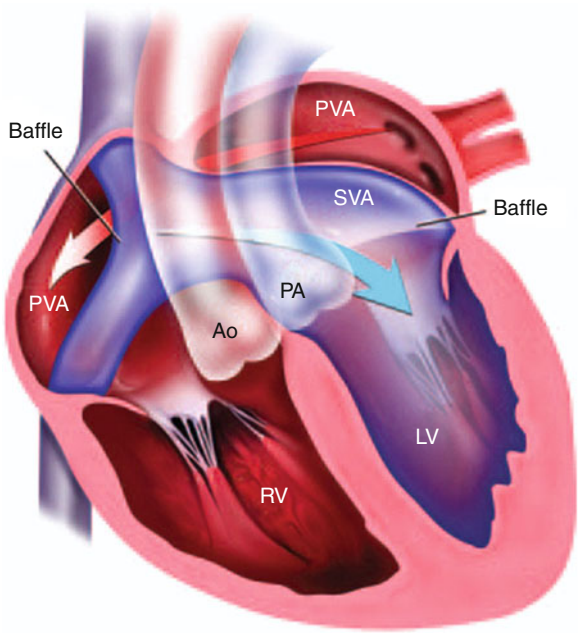
Table 260.1
Indications for pulmonary valve replacement in tetralogy of Fallot ACC/AHA Guidelines (From Warnes CA, Williams RG et al. (2008) ACC/AHA 2008 guidelines for the management of adults with congenital heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (writing committee to develop guidelines on the management of adults with congenital heart disease). Circulation 118(23):e714–e833)

Class I
Severe pulmonary regurgitation with symptoms or decreased exercise tolerance
Class IIa
Moderate to severe RV dysfunction
Moderate to severe RV enlargement
Development of sustained and/or symptomatic atrial and/or ventricular arrhythmias
Moderate to severe tricuspid regurgitation
Residual RVOT obstruction with peak echocardiography gradient >50 mmHg
Residual RVOT obstruction with RV/LV pressure ratio gradient >0.7
Residual RVOT obstruction with progressive and/or severe dilatation of the RV
Residual VSD with left to right shunting >1.5:1
A combination of multiple lesions leading to RV enlargement or RV dysfunction

Presentation and Complications

Most arterial switch patients are asymptomatic and come to medical care as routine follow-up. Occasionally, there may be a pathologic murmur of supravalvar stenosis due to stretching of the great vessels during surgery. Rarely, patients will have anginal chest pain. There is concern of coronary artery obstruction related to the operation and there is some data to suggest patients develop early CAD due to abnormal coronary flow hemodynamics.

There is a large body of data on the adult experience of D-TGA patients that have undergone an atrial switch procedure (Mustard or Senning). In these operations, the venous flow in the atria is redirected such that systemic venous blood flows to the left ventricle and out the pulmonary artery, and pulmonary venous blood flows into the right ventricle and out the aorta (*Fig. 260.2*). Patients with this surgery are no longer cyanotic but have



Gaca, Radiology 2008

Figure 260.2
Diagram of the Mustard repair of transposition of the arteries (Gaca, Radiology 2008)

a systemic right ventricle that can eventually develop dysfunction leading to heart failure. Systemic or pulmonary venous obstruction as well as leaks in the atrial patches can develop requiring surgical or catheter-based intervention. Finally, atrial switch patients have a very high risk of both tachy- and bradyarrhythmias as well as a risk of sudden death. If a pacemaker is required, there is the additional potential complication of systemic venous baffle or superior vena cava obstruction due to the pacemaker wires.

Management

The follow-up of D-TGA patients is dictated by the type of surgical intervention. It is recommended that patients with D-TGA and atrial switch have at least annual follow-up with an adult CHD expert; those who have undergone the arterial switch operation may be seen every 2 years. Patients should have routine imaging with TTE at an adult CHD center. Saline contrast studies may be beneficial to look for baffle leaks or venous obstruction. Given the poor echocardiographic windows of adults, intermittent MRI or CT is often required to better define the anatomy. Those with an atrial switch should have exercise testing to track functional status as well as routine EKG and ambulatory ECG to screen for occult arrhythmia. Those with the arterial switch are recommended to have intermittent exercise testing to screen for ischemic changes as they enter adulthood due to the manipulation of the coronary arteries during surgery.

For some complications, medical or surgical therapy may be initiated. For the atrial switch patients, ventricular dysfunction is treated with typical heart failure therapies. If severe tricuspid regurgitation, vena cava, or baffle obstruction or a baffle leak develop, intervention may be required. Similarly, arterial switch patients may require intervention for coronary or great vessel obstructions. In either case, it is recommended that interventions occur at adult CHD centers.

Survival and Long-Term Outcomes

Given the multitude of complications and intricate management, the long-term survival of the atrial switch patients is limited. Some long-term outcome studies suggest 70% survival at 20 years but with extensive morbidity and sudden death occurring in ~5–10%. Those patients who have undergone an arterial switch operation seem to have a better outcome in early reports. The medium-term survival of those with an arterial switch reaches >85% at 15 years. There is limited long-term outcome experience in arterial switch patients as the oldest cohort is in their third decade.

Congenitally Corrected Transposition of the Great Arteries

Presentation

Congenitally corrected transposition of the great arteries (CCTGA) or L-transposition of the great arteries (L-TGA) is a very rare anomaly. It can present in multiple ways depending on anatomy and associated lesions. In this condition, flow is physiologically correct and anatomically inverted. On the right side of the heart, blood flows from the right atrium into a morphologic left ventricle and then into a posterior and rightward pulmonary artery. Similarly, on the left side, blood flows from the left atrium into a morphologic right ventricle and then to the anterior and leftward aorta. The most obvious problem is the presence of a right ventricle subject to systemic blood pressure, similar to the atrial switch patients. Associated abnormalities occur in up to 90% of patients and can include dextrocardia (~20%), VSD (up to 70%), pulmonary stenosis, malformed tricuspid valves (up to 90%), and rhythm abnormalities.

A patient's presentation in adulthood depends on any associated lesions and complications occurring with age. Patients with associated lesions will often present in childhood and require surgery. Presentation can also occur de novo in adulthood with a murmur, heart failure, or a rhythm complication. Occasionally, the adult will be asymptomatic and present to care due to an abnormal finding on EKG or chest x-ray.

Complications

The complications in adults also depend on underlying anatomy and prior interventions. Those with a failing systemic right ventricle or severe systemic AV valve regurgitation will have complications of heart failure. Patients are also at risk for arrhythmia and sudden death, and have a 2% per year risk of developing complete heart block. Those with operations in childhood may have sequelae of the surgeries in addition to the other problems.

Management

It is recommended that all patients have regular follow-up with a specialist in adult CHD and have periodic imaging

with either echocardiography or MRI. Exercise testing to assess functional status is often performed. If there is any suggestion of progressive heart block on EKG or symptoms, Holter monitoring is suggested. Any sign of complete heart block or rapidly progressive lower grade conduction disturbance is an indication for pacemaker consideration. Medical management is recommended for heart failure symptoms and occasionally patients may also require valve surgery on the systemic AV or aortic valves. Some adults may be considered for a surgical intervention called a "double switch" procedure where atrial and arterial switch procedures are performed. This is a highly complex operation, and the indications and results are still being studied; it is not recommended routinely. Any interventions in CCTGA patients should be performed by a surgeon with experience in adult CHD.

Outcomes

As with the presentation and complications, long-term outcome depends on whether or not the patient has associated lesions. The survival and morbidities are highly variable. In one cohort, initial diagnosis was not made until adulthood in two thirds of the patients, with 20% over age 60 years. In small studies of patients with childhood repairs, 20-year survival of 60–70% has been reported. By age 45 years, two thirds of patients with associated lesions and one quarter of patients without associated lesions had developed heart failure.

Single Ventricle

Presentation

Single ventricle physiology in adults may result from a wide variety of underlying anatomic abnormalities, including double inlet left ventricle and tricuspid atresia. Survival into adulthood of completely unoperated single ventricle physiology is extraordinarily rare; some form of surgical palliation is required to allow survival into adulthood. Due to the relatively recent surgical success in treating hypoplastic left heart syndrome, very few of these children have yet reached adulthood. This population will grow in coming years, but currently, their outcomes as adults remain to be seen.

The majority of single ventricle patients have been palliated with some type of Fontan repair, which directs systemic venous return directly to the pulmonary circulation, alleviating cyanosis but resulting in a very unique physiology (see Chap. 251, "The Single Ventricle"). The era of surgical intervention generally dictated the type of Fontan repair, so many adults have variations of the original repair; the intent of all of these variations is to direct right atrial blood directly to the pulmonary artery. Younger patients will more commonly have either lateral tunnel or extracardiac Fontan repairs. The presentation of the adult with single ventricle physiology varies widely. Some may be asymptomatic, though many will present with arrhythmias, thromboembolic events, protein-losing enteropathy, or heart failure symptoms. Arrhythmias are often markers of hemodynamic deterioration and are associated with increased risk of thrombus.

Liver dysfunction is an important complication of the Fontan physiology, the significance of which has only relatively recently been identified. A significant number of Fontan patients will have hepatic fibrosis or cirrhosis, with synthetic dysfunction and the other complications associated with cirrhosis such as varices.

The uniqueness of the Fontan physiology in adults warrants particular attention when non-cardiac issues arise, particularly those which may require surgical intervention. These patients should be treated in centers with experience with adult Fontan patients.

Complications

All Fontan patients may have complications including atrial arrhythmias, sinus node dysfunction, and low cardiac output symptoms. Those patients with more "modern" Fontan repairs, such as lateral tunnel and extracardiac total cavopulmonary connections seem to have fewer complications than the early era of patients who underwent "atriopulmonary" Fontan repairs. The atriopulmonary Fontan results in a massively dilated right atrium that is prone to develop thrombosis due to sluggish blood flow, atrial tachycardias due to elevated atrial pressures and atrial stretch, and sinus node dysfunction due to fibrosis. Though less frequent than the older style Fontan, lateral tunnel and extracardiac Fontans (*Fig. 260.3*) may also develop atrial tachyarrhythmias and sinus node dysfunction. Atrial arrhythmias are generally poorly tolerated and require aggressive treatment.

Thromboembolic events are distinctly detrimental and may be fatal as the Fontan physiology requires a low pulmonary vascular resistance for systemic ventricular filling and maintenance of cardiac output. Ventricular dysfunction can develop over time and may result in heart failure. The long-term impact of liver dysfunction remains

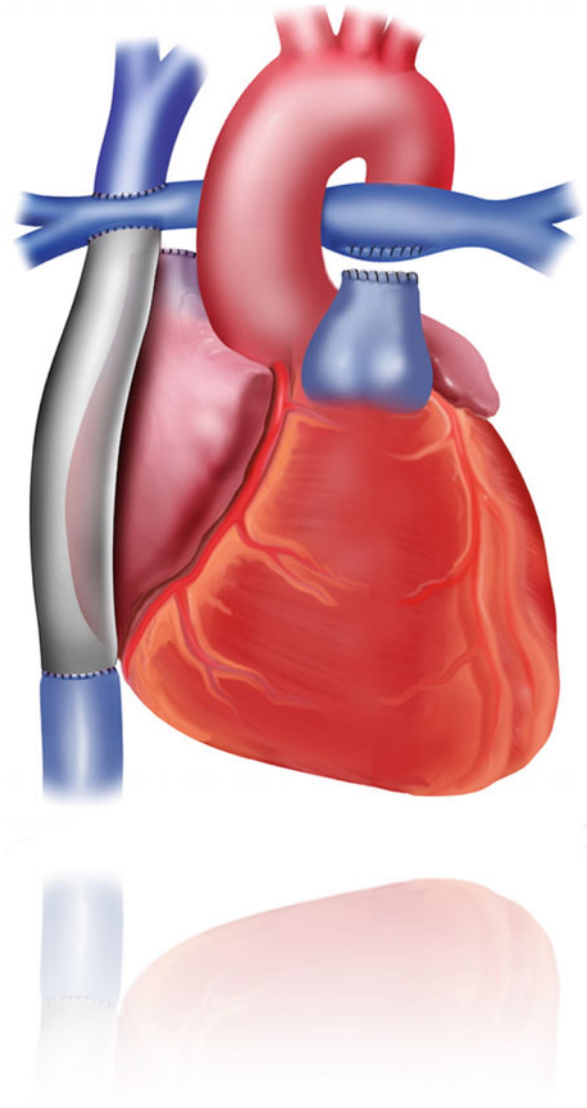


Figure 260.3
Diagram of a lateral tunnel Fontan repair with bidirectional Glenn (Gaca, Radiology 2008)

uncertain, but will likely be a significant cause of morbidity and mortality as adults with Fontan physiology age.

Management

Arrhythmias in this patient population should be managed aggressively, with efforts to ensure patients maintain sinus rhythm. Pacemaker placement may be needed for sinus node dysfunction, but the nature of the surgical repair makes this challenging from a transvenous approach in many cases, and therefore, surgically placed leads placed on the epicardial surface of the heart are often needed. Patients with atriopulmonary Fontan repairs may benefit from conversion to a lateral tunnel or extracardiac Fontan. These conversions are typically done as surgical treatment of atrial arrhythmias, with atrial reduction and intraoperative ablation a standard part of the surgery.

The role of anticoagulation in Fontan patients remains controversial, though patients with atriopulmonary Fontan repair, a history of atrial arrhythmias, known thrombus or a history of thromboembolic events should be anticoagulated.

All adult patients with single ventricle physiology should be followed regularly by ACHD cardiologists.

Outcomes

The survival of Fontan patients is over 80% at 20 years, but there is steady attrition due to heart failure, sudden death, and thromboembolic complications.

Pulmonary Stenosis

Presentation

The initial presentation of pulmonary stenosis in an adult may be identification of a murmur in an otherwise asymptomatic patient. Moderate or greater pulmonary stenosis may present with exercise intolerance. Many adult patients with pulmonary stenosis have undergone either surgical or percutaneous catheter-based balloon valvuloplasty. Those who have undergone intervention may develop pulmonary regurgitation or progressive restenosis.

Complications

If significant, pulmonary stenosis may result in right ventricular hypertrophy and increased right ventricular systolic pressures. In those patients who undergo procedures to alleviate stenosis, residual regurgitation may result in right ventricular dilation. In both cases, atrial or ventricular arrhythmias may result, or patients may have diminished exercise capacity. In patients with only mild stenosis or regurgitation however, the hemodynamic burden rarely causes any significant complications. Unlike the repair of

TOF, a transannular patch is rarely needed in these patients, but if one was used in a surgical repair, the risk of arrhythmias and right ventricular dysfunction will be higher.

Management

Patients with minimal stenosis or regurgitation can be followed expectantly, and guidelines suggest an evaluation every 2–5 years. Those with more significant lesions may require reintervention. Residual pulmonary stenosis can often be treated with balloon valvuloplasty, though those patients with significant regurgitation may require valve replacement. Arrhythmias are managed in the usual fashion, but the evaluation should ensure there is no hemodynamic abnormality that should be addressed concomitantly.

Outcomes

Adults with isolated pulmonary stenosis generally do well, with the degree of stenosis or regurgitation dictating the likelihood of complications. Those patients with minimal valve disease rarely have progressive disease and have life expectancies similar to age-adjusted norms. Those with more severe stenosis require intervention, but also should do well if the stenosis is successfully alleviated.

Aortic Valve Disease/Bicuspid Aortic Valve

Presentation

Bicuspid aortic valves, aortic stenosis, and aortic regurgitation are common in adulthood; consequently there are robust guidelines on the diagnosis and management of aortic valve disease in adults. The majority of adults with aortic valve disease are asymptomatic, but once symptomatic, valve replacement is recommended. This is true regardless of age, as the outcomes of symptomatic aortic valve disease are significantly worse than when asymptomatic. Therefore, a careful history is needed to ensure a patient is asymptomatic, focusing on exercise tolerance, angina, or syncope. Bicuspid aortic valves are often associated with aortic dilation, and in some patients, the aortic dilation may be the more concerning abnormality.

Some adults with aortic valve disease required intervention in childhood. Those interventions may range from balloon valvuloplasty to valve replacement. The Ross repair, in which the pulmonary valve is used to replace the aortic valve, and a bioprosthesis is put into the pulmonary position, is often used in children in the hope that the pulmonary valve used as the "aortic valve replacement" will grow with the child. Adults with prior aortic valve intervention may present with symptoms if there is progressive dysfunction of either the native valve or the prosthesis.

Complications

Severe aortic stenosis may cause syncope, angina, or heart failure in adult patients. In those patients with dilated aortic roots associated with a bicuspid aortic valve, dissection may occur, though the frequency is not clear. Severe aortic regurgitation may result in heart failure or arrhythmias. Mild to moderate valve dysfunction would not be expected to cause symptoms; however, these patients require regular follow-up to assess for progression of valve disease. The vast majority of patients with bicuspid aortic valves will require replacement sometime in adulthood, either due to stenosis, regurgitation or both. Those patients with dilated aortas may require surgical replacement of the dilated segment, either at the time of valve surgery or if the aorta is greater than 5.0 cm.

Management

Adults with aortic valve disease require regular follow-up, including history, exam, and imaging. The frequency of evaluation is dictated by the severity of valve disease, with those patients with severe disease requiring the most frequent follow-up. Symptomatic patients should undergo valve surgery, usually replacement. There is no role for medical therapy in aortic stenosis. The role of vasodilators in aortic regurgitation is controversial, though is reasonable if patients have LV enlargement or hypertension. There is not a clear role for medical therapy solely for aortic aneurysm in BAV, though control of hypertension is important. Patients with significant aortic valve disease should be seen regularly by cardiologists, though the disease is common enough in adults that an ACHD center is not necessarily required.

Outcomes

Outcomes after surgical repair or replacement are generally good, but dependent on left ventricular function at the time

of surgery. The outcomes of valve replacement may vary depending on the type of valve used, mechanical vs. bioprosthesis, but there is not yet clear data that one valve replacement type is clearly better than the other. Thus, while mechanical valves are typically used in young patients due to their superior longevity, the necessary anticoagulation poses its own risks, particularly if patients are poorly compliant with therapy. The outcomes of the Ross repair include a need for pulmonary valve replacement and/or aortic valve replacement in up to 25% of patients at <10 years after initial repair. The survival for young adults with mild bicuspid aortic valve disease is not different than age-adjusted norms, but the severity of aortic stenosis and regurgitation are associated with cardiac events.

Coarctation of Aorta

Coarctation of the aorta (COA) is a narrowing in the aorta that causes restriction of blood flow to more distal organs and vessels. COA can be in one location on the arch (discrete) or associated with a diffusely small arch. This section reviews discrete COA.

Presentation

The adult patient with COA typically presents as: (1) diagnosed in infancy or childhood and had a repair intervention at that time or (2) new diagnosis in adulthood. Those patients with a young age intervention may present in adulthood for follow-up or with hypertension, coronary artery disease (CAD), aneurysm at the COA site, or with a recurrent COA.

Patients with unrepaired COA presenting in adulthood usually have difficult to control hypertension and may have claudication. They also may be identified due to an abnormal chest x-ray with notching under the ribs or EKG with left ventricular hypertrophy. On exam, patients have diminished and delayed femoral pulses compared to right radial pulse and will have a blood pressure gradient between the higher pressure right upper extremity and the lower pressure leg measurement. Rarely, adults present with CAD or a stroke from a ruptured cerebral aneurysm.

Complications

Adults with unrepaired CAO may have the end-stage effects of prolonged hypertension, including left ventricular hypertrophy, heart failure, and coronary artery disease. Those with repair interventions in childhood may have complications of recurrent stenosis or aneurysm formation at the repair site. COA is also associated with other conditions including resting hypertension, exercise-induced hypertension, ascending aortic dilatation, and cerebral aneurysms.

Management

It is recommended that adults with repaired COA have routine follow-up at an adult CHD center and interventions performed by a CHD specialist. Regular imaging is important to screen for recurrent stenosis or for aneurysm formation, including TTE and CT or MRI at regular intervals (*Fig. 260.4*). Upper and lower extremity blood pressure should be checked routinely and some specialists recommend testing for exercise-induced hypertension. Some specialists also recommend screening brain imaging for cerebral aneurysms. Patients with recurrent COA or aortic aneurysm typically require intervention. For the recurrent stenosis a catheter-based approach with balloon angioplasty and stent placement is the usual procedure; otherwise surgical repair is indicated.

Treatment of native coarctation remains controversial. Surgical intervention has been the historical treatment but carries higher risks in the older patient. Catheter intervention is an appealing option as it avoids some of the surgical complications, but it is a new strategy. The largest risk of catheterization is dissection or rupture during or after the procedure. Older patients at the time of repair are more likely to have persistent hypertension and early CAD.

Outcomes

Historical studies suggest that patients with COA have an average life span into the third or fourth decade and die of cardiovascular complications. In the current era of earlier detection and repair, it is expected that outcomes improved significantly. It is hoped that earlier diagnosis and repair and screening for associated abnormalities will prolong the life span and the quality of life.

Ebstein's Anomaly

Presentation

Ebstein's anomaly in adult patients may present as either repaired or unrepaired. Unrepaired patients have varying

Figure 260.4
CT Aortagram of an adult with interposition graft repair of coarctation of the aorta performed in childhood

degrees of tricuspid regurgitation, right atrial and ventricular enlargement, and may have atrial septal defects. If the disease is mild, patients may be asymptomatic. If the disease is severe, patients may have atrial tachyarrhythimas, right-sided heart failure, or cyanosis due to right to left shunting across an atrial septal defect. Patients who have undergone valve repair or replacement are often asymptomatic.

Complications

The complications of Ebstein's anomaly in adults typically result from tricuspid regurgitation and right heart failure. Atrial arrhythmias may occur, including atrial fibrillation or atrial tachycardia related to bypass tracts, such as Wolff–Parkinson–White. Cyanosis is uncommon, and may be provoked with exercise. The cyanosis is due to right to left shunting across an ASD or PFO, and may be related to the jet of tricuspid regurgitant directed at the ASD, rather than due to markedly elevated right atrial pressures.

Management

Adults with unrepaired Ebstein's anomaly may require repair if symptoms develop or if cyanosis is present. Thus, those patients with unrepaired Ebstein's should be followed regularly. Arrhythmias should be treated aggressively, as those patients with significant disease may not tolerate atrial tachycardia well. Those who have undergone repair or replacement will need continued monitoring to ensure valve dysfunction does not develop.

Outcomes

The outcome for unrepaired patients is not well known, but is dependent on the severity of disease. Patients with mild disease will likely do well, while those with more severe disease, right to left shunting or atrial arrhythmias are at higher risk of adverse outcomes. Series evaluating patients who have undergone repair or replacement suggest good outcomes at over 20 years, though arrhythmias remain a concern before and after surgery.

Eisenmenger Syndrome (ES)

Presentation

Adults with ES have a history of a large left to right shunt that went unrepaired in infancy and childhood and led to the development of irreversible pulmonary vascular disease (PVD). The PVD leads to equalization of pulmonary and systemic vascular resistances and to a reversal of the shunt creating systemic cyanosis. Fortunately, patients with this condition are becoming more uncommon with improved diagnostic and therapeutic interventions in childhood; however, many patients still require care. Patients with Eisenmenger physiology commonly present with dyspnea on exertion, palpitations, edema, hemoptysis, syncope, and progressive cyanosis. Many patients begin to develop symptoms toward the third decade of

life and worsen with age. As patients age, they may present with complications of other organ systems related to persistent cyanosis as described below.

Complications

ES can be complicated by right ventricular failure, arrhythmias, hemoptysis, and sudden death. The physiologic changes and cyanosis lead to multiorgan system complications. A secondary erythrocytosis can cause intravascular sludging and organ damage particularly in the cerebrovascular circulation. Renal dysfunction, bone pain, and hyperuricemia can occur.

Management

All patients with ES should be followed by adult CHD physicians. The primary goal of management is to prolong survival, while at the same time improving quality of life as there is no primary surgical correction. For some patients, surgical intervention may include either heart–lung transplant or lung transplant with cardiac repair. However, these are complicated and difficult decisions and must be made independently with the patient and the adult CHD specialist.

Much of the management surrounds lifestyle adjustments to avoid complications. Due to the erythrocytosis, it is highly important to avoid iron deficiency and to maintain adequate hydration. Patients are also asked to avoid strenuous exercise, high-altitude exposure, and pregnancy. At least annual follow-up is recommended and should include digital oximetry and blood tests for hemoglobin, platelets, iron stores, renal function, and uric acid. Any new medications must be evaluated quite closely as any changes in pulmonary and systemic vascular resistance can affect functional status. In general, therapeutic phlebotomy has a very limited role and should only be performed in patients with hemoglobin greater than 20 g/dl and associated symptoms of hyperviscosity and no evidence of dehydration.

Medical therapies for ES patients are limited. Some may benefit from oxygen therapy. Those with ventricular dysfunction may be treated with digoxin or diuretics. Anticoagulation for ES is controversial as there is the risk of hemoptysis and there are in vitro reports of underlying coagulation and platelet abnormalities. Recent studies have shown a beneficial effect of pulmonary vasodilator therapy in patients with ES. These medications were shown to improve exercise intolerance, oxygen saturation, functional capacity and, in some cases, survival.

Outcomes

While survival of ES patients is better than those with primary pulmonary hypertension, outcomes remain poor and morbidity is high. While poor functional class is a predictor of mortality, many patients will survive into their 30s and older. Heart–lung transplantation and lung transplant with cardiac repair are options for some patients. However, as natural survival prospects are improving and better therapeutic options are being developed for pulmonary hypertension, patients considered for these treatments must be carefully selected.

Lifestyle Issues

Adults with congenital heart disease face the same issues as their peers without congenital heart disease. They may be obese, may have poor diets, and may develop typical adult diseases, including acquired heart disease. As with any other patient, it is important to provide counseling regarding maintaining or achieving a normal body weight, eating a heart healthy diet, controlling risk factors for diabetes and acquired heart disease, and regular physical activity. However, many adults with CHD were advised against exercise as children or have exercise limitations due to their heart disease, and thus counseling regarding exercise habits for these patients can be a challenge. In general, moderate aerobic activity is appropriate. Weight lifting may not be appropriate for some patients, or may need to be modified to a "low weight, high repetition" type of exercise; however, all exercise recommendations must be tailored to the individual patient based upon their disease and the severity of disease. There are guidelines available that are lesion specific and that address competitive sports (see Bibliography).

Reproductive health is a common concern among adults with CHD; however, there is data demonstrating that communication between patients and providers regarding family planning is relatively poor. Many women have misinformation regarding their ability to have children, and many may be misinformed regarding contraceptive options. Both contraception and pregnancy can pose unique challenges, and recommendations must again be tailored to the individual patient. There are some patients for whom estrogen-containing birth control is risky and there are some patients for whom pregnancy would be ill advised (*Table 260.2*). Despite those concerns, many women with CHD can successfully carry a pregnancy to term, provided they are evaluated and managed by appropriately trained providers.

Table 260.2
Predictors of adverse maternal events during pregnancy

Cardiac events prior to pregnancy
CHF
Arrhythmia
Poor functional status
NYHA Class II or IV
Cyanosis
Left heart obstruction
Symptomatic or severe mitral stenosis
Severe aortic stenosis
Systemic ventricular dysfunction
EF $<$ 40%
Pulmonary hypertension
Eisenmenger syndrome
Systolic pulmonary pressures $>$50% of systemic pressures
Marfan syndrome with aortic root $>$4.0 cm
Severe symptomatic aortic or mitral regurgitation
NYHA Class III or IV

Contraception recommendations must balance the woman's risk of complications of pregnancy and the risk of the contraceptive method. Estrogen-containing contraception, such as the commonly prescribed oral contraceptive pills, is associated with an increased risk of arterial and venous thrombosis. For women with heart disease that may predispose them to thrombus (mechanical valves or Fontan circulation), the addition of estrogen increases that risk further. Progesterone-only alternatives, such as the mini-pill or DepoProvera, are not thrombogenic, but may be less an effective contraceptive and in the case of DepoProvera, may be associated with bone density loss after long-term use. Intrauterine devices, including the Mirena IUD, which contain levoprogestrone, may be options, but the risk of insertion and endocarditis must be considered. Sterilization is rarely recommended, as the women who are at highest risk of pregnancy are also at highest risk of a surgical procedure, in particular those women with ES. Ultimately, the recommendation of the type of contraception must be individualized to the patient and her heart disease, risk of pregnancy, lifestyle and her desires regarding type of contraception.

There is no data to guide recommendations regarding alcohol use in adults with CHD. While there may be benefit in other acquired heart disease to moderate alcohol use, this has not been studied in CHD. Adults with CHD should not smoke, use tobacco products or recreational drugs.

261 Cardiomyopathies and Heart Transplantation

Mariska S. Kemna · Yuk M. Law

Cardiomyopathies

Definition

Cardiomyopathy refers to a heterogeneous group of diseases which primarily involve the myocardium, leading to symptoms of heart failure. They are most commonly divided into three major phenotypes, based on anatomy, physiology, and symptoms. *Dilated* cardiomyopathy primarily affects the systolic function, while *hypertrophic* cardiomyopathy and *restrictive* cardiomyopathy mostly affect the diastolic function of the heart. Although all three have different characteristics, overlap between these phenotypes does occur. Left ventricular non-compaction was recently recognized as a separate cardiomyopathy with mixed features of dilated and restrictive cardiomyopathy, affecting both systolic and diastolic function.

Dilated Cardiomyopathy

Etiology

Dilated cardiomyopathy accounts for approximately 55% of all cases of cardiomyopathy in children. It is characterized by a dilated left ventricle with decreased systolic function. Most cases of primary cardiomyopathy are idiopathic, although 30–50% of patients have a family history of dilated cardiomyopathy, suggesting a genetic component. Gene mutations that have been identified in primary cardiomyopathy encode regulatory or contractile proteins within the myocyte. Primary cardiomyopathies are sometimes (9%) found in association with neuromuscular disorders, such as Duchenne or Becker's muscular dystrophy, because cardiac and skeletal muscles share many of the same contractile and cytoskeletal proteins.

Damage to the heart muscle can also occur secondary to other disease processes, of which viral myocarditis is the most common. Many viruses can cause *myocarditis*, but the majority of cases are caused by enterovirus, adenovirus, or parvovirus. Viral proteases can cleave the cytoskeletal protein dystrophin, leading to irreversible cardiac injury and dilated cardiomyopathy. An excessive inflammatory response contributes to the myocardial injury. Although the majority (60%) of patients make a full recovery, depressed ventricular function and/or dilated cardiomyopathy is seen in the rest. Freedom from death or transplantation 5 years after experiencing myocarditis is approximately 74%.

In the developing world, *HIV* is the leading infectious cause for dilated cardiomyopathy. Of HIV-infected children, 8–15% develop dilated cardiomyopathy related to direct viral damage, drug toxicity, or nutritional deficiencies.

Nutritional deficiencies can cause dilated cardiomyopathy as well (carnitine, thiamine, selenium, phosphate) and *inborn errors of metabolism* account for approximately 4% of all dilated cardiomyopathies in the USA.

Chemotherapy, especially anthracyclines, is an important cause of childhood dilated cardiomyopathy in the developed world, which can develop long after chemotherapy is completed. Anthracyclines are successfully used to treat many types of childhood cancers, but have a high degree of cardiotoxicity, especially in dosages above 550 mg/m^2. Six years after anthracycline treatment, abnormal left ventricular structure or function is found in almost 65% of childhood acute lymphoblastic leukemia survivors.

A relatively rare but correctable cause for dilated cardiomyopathy in early infancy is *anomalous origin of the left coronary artery from the pulmonary artery* ("ALCAPA"). The left coronary artery originates from the pulmonary artery rather than the aorta. Once the pulmonary vascular resistance falls, around 1–3 months of age, the decrease in pulmonary artery pressure results in a fall in coronary perfusion pressure and reversal of direction of coronary flow leading to myocardial ischemia.

Lastly, incessant or sustained primary *tachyarrhythmias* of the heart can present as heart failure with ventricular dysfunction caused by decreasing diastolic filling time, lack of atrioventricular synchrony, and excessive demand of the myocardium.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_261,

Epidemiology

The annual incidence of dilated cardiomyopathy in all children in the USA is 0.57 per 100,000, tenfold lower than in the adult population. These pediatric incidence rates are similar to rates found in Finland and Australia.

In children, most cases occur in infants less than a year of age (4.4 cases per 100,000/year). There is a predilection for boys versus girls, due to X-linked inheritance patterns (0.66 vs 0.47 cases per 100,000/year) and blacks versus whites (0.98 vs 0.46 cases per 100,000/year).

Pathogenesis

Myocytes do not divide, or at best very slowly. Myocardial injury may lead to compensatory hypertrophy of surrounding myocytes. A myocyte is composed of myofibrils, which in turn are built out of sarcomeres. A sarcomere is the contractile unit of the cell and consists of overlapping contractile proteins (actin, myosin, troponin, tropomyosin) which interact with the cytoskeletal proteins (dystrophin, tafazzin, desmin). Sarcomere contraction requires interaction between contractile and cytoskeletal proteins. Myocyte damage results in less contractile force generation and thus decreased stroke volume and cardiac output.

In the failing heart, compensatory responses try to maintain cardiac output. The two most important are:

1. Frank–Starling mechanism, in which elevated diastolic volume increases the stretch on the myofibers, which in turn increases the stroke volume.
2. Neurohormonal activation through the sympathetic nervous system, renin-angiotensin-aldosterone system, and antidiuretic hormone (ADH), all of which help to maintain blood pressure and cardiac output by increasing heart rate, vasoconstriction, and water and sodium retention. Unfortunately, over time, the continual activation of the neurohormonal axis has detrimental effects on the myocardium, so-called "remodeling."

As the compensatory mechanisms start to fail, the stroke volume decreases, the left ventricle enlarges, and the patient with heart failure decompensates. Left ventricular dilation with decreased contractile function is the hallmark of dilated cardiomyopathy, and it often involves both ventricles. The increase in ventricular end-diastolic pressure and volume ultimately leads to dilation of the atria as well. Further enlargement of the ventricle may cause the mitral and tricuspid valve leaflets to not coapt well, with ensuing valvular regurgitation. The valvular regurgitation further compromises cardiac output and leads to progressive dilation of atria and ventricles.

Pathology

Dilated cardiomyopathy is generally characterized by dilation of all four heart chambers. Microscopically, one can find areas of myocyte degeneration, hypertrophy, and fibrosis.

Clinical Symptoms and Signs

Clinical presentation can vary widely, depending on the age of the child and the degree of heart failure. Patients can be asymptomatic or display one or more symptoms of heart failure. The onset of symptoms can be quite insidious as the heart is initially able to compensate for the decreased cardiac output. Tachycardia is one of the earliest symptoms and occurs when the heart is trying to compensate for the decrease in stroke volume. When heart failure progresses, the heart is unable to meet the metabolic demands of the body and additional symptoms develop. The nature of these symptoms varies strongly with age. Infants frequently present with feeding intolerance and failure to thrive since feeding and growing encompass the majority of their metabolic demand. They may appear too tired to complete a full feed and take frequent small feeds instead, rendering them hungry and irritable. Additional symptoms include tachypnea and increased work of breathing, pallor due to vasoconstriction, and increased sweating due to sympathetic stimulation.

Older kids often present with exercise intolerance consisting of easy fatigue and dyspnea with exertion. More severe heart failure can produce dyspnea in the supine position (orthopnea) or even at rest, as a result of pulmonary venous congestion. Additional symptoms of increased venous pressure include peripheral edema and hepatomegaly. Insufficient cardiac output with forward failure causes abdominal pain, nausea and vomiting due to inadequate mesenteric perfusion. Other symptoms can include palpitations and syncope.

Heart failure symptoms can be graded by the Ross classification (*Table 261.1*), which is similar to the New York Heart Association (NYHA) classification used in adults. A newer classification (*Table 261.2*) classifies patients according to their stage in heart failure.

Table 261.1
Ross classification of heart failure in children

Class	Interpretation
I	Asymptomatic
II	Mild tachypnea or diaphoresis with feeding in infants
	Dyspnea on exertion in older children
III	Marked tachypnea or diaphoresis with feeding in infants; prolonged feeding times with growth failure due to heart failure
	Marked dyspnea on exertion in older children
IV	Symptoms such as tachypnea, retractions, grunting, or diaphoresis at rest

Table 261.2
Heart failure staging in pediatric heart disease

Stage	Interpretation
A	Patients at risk for developing heart failure, who have normal cardiac function
B	Asymptomatic patients with abnormal cardiac structure or function
C	Past or present symptoms of heart failure in patients with abnormal cardiac structure or function
D	End-stage heart failure requiring continuous infusion of inotropic agents or mechanical circulatory or ventilatory support

Physical examination may reveal tachycardia, increased work of breathing, and weak pulses. Pulmonary crackles can be heard upon auscultation and indicate pulmonary edema. Cardiac auscultation may reveal a gallop rhythm (S3 and/or S4) and occasionally a holosystolic murmur, caused by mitral or tricuspid regurgitation. Venous congestion causes hepatomegaly in all age groups and jugular venous distention in older children. Dependent lower extremity edema is mostly seen in older children, while infants may display facial edema. Special attention should be paid to the existence of symptoms that could provide a clue to the underlying cause of the cardiomyopathy, such as hypotonia, metabolic abnormalities, or dysmorphic features.

Diagnosis

Chest X-Ray

Chest X-ray typically shows cardiomegaly (cardiothoracic ratio >0.5) and features of pulmonary venous congestion. Pleural effusions may be present as well.

ECG

ECG usually reveals sinus tachycardia with nonspecific ST segment and T wave changes, as well as hypertrophy in the left precordial and inferior leads. Occasionally, the ECG provides specific clues toward the etiology of the disease such as Q waves in I, AVL, and V4-6 in ALCAPA. Since long-standing tachyarrhythmias can be associated with ventricular dysfunction, rhythm and P-wave morphology should be carefully assessed.

Echocardiography

The diagnosis of dilated cardiomyopathy is usually established by echocardiography. Characteristic findings include dilated ventricles with globally decreased function. Sometimes mitral valve regurgitation is noted, secondary to left ventricular dilation and/or papillary muscle dysfunction. Echocardiography is used to assess the degree of dysfunction as well as exclude correctable causes of ventricular dysfunction. The coronary arteries should be interrogated with color flow to assess for ALCAPA. Left ventricular outflow tract and aortic arch should be carefully interrogated since left ventricular outflow obstruction in the newborn, such as coarctation, can masquerade as cardiomyopathy. The severity of ventricular dysfunction can be quantified and followed longitudinally by measuring the ejection fraction, fractional shortening, and left ventricular end-diastolic diameter. Atrioventricular inflow patterns and estimates of right ventricular pressure by Doppler exam of tricuspid regurgitation provide information about diastolic dysfunction. Finally, the intraventricular cavity should be carefully evaluated for the presence of thrombi.

Cardiac Catheterization

Cardiac catheterization can provide useful information regarding the hemodynamics and guide therapy, but is not typically used as a diagnostic modality. However, endomyocardial biopsy may be helpful when myocarditis

is being considered. However, findings can be nonspecific, and sensitivity is limited to approximately 50%. In addition, the risk of perforating the ventricular wall is real, especially in infants. If endomyocardial biopsies are obtained, polymerase chain reaction (PCR) can be performed to look for viral nucleic acid from the common viruses that cause myocarditis such as enterovirus, adenovirus, parvovirus B19, human herpes virus 6, and, if clinically indicated, cytomegalovirus, EBV, HSV, HIV, influenza, and RSV.

Holter Monitor

Patients with severely depressed left ventricular function are at increased risk for developing tachyarrhythmias. They can be easily compromised due to lack of cardiac reserve. Annual Holter recordings help identify subclinical tachyarrhythmias.

Metabolic Evaluation

A large number of metabolic conditions can result in cardiomyopathy. It is therefore prudent to consider metabolic screening tests, especially in infants, when the diagnosis of dilated cardiomyopathy is entertained, including plasma acylcarnitine profile, lactate/pyruvate ratio, serum amino acids, urinary organic acids. Creatinine kinase is useful in identifying skeletal myopathy. If a mitochondrial disease is suspected from the screening labs, a skeletal muscle biopsy may be indicated to confirm the diagnosis.

Viral Studies

Viral studies should be obtained if myocarditis is suspected, including serologies, nasal wash, and blood PCRs for the viruses mentioned above.

BNP

Brain-natriuretric protein (BNP) levels are often elevated and can be useful for diagnosis and evaluation of treatment response.

Genetic Testing

Thus far, approximately 25 mutations have been identified in relation to dilated cardiomyopathy, mostly involving regulatory, cytoskeletal, or contractile proteins. Genetic screening in patients with clinical symptoms of dilated cardiomyopathy is costly, and mutations are found in only a quarter of patients. Screening of first-degree relatives for mutations is most effective once a specific mutation is identified in the index patient.

Differential Diagnosis

Other underlying causes for heart failure should be excluded, including congenital heart disease (especially coarctation or other left-sided obstructive lesions), ALCAPA, myocarditis, Kawasaki disease, and arrhythmias.

Treatment

Treatment of dilated cardiomyopathy in children consists of supportive therapies for congestive heart failure, prevention of complications, as well as etiology specific treatment.

Supportive Treatment

Acute Stage

Supportive treatment in the acute decompensated stage of the disease might consist of intravenous inotropic support as well as mechanical ventilation to reduce the workload on the heart. Agents most commonly used for inotropic support are the ß adrenergic agonists dobutamine or dopamine, often in combination with the phosphodiesterase inhibitor milrinone, which possesses inotropic as well as afterload reducing and ventricular relaxation effects. Intravenous loop diuretics are often added in the acute phase, especially if there is evidence of pulmonary or systemic venous congestion.

Chronic Phase

The ultimate goal of chronic treatment is alleviation of symptoms, prevention of cardiac remodeling, and improvement of cardiac function.

Fluid/Feeding Regimen

The benefits of fluid restriction in heart failure are widely accepted. On the other hand, adequate calorie intake should be a high priority in patients with congestive heart failure since the metabolic demands are higher and patients often struggle to feed. To avoid malnutrition, many patients receive high-calorie additives or supplemental enteral feeds.

Diuretics

Diuretic therapy reduces symptoms of systemic and pulmonary congestion by reducing the venous return to the heart. Loop diuretics in combination with aldosterone antagonists to compensate for potassium loss are widely used. In addition, studies show a mortality reduction in patients with severe heart failure treated with aldosterone antagonists, possibly explained by blockage of fibroblast proliferation in the myocardium.

Angiotensin-Converting Enzyme Inhibitors (ACEi) and Angiotensin Receptor Blockers (ARB)

As indicated earlier, neurohormonal compensatory responses in heart failure often lead to excessive vasoconstriction, volume retention, and cardiac remodeling. These effects can be partly reversed by angiotensin-converting enzyme inhibitors (ACEi), whose beneficial effects include vasodilation (afterload reduction) as well as volume excretion. Multiple studies have shown that ACEi extend survival in pediatric and adult patients with heart failure. Angiotensin receptor blockers (ARB) can be used in patients who do not tolerate ACEi, but its efficacy in children with heart failure has yet to be proven.

Beta Blockers

Beta blockers have become one of the mainstays of therapy in adults with heart failure, after large clinical trials in the 1990s showed improved survival with the use of carvedilol and metoprolol in adults with mild or moderate heart failure. Beta blockers ameliorate the damaging effects that chronic sympathetic stimulation has on the heart and thus improve cardiac remodeling. They are best tolerated in stable patients as they can cause a temporary worsening due to their negative inotropic effects. They should be started at low doses and gradually increased. Carvedilol is widely used in children with mild or moderate heart failure. Unfortunately, a recent randomized controlled clinical trial in children studying the effects of carvedilol was inconclusive, hampered by insufficient study power and the relatively high rate of spontaneous improvement in young children with dilated cardiomyopathy.

Digoxin

Digoxin improves cardiac contractility and reduces sympathetic tone. It can improve symptoms in heart failure, but there is no evidence that it improves survival.

Cardiac Resynchronization Therapy

Biventricular pacing or cardiac resynchronization therapy (CRT) may improve the synchrony between right and left ventricular contraction, which is often disturbed in patients with cardiomyopathy due to ventricular dilation and accompanying bundle branch block. A biventricular pacemaker can be programmed to stimulate both ventricles and can resynchronize the ventricular-ventricular interaction, resulting in a more coordinated contraction. Benefits are proven in adult patients with at least moderate heart failure and evidence of ventricular dyssynchrony. Early studies in children with heart failure and evidence of dyssynchrony suggest improvement of measured ejection fraction and functional status, with the best effect seen in children with heart failure due to congenital heart disease, rather than DCM.

Treatment of Complications

Any tachyarrhythmias should be aggressively treated with antiarrhythmic medications.

Anticoagulation with warfarin, heparin, or low molecular-weight heparin is indicated when there is evidence of intracardiac thrombus formation. Some centers use anticoagulation as primary prevention if the left ventricular function is severely impaired.

Ventricular Assist Devices

Multiple ventricular assist devices (VADs) are currently in development, and few models are used in the pediatric population. The Berlin heart and Thoratec VAD have been used as a bridge to heart transplant in children. Newer VADs are being developed that are smaller in size and therefore more tailored for permanent implantation.

Heart Transplantation

If all other therapies fail, heart transplantation can be performed. This is discussed separately in this chapter.

Etiology Specific Treatment

All patients with ventricular dysfunction should be carefully evaluated for treatable causes. Patients with *ALCAPA* usually recover ventricular function after reimplantation of the coronary artery. Immunomodulation with intravenous immune globulin (IVIG) and/or prednisone is commonly used to treat *myocarditis*. Results from an early study suggested an improvement in left ventricular function, but not survival, in children with myocarditis who received IVIG. However, a more recent randomized, prospective trial in adults with recent onset cardiomyopathy or myocarditis did not elicit any benefit from IVIG. Immunosuppression with prednisone is controversial as

well, with studies showing conflicting results. Despite the conflicting evidence, most pediatric cardiologists administer IVIG and/or prednisone when the diagnosis of myocarditis is suspected. Studies in mice have suggested increased viral replication and mortality if immunosuppressive therapy with prednisone is given early in the disease process. It is therefore prudent to administer prednisone only once the acute viral phase has subsided. *Nutritional deficits* should be supplemented, and specific therapy might be indicated for metabolic disorders. Some centers add a vitamin cocktail (riboflavin, carnitine, coenzym Q10, and thiamine) to the therapy if a mitochondrial disorder is suspected.

Future Directions

Gene Therapy

Success has been achieved with gene therapy in animal models, but finding an efficient delivery system (vector) remains a challenge and clinical gene therapy is likely still far away.

Tissue Engineering

Although promising, transplantation of isolated cells (e.g., embryonic stem cells, fetal cardiac cells) is still hampered by lack of sufficient engraftment in the heart.

Prognosis

The Pediatric Cardiomyopathy Registry showed a 5 year freedom from death or transplantation of 55% for all children with dilated cardiomyopathy. However, the outcomes for children with dilated cardiomyopathy depend on age at presentation and the underlying cause for dilated cardiomyopathy. Patients with idiopathic dilated cardiomyopathy or an underlying neuromuscular disorder have the worst long-term prognosis, while patients with a malformation syndrome or metabolic disease have the most favorable long-term outlook (◉ *Fig. 261.1*). Younger patients have a higher likelihood of recovery, while children >6 year are more likely to die or receive a heart transplant.

Prevention

Echocardiographic screening of first-degree relatives is indicated. Screening via mutation analysis in first-degree relatives is possible if a specific mutation is identified in a family member with dilated cardiomyopathy.

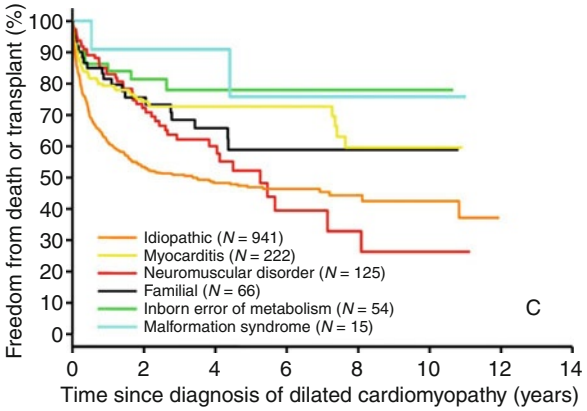

Figure 261.1
Freedom from death or transplantation for children with dilated cardiomyopathy (Reprinted from Wilkinson JD, Sleeper LA, Alvarez JA et al (2008) The Pediatric Cardiomyopathy Registry 1995–2007. Prog Pediatr Cardiol 25(1):31–36. With permission from Elsevier)

Restrictive Cardiomyopathy

Etiology

Restrictive cardiomyopathy (RCM) is a rare disease in which the diastolic function of the heart is affected, while the systolic function is often preserved. It accounts for only about 2.5–5% of all cardiomyopathies in children. A wide array of myocardial diseases can lead to restrictive cardiomyopathy, including many metabolic storage diseases and amyloidosis in adults. However, in the pediatric population, it is most commonly idiopathic, outside of the tropics. Family history is positive in approximately 30% of patients with idiopathic RCM, which alludes to a genetic predisposition. In the tropics, endomyocardial fibrosis is the most common form of RCM. Its geographical distribution suggests a relation to parasitic infections.

Pathogenesis

Increased stiffness and impaired relaxation of the ventricular wall lead to significant diastolic dysfunction. This ventricular noncompliance causes disproportionate increases in ventricular pressure as a result of relatively small changes in ventricular volume. Eventually, both atria become grossly enlarged, and pulmonary hypertension develops due to chronic left atrial hypertension and pulmonary venous congestion. With time, pulmonary vascular remodeling can create irreversible pulmonary hypertension.

Clinical Symptoms and Signs

Children with RCM often present with respiratory symptoms due to the development of pulmonary edema. The median age of presentation is 3–4 years. Not infrequently, a child has been treated for asthma or recurrent respiratory tract infections before the diagnosis of RCM is established. A child may also present with exercise intolerance or syncope. On physical exam, a gallop rhythm can be heard. If the pulmonary artery pressure is elevated, the second heart tone may be loud. Signs of congestive heart failure that can occur with RCM are jugular venous distention, pulmonary rales, hepatomegaly and, occasionally, peripheral edema.

Diagnosis

Cardiomegaly with pulmonary venous congestion on chest X-ray can be the first indicator of RCM in a child with respiratory symptoms. A 12-lead ECG often shows biatrial enlargement, as well as nonspecific ST- and T-wave abnormalities. The diagnosis is established by echocardiogram which classically shows an "ice cream cone appearance" created by grossly enlarged atria resting on top of relatively small ventricles. Echo Doppler indicators demonstrate diastolic dysfunction The systolic function is normal in most patients with RCM. Once the diagnosis is established by echo, cardiac catheterization can be performed to assess atrial and left ventricular end-diastolic pressures ("filling pressures"), as well as pulmonary artery pressures and pulmonary vascular resistance. If a differential diagnosis of constrictive pericarditis is entertained, catheterization may be useful in differentiating between constrictive or restrictive physiology. Filling pressures in constrictive pericarditis are equal in all four heart chambers, whereas the left-sided filling pressures in RCM are consistently 5–10 mmHg higher than the right-sided filling pressures.

Genetic testing may reveal some of the same sarcomeric protein mutations found in patients with hypertrophic or dilated cardiomyopathy. A recent study found a 30% prevalence of sarcomeric mutations in children with RCM.

Differential Diagnosis

Other causes of restrictive cardiomyopathy should be considered, including metabolic storage diseases, infections, or drug therapy. In the adult population, amyloidosis is the leading cause of RCM. It is often quite difficult to distinguish RCM from constrictive pericarditis, although the prognosis and treatment of the two diseases are very different. Constrictive pericarditis is often secondary to connective tissue disease or an infection (most commonly tuberculosis in the developing world), and the majority of these patients recover completely, often after a surgical pericardiectomy.

Treatment

Gentle diuretic therapy is indicated if there is evidence of pulmonary venous congestion. The stiff ventricle requires high filling pressures to preserve cardiac output and, therefore, overdiuresis should be avoided. There is no proven benefit of beta blockers or ACE inhibitors in RCM. Because of the dismal prognosis and lack of effective treatment strategies, heart transplantation is considered early in the disease process before irreversible pulmonary vascular disease develops.

Prognosis

The prognosis in children with idiopathic or familial RCM is thought to be poor. Multiple small series have shown a mortality rate of approximately 30–50% at 2 years with early death caused by progressive heart failure or tachyarrhythmias. However, it remains challenging to predict the prognosis in an individual patient since the occasional patient will survive up to 10 years without transplantation, and prognostic studies are hampered by small patient cohorts due to the rarity of the disease. Left atrial size and elevated pulmonary vascular resistance appear to be predictive of mortality, and an increase in pulmonary vascular resistance should prompt early evaluation for heart transplant since progression to irreversible pulmonary hypertension may preclude successful heart transplantation.

Hypertrophic Cardiomyopathy

Etiology

Hypertrophic cardiomyopathy (HCM) accounts for approximately one third of all cardiomyopathies. It is characterized by excessive hypertrophy of the left or both ventricles in the absence of an external stimulus for cardiac hypertrophy such as hypertension or an infiltrative process from metabolic

disease. Systolic function is often normal, but can be decreased especially in the later stages of the disease. In contrast, diastolic function is often abnormal, due to increased stiffness or abnormal relaxation of the ventricle. Primary HCM is largely a genetic disease. Many gene mutations have been identified, all involving the sarcomeric proteins, including β-myosin, myosin binding protein, troponin T, and α-tropomyosin. We do not yet have the ability to accurately predict the mutation from the hypertrophic phenotype. Furthermore, penetrance is widely variable. Thus, the presentation and phenotype can show remarkable variation, even within the same family. The inheritance pattern is autosomal dominant, but about half of all cases are the result of de novo mutations.

Epidemiology

HCM has an annual incidence of 4 per 1,000,000 in children, increasing to 1:500 in young adults. Similar rates of detection have been found among the adult population of the USA, Japan, and China. The disease has received much press as the number one cause of sudden cardiac death in young athletes.

Pathogenesis

Excessive hypertrophy of part of, or the whole ventricle is the hallmark of the disease, resulting in decreased compliance and relaxation of the affected ventricle. Although more common in the left ventricle, the right ventricle can also be affected in young children. Impaired diastolic function leads to increased filling pressures of the left ventricle, which in turn leads to increased pulmonary venous pressures with pulmonary venous congestion, resulting in dyspnea. In addition, disproportionate hypertrophy of the proximal (subaortic) interventricular septum can lead to left ventricular outflow tract obstruction (LVOTO) during systole. Turbulent flow across the outflow tract creates a suction effect, called the Venturi effect, on the mitral valve leaflet, causing abnormal systolic anterior motion of this leaflet in the direction of the protruding thickened septum, leading to further increase in obstruction and possibly promoting more ventricular hypertrophy.

Pathology

The hypertrophy can involve any part of the ventricle. The distribution can be quite diverse, especially in children, ranging from asymmetric hypertrophy of the septum (most common), to concentric hypertrophy, to localized apical involvement. Microscopically, the myocytes are hypertrophied and myocardial fibers are in a pattern of disarray with increased fibrosis.

Clinical Symptoms and Signs

Many patients with HCM are asymptomatic and are diagnosed during family screening. Symptoms are variable and not necessarily related to the severity of hypertrophy and outflow tract obstruction. Patients most commonly present with dyspnea and exercise intolerance due to diastolic dysfunction with pulmonary venous congestion. Infants most commonly present with increased work of breathing and feeding problems. Patients may experience chest pain, especially in the setting of left ventricular outflow tract obstruction, when the elevated ventricular systolic pressure increases ventricular wall stress and myocardial oxygen consumption. In addition, the coronary arteries may be narrowed, and there is often a significant mismatch between coronary flow and increased left ventricular mass, further contributing to myocardial ischemia. The chest pain can appear atypical in nature, occurring at rest as well as during exercise. Ventricular arrhythmias can cause palpitations and syncope, especially in older children. In addition, there is an association with sudden death, presumably related to ventricular arrhythmia, but perhaps compounded by outflow obstruction and myocardial ischemia.

Physical exam is often normal, especially in mild forms of the disease. It may reveal a S4 gallop due to atrial contraction into a stiff left ventricle. A systolic ejection murmur can be detected in patients with left ventricular outflow tract obstruction. The murmur is loudest at the left lower sternal border and is dynamic in nature, i.e., its loudness is affected by specific maneuvers. During the Valsalva maneuver, which increases the intrathoracic pressure and decreases venous return to the heart, the mitral valve leaflet is brought closer to the septum, which will increase the gradient across the outflow tract and the loudness of the murmur. In contrast, the murmur will be decreased in a squatting position, secondary to increased venous return and volume of the left ventricle in conjunction with increased resistance to outflow, thus lessening the pressure drop across the left ventricular outflow tract. Occasionally, there is mitral valve regurgitation, which produces a holosystolic murmur at the apex. When the right ventricle is involved in the disease process, subpulmonic stenosis can cause a loud systolic ejection murmur at the right upper sternal border.

Diagnosis

Echocardiography is the hallmark of diagnosis and shows inappropriate hypertrophy of the left or both ventricles. The hypertrophy is frequently asymmetrical in nature, affecting the septum more severely than the rest of the heart. However, HCM can manifest as many different patterns of hypertrophy, including apical or concentric hypertrophy. The septal thickness is abnormal if it measures more than two standard deviations above the mean indexed to body surface area (or 15 mm in adults). The left ventricular outflow tract should be carefully interrogated. Diastolic dysfunction can be assessed by Doppler hemodynamics as well as tissue Doppler. A 12-lead ECG may show left ventricular hypertrophy or biventricular hypertrophy, ST- and T-wave changes and abnormal Q waves. Unfortunately, a 12-lead ECG is not sensitive enough for screening since approximately 25% of patients with HCM have a normal ECG. However, the ECG can be helpful in the differential diagnosis since Pompe's disease shows giant QRS complexes.

Exercise testing is usually performed in children once they are at least 8 years of age to objectively assess functional status and risk-stratify the patient. A hypotensive response to exercise or failure to increase blood pressure appropriately (>20 mmHg) represents a risk factor for sudden death. Exercise occasionally elicits high-grade arrhythmias or ischemic changes. Holter recording can show atrial or, more frequently, ventricular arrhythmia with the latter having negative prognostic implications.

Genetic Testing

Over 400 mutations in 10 sarcomeric genes have been identified in HCM, most of them in the myosin heavy chain and myosin binding protein. Additional mutations continue to be identified. The likelihood of finding a sarcomeric mutation in a patient with HCM is between 50% and 80%, depending on the age, familial occurrence, and pattern of hypertrophy. However, there is sufficient heterogeneity in the clinical manifestations of a given gene mutation, that even when a patient's mutation is known, his or her clinical course cannot be predicted with any degree of certainty.

Differential Diagnosis

Other causes for hypertrophy should be excluded, including hypertension, aortic stenosis, and coarctation. In younger children (<2 years), at least half of the cases of HCM can be attributed to another disease, including metabolic or genetic disorders. Infants born to diabetic mothers can have transient biventricular hypertrophy, and 20% of patients with Noonan syndrome have HCM, as do 50% of all patients with Friedreich's ataxia. An Australian population study in 0–10 year old patients with HCM found a 57% incidence of an underlying syndromic, metabolic, or genetic disorder. However, a recent study from the US Pediatric Cardiomyopathy Registry showed that 75% of the pediatric subjects had idiopathic HCM. In older children, the most important differential diagnosis is an "athlete's heart" which is defined as a physiologic hypertrophy of the heart muscle due to intense sports participation, most frequently rowing, biking, or weightlifting. This distinction is important, but can be difficult to make, and often relies on Doppler assessment of diastolic function.

Treatment

Drug therapy is indicated if patients are symptomatic. Some clinicians advocate treatment with beta blockers in asymptomatic high-risk patients (e.g., severe left ventricular outflow tract obstruction or severe left ventricular hypertrophy), but a survival benefit has not been proven in this patient group. Once a patient becomes symptomatic, treatment with beta blockers or calcium channel blockers (verapamil or diltiazem) is initiated. Beta blockers reduce the heart rate, thereby prolonging diastole and giving the hypertrophied ventricle more time to fill. They have a negative inotropic effect which decreases the left ventricular outflow tract gradient and reduces myocardial oxygen demand. Calcium channel blockers work largely through the same mechanism, but may also improve ventricular relaxation and coronary flow. If there is significant left ventricular outflow tract obstruction, beta blockers are preferred over calcium channel blockers because of the vasodilatatory side effects of the latter. If treatment is ineffective, disopyramide may be added. This is an antiarrhythmic drug with negative inotropic properties that also vasoconstricts. As a general rule, diuretics and vasodilatory drugs should be avoided, especially in patients with left ventricular outflow tract obstruction, since decreased filling of the hypertrophied heart will worsen the left ventricular outflow tract gradient and cardiac output. In addition, digoxin is contraindicated because of its positive inotropic effect. However, a small subgroup of patients with advanced HCM have symptoms of congestive heart failure due to decreased systolic function. They might benefit from

diuretics, ACE inhibitors, or beta blockers, conform established treatment recommendations for congestive heart failure with systolic dysfunction.

Nonpharmacologic therapies for HCM include surgical myectomy, in which the subaortic septal ridge is peeled away, and alcohol septal ablation. Both procedures intend to reduce left ventricular outflow tract obstruction. The latter is a catheter-based procedure, during which alcohol is injected directly into a coronary perforator to induce a controlled myocardial infarction. These therapies are only appropriate for patients with refractory symptoms and severe outflow tract obstruction. Since the experience with alcohol septal ablation in children is limited, surgical myectomy is preferred.

Indications for Implantable Cardioverter Defibrillator (ICD) Placement

There are multiple prognostic factors for sudden death, the most important being:

1. History of cardiac arrest or sustained ventricular tachycardia
2. A positive family history for sudden cardiac death
3. Documented non-sustained ventricular tachycardia
4. A hypotensive response to exercise (i.e., decrease of blood pressure with exercise or a lack of increase of at least 20 mmHg)
5. Unexplained syncope
6. Extreme left ventricular hypertrophy (septal thickness >30 mm in adults)

When two or more risk factors are present, or syncope alone in children, the annual mortality rate is estimated to be >5%, and ICD placement is recommended.

Exercise Limitations

Patients with HCM should be excluded from competitive or high-intensity noncompetitive sports and isometric exercises because of the increased risk of sudden death. The Bethesda conference on sports participation from the American College of Cardiology recommends only low-intensity competitive sports for all patients with HCM (bowling, golf, cricket). However, some cardiologists advocate for recreational (noncompetitive) aerobic exercise of moderate intensity (biking, swimming, jogging) in their patients with HCM, based on studies showing an increased risk of sudden death and decreased emotional and physical well-being in patients who do not participate in regular exercise. It would seem prudent to discourage young patients from activities that result in sudden strenuous exertion, particularly when under peer pressure. They should always be allowed to rest as needed during exercise.

Prognosis

The risk of sudden death in adult patients with HCM is approximately 0.5–1% per year in community-based population studies and 3–5% per year in patients referred to tertiary centers. Rates for older children with HCM are similar, but the clinical course is highly dependent on age, and hypertrophic heart disease presenting in infancy carries a worse prognosis, especially if it is secondary to metabolic or genetic disorders. Proposed mechanisms for sudden death include arrhythmic events, myocardial ischemia, and end-stage heart failure. A recent Australian study which evaluated all children with HCM between 0 and 10 years of age found that 83% were free of death or transplantation after 5 years and 76% after 10 years. Approximately 5% of HCM ultimately progresses into a burn-out disease with systolic dysfunction and symptoms of congestive heart failure.

Prevention

Most sarcomeric mutations are inherited in an autosomal dominant pattern and first-degree relatives (parents, siblings, offspring) should be screened by echocardiogram for HCM every 5 years, and yearly through adolescence since the degree of hypertrophy can increase significantly during puberty. If a gene mutation is identified in the diseased family member, first-degree relatives can be screened for the same mutation. A negative mutation analysis would obviate the need for lifelong echocardiograms, whereas a positive test would warrant lifelong screening echocardiograms. The natural history of each mutation varies, and even in families with the same gene mutation, the phenotype might express itself differently among affected family members.

Left Ventricular Non-Compaction

Etiology

Left ventricular non-compaction (LVNC) is a rare form of cardiomyopathy that has been described since the early 1990s. It is characterized by multiple prominent ventricular trabeculations and deep intertrabecular

recesses within the myocardium. Its annual incidence in children is <0.1 per 100,000. There is familial occurrence in 25% of children with LVNC.

Pathogenesis

LVNC can present as isolated noncompaction or in conjunction with other heart disease (20%). Isolated noncompaction is thought to represent an arrest in the normal compaction of the myocardium during organogenesis. Multiple genetic mutations have been identified related to LVNC, including tafazzin (TAZ, leading to Barth syndrome), dystrobrevin (DTNA), and lamin gene mutations (LMNA), as well as sarcomeric protein mutations similar to those found in HCM. In addition, LVNC can occur with chromosomal disorders, neuromuscular diseases, mitochondrial disorders, DiGeorge syndrome, and Fabry's disease.

Pathology

There is hypertrabeculation of the left ventricular myocardium with histopathology showing interstitial fibrosis and endocardial fibroelastosis. Both ventricles are involved in approximately 25% of cases. The clinical phenotype can undulate between ventricular dilation and hypertrophy.

Clinical Symptoms and Signs

Symptoms may be secondary to heart failure, arrhythmias (both atrial and ventricular), or thromboembolic events. Up to two thirds of patients have depressed systolic function, but diastolic dysfunction is common as well. The most common presentation in children is heart failure. Pignatelli reviewed the clinical course in 36 children with LVNC. At a median age of 90 days, 40% of patients presented with symptoms of heart failure, while another 40% were asymptomatic. Thromboembolic events are seen in about 10% of adult patients and are due to thrombus formation in the deep intertrabecular recesses. They are more likely to occur when the systolic function is depressed. Pignatelli did not report any systemic embolism in his pediatric patient group.

Diagnosis

A consensus on features required for a diagnosis of LVNC has not been established. The following echocardiographic criteria have been advocated.

The diagnosis is established by echocardiography when three criteria are met:

1. The presence of multiple echocardiographic trabeculations (>3)
2. Evidence of Doppler flow into the intertrabecular recesses
3. A ratio of non-compacted to compacted myocardium of >2:1 at end-systole; sometimes a ratio of 1.4:1 is used in children

An MRI may be helpful to evaluate the ventricular morphology when echo findings are inconclusive. Abnormal ECG findings are seen in 75% of patients and may include biventricular hypertrophy, T-wave inversion, preexcitation, and premature atrial and ventricular contractions. Annual Holter studies are indicated because of the increased risk of atrial and ventricular tachycardia. Skeletal muscle biopsy may be indicated if urine and blood tests reveal a concern for underlying mitochondrial or metabolic disease.

Genetic testing: Genetic screening should be considered when there is a positive family history or when clinical features suggest the aforementioned mutations. Multiple gene mutations have been linked to LVNC, with both X-linked (TAZ gene mutations) and autosomal dominant inheritance patterns. There are likely still many unidentified genetic mutations related to LVNC. As in HCM, the clinical presentation between patients with the same mutation can vary widely.

Differential Diagnosis

Occasionally, it is hard to differentiate the echocardiographic findings of LVNC from normal occurring ventricular trabeculations. In addition, LVNC may present with a phenotype similar to dilated or hypertrophic cardiomyopathy and disease processes may overlap. Some of the same genetic mutations seen in LVNC, can be found in dilated and hypertrophic cardiomyopathy.

Treatment

The specific treatment depends on the clinical and echocardiographic findings. In patients with systolic dysfunction, therapy with ACE inhibitors and/or beta blockers is warranted. Diuretics should be added if symptoms of venous congestion exist. If there is solely diastolic dysfunction, diuretics may be the only medication needed for symptomatic relief. Patients with a hypertrophied

phenotype could benefit from beta blockers. Many centers routinely start antiplatelet medication (aspirin) or full anticoagulation if there is a history of thromboembolic events or severely depressed systolic function. Some centers add vitamin cocktails (thiamine, carnitine, riboflavin, coenzyme Q10) to the cardiac therapy if there is clinical evidence of mitochondrial dysfunction.

Prognosis

The natural history of LVNC is largely unknown. It is a diverse disorder, and many asymptomatic cases are undiagnosed. On the other hand, some degree of left ventricular trabeculations can be seen in the normal heart, leading to overdiagnosis in other patients. Pignatelli described a 3 year survival of 78% in a pediatric cohort with LVNC. Nine out of 36 patients experienced transient periods of recovery. Prognosis is worse in patients with concomitant congenital heart disease.

Prevention

Prevention of disease is not possible. For the purpose of genetic counseling and early diagnosis, screening echocardiograms can be obtained in first-degree relatives. If a gene mutation is identified in the diseased family member, first-degree relatives can be tested for the same mutation.

Pediatric Heart Transplantation

History

Human heart transplantation was first performed by Dr. Christian Barnard in Cape Town, South Africa, in 1967. The 54 year old recipient lived for 18 days, ultimately succumbing to pneumonia. The first pediatric heart transplant was performed only 3 days later by Dr. Kantrowitz at Maimonides Medical Center in Brooklyn, New York. A donor heart from an anencephalic infant was transplanted into a recipient with severe Ebstein's anomaly of the tricuspid valve with functional pulmonary atresia. The infant lived for 6 hours. In the following years, many centers performed heart transplantations, but results were disappointing due to the lack of effective immunosuppressive drugs to control allograft rejection. The introduction of anti-thymocyte preparations in the 1970s and cyclosporine in the 1980s allowed for a revival and expansion of heart transplantations in adults and children.

Indications

Evidence-based guidelines for heart transplantation in children have been more difficult to establish than in the adult population because of the relatively small patient population and diverse cardiac diagnoses. In addition, criteria for adult heart transplantation hinge heavily on exercise testing, which cannot be reliably performed in younger children. A working group from the American Heart Association recently reexamined and reaffirmed previously used indications for pediatric heart transplantation, which include:

Progressive heart failure with deterioration of functional status despite optimal medical care
Need for ongoing inotropic or mechanical circulatory support
Complex congenital heart disease without good surgical options
Malignant arrhythmias
Progressive pulmonary hypertension secondary to left ventricular failure or restrictive cardiomyopathy
Growth failure secondary to heart disease

Epidemiology

Pediatric heart transplants account for approximately 10% of all heart transplants worldwide with a total of about 400 cases per year. Throughout the years, infants have constituted one quarter of all pediatric transplant recipients. Heart transplantation is now less used as primary therapy in infants with congenital heart disease than it was 10 years ago, due to improved outcomes in congenital heart surgery, especially the Norwood procedure for hypoplastic left heart syndrome. Still, the current majority of infant heart transplant recipients (2/3) carry a diagnosis of congenital heart disease, while the remainder has cardiomyopathy. This distribution is reversed in teenagers and about equally divided in school age children. Dilated cardiomyopathy accounts for 75% of cardiomyopathies, with the remaining 25% almost equally divided between restrictive cardiomyopathy, hypertrophic cardiomyopathy, and myocarditis.

Workup of the Heart Transplant Recipient

A full workup of a heart transplant candidate should include the following:

Lab work: blood type, anti-HLA antibody screen ("Panel Reactive Antibodies or PRA") to evaluate for

preexisting sensitization to HLA antigens, complete blood count, anticoagulation panel, liver and kidney function tests, infectious serologies (see below).

Cardiac catheterization to assess pulmonary vascular resistance and occasionally to delineate the exact anatomy in congenital heart disease. Newborns without risk factors for pulmonary vascular disease do not always need a cardiac catheterization prior to transplant.

Exercise study to help assess functional capacity in older recipients (>8 years old).

Consultations from:

- Nutrition
- Social work, with special attention to whether there are concerns for medical noncompliance
- Psychiatric evaluation, if indicated
- Infectious disease specialist, who will at least request HIV, hepatitis, EBV, CMV, varicella, and toxoplasmosis serologies, as well as up-to-date vaccination status
- Anesthesia
- Cardiovascular surgeon

There are few contraindications to heart transplantation, and most are not absolute. Their purpose is to increase the likelihood that the recipient will survive the transplant, and be able to enjoy a near normal quality of life after transplantation. As mentioned, pulmonary vascular resistance should be evaluated prior to transplant. Patients with significant left ventricular dysfunction often have long-standing pulmonary venous congestion, which can cause vascular remodeling and consequently elevated pulmonary vascular resistance. This can lead to right ventricular failure post transplant since the donor heart is not used to these elevated pulmonary artery pressures. With the introduction of pulmonary vasodilators such as prostacyclin and nitric oxide, the acceptable upper range for pulmonary vascular resistance is expanding. Most centers will accept patients for heart transplantation if their pulmonary vascular resistance drops after administration of pulmonary vasodilators (nitric oxide, prostacyclin, oxygen). The presence of an active, untreated infection precludes transplantation, considering the requirement for immunosuppressive therapy. Renal insufficiency with a creatinine >2 mg/dL decreases the chance of a good outcome after heart transplantation, unless a heart–kidney transplant is planned. A coexisting life-threatening illness forms an absolute contraindication. Potential for noncompliance with medications is a relative contraindication and needs to be carefully addressed prior to transplantation.

Donor Factors

A donor heart is matched to recipient size. A donor to recipient weight ratio of 0.9–2.5 is often used. Donor and recipient blood types need to be matched for non-infant recipients. In 2001, West et al. showed successful transplantation of ABO-incompatible donor hearts in infants. The immaturity of the infant immune system, which has not yet formed antibodies to the major blood-group antigens, is thought to enable the development of tolerance post transplant. This practice is now widely used, thereby broadening the available donor pool for infant recipients. Unlike other solid-organ transplants, heart transplant donor and recipients are generally not matched for HLA type, partly due to the restrictions in donor ischemic time. However, in recipients with preformed HLA antibodies ("sensitized" recipients), donor organs with corresponding HLA antigens will need to be avoided.

Posttransplant Complications

Primary graft failure is the most common cause of death in the first 30 days following heart transplant and is associated with many factors, including poor donor organ quality, prolonged ischemic time, preexisting pulmonary hypertension in the recipient, as well as preexisting congenital heart disease in the recipient.

There is an increased risk of *infection*, especially in the early posttransplant period, when the immunosuppressive burden is the highest. Blood infections and bacterial pneumonias are the most common infections in the immediate posttransplant period due to necessary invasive lines and endotracheal tubes. Viral infections (especially CMV and EBV) may be transmitted from a positive donor into a naïve recipient, or previously infected recipients can experience a reactivation of latent virus. For these reasons, recipients receive prophylaxis with ganciclovir for 3 months after transplant when there is evidence of CMV positivity in donor or recipient.

Rejection remains an ongoing concern, with the highest risk in the first year after transplant, when one third of transplant recipients experience some degree of acute cellular rejection. Multiple immunosuppressive drugs are available and used for prevention of rejection. A distinction should be made between induction therapy and maintenance therapy. *Induction therapy* is the prophylactic administration of immunosuppressive drugs in the immediate postoperative period when donor antigen expression is highest. It is used in approximately 50% of

pediatric heart transplant recipients. While the ultimate goal is to induce graft tolerance, the immediate goal is the prevention of T-cell activation, which can prevent early rejection and allow for later introduction of maintenance immunosuppression with nephrotoxic calcineurin inhibitors. Many centers use corticosteroids as well as polyclonal T-cell antibody preparations (ATG) as induction therapy, whereas other centers use IL-2 receptor antibodies (daclizumab and basiliximab). *Maintenance immunosuppression* is introduced once the renal function has stabilized, usually somewhere within the first 5 days after transplant. Calcineurin inhibitors (cyclosporine, tacrolimus) are the cornerstone of most immunosuppressive protocols. Calcineurin is a phosphatase that regulates cytokine production within the T-cell. Most centers prefer to use multiple classes of immunosuppressive drugs, therefore allowing for lower doses and less side effects of each individual immunosuppressive drug. Besides calcineurin inhibitors, antiproliferative agents are often used. Examples are mycophenolate mofetil or azathioprine, which are purine analogues that inhibit T- and B-cell proliferation. Sirolimus is a different class of antiproliferative drug that has the added advantage of inhibiting smooth muscle and endothelial cell proliferation as well T- and B-cell proliferation. Because of these effects, it can be beneficial in preventing transplant coronary artery disease. It is also used as a partial replacement for calcineurin inhibitors when there is concern for nephrotoxicity. Corticosteroids are part of maintenance immunosuppression in many centers. Because of the many side effects associated with long-term use, there is a trend toward early steroid withdrawal. Currently, about half of centers continue to give corticosteroids at 1 year post transplant.

Frequent monitoring for rejection is mandatory since rejection can occur without symptoms. Monitoring can be performed noninvasively, based on echo parameters of diastolic and systolic function, or invasively by catheter-based cardiac biopsy. Clinical symptoms and signs of rejection include dyspnea, tachycardia, gallop rhythm, general malaise, and other signs of congestive heart failure.

Long-Term Sequela

The risk for rejection and infection continues to be present throughout life, albeit significantly lower than in the early posttransplant period. Allograft vasculopathy is the leading cause of death among pediatric heart transplant recipients who survive >5 years. It differs from classic coronary artery disease: it presents at an earlier age and is more progressive and diffuse in nature. Almost 20% of pediatric heart transplant recipients have evidence of allograft vasculopathy 5 years after transplant, although the infant recipient appears relatively spared (*Fig. 261.2*). The process is likely immune and nonimmune mediated. It is

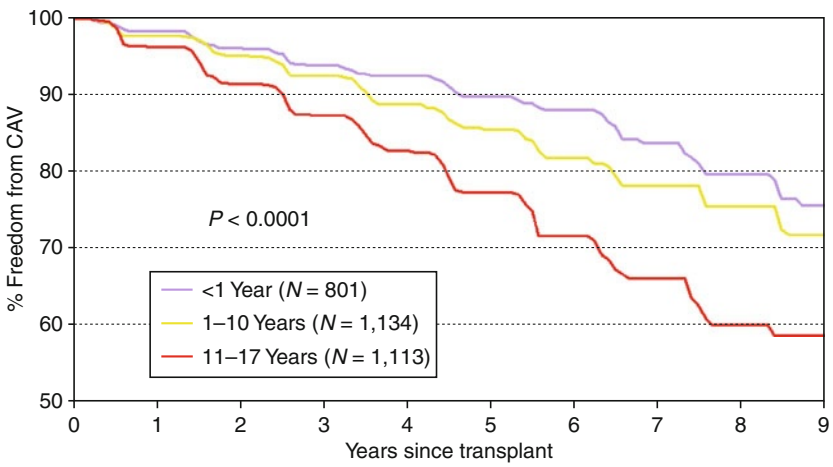

Figure 261.2

Freedom from coronary artery vasculopathy for pediatric heart transplants recipients (data collected by the International Society for Heart and Lung Transplantation 1994–2008), stratified by age group (Reprinted from Kirk R, Edwards LB, Aurora P et al (2009) Registry of the International Society for Heart and Lung Transplantation: twelfth official pediatric heart transplantation report – 2009. J Heart Lung Transplant 28:993–1006. With permission from Elsevier)

associated with rejection, particularly antibody mediated rejection, while traditional cardiovascular risk factors, promoted by immunosuppressive therapy (hyperlipidemia, diabetes, hypertension, CMV infection) are likely to contribute as well. Once it develops, the prognosis is grim, with less than 50% survival at 2 years. Sirolimus appears to help stall the development and progression of allograft vasculopathy. Unfortunately, lesions are usually not amenable to catheter based intervention due to their diffuse nature, and retransplantation is often the only treatment option.

Renal dysfunction is an important consideration, with 10% of heart transplant recipients developing severe renal disease 10 years after transplant, secondary to chronic

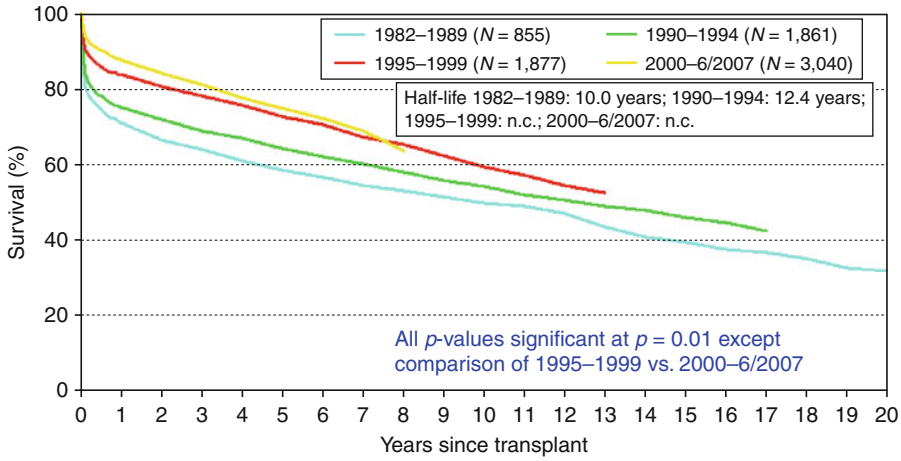

Figure 261.5

Kaplan–Meier survival curve by era for pediatric heart transplants recipients (data collected by International Society for Heart and Lung Transplantation 1982–2007) (Reprinted from Kirk R, Edwards LB, Aurora P et al (2009) Registry of the International Society for Heart and Lung Transplantation: twelfth official pediatric heart transplantation report – 2009. J Heart Lung Transplant 28:993–1006. With permission from Elsevier)

administration of nephrotoxic drugs on top of frequently preexisting renal disease, due to a history of heart failure with low cardiac output. In addition, many heart transplant recipients develop chronic hypertension as an adverse effect of the medications. Another long-term consequence of the immunosuppressive medications is an increased incidence of malignancies (8.3% for 10 year survivors), which are mostly lymphoid tumors. Posttransplant lymphoproliferative disease (PTLD) is associated with primary Epstein Barr virus (EBV) infection post transplant and encompasses a wide spectrum of diseases from benign lymphoid hyperplasia to aggressive monoclonal lymphoma. Reduction of the immunosuppressive burden often provides sufficient treatment, but occasionally additional treatment with chemotherapeutic agents is warranted.

Despite the many long-term medical issues, most heart transplant recipients enjoy a good quality of life with few limitations (*Fig. 261.3*).

Survival

The current 1-year survival after heart transplant is 88% in children >1 year old and 82% in younger children. The 5 year survival for all age groups is 75%. While the infant group has a higher initial mortality (*Fig. 261.4*), they appear to have a survival benefit once they survive the first year ("conditional survival"), likely due to the relative immaturity of the infantile immune system at time of transplant, making graft tolerance more likely. With advancements in immune suppressive management, survival statistics do improve (*Fig. 261.5*). Unfortunately, not all patients listed for transplant survive until transplantation, and waitlist mortality can be as high as 20%.

262 Pediatric Intensive Care Physical Environment

Abdul-Rahman M. Abu-Taleb

Introduction

Pediatric intensive care has progressed over the years and has become a well established and reputable subspecialty. Patient acuity, over the last 10 years, has increased, resulting in a growing need for more Pediatric Intensive Care Unit (PICU) beds and sophisticated monitoring equipment. Cutting edge technological advancements in the treatment of childhood diseases have also contributed to the increased use of pediatric intensive care beds. Along with these positive developments, requirements were identified to set higher standards in all directions, including optimal physical environment for critically ill children and their families. The role of the actual physical environment has a major impact on the successful management and optimal healing outcome of critically ill children. PICU designers must include hospital administrators and the end-users in the planning to overcome many logistic constrains. Meeting the objectives requires good long-term planning taking into consideration growing patient population, establishment of new services, treatment modalities, team composition, and function. This long-term planning will enable the physical requirements of the unit to last longer with only minor modifications in the future, if the need arises. Aside from location, space, and staffing, the potential of future PICUs to fulfill patients and families needs is by fulfilling additional requirements such as ambient and atmospheric features, functional and technological settings, psychological, spiritual, cultural needs, and finally social support for patients and families to meet their psycho-social needs. Unit policies should reflect a patient- and family-centered approach.

Ambient and atmospheric features address acoustic, light, and temperature effects as PICU tends to be a noisy and brightly illuminated place due to continuous procedures and the large number of care providers. The continuous sounds from ventilators and beeping of monitors create a disturbed atmosphere to patients and their families and causes additional stress; consequently, atmospheric intervention (ambience) should be strongly considered in the unit's design to support and promote the healing process. Dim lighting tends to reduce the level of activity and noise of staff in contrast to bright illumination. Temperature (air-conditioning) and lighting controls should be within the reach of staff and families. Private and semi-private rooms as well as soffits will decrease noise level and add more comfort to the patient and family. Additional friendlier physical environment approach in PICU is the selection of appropriate color schemes, decor, and selection of interior finishes that resemble home to create a soothing, reassuring atmosphere. The results are a comfortable, family-focused, state-of-the-art facility that presents a less threatening environment for both the children and their families and offers the best care.

These suggestions should not compromise unit functionality regarding infection control, easy maintenance, durability, stain resistance, flame resistance, non-toxicity, light fastness, aesthetics, and cost. A relaxing atmosphere with positive psychological impact on patients and their parents also include provision of windows for daylight to maintain circadian rhythms, and to have views to outside gardens that can be used as special areas for patients, families, and staff for relaxation.

The design of PICU patient's rooms can incorporate functionality, as well as up-to-date technological requirements to suit the needs of patients, care givers, and families. This can be achieved by applying a zoning system within a patient room. Each room will have three zones for patient, family, and care givers (*Fig. 262.1*). Attention should be devoted also to visibility between patient and care givers in a way that an acceptable level of privacy is still maintained.

A major part of excellence in patient care is addressing family support through frequent and proper counseling and providing social support as needed. A family counseling area and a large family lounge to accommodate different groups of individual families are essential to provide comfort and the image of welcoming and integrating the patient and his parents. It is especially important to involve families in the care of their children and promote

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_262,

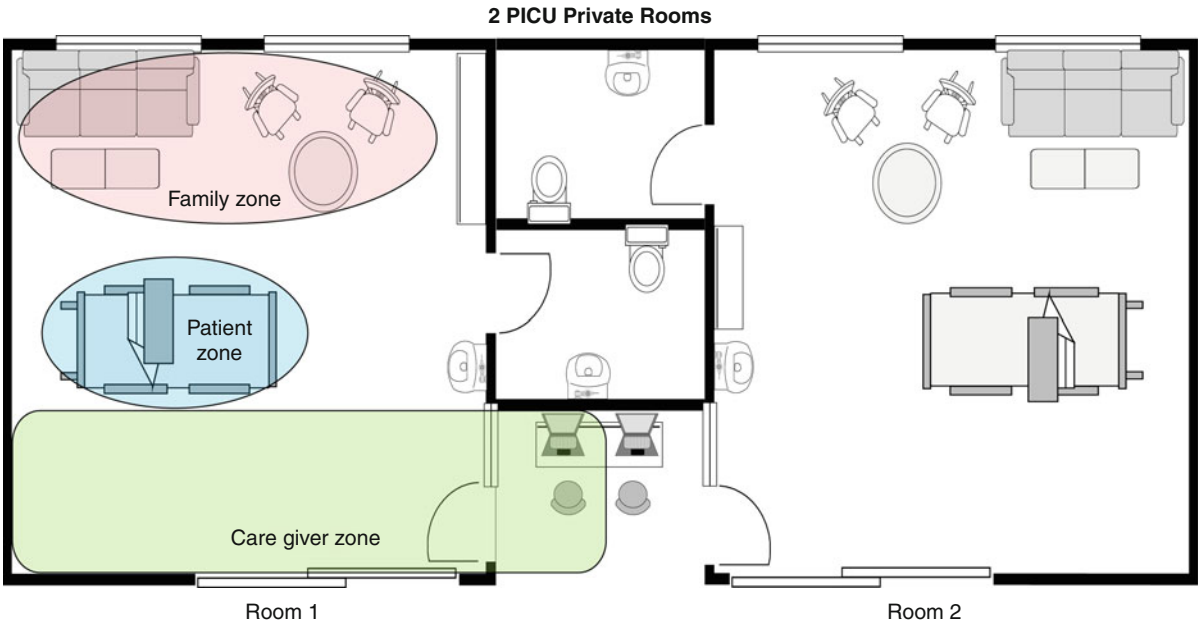

Figure 262.1
Two PICU private rooms with patient zone, care giver zone, and family zone promoting child- and family-centered care

them as partners in the care; not only does it help ease parents' anxiety to be nearby, but also recent studies indicate that their presence can actually reduce recovery time.

Managing critically ill children used to focus mainly on a biomedical approach. Care should move more and take a holistic approach aiming to offer health care providers, in particular the nursing staff, dependent relationship resulting in genuineness, warmth, active listening, nonjudgmental, and empathy. Focusing on a family-centered care and the physical environment in PICU will promote privacy, interaction, social support, comfort, and functionality as mentioned above.

Allocation of Space

The location and size of the unit is important and will vary as a result of differences in hospital architecture, size, space, and design. PICU location should be within or close to pediatric services and simultaneously be as close as possible to important support services such as the operating room, recovery room, emergency department, radiology department, laboratory, cardiac catheterization laboratory, and elevators. Proximity to the physician's on-call rooms, medical and nursing director's offices, and family waiting and sleeping areas is essential. Access to the PICU should be monitored to maintain patient and staff safety and confidentiality.

The amount of space devoted to the unit may constitute a real challenge and is the most difficult decision to make, as the allocated size is essential to the effectiveness and efficient functioning of the unit. Additionally, size of the unit is strongly dependent on the number of beds, isolation rooms, private rooms, semi-private rooms, and support services area needed.

It is highly recommended to have site visits to well-established PICUs around the country and study different PICU designs and consequently selecting the best features and tailoring them to the specific needs of the center.

Patient Care Areas

Caring for critically ill children is a complex task. Thoughts should be given to private and semi-private rooms (enclosed cubicles) versus multiple-bed area (open bay system), or a combination of both, keeping in mind that the need for private rooms and semi-private rooms for pediatric patients has increased over the last decade and is superior to a multiple-bed area system. However, the decision depends on availability of resources (finance and staffing), availability of space, and level of

acuity care. The design of the PICU area (open beds and private rooms) should have a friendly layout, thus maintaining functionality and providing optimal care in a less threatening environment for both the children and their families by making the PICU a patient- and family-centered place of care.

The number of beds has to be identified before the decision about allocating space for the unit can be made. Factors that influence optimal PICU bed number in a given center addresses the population to be served, existing services and planned projects, size of the active pediatric department, number of acutely ill pediatric patients previously treated in the center, maximal occupancy, average length of stay, high turnover, and short stays; all these aspects must be taken into consideration in the final decision of the total PICU bed number. Knowing that the demand for pediatric high acuity and step-down beds has continued to grow is also important. Also the number of isolation and private or semi-private rooms will have a significant impact on the bed number and may limit the overall bed capacity of the unit. Personnel shortages and cost-containment are few of the many reasons faced by the planners in making the decision between a multiple-bed area arrangement or private rooms and semi-private rooms. The recommendation in general is to provide at least one isolation room for each ten beds or one for each unit, if the overall bed capacity is less than ten beds. Test results, however, have shown that usually more than one isolation room is necessary. In fact modern units are moving away from multiple-bed area system (open bay system) toward more private rooms and semi-private rooms, as the need for private rooms for pediatric patients has increased over the last decade. Parents need adequate space in order to stay with their sick child at all times and have the necessary privacy, which is consistent with family-centered care. In addition, infection control requirements have also changed over the last decade. The need for isolation rooms has increased dramatically due to infectious diseases as well as an increase in the number of immunocompromised patients who need to be protected from infectious organisms. Other variables need to be considered that may affect future bed use, such as new programs or expanded services that involve a PICU stay. In addition, thoughts need to be made in case a step-down area is to be included within the unit location which usually has a multiple-bed area arrangement.

Different room types are required within the PICU, including rooms for patient isolation. The minimal space requirement for an open PICU bed is 200–225 sq. ft (18.58–20.9 m^2) with at least 5–8 ft (1.52–2.44 m) distance (clearance) between beds. The required space per bed must be large enough to accommodate routine (monitors, ventilator, IV poles, and pumps) and special equipment such as High Frequency Oscillatory Ventilator (HFOV), hemodialysis, Extracorporeal Membrane Oxygenation (ECMO), echocardiography, ultrasound, and x-ray. The designated space per bed and the clearance between beds must accommodate emergency procedures such as resuscitation and minor or major emergency surgical procedures, as these actions will involve additional care providers and equipment. Sufficient space around the head of each bed or crib must be available for rapid airway access in emergency situations. Equipment columns suspended from the ceiling are very helpful in organizing workspace. Isolation rooms as well as private rooms require at least 250 sq. ft (around 23.23 m^2) to have adequate workspace for the equipment and other life-support systems that is often necessary in critical care situations such as in-room dialysis and other equipment. The isolation rooms, if used for immunocompromised children, are best prepared with an anteroom (including a sink, place to change gowns, and drawers to keep gloves, masks, protective eyewear, and other items) and have controlled airflow (negative and positive pressure airflow capabilities) to minimize the spread of airborne infections. The space in isolation and private rooms can be divided into zones as mentioned earlier (Fig. 262.1). This will optimize the space to accommodate the needs of patient, parents, and care providers. Equipment columns suspended from the ceiling to make the rooms flexible allows PICU staff to arrange bedside equipment for the patient's best care and comfort. With a daybed, recliner or comfort chair, bathroom, TV/VCR, and storage space in each room, parents are able to stay at their child's bedside. Use of regular curtains should be discouraged as they are susceptible to dust build-up and have infection control disadvantage; instead, use of adjustable integral blinds between layers of glass are effective in full blocking of light and/or interior views and have infection control advantage.

Highly technologically sophisticated PICU in tertiary care facilities, regardless of the chosen bed system (multiple bed area system or private and semi-private rooms), will require special considerations regarding individual bed space design. Headwalls or columns that are capable of providing virtually every physical resource needed at the bedside offers great flexibility in space management. All necessary electrical outlets, grounding inlets, vacuum and oxygen and air outlets, alarm buttons, communications systems, temperature and lighting controls, equipment brackets, and storage capabilities can be tailored according to the needs. A multidisciplinary team

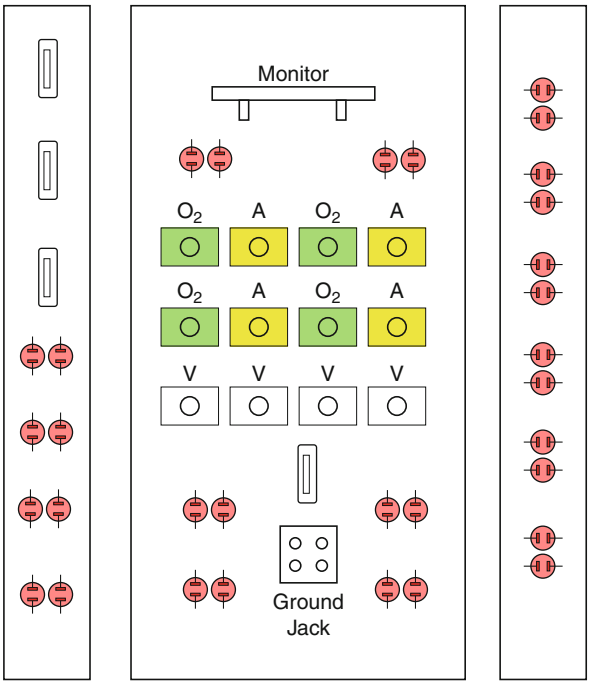

Figure 262.2
Schematic layout drawing of a PICU power-column with example of different outlets

consisting of health care provider groups (physicians, nurses, and respiratory therapists), biomedical engineers, and architects need to collaborate to achieve the best possible layout for headwalls or columns (*Fig. 262.2*). The number of electrical and gas outlets needed per bed to cope with tertiary PICU requirements is usually higher than generally recommended. At least, 24 electrical outlets for each bed are required, 12 out of them should be linked and connected to the emergency power source that will quickly resupply power in the event of power interruption. Gas outlets requirements are four outlets for each, oxygen, vacuum and air, and need to be arranged on the headwalls or columns of each bed. Full range of accessibility to the patient (360°) should be maintained at all times, as well as easy access to equipment and outlets.

Support Services

Requirements for support areas within the PICU include separate rooms for clean and soiled linens, laboratory area for rapid determination of blood gases and other essential studies (electrolytes), respiratory therapist area, medication room (including a refrigerator and a narcotics locker), a satellite pharmacy to provide routine and emergency medications at the point of ordering, a large storage room for equipment to accommodate the needs of a large, technologically sophisticated unit (with numerous electrical outlets at both floor height and counter height so that the chargeable equipment can remain plugged in), staff lounge, restrooms and lockers for staff and families, as well as physician's on-call rooms (for attending physicians, fellows and residents). Nursing stations with enough working space for nurses and fully networked to provide computer access to clinical information system and a central monitor station are placed in the unit to maintain observation and monitoring of patients. Access to patient's information from any electronic nursing station including rapid and reliable system for reporting laboratory results must be made available. The unit must include a multi-level communication system allowing immediate dissemination of information utilizing beepers, overhead paging and nurse call system. The presence of Picture Archiving and Communication System (PACS) terminals or stations to review radiographs in the unit is essential. Pneumatic tube system connecting the PICU with the laboratory, pharmacy and other support services is highly desirable. Offices for unit director, nurse manager and a conference room for staff personnel is essential and should be located in the PICU or near

the unit. These above mentioned support services facilities should be located in the PICU area and additional space needs to be included in the floor plan of the unit. Other services that should be proximate to the unit include dietary, social services, family waiting area, grieving room, quiet room and a separate room for family counseling- necessary for private discussions between the staff and the family. A conference area and staff toilets, as well as secretarial area are essential. A separate facility for patient's families, including space for sleeping and bathing, and an area for storing patients' personal effects is essential.

Requirements of the end users concerning additional space for support services beyond the recommended standards must be taken into consideration and discussed in multidisciplinary meetings with all players including the PICU team, planners, and administration. In these meetings, additional issues can be addressed such as equipment needs, PICU personnel, communication, and the impact of the PICU on other hospital services.

Part of the PICU requirement is to provide sleeping space for parents. Frequent communication and discussion with PICU staff is very important, as patient status usually is a dynamic process and requires the family presence. Space should also be allocated for additional family support facilities (see below).

Family Support Areas

The focus on creating an environment to provide medical care to critically ill patients, while incorporating the needs and support to their families is a basic approach toward patient- and family-centered care. Providing supportive environments for families aims to meet their unique psycho-social needs. Family support areas, therefore, are important and part of the overall care for critically ill children. It helps health care provider teams, with no doubt, in being sensitive and responsive to diversity across ethnic, geographic, age, and economic lines as well as in meeting the unique needs of each child and family. Licensing standards in many countries obligate hospitals to provide family support areas connected to the PICU. These family support facilities consist of providing sleeping areas for parents (plush couches, sleeper chairs or recliner, preferably separate from the visitors waiting area), family consultation rooms, family lounges with several small sections to offer privacy for different family groups, grieving rooms, quiet rooms, lavatories and showers, laundry and locker facilities, kitchenette, vending areas, and telephone booths.

263 Pediatric Resuscitation

Abdul-Rahman M. Abu-Taleb

Introduction

Cardiopulmonary arrest in children is rare. Cardiac arrest as a sudden, primary event is uncommon in the pediatric age group (Table 263.1). More often, cardiac arrest occurs as a secondary, terminal event precipitated by diverse causes. It occurs following a progressive deterioration of the respiratory or circulatory function leading to respiratory failure with profound hypoxia, acidosis, and tissue hypoperfusion or hemodynamic collapse (Fig. 263.1). Common etiologies and underlying conditions that predispose children to develop cardiopulmonary arrest are summarized in Table 263.2. Respiratory failure resulting in hypoxemia, hypercapnia, and acidosis is the most common pathway especially in the very young child.

The outcome of cardiopulmonary resuscitation (CPR) following cardiac arrest in children is very poor. Survival rate is between 5% and 12%. The reason for this poor outcome following cardiopulmonary arrest in children is multifactorial. In contrast to adults, children have a higher incidence of asystole as the predominant rhythm. In addition, cardiopulmonary arrests in the young child are often unwitnessed, and the initiation of resuscitation efforts may be delayed. Even under the best circumstances, resuscitation of a child who is pulseless and not breathing may not be possible, and the incidence of neurologically damaged survivors post-resuscitation is high. However, patient with witnessed respiratory arrest or sudden cardiac dysfunction can be easily resuscitated. Furthermore, children with respiratory arrest alone do far better when prompt resuscitation is provided, and most patients remain neurologically intact. Long-term survival in these children is between 42% and 82%.

Management

For optimal resuscitation outcome, early initiation of treatment, knowledge, technical skills, and practice in the resuscitation field is essential. Knowledge of age and/or weight-related cardiopulmonary data, and information on equipment size and emergency drugs as outlined in Pediatric Advance Life Support guidelines is required. Training courses in CPR, i.e., basic life support courses (BLS), are offered periodically to health professionals to overcome difficulties in retaining acquired knowledge and technical skills. Attendance at courses, such as Pediatric Advance Life Support (PALS) developed by the American Heart Association (AHA) and the American Academy of Pediatrics (AAP), should be required particularly for emergency department and pediatric intensive care staff, and as well for all health care givers involved in the care of children. PALS guidelines provide a structured and well-described approach to the assessment and treatment of children, and hence, facilitate providers to conduct rapid evaluation and timely intervention for life-threatening conditions.

With the initiation of CPR, a team leader must be identified to assume the responsibility during the resuscitation phase. This team leader is responsible for assigning specific tasks to team members, ensuring timely administration of drugs, and ordering appropriate procedures. The team leader is also responsible for setting limits for the duration of the resuscitation attempt.

The timely recognition of unstable infant or child is important. The health care provider should be able to diagnose and help prevent an impending arrest by a systematic rapid clinical assessment of the cardiopulmonary and neurologic function (Table 263.3), followed by a secondary and tertiary assessment to focus on medical history, laboratory, radiographic, and other advanced tests that help to clarify the child's status. Based on the assessment, the child is categorized as:

1. Stable
2. In compensated respiratory failure or shock
3. In respiratory failure or shock
4. In cardiopulmonary failure

Verifying unresponsiveness is by calling loudly the child's name and tapping the child. The first responder should call for help once unresponsiveness is established and activate immediately the emergency medical services (EMS) system and get an automated external defibrillator (AED) if the child is 1 year of age or older, while the second responder continues

with CPR. If only one health care provider is present, he should activate the EMS and get an AED before starting CPR; however, for lone lay responder it is acceptable to start first and continue with CPR for five cycles (about 2 min) before activating the EMS system and getting an AED. One cycle of CPR for the lone rescuer is 30 compressions and 2 breaths. One CPR cycle for two rescuers is 15 compressions and 2 breaths. In case of only one rescuer and if there is no trauma, rescuer may carry a small child to the telephone. The EMS

dispatcher can guide the rescuer through the steps of CPR. If trauma is suspect or present, the second rescuer may assist by stabilizing the child's cervical spine (see below) and supporting the head and body to minimize turning, bending, or twisting of the head and neck, if the child must be moved for safety reasons.

Managing the Airway

The primary goal of cardiopulmonary resuscitation is to restore spontaneous circulation. The first priority, however, is managing the airway effectively, which must be open and stable, regardless of the underlying cause. Accessing and securing the airway with sufficient ventilation may need only simple maneuvers including the head tilt and chin lift or jaw positioning in trauma patients (for health care providers only), suctioning, pharyngeal airways, and bag-mask ventilation or mouth-to-mouth ventilation in older children and mouth-to-mouth and nose in infants. Endotracheal intubation is performed when these simple maneuvers fail to maintain adequate ventilation. It should be appreciated that the airway of children is easily obstructed because of obstruction of the hypopharynx by the relative large tongue and the neck soft tissue.

If no trauma is suspected, place the head in a neutral position by using a slight head tilt and chin lift "sniffing position" (*Fig. 263.2*). Through a proper positioning, the airway will be in alignment and accessible. If trauma is present or suspected, the cervical spine must be protected. The head should be in a neutral position avoiding hyperextension of the neck. Opening the airway is done by using the jaw thrust maneuver (*Fig. 263.3*). Suction may be

Figure 263.2
Opening the airway with the head tilt-chin lift maneuver. One hand is used to tilt the head and extending the neck. The index finger of the rescuer's other hand lifts the mandible outward by lifting on the chin. Head tilt should not be performed if cervical spine injury is suspected

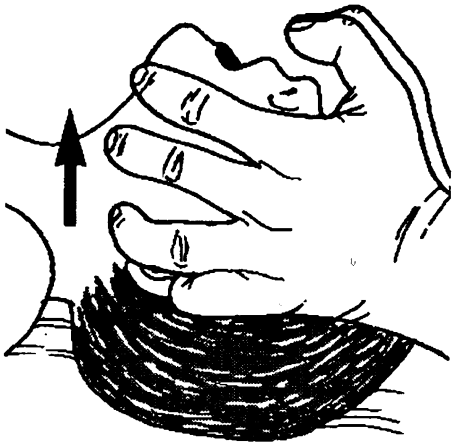

Figure 263.3
Opening the airway with the jaw thrust maneuver. The airway is opened by lifting the angle of the mandible. The rescuer uses two or three fingers of each hand to lift the jaw, while the remaining fingers guide the jaw upward and outward

needed to clean the airway of secretion, vomits, blood, and foreign bodies. If advanced airway management is provided and patient is intubated, checking for proper tube position especially when patient is moved and during transport is essential. Laryngeal mask airways are acceptable when used by experienced providers.

Resuscitation Maneuvers

After establishing unresponsiveness, calling for help, and getting an AED, two slow breaths are given while observing chest rise. If airway remains obstructed after proper repositioning and failure to obtain chest rise, a foreign body airway obstruction (FBAO) is suspected. To relieve a complete upper airway obstruction in a child, Heimlich maneuver (subdiaphragmatic abdominal thrusts) is recommended. This maneuver consists of quick upward abdominal thrusts delivered by placing the heel of the hand just above the umbilicus in the midline and covered by the other hand. The thrusts can be repeated until the FBAO is expelled. The recommendation for infants is to give four back blows, followed by four chest thrusts as indicated. In a hospital setting, removal of foreign objects with direct laryngoscopy using Magill's forceps may be more appropriate. If these procedures do not relieve obstruction and victim becomes unresponsive, endotracheal intubation is indicated. However, very rarely, endotracheal intubation fails to establish an effective airway. In such cases, a Transtracheal Catheter Ventilation to bypass the obstruction can be done by insertion of a 14–16 gauge intravenous cannula into the crycothyroid membrane. The adapter of a 3.0 mm endotracheal tube can be easily connected to the luer adapter of the catheter. This temporizing measure may support the application of oxygen and positive ventilation for a limited period of time and should only be performed by a properly trained health care provider.

Once patient is intubated and chest rise is observed, carotid pulses in older children or brachial pulses in infants are checked for no more than 10 s. If none is palpable, chest compressions deep enough (one-third to one-half the depth of the chest) to generate a pulse are begun with proper hand position and at a rate of 100/min (*Table 263.4*). The back of the patient is supported with the opposite hand or with a pediatric backboard. Chest compressions at a rate of 100/min and ventilation are to be performed simultaneously without pauses for ventilation. "Cycles" of CPR are no longer recommended. The rescuer should allow for complete chest recoil after a compression and minimize interruptions between compressions. The rescuer providing ventilation will deliver eight to ten breaths per minute at the same time. Chest compression effectiveness can be checked by palpating the brachial or femoral pulse. The cardiac output (CO), during chest compression, varies and depends on the effectiveness of the compression. CO during compression can reach between 20% and 80% of normal.

When these basic resuscitation maneuvers fail to restore circulation, advanced life support techniques are indicated. The patient should be attached to a cardiac monitor or paddles to observe the heart rhythm acting on abnormal rhythm in a timely and appropriate manner (see "Defibrillation"). A crucial step in resuscitation is the establishment of vascular access for administration of medications and fluids. The procedure should be done without interrupting CPR. If the approach to venous access (peripheral or central) is difficult and cannot be rapidly instituted, the intraosseous route should be used. The intraosseous or intramedullary infusion is recognized as effective for all resuscitative drugs and fluids in all ages. It is safe and simple. Meanwhile, for immediate drug

Table 263.4
Parameters for cardiopulmonary resuscitation in children

Age	Breathing rate	Compressions		Hand placement for compression
		Rate	Depth	
Neonates and infants	Initial two breaths at 1–1.5 s/breath than 20/min	100–120	0.5–1 in.	Two of three fingers at midsternum, one finger below nipple line, or two thumbs at midsternum with hands encircling chest. Ratio 15:2 (pause for ventilation)
1–7 years	Initial two breaths at 1–1.5 s/breath than 15–20/min	80–100	1–1.5 in.	Three fingers or heel of one hand, two fingers above xyphoid. Ratio 15:2 (pause for ventilation)
Over 7 years	Initial two breaths at 1–1.5 s/breath than 12/min	80–100	1.5–2 in.	Heel of both hands with body pressure, two fingers above xyphoid. Ratio 15:2 (pause for ventilation)

administration the endotracheal route can be used. The four resuscitative drugs acceptable for endotracheal administration are epinephrine, atropine, lidocaine, and naloxone. This in conjunction with the intraosseous route will allow early drug delivery while conventional intravenous access is sought. *Table 263.5* outlines the most important drugs used during resuscitation.

Resuscitation Drugs and Fluid

Resuscitative drugs and fluid are used to increase myocardial perfusion, contractility, pulse rate, and preload; decrease afterload; and correct hypoxemia and acidosis.

Oxygen

Effective airway management is essential for successful cardiopulmonary resuscitation. As respiratory failure is the most common cause leading to cardiac arrest in children, 100% oxygen should be given through a secured airway to prevent irreversible damage to vital organs (brain and heart).

Fluid

Fluid resuscitation in shock and circulatory collapse is essential, as shock can be the primary cause of

Table 263.5
Drug doses in pediatric cardiopulmonary resuscitation

Interventions	Dose	Route	Comment
Epinephrine for asystole or pulseless arrest (1:10,000 solution)	0.01 mg/kg (0.1 ml/kg)	IV, IO	Repeat every 3–5 min
Use (1:1,000 solution) for ET route	0.1 mg/kg (0.1 ml/kg)	ET	Repeat every 3–5 min
Epinephrine for bradycardia (1:10,000 solution)	0.01 mg/kg (0.1 ml/kg)	IV, IO	Same as above
Use (1:1,000 solution) for ET route	0.1 mg/kg (0.1 ml/kg)	ET	
Atropine sulfate 0.1 mg/ml	0.02 mg/kg	ET, IV, IO	Repeat every 5 min
			Minimum dose = 0.1 mg
			Maximum dose = 0.05 mg for infants and 1 mg for children
$NaHCO_3$ 8.4% solution 1 mEq/ml	0.5–1 mEq/kg	IV, IO	Use with caution and only after adequate ventilation
Glucose: D_{50} *W*. Mix D_{50} 1:1 with water or NS to get D_{25} W or D_{25} NS. Use D_{25} for children and $D_{12.5}$ for neonates	0.5–1.0 g/kg (1–2 ml/kg of $D_{12.5}$ for children $<$2 years)	IV, IO	Check Chemstix, give for value $\leq$ 45 mg/dl. Avoid IO administration if possible
Amiodarone 50 mg/ml, 15 mg/ml	5 mg/kg over 20–60 min (maximum 300 mg)	IV, IO	Repeat to maximum daily dose 15 mg/kg (2.2 g in adolescent)
Lidocaine HCL 10 mg/ml	1 mg/kg	ET, IV, IO	Repeat 1 mg/kg $\times$3, every 8 min then follow bolus with infusion at 20–50 mcg/kg/min
	2–3 mg/kg if given via ET route		
Calcium chloride or gluconate	5–7 mg elemental calcium	IV	Only with hypocalcemia
Naloxone 0.4 mg/ml and 1 mg/ml	0.4–2 mg (children)	ET, IV, IO	Pure opiate antagonist
	0.4 mg (neonates)		
Epinephrine infusion	Initial at 0.1 mcg/km/min	IV	Titrate to desired effect (0.1–1.0 mcg/kg/min)
Dopamine infusion	2–20 mcg/kg/min	IV	Titrate to desired effect
			Alpha adrenergic effect at dose $>$15 mcg/kg/min
Doputamine infusion	2–20 mcg/kg/min	IV	Titrate to desired effect

cardiopulmonary arrest. Initially, a bolus of 20 ml/kg of isotonic crystalloid or lactated Ringer's should be used and given over 10–15 min. In trauma patient blood transfusion may be indicated. Subsequent boluses up to 60 ml/kg and more may be needed in circulatory collapse.

Epinephrine

Epinephrine is the drug of choice and is indicated in all pediatric cardiac arrest setting when basic life support does not restore circulation. Restoration of circulation is attributed to the epinephrine action as it stimulates spontaneous cardiac contraction in asystole, in addition to the vigorous CPR and sufficient fluid resuscitation. During the administration of epinephrine, the alpha-adrenergic action of epinephrine will result in peripheral vasoconstriction and, subsequently, increase in both the systemic vascular resistance (SVR) and blood pressure leading to improvement in the coronary perfusion. An increase in the myocardial contractility and heart rate results from the beta-adrenergic action of epinephrine. The increase in SVR and arterial blood pressure during CPR will also improve the cerebral perfusion pressure.

Epinephrine can be given IV, IO and through the endotracheal tube; however, the dose varies depending on the route of administration. The preferred route for epinephrine administration is IV or IO. The recommended initial dose for symptomatic bradycardia and cardiac arrest (pulseless) is 0.01 mg/kg (0.1 ml/kg of the 1:10,000 solution), which is to be given through the intravenous or intraosseous route. Additional doses of epinephrine should be given every 3–5 min, if restoration of circulation did not occur. High dose of epinephrine in pediatric cardiopulmonary arrest is no longer recommended. The recommended endotracheal epinephrine dose is 0.1 mg/kg (0.1 ml/kg of the 1:1,000 solution). To reach an optimal endotracheal drug delivery, epinephrine should be diluted in 3–5 ml normal saline (NS) and instilled into the endotracheal tube through a suction catheter beyond the distal tip of the endotracheal tube and flushed afterward with 3–5 ml NS. It should be kept in mind that the use of two different dilutions of epinephrine can lead to possible errors in concentration selection and dosage.

Atropine

Atropine, a parasympatholytic drug, increases the heart rate. The resulted tachycardia post-atropine administration is usually well tolerated in pediatric patients. It can be administrated through the endotracheal route, IV, and IO. Atropine is effective in an unstable child with bradycardia and in bradyarrhythmia associated with second and/or third degree heart block, and also to block the vagal-induced bradycardia that may occur during suctioning and intubation maneuvers. Its usefulness in asystole is questionable.

Bradycardia (heart rate < 60/min) with hypoperfusion in children must be treated as cardiac output in neonates, infants, and small children is mainly heart rate dependent. Reasons for bradycardia should be sorted out and treated vigorously (hypoxia, hypothermia, hypoglycemia, acidosis, hypotension, and heart block). Epinephrine is more effective in the treatment of bradycardia with hypoperfusion and/or hypotension; however, for blocking vagal-induced bradycardia atropine is the drug of choice.

Atropine dose is 0.02 mg/kg administrated through intravenous and/or intraosseous route. For the endotracheal administration the dose is 0.03 mg/kg, which should be diluted in 3–5 ml NS, instilled into the endotracheal tube through a suction catheter beyond the distal tip of the endotracheal tube, and flushed afterward with 3–5 ml NS. Subsequent doses can be given every 5 min to a maximum of 0.5 mg in infants and 1.0 mg in children. It should be realized that most often bradycardia results from hypoxia, and treatment should initially be directed at ventilation and oxygenation.

Sodium Bicarbonate

Sodium bicarbonate has been used in cardiac arrest to treat acidosis. Severe acidosis (pH < 7.2) has many adverse effects on the cardiovascular function, and treatment of both metabolic and respiratory acidosis is essential. However, it is important to understand that the frequent observed combined respiratory and metabolic acidosis during cardiorespiratory arrest arise from the hypoxia-induced anaerobic metabolism and the respiratory failure. The most effective way to correct the acidosis (metabolic and respiratory) can be often achieved by providing adequate oxygenation, ventilation (decrease $PaCO_2$), fluid resuscitation, and epinephrine treatment to improve tissue perfusion. Increasing the epinephrine dose may counteract some of the effects of acidosis on the cardiovascular function.

There are numerous important side effects of sodium bicarbonate. Hypercapnia (increased PCO_2), which may worsen intracellular acidosis, and myocardial depression are some of the side effects of inappropriate bicarbonate use. For this reason, current recommendation from the

AHA suggests to consider the use of bicarbonate during CPR, only if severe metabolic acidosis is present in association with prolonged cardiac arrest. However, bicarbonate may be life-saving in unstable hemodynamic state (pre-arrest state), hyperkalemia, hypermagnesemia, and intoxication from tricyclic antidepressant or from other sodium channel blocking agents. If cardiac arrest continues after the airway is secured and adequate ventilation is provided, chest compression and epinephrine administration is accomplished. 1 mEq/kg of sodium bicarbonate can be given only through the intravenous or intraosseous route. Additional doses can be given if indicated after obtaining an arterial blood gas and after restoring circulation. If blood gases are not available or unreliable subsequent doses of 0.5 mEq/kg can be given over 1–2 min for every 10 min.

In cases of respiratory arrest, the encountered acidosis is mainly caused by respiratory failure leading to combined metabolic and respiratory acidosis and resolves with adequate ventilation and fluid resuscitation. Sodium bicarbonate in such cases is unnecessary and should be avoided. If sodium bicarbonate is excessively used, metabolic alkalosis may occur with adverse effects (e.g., Hypokalemia, decreased ionized calcium and shift of the oxy-hemoglobin dissociation curve to the left causing reduced oxygen delivery to the tissue). Other adverse effects of sodium bicarbonate are hypernatremia and hyperosmolarity. In general, the routine use of sodium bicarbonate remains controversial due to lack of convincing evidence of benefits and the presence of potential adverse effects.

Calcium

Calcium should not be used during resuscitation. There are very specific indications for the use of calcium during CPR, which are:

- Documented hypocalcemia
- Hyperkalemia
- Hypermagnesemia
- Calcium channel blocker overdose

The current recommended dose for calcium is 5–7 mg/kg elemental calcium. Subsequent doses should be given only if hypocalcemia (low serum ionized calcium level) persists.

Glucose

Hypoglycemia may occur during cardiopulmonary arrest of any etiology, particularly in neonates, infants, and small children. Any disease exposing this age group to extraordinary stress can lead to significant hypoglycemia; hence, checking for glucose level in any stressed young patient is essential to rule in or exclude the presence of hypoglycemia. This is more important in cardiopulmonary arrest, as energy resources are quickly depleted in young children due to increased loses (diarrhea and vomiting) or decreased intake prior to arrest. Once hypoglycemia is manifest, prompt treatment with glucose is essential. Hypoglycemia can imitate the signs and symptoms of patients in shock (tachycardia, poor perfusion, altered mental status, and hypotension); therefore, rapid bedside glucose test should be done in all neonates, infants, and small children who are critically unstable. The consequences of late recognition and/or late treatment of hypoglycemia can lead to brain damage and worsen the overall neurological outcome of patients surviving cardiopulmonary arrest. However, glucose should not be administrated routinely during pediatric cardiopulmonary resuscitation unless hypoglycemia is present, which is more common in neonates and small infants as mentioned before. The controversy in the routine use of glucose is based on the detrimental effects on the brain caused by hyperglycemia. If hypoglycemia is documented (i.e. rapid bedside glucose test), glucose administration of 0.5–1.0 g/kg should be given, diluted to a concentration of 25% for children and 12.5% for neonates (*Table 263.5*).

Complications of Resuscitation

Failure to restore spontaneous circulation after initiating appropriate advance life support (endotracheal intubation, adequate ventilation, oxygenation with 100% oxygen, cardiac compression, and standard administration of epinephrine), the patient's condition should be reassessed for complications. The first priority is to check the patency of the airway and the adequacy of the ventilation. Major problems include endotracheal tube obstruction with mucous plug, tube displacement (intubation of the esophagus or right mainstem bronchus), and tension pneumothorax. Confirmation of tube placement in the presence of a perfusing rhythm can be assessed by checking exhaled carbon dioxide (CO_2), and the placement of an esophageal detector device for children weighing >20 kg may be considered. In addition, adequate chest rise and good breath sounds will most likely eliminate esophageal intubation and endotracheal tube obstruction. Correct placement must be verified during transportation and whenever patient is moved. On the other hand, infants and small children assessment may be difficult, and direct laryngoscopy may be necessary to confirm proper intubation. However, if there is no improvement, a needle

thoracocentesis of both chest sides is indicated to rule out tension pneumothorax. *Table 263.6* shows the most important standard interventions during CPR in sequence. Circulatory complications including cardiac tamponade, fine ventricular fibrillation, and pulseless electrical activity (PEA) can occur and constitute a challenge during CPR. If there is still no improvement after a rapid and thorough reassessment of the airway patency and rhythm, a needle pericardiocentesis can exclude cardiac tamponade as a cause for lack of spontaneous circulation. Possible contributing factors during arrest that needs to be considered and treated are:

- Hypovolemia
- Hypoxia
- Hydrogen ion (acidosis)
- Hypokalemia/hyperkalemia
- Hypoglycemia
- Hypothermia
- Toxins
- Tension pneumothorax
- Trauma
- Tamponade, cardiac
- Thrombosis (coronary or pulmonary)

These can be remembered as the H's and T's of Pulseless Arrest.

Defibrillation

Defibrillation (asynchronous delivery of energy, i.e., the shock is delivered randomly during the cardiac cycle) and cardioversion (delivery of energy that is synchronized to the QRS complex) are methods of delivering electrical energy to the heart through the chest wall, in an attempt to restore the heart's normal rhythm. Defibrillation and cardioversion may be accomplished manually, which requires users to recognize the dysrhythmia and preselect the energy to be delivered. Automated external defibrillators (AEDs) are computerized machines that automatically diagnose ventricular fibrillation (VF) or pulseless ventricular tachycardia (VT) and use voice prompts to instruct rescuers to defibrillate. The ease of use and reliability increased their popularity among health care givers. It can be used in children over 1 year of age according to the AHA and international guidelines.

The majorities of children with cardiopulmonary arrest are out-of-hospital arrests and are apneic and pulseless on arrival to the emergency department (ED). Respiratory failure and subsequently arrest is the leading cause for asystole cardiac arrest, which is not to be treated with defibrillation. However, recent studies have shown an increased incident of VF as the primary pathological rhythm in children 8 years of age and above with an incident

Table 263.6
Standard interventions in advanced life support

Airway	Breathing	Circulation
Head tilt	Mouth-to-mouth	Chest compressions

Needle cricothyroidotomy		Chronotropic agents
		Dromotropic agents
		Afterload modulator
		Acid-base buffers
		Calcium-potassium balance
		Cardioversion-defibrillation
		Pericardiocentesis

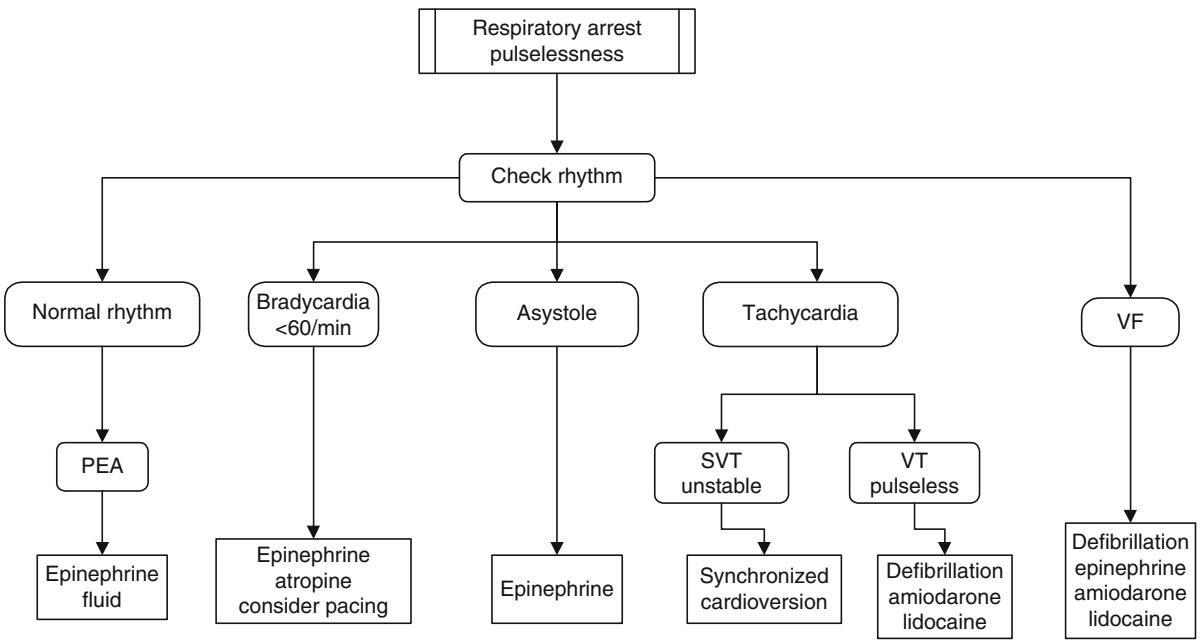
around 27%. VF and/or ventricular tachycardia (VT) are less common in infants and younger children below the age of 8 years. The fact that these new observations indicate that children who had out-of-hospital arrests can experience VF and their survival is better than those with asystole (35% vs 11%) once approached with early defibrillation mandates clinicians caring for children to be well skilled in the methods of counter-shock delivery.

VF and pulseless VT are mostly observed in children with complex congenital heart disease, submersion victims, and in children arresting in the hospital. Conditions that predispose to VF include ischemia, hypoxia, hypothermia, acidosis, and electrolyte imbalances. Defibrillation is the definitive treatment for VF and pulseless VT to reinstate normal cardiac depolarization and contraction, but is inappropriate for asystole (*Fig. 263.4*). If the problem is a fine ventricular fibrillation that is resistant to defibrillation, the use of epinephrine may convert the pattern from fine to coarse that is more responsive for defibrillation. It is, however, important to obtain a second lead to ensure that rhythm is a fine VF, rather than asystole.

Since the routine uses of the biphasic defibrillators have replaced the old monophasic defibrillators, three stacked shocks in rapid sequence are no longer recommended. Instead, one shock will be delivered as newer generation biphasic defibrillators have a first-shock efficacy around 90%. In the event of failure after the first-shock, subsequent shocks in rapid sequence are also likely to fail and in this setting CPR should follow for at least 2 min prior to a second defibrillation attempt. Coordination of shock delivery and chest compressions according to the AHA guidelines recommend that patients who experience unwitnessed arrest should undergo five cycles or 2 min of CPR prior to attempted defibrillation.

For defibrillation, the current recommendation suggests an initial energy dose of 2 J/kg and the subsequent doses of 4 J/kg using the proper paddles or electrode pads (size 4.5 cm for infants and 8–13 cm for older children) with a good electrode interface (i.e., electrode cream). The paddles or electrodes are placed on the chest so that an adequate portion of the delivered shock passes through the myocardium. The anterior/apex position is preferred and for infants the anterior/posterior position to avoid pads contacting each other.

Defibrillation dose is 2 J/kg for the first attempt. If VF or VT without pulse continues after defibrillation, a second attempt with 4 J/kg is made after 2 min of continuous CPR. Subsequent attempts with 4 J/kg remain the standard defibrillation dose for children with VF and pulseless VT.



PEA = Pulseless electrical activity, SVT = supraventricular tachycardia, VF = ventricular febrilation, VT = ventricular tachcardia

Figure 263.4
Algorithm for drugs and defibrillation during CPR

Hence, in the case that VF or pulseless VT persists, a third attempt should be performed with the same energy. CPR should be continued between and after these attempts. If ventricular fibrillationVF or pulseless ventricular tachycardia persists or occurs frequently in the absence or nonavailability of amiodarone, the use of lidocaine may help. Cardiac rhythms that should not be treated with electrical current include sinus rhythm, stable supraventricular tachycardia (SVT), asystole, pulseless electrical activity, and bradycardia.

Cardioversion is the treatment of choice in unstable patients with organized cardiac rhythms such as SVT, which constitutes the most common pediatric arrhythmia requiring cardioversion. Other less frequent rhythms requiring cardioversion are atrial fibrillation, atrial flutter, or ventricular tachycardia with palpable pulse. The dose of synchronized cardioversion for the first attempt is 0.5–1 J/kg and the subsequent doses are 2 J/kg.

264 Shock Syndrome

Abdul-Rahman M. Abu-Taleb

Introduction

The clinical syndrome of shock is one of the most dramatic, progressive, and life-threatening conditions faced by the medical staff in the pediatric critical care setting.

Shock is a condition of sustained and progressive circulatory dysfunction that results in tissue hypoperfusion and inadequate delivery of oxygen and substrates to meet tissue metabolic demands. The status of anaerobic metabolism generates less intracellular adenosine triphosphate (ATP) to meet cell requirements, resulting in accumulation of lactic acid. This acute energy failure will lead to generalized cellular hypoxia and derangement of critical biochemical processes including the delay in removal of the end products of metabolic processes. Once these abnormalities become irreversible it will subsequently result in cell death. Shock may be the end result of many different diseases or injuries. If shock is not early recognized and treated adequately, multiorgan failure (MOF) and death can be the outcome (shock is the final common pathway to death). It accounts for more morbidity and mortality in children worldwide than any other diagnosis; dehydration and hypovolemic shock alone result in more than two million deaths in infants and children worldwide. Mortality rate in children with sepsis is still around 10%. Morbidity may be widespread and can include renal failure, brain damage, gut ischemia, hepatic failure, metabolic derangements, diffuse intravascular coagulation (DIC), acute respiratory distress syndrome (ARDS), and cardiac failure.

Inadequate tissue perfusion and decreased oxygen delivery can result from either limitation or maldistribution of blood flow, which can be the result of failure of one or more of three components of the intact circulation:

1. An adequate circulating blood volume to maintain proper preload status. In the event of hemorrhagic hypovolemia, oxygen carrying capacity is inadequate as well as the preload, resulting in the manifestation of shock.
2. The heart as a pump to generate enough flow to meet the body's variable demands at rest and during stress. Once cardiovascular compromise occurs various compensatory mechanisms drive preload, cardiac contractility, and afterload to interact to improve stroke volume (SV) and cardiac output (CO). However, SV in neonates and infants is relatively fixed. The response to improve cardiac output in this group during hypoperfusion is in an increase in heart rate (tachycardia) rather than an increase in SV. Hence, newborns and infants are particularly dependent upon heart rate to increase their cardiac output.
3. The vascular system as a network of arteries and veins that is able to expand and constrict in order to regulate the flow of blood to various organs and body compartments. By an increase of the systemic vascular resistance (SVR) the perfusion pressure for vital organs (brain, heart) will be maintained in the event of a decrease in cardiac output.

The limitation or maldistribution of blood flow will lead to inadequate tissue perfusion and oxygen delivery leading to the clinical manifestation of shock. The effects of inadequate tissue perfusion and poor oxygen delivery are initially reversible if early goal-directed therapeutic interventions are initiated to reverse the poor tissue perfusion and improve oxygen delivery. However, because of the dynamic and progressive nature of shock, three clinical phases of shock can be identified, which are:

1. *Compensated phase*: A cascade of intrinsic compensatory mechanisms is activated in this phase and patient is presented with early signs of shock (compensated shock). The difficulty to recognize the early stage of shock is explained by the great ability of children to compensate thus, making the diagnosis in this phase very challenging. In the compensated phase, perfusion of vital organs (brain, heart) is maintained by the same intrinsic compensatory mechanisms. Blood pressure at this stage is still within normal range.
2. *Uncompensated phase*: With failure to provide adequate treatment, the patient's intrinsic compensatory mechanism fails and becomes hypotensive (hypotensive shock). In this phase, signs of end organ hypoperfusion are obvious such as altered mental status, oliguria or

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_264,

anuria, prolonged capillary refill >2 sec., hypoxia, and hypotension. From this point onwards progression to cardiovascular collapse and subsequently cardiac arrest is only a matter of minutes if aggressive therapeutic intervention is not rapidly applied.

3. *Irreversible phase*: Irreversible shock occurs when significant damage to vital organs is present. At this stage cellular metabolism is no longer able to generate enough energy to sustain cell viability. In many cases with irreversible shock states multiorgan failure will occur and mortality is high.

Children have the ability to compensate very well at the early stage of shock regardless of the cause. Therefore, it is difficult to recognize that the patient is in shock at this stage. However, early diagnosis and treatment of compensated stage of shock is crucial to prevent a catastrophic outcome. In the early stage, most shock forms are similar in their presentation (tachycardia, prolonged capillary refill and irritability) and compensatory mechanisms (increase in heart rate, cardiac contractility, SVR and venous tone). The initial management for all shock forms is in providing adequate oxygenation (100% oxygen) through secured airway and stabilizing the hemodynamic condition (fluid resuscitation, use of inotropes and vasopressors). This initial management is time sensitive and should happen within the first hour of arriving in the hospital. The process is described as early goal-directed therapy for shock and refers to the rapid initiation of aggressive systematic approach to resuscitation regardless of the etiology. During the initial stabilization process, clues to the exact cause or causes of shock must be diagnosed so that subsequent appropriate therapy can take place. The presence of more than one cause for shock in a critically ill patient can constitute a challenge to the care givers during the initial presentation. As an example a child with suspected septic shock can also have significant hypovolemia and cardiac depression. This frequent scenario of overlapping shock forms should be considered and needs early and careful diagnosis of causes for proper therapeutic measures.

Shock Forms

Several etiologic classifications of shock are recognized (◉ *Table 264.1*). The major categories are as follows:

1. Hypovolemic – fall in intravascular volume
2. Cardiogenic – fall in cardiac output
3. Distributive/Vasogenic (most often due to sepsis) – fall in systemic vascular resistance

Hypovolemic Shock

Hypovolemic shock is the most common type of shock encountered in the pediatric population. It is caused by acute decrease in intravascular volume relative to the vascular capacity. The reduction in the intravascular volume is such that ventricular filling (preload) is insufficient and effective tissue perfusion cannot be maintained. In general, previously healthy children can compensate for acute hypovolemia if volume loss does not exceed 15–20% by activating a chain of endogenous (adrenergic) compensatory mechanisms. These compensatory mechanisms will increase the cardiac output by increasing the heart rate, SVR and cardiac contractility to maintain normal blood pressure. Consequently it will result in a redistribution of blood flow from peripheral structures (skin, muscle, kidneys, and splanchnic organs) to the vital organs, heart and brain. At this stage, preserving adequate tissue perfusion to the rest of the body may not be achieved and as a result signs of hypoperfusion will manifest such as prolonged capillary refill >2 sec., cool extremities and low urine output. However, if volume loss exceeds 30%, hypovolemic shock will result in the development of hypotension, cardiovascular collapse, and cardiac arrest. Time to progress from compensated to uncompensated status may take hours; however, it takes only minutes to cardiovascular collapse and subsequent cardiac arrest if shock progresses to uncompensated status. Therefore, delayed or under diagnosed severe dehydration can lead to significant morbidity and mortality. Dehydration and hypovolemic shock result in more than two million deaths annually in infants and children worldwide. In the United States, fluid and electrolyte imbalances from acute gastroenteritis result in 1.5 million outpatient visits, 200,000 hospitalizations, and 300 deaths/year. Severely dehydrated children may have increased morbidity such as protracted vomiting, electrolytes disturbances (e.g., hypernatremia, hyponatremia, and hypoglycemia), metabolic acidosis, and acute renal failure leading to hypovolemic shock within few hours. The common infectious etiologies for gastroenteritis include bacterial causes such as *Salmonella, Shigella, Campylobacter* species, and *Escherichia coli,* and viral causes, such as rotaviruses, adenoviruses, norovirus, and enteroviruses.

Trauma is a leading cause of mortality in older children (>1 year) and acute hemorrhage is a major component leading to death in traumatic children. Rapid loss of intravascular volume will reduce ventricular preload, resulting in decreased stroke volume, cardiac output, and oxygen delivery (DO_2). To prevent cardiovascular collapse, hemorrhagic shock must be quickly identified

Table 264.1
Shock forms and etiologies

Hypovolemic shock	Cardiogenic shock	Distributive/vasogenic shock
1- Blood loss:	1- Cardiomyopathy:	1- Septic shock
- Trauma (external and internal)	- Myo-, peri-, and endocarditis	2- Anaphylactic shock
- Fractures	- Hypoxia	3- Neurogenic shock
- GI-bleeding, intraabdominal	- Ischemia	4- Intoxication (i.e., barbiturate)
- ICH (neonates: IVH/ICH)	- Acidosis	
- Surgery	- Hypoglycemia	
2- Water loss:	- Hypothermia	
- Vomiting	2- Dysrhythmia:	
- Diarrhea	- Bradycardia	
- Diabetic ketoacidosis (DKA)	- AV block	
- Diabetes insipidus (DI)	- SVT	
- Heat stroke	- VT	
- Adrenal insufficiency	3- Congenital heart disease	
3- Plasma loss:	- Aortic stenosis	
- Trauma	- Coarctation	
- Burns	- Severe pulmonary stenosis	
- Hypoproteinemia (i.e., Nephrotic syndrome)	- Left heart hypoplasia	
- Capillary leak (i.e., Sepsis, anaphylaxis)	4- Pneumothorax	
- Third spacing (i.e., Peritonitis, intestinal obstruction)	5- Tamponade	
	6- Pulmonary embolus	
	7- Drug intoxication	

GI gastrointestinal, *ICH* intracranial hemorrhage, *IVH* intraventricular hemorrhage, *DI* diabetes insipidus, *SVT* supraventricular tachycardia, *VT* ventricular tachycardia

and treated (see *Table 264.2* Classification of hemorrhagic shock). Less frequent are the nontraumatic bleeding such as gastrointestinal hemorrhage, acute intraventricular hemorrhage of the newborn, and postoperative hemorrhage. Sequestration crises in sickle cell anemia can occasionally lead to acute hypovolemic shock. Other causes of hypovolemic shock include capillary leak (i.e., sepsis) and tissue third spacing (i.e., peritonitis) where patients are intravascular volume depleted in spite of their edematous appearance (see *Table 264.1*).

On physical examination, the most helpful signs for detecting dehydration (intravascular and interstitial depletion) in children regardless of etiologies are prolonged capillary refill >2 sec., absence of tears, abnormal skin turgor, degree of sunken eyes, mucous membrane dryness, degree of depressed (sunken) anterior fontanel abnormal respiratory pattern, altered mental status, and general appearance. *Table 264.3* shows the clinical signs and symptoms of volume loss in infants and children according to the severity of hypovolemia.

Cardiogenic Shock

Cardiogenic shock results from cardiac dysfunction (pump failure) manifested as impaired myocardial contractility and dysrhythmias leading to poor cardiac output and high SVR. When heart failure is present, neurohumoral vasoactive mechanisms are activated resulting in increasing systemic vascular resistance. Increasing SVR (afterload) increases the work load on the left ventricle and decreases cardiac output, worsening the cardiogenic shock. Proper use of inotropes and reduction of the afterload are necessary to treat progressive heart failure and stop the vicious cycle. Reasons leading to cardiogenic shock are:

1. Decrease in the preload mainly as a result of obstruction to venous return such as tension peumothorax and cardiac tamponade
2. Congenital heart defects with left ventricle outflow obstruction leading to an increase in afterload

Table 264.2
Classification of hemorrhagic shock

	Class I (very mild)	Class II (mild)	Class III (moderate)	Class IV (severe)
Percent blood volume loss	<15%	15–30%	30–40%	>40%
Heart rate	Normal	Slightly	Moderately increased	Markedly increased
Respiratory rate	Normal	Slightly increased	Moderately increased	Markedly increased, markedly decreased, or absent
Blood pressure	Normal or slightly increased	Normal or slightly decreased	Decreased	Decreased
Pulses	Normal	Normal or decreased peripheral	Weak or absent peripheral	Absent peripheral, weak or absent central
Skin	Warm and pink	Cool extremities, mottled	Cool mottling extremities, or pallor	Cold extremities with pallor or cyanosis
Capillary refill	Normal	Prolonged	Markedly prolonged	Markedly prolonged
Mental status	Slightly anxious	Mildly anxious, confused, combative	Very anxious, confused, or lethargic	Very confused, lethargic, or comatose
Urine output	Normal	Slightly decreased	Moderately decreased	Markedly decreased or anuria

Data from: Hazinski, MF, Barkin, RM. Shock. In: Pediatric emergency medicine: Concepts and clinical practice, Barkin, RM (Ed), Mosby-Yearbook Inc, St. Louis, MO 1997. p. 118; and Waltzman, ML, Mooney, DP. Major trauma. Table 264.3
Clinical signs and symptoms of hypovolemia in children

Clinical signs	Mild 5–7%	Moderate 8–10%	Severe >10%
Skin color	Pale	Gray	Mottled
Perfusion of extremities	Warm to hands/feet	Warm to elbow/knee	Cool throughout
Capillary refill time	1–3 sec	3–5 sec	Over 5 sec
Heart rate	Normal	↑	↑↑
Respiratory rate	Normal	Normal	↑
Pulses	Normal	Distal weak or absent	Proximal weak or absent
Skin turgor	↓	↓↓	Tenting
Eyes	Normal	Sunken	Markedly sunken
Mucous membranes	Dry	Very dry	Cracked
Fontanel	Flat	Depressed	Sunken
Blood pressure	Normal	Normal	↓
Mental status	Normal	Lethargic	Lethargic to coma
Urine output	↓	↓↓	Anuric

3. Poor myocardial contractility resulting mainly from cardiomyopathies of different etiologies

On the other hand, cardiogenic shock during infancy and childhood may represent clinically a diagnostic and therapeutic challenge for several reasons, including:

1. Some of the signs and symptoms of cardiogenic shock are similar to those of hypovolemic shock, for example, poor perfusion (prolonged capillary refill), cool extremities, increased heart rate, altered mental status, and decreased urine output.

2. Cardiac failure can occur in patients with shock that is not primarily due to a myocardial insult.
3. Myocardial dysfunction is frequently a late manifestation of shock of any etiology.

Table 264.4
Reasons leading to cardiogenic shock

Decrease in preload
Obstruction to venous return
Tension pneumothorax
Hemopericardium
Pneumopericardium
Pericardial effusion
Increase in afterload
Obstructive congenital HD
Increase in PVR (i.e., massive pulmonary embolism)
Increase in SVR (i.e., late stage of sepsis)
Decrease in myocardial contractility
Cardiomyopathy due to
Myocarditis
Pericarditis
Endocarditis
Hypoxia
Ischemia
Acidosis (pH $<$ 7.2)
Hypoglycemia
Hypocalcemia
Hypothermia

History of congenital heart disease (CHD), signs of heart failure, and worsening of clinical condition during aggressive fluid management should be immediately linked to a cardiogenic etiology, particularly in those patients without readily apparent cause for shock. Since treatment of this condition depends on restoring and improving pump function, continuing with aggressive fluid administration may cause rapid deterioration. In volume depleted patients with cardiogenic shock, fluid should be administered slowly and given in boluses of 5–10 ml/kg. Reasons for cardiogenic shock apart from CHD are, for example, cardiomyopathies, acute myocarditis, subacute bacterial endocarditis, and drug intoxication (*Table 264.4*).

Cardinal signs of cardiogenic shock include the presence of gallop rhythm, respiratory distress, hepatomegaly, cardiomegaly, and pulmonary venous congestion seen on the chest radiography (*Table 264.5*).

Distributive Shock

Distributive shock is a condition that occurs when inappropriate distribution of blood flow and increased capillary permeability are present. Septic shock is the best example of this form of shock. Timely recognition and treatment of pediatric septic shock improves outcome and saves lives. The early recognition of tachycardia, bounding pulses, prolonged capillary refill $>$2 s, hypoxia, and hypotension on arrival to the hospital sets out a time-sensitive goal-directed treatment approach starting by providing adequate oxygenation (100%), followed by establishing emergency vascular access to enable a goal-directed stepwise administration of fluid and to start infusion of dopamine (can be given through peripheral lines or

Table 264.5
Historical information and clinical signs in different shock forms

	Hypovolemic shock	Cardiogenic shock	Distributive shock
History:	Trauma, vomiting and/or diarrhea	CHD, cardiac surgery, poor feeding, and respiratory distress	Fever, lethargic, poor skin color, and irritability
Clinical signs:			
Heart rate	Increased	Increased	Increased
Chest x-ray			
1- Heart size	Small	Large	Small
2- Lungs	Clear	Wet	Clear (in the early stage)
Gallop rhythm	Not present	Present	Not present
Capillary refill time	Prolonged	Prolonged	Normal (in the early stage)

intraosseous access until central line is established) and epinephrine for reversal of shock within the first hour of arriving in the emergency department. Lastly broad-spectrum antibiotics should be also given within the first hour of arrival to the hospital.

Clinical Recognition of Shock State, Assessment and Monitoring

Survival from shock requires early diagnosis and treatment. Once decompensation and significant hypotension develop, the risk of death is high. Usually (past and present medical) history taken from the parents, and the clinical evaluations taken by the medical team caring for the child prior to admission to the pediatric intensive care unit will facilitate early etiologic classification of shock, and help in directing appropriate treatment (i.e., history of vomiting and diarrhea suggest hypovolemia; history of fever, lethargy, and poor skin color suggest sepsis; history of CHD with poor feeding and respiratory distress suggest heart failure). The clinical presentation of shock, in general, has the following common findings:

- Tachycardia: This is one of the important early indicators of shock. Benign causes of tachycardia are very common (fever, pain, and anxiety) and needs to be ruled-out, particularly at the early stage of shock where most signs and symptoms of shock are not yet very clear.
- Tachypnea: This is most likely to compensate for metabolic acidosis. However, in progressive and advanced stage of shock tachypnea fail to compensate metabolic acidosis.
- Poor skin perfusion: This is present in the form of prolonged capillary refill time >2 s, cool extremities, pale, clammy and mottled skin. Skin hypoperfusion is caused by vasoconstriction to spare the flow and redirect it to vital organs (brain, heart).
- Hypoxia: If shock continues to progress, patient will become hypoxic (O_2 saturation < 95%) requiring oxygen supplement.
- Oliguria: Shunting the renal circulation to the vital organs will lead to renal hypoperfusion resulting in oliguria and anuria in severe shock.
- Hypoglycemia: Hypoglycemia can present in shock particularly in newborns and infants, and requires prompt recognition and treatment.
- Impaired mental status: In compensated shock, normal mental status indicates preserved brain perfusion; however, in deep shock hypoperfusion of the brain is present and altered mental status is apparent.
- Metabolic acidosis: As an outcome of energy failure during shock lactic acid accumulates as cells switch to anaerobic metabolism resulting in metabolic acidosis.
- Hypotension: Hypotension occurs once shock progresses to uncompensated phase. It is a very late and ominous finding. Blood pressure below the 5th percentile for age is defined as hypotension as follows:

Age	Minimum systolic blood pressure (5thpercentile)
– 0–1 month	60 mmHg
– >1 month to 1 year	70 mmHg
– 1–10 years of age	70 mmHg + (2 x age in years)
>10 years of age	90 mmHg

It cannot be overemphasized that the most effective and sensitive physiological monitoring available is the repeated and careful examination of the child's physical status by a competent observer. *Tables 264.5* gives a summary of historical and clinical signs that will help in differentiating shock forms. *Table 264.8* shows the lower values (5th percentile) for heart rate, leukocyte count, and systolic pressure and the upper values (95th percentile) for heart rate, respiration rate, and leukocyte count.

Treatment of Shock States

When confronted with a child in shock, etiology can often be determined from the history and physical examination as discussed earlier. Specific treatment of shock conditions follows as any disease process resuscitation and stabilization. Immediate priorities include establishment of patent airway, administration of 100% oxygen, and establishing IV access (*Fig. 264.1*). This initial management has to be goal directed as mentioned earlier; it is time sensitive and should happen within the first hour of arriving in the emergency department. The American Heart Association recommends quick establishment of intraosseous access in children of any age if peripheral intravenous access is not rapidly obtained.

Hypovolemic Shock

Identification of life-threatening conditions and rapid management is crucial in hypovolemic children. Securing the airway, oxygen supplement and stabilizing the

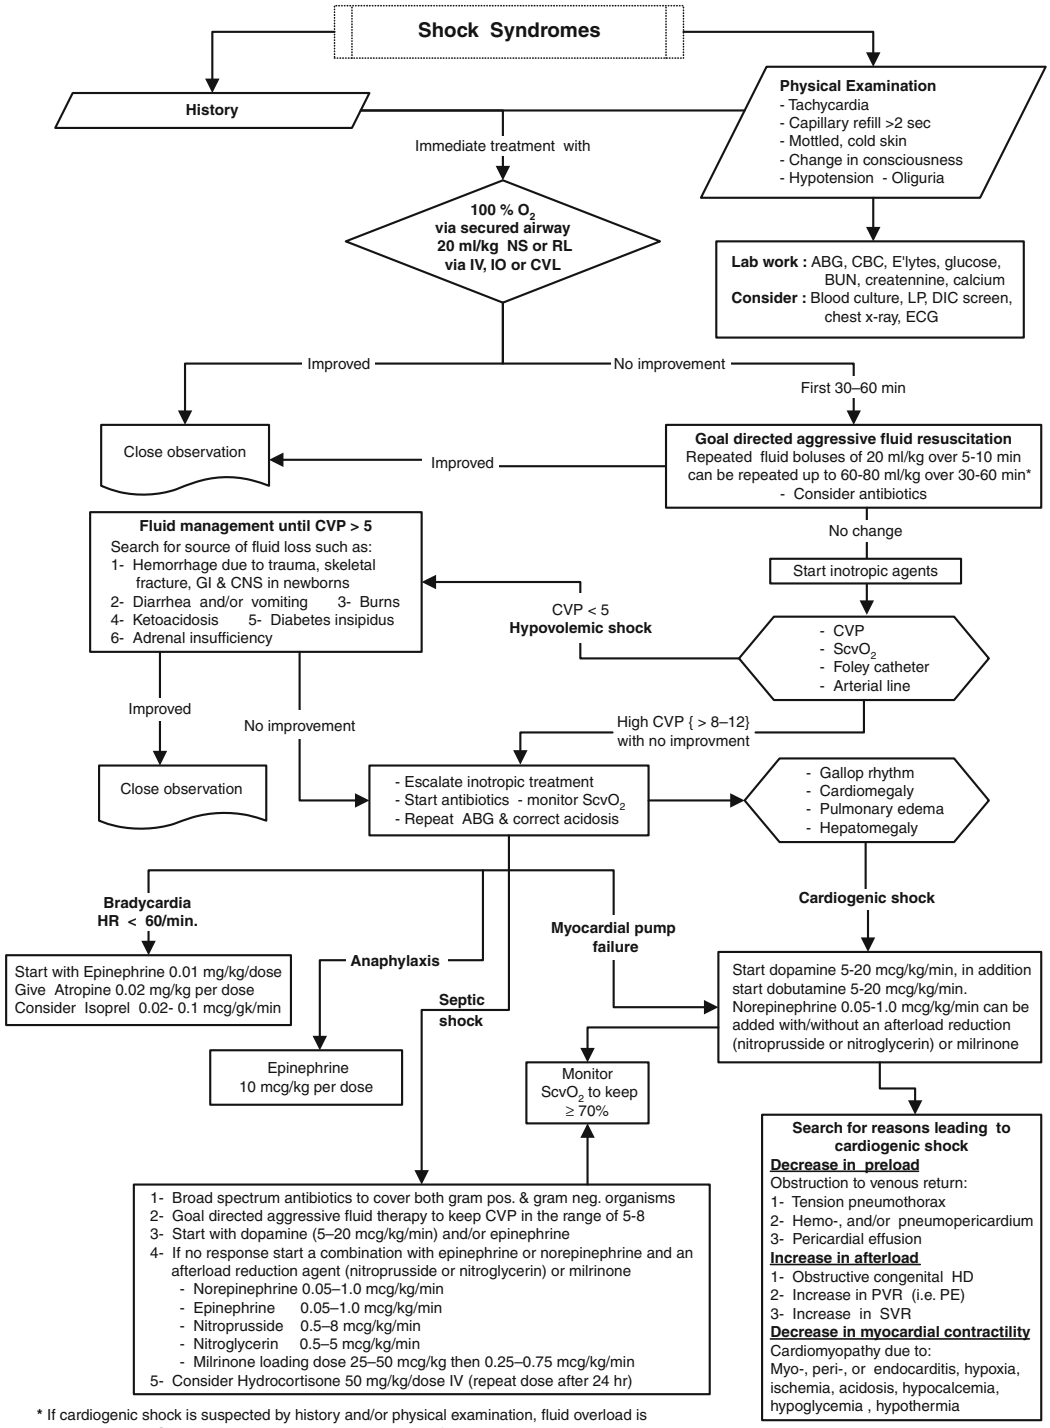

Figure 264.1
Algorithm for treatment of shock syndromes

circulation are the initial steps. If peripheral intravenous access is not rapidly obtained, intraosseous access should be established quickly in patients of any age. Once vascular access is established, aggressive fluid resuscitation with boluses of 20 ml/kg isotonic saline or Ringer's lactate is given. If there is no improvement and hypotension or hypoperfusion remains, patient should receive additional boluses over 5–10 min. Fluid resuscitation can be repeated in some cases up to 60–80 ml/kg until response is evident. Generally the observation is that fluid resuscitation is not given sufficiently to severely dehydrated children. Caution is warranted with aggressive fluid resuscitation in cases of apparent cardiac depression and/or heart failure (i.e., cardiogenic shock) as it may worsen the cardiovascular status. In most situations initiating fluid resuscitation with crystalloid is sufficient, unless obvious hemorrhage is present or hypotension persists. The blood volume should be augmented with a blood transfusion (type O negative, type specific, or cross-matched blood). Any source of fluid loss should be identified. Following the trend of central venous pressure (CVP) readings is very useful in guiding the fluid management. If the child is still hypovolemic, additional fluids are given as mentioned until CVP reading is 5 mmHg or more indicating normovolemia (*Fig. 264.1*). High CVP readings >12 mmHg with persistent hypoperfusion is against hypovolemia as the sole etiology and fluid administration risks fluid overload, and other causes such as right heart failure should be considered. Response to treatment is indicated by an improvement in blood pressure, tissue perfusion (capillary refill time), decreasing heart rate, and an increased urine output. Should the signs of shock persist with an appropriate filling pressure (CVP), vasoactive and inotropic therapy is to be considered. In the absence of central venous access, vasoactive medications and inotropes should not be delayed when clinically indicated. Investigations including arterial blood gases, electrolytes, glucose, chest x-ray, septic workup, and coagulation studies are important to guide therapy and help in the recognition of complicated shock course and possible comorbid causes.

Cardiogenic Shock

The aim of treatment in cardiogenic shock is to increase the cardiac output. This can be achieved by increasing the heart rate and stroke volume. Since neonates have noncompliant ventricles with limited ability to increase stroke volume, cardiac output is heart rate dependent. For this reason, treatment of cardiogenic shock conditions involving neonates with low heart rate (below 120/min) should include atropine or a sympathomemetic agent. Drugs that can improve both the heart rate and contractility are inotropes (i.e., dopamine and epinephrine). Isoproterenol infusion may be used in treating relative or absolute bradycardia (associated with poor perfusion) resistance to atropine (*Fig. 264.1*). Limitation for increasing the heart rate in an infant is obstructive heart lesions. However, heart rate above 170/min should be avoided because stroke volume at that point starts to decrease.

Stroke volume is affected by preload, afterload, and contractility. Maximizing myocardial performance is ensured by optimizing the preload (carful fluid challenges with 10 ml/kg to avoid fluid overload as it can increase pulmonary venous pressure and result in pulmonary edema, diuretics to reduce pulmonary edema, and the use of venodilators), decreasing the afterload (sedation, correction of hypothermia and vasodilators), and improving contractility (oxygen treatment, use of inotropic drugs, and correction of acidosis and other metabolic abnormalities). Arrhythmias should be treated if present. After reaching an optimum CVP level (after which increasing CVP does not improve stroke volume), further volume substitution should be avoided. By this stage an increase in the afterload or decrease in the contractility is most likely present, indicating a high systemic vascular resistance. Treatment can be initiated with a continuous infusion of dopamine, starting at 5–10 mcg/kg/min, and titrating the infusion until improved tissue perfusion is restored (*Fig. 264.1*). The use of dobutamine (starting at 5–10 mcg/kg/min) and/or epinephrine (0.05–1.0 mcg/kg/min) may be necessary. Utilizing the benefits of a strong inotropic agent, and at the same time blocking the undesired vasoconstriction effect can be achieved by using a combination of a strong inotropic drug (epinephrine 0.05–1.0 mcg/kg/min or norepinephrine 0.05–1.0 mcg/kg/min) and an afterload reduction agent (nitroprusside 0.05–8.0 mcg/kg/min or nitroglycerin 1–5 mcg/kg/min). On the other hand, the use of milrinone (25–50 mcg/kg as loading dose then 0.25–0.75 mcg/kg/min), a phosphodiesterase III Inhibitor agent, produces a positive inotropic effect with concurrent vasodilation hence, reducing afterload (decreasing SVR), while at the same time increasing cardiac contractility. Often milrinone is used in combination with epinephrine to offset epinephrine's alpha receptor effects, and also as a first-line drug together with small doses of other inotropes to improve tissue perfusion provided that blood pressure is maintained. *Table 264.6* shows commonly used cardiovascular drugs in shock with their actions, advantages, and side effects.

Table 264.6
Pharmacologic support of the shock patient

Drug	Dose	α-effect	β-effect	Vasodilator effect	Actions and advantages	Disadvantages and side effect
Dopamine	1–20 mcg/kg/min	+ to +++ (dose-related)	+ to +++ (dose-related)	At low doses, renal vasodilation occurs (dopaminergic receptors)	Moderate inotrope, wide and safe dosage range, short half-life.	May cause worsening of pulmonary vasoconstriction
Dobutamine	1–10 mcg/kg/min	0	+++		Moderate inotrope, less chronotropic, fewer dysrhythmias than with isoproterenol or epinephrine.	Marked variation among patients
Epinephrine	0.05–1 mcg/kg/min	++ to +++ (dose-related)	+++		Significant increases in inotropy, chronotropy, and SVR.	Tachycardia, dysrhythmias, renal ischemia, systemic and PVR
Norepinephrine	0.05–1 mcg/kg/min	+++	+++		Powerful vasoconstrictor (systemic and pulmonary); rarely used except possibly in patients with very low SVR or in conjunction with vasodilator.	Reduced cardiac output if afterload is too high, renal ischemia
Isoproterenol	0.05–1 mcg/kg/min	0	+++	Peripheral vasodilation	Significant increase in inotropy and chronotropy. SVR can drop, and PVR should not increase and may decrease.	Significant myocardial oxygen consumption increases, tachycardia, dysrhythmias
Nitroprusside	0.05–8 mcg/kg/min	0	0	Arterial and venous dilation (smooth muscle relaxation)	Decreases SVR and PVR, very short-acting. Blood pressure returns to previous levels within 1–10 min after infusion is stopped.	Toxicities (thiocyanates and cyanide), increased intracranial pressure and ventilation–perfusion mismatch, methemoglobinemia, increased intracranial pressure
Milrinone	0.25–0.75 mcg/kg/min	0	0		Phosphodiesterase III inhibition. Decreases SVR and PVR, increases myocardial contractility with only mild increase in myocardial O_2 consumption. Usually used with low-dose dopamine or dobutamine.	

0, no effect; +, small effect; ++, moderate effect; +++, potent effect
PVR pulmonary vascular resistance, *SVR* systemic vascular resistance

The simultaneous use of these drugs can result in hemodynamic improvement and an increase in the cardiac output by improving the contractility and decreasing the SVR. However, this strategy of treatment has to be well balanced depending on the circulation status, and requires monitoring of arterial blood pressure, CVP, $ScvO_2$ and, if possible, a pulmonary artery catheter (PA). The importance of treating hypoxemia, acidosis, hypoglycemia and other electrolytes disturbance, and hypothermia to improve both the contractility and the efficiency of the inotropic drugs should be emphasized. *Table 264.4* shows reasons leading to cardiogenic shock.

Septic Shock

Sepsis is the most likely cause of distributive shock in children. Once sepsis is suspected, prompt treatment with broad-spectrum antibiotics to cover both gram-negative and gram-positive organisms is essential. It should be given within the first hour of arriving in the Emergency Department. Specific antibiotic treatment follows the sensitivity of the organisms. The source of infection must be treated including drainage and debridement of abscesses. Because of a decrease in the systemic vascular resistance (SVR) during the early stage of septic shock (hyperdynamic stage), the vascular capacity is increased and the circulating blood volume is pooled to the periphery leading to relative volume depletion. Furthermore, capillary leak leads to third spacing of fluid. The consequence is relative and absolute intravascular volume depletion. The proper management in this stage is the early goal-directed aggressive volume replacement therapy of 60–80 ml/kg within 30–60 min, in addition to antibiotics. Despite early and adequate fluid resuscitation hypoxia, acidosis, and hypotension may persist particularly in the later stage of septic shock (cardiogenic stage); increase in SVR, myocardial dysfunction, maldistribution and decrease in cardiac output (CO) dominate the clinical picture (*Table 264.7*). This condition known as fluid-resistant shock status is frequently observed and dictates the early use of inotropic agents during the first hour, and to be titrated to effect (improved tissue perfusion). The choice of inotropic agents is dependent on the myocardial contractility and SVR status. The status of CO and SVR, known as hemodynamic profile can often change during septic shock stages and mandate frequent clinical reassessment to warrant therapeutic end points. Changes to the hemodynamic profile can present as follows:

1.	↑ CO & ↓ SVR	(warm shock)
2.	↓ CO & ↓ SVR	(cold shock)
3.	↓ CO & ↑ SVR	(cold shock)

Table 264.7
Early and late stage of septic shock

Early stage (hyperdynamic)	Late stage (cardiogenic)
– Hyperthermia	– Hypothermia
– Tachycardic	– Tachycardic
– Tachypnea	– Bradypnea
– Warm extremities	– Cold mottled extremities
– Bounding pulse	– Weak, thready pulse
– Normal capillary refill time	– Prolonged capillary refill time
– Normotensive/ hypertensive	– Hypotensive
– Hypoxia	– Hypoxia
– Polyuria	– Oliguria/anuria
– Increased cardiac output	– Decreased cardiac output
– Decreased SVR	– Increased SVR
– Normal CNS	– Obtunded, comatose
– Respiratory alkalosis	– Metabolic acidosis
– Hyperglycemia	– Hypoglycemia
– Normal coagulation	– Disseminated intravascular coagulopathy

In cases of high CO and low SVR (warm shock), the choice of inotropic agents after aggressive fluid resuscitation is dopamine starting at 5–10 mcg/kg/min to a maximum of 20 mcg/kg/min. In cases of dopamine refractory septic shock begin epinephrine or norepinephrine infusion starting at 0.05 mcg/kg/min to a maximum of 1.0 mcg/kg/min. Infusions should be titrated until improved tissue perfusion is restored and shock is reversed. In case where epinephrine-resistant low CO and high SVR (cold shock) is present, management should include as first-line therapy nitrosovasodilators agents (nitropusside 0.05–8.0 mcg/kg/min and nitroglycerin 1–5 mcg/kg/min) or a type III phosphodiesterase inhibitor (milrinone) loading dose 25–50 mcg/kg over 10 min and infusion starting at 0.25 mcg/kg/min to a maximum of 0.75 mcg/kg/min. The nitrosovasodilators act as vasodilators and afterload reduction, both works in reducing the

Table 264.8

high SVR. Milrinone on the other hand has an excellent inotropic effect and at the same time decreases the SVR. If loading dose of milrinone is used, careful monitoring of the blood pressure is crucial as hypotension can occur or get worse.

Monitoring the central venous O_2 saturation ($ScvO_2 \geq 70\%$) gives an indirect measure of the balance between systemic oxygen delivery and demands, and adds an important monitoring toll of the cardiovascular status. It enables crucial adjustments to fluid and inotropic agents. $ScvO_2 < 70\%$ will indicate most likely more need for fluid boluses and/or increase in the inotropic agents. $ScvO_2 \geq 70\%$ indicates that the hemodynamic status is improving.

Frequently, patients can present with a mixed picture of warm and cold shock. For example, a child with septic shock can also present with significant hypovolemia and cardiac depression. These frequent overlapping shock forms should be considered and needs early and careful diagnosis of causes for proper therapeutic measures. Invasive monitoring can assist the treating team to identify such conditions.

As the hemodynamic profile of children with septic shock often changes as mentioned above, frequent reassessment is required. Once treatment is in progress, clinical and therapeutic end points should be used as indirect markers of cardiac output in order to monitor progress and response to treatment. These end points include capillary refill <2 s, warm extremities, normal mental status, urine output >1 ml/kg/h, central venous O_2 saturation $\geq 70\%$, and normalization of lactate. Presence of these therapeutic end points indicates successful resuscitation and reversal of shock.

Steroids may be considered in the treatment of septic shock with low CO and high SVR hemodynamic profile. The presence of adrenal insufficiency should be considered in any child with epinephrine-resistant shock. Treatment with hydrocortisone should begin with 50 mg/kg followed by the same dose over 24 h. Stress dose is 2 mg/kg followed by the same dose over 24 h. Adrenal insufficiency can be diagnosed if the level of cortisol is less than 18 mg/dl. Hydrocortisone has been preferred due to its glucocorticoid and mineralocorticoid property, and due to its potency. An algorithm summarizing an approach to therapy of shock syndromes is shown in *Fig. 264.1*.

265 Fluid Management in Children

Abdul-Rahman M. Abu-Taleb

Introduction

The knowledge of fluid and electrolyte physiology in health and disease is essential for the proper management of fluid and electrolytes disturbances in the acutely ill child. The aim is to maintain normal volume and composition of body fluids and to ensure the correction of any existing abnormalities if needed. Dehydration leading to hypovolemia due to vomiting and diarrhea remains the most common clinical abnormality requiring fluid and electrolyte replacement therapy in childhood.

Total Body Water and Compartments

In the newborn age, total body water accounts for 75% of the weight. It decreases to account for 60% at 1 year of age and above. The total body water is divided into intracellular and extracellular compartments. The intracellular fluid (ICF) represents the fluid within the living cells. The percentage of the ICF increases from 30% of body weight at birth to 40% at 1 year of age, remaining relatively constant thereafter. The extracellular fluid (ECF) represents all body fluid outside of cells and decreases over the same period from about 45% at birth to 20% at around 1 year of age and above (*Table 265.1*).

The ECF is made up of:

The blood volume
The interstitial fluid
The transcellular fluid (gastrointestinal secretion and spinal, peritoneal, intraocular, and synovial fluid)

The intravascular volume varies from 7% to 8% of body weight or 70–80 mL/kg body weight in newborns, and decreases rapidly in the first year of life and then more gradually toward adult value around 65 mL/kg body weight. The volume of the interstitial fluid within organs, and the accumulation of fluid in potential spaces (intraperitonial, pleural, and pericardial) varies widely in critically ill children. The balance and appropriate distribution of fluid within these interstitial spaces is maintained by:

The colloid oncotic pressure
The membrane permeability
The hydrostatic pressure

Water Balance

Water balance in critically ill children is achieved by administration of maintenance fluid requirements and by replacement of ongoing losses of water and electrolytes occurring via normal physiologic processes (*Table 265.2*). Most losses arise from insensible water losses (respiratory tract system and skin) and sensible losses (mainly urine and to a less extent stool, unless diarrhea is present). The needs of maintenance fluid can vary with physical exertion and complicating clinical conditions that alter either insensible or sensible water losses like cases with colostomy or ileostomy. In addition, special cases such as premature infants will have increased insensible water losses from skin due to large surface area for mass and thinner epidermis. Furthermore, losses are greater if the premature infant is handled in an open radiant heater or exposed to phototherapy. For this reason, premature infants and term newborns need frequent assessment to enable proper calculation of fluid and electrolyte requirements and must account for maintenance requirements and ongoing losses. The fluid requirements for newborns are listed in *Table 265.3*.

There are two commonly used systems for estimating maintenance fluid requirement for children beyond the neonatal period (*Table 265.4*):

1. Estimating maintenance fluid for a 24-h period by the caloric expenditure method: 100 mL of water is required for each 100 metabolized calories (most used method).
2. Estimating maintenance fluid for a 24-h period by the body surface area (BSA) method (using nomograms for BSA): 1,500–1,700 mL/m^2.

Table 265.2
Maintenance water loss components (mL/kg/day)

	Newborn	6 m	1–5 year	5–10 year	Adolescent
Urinary (mL/kg/day)	40–60	60–80	40–60	30–50	40
Insensible (mL/kg/day)	40–60	40–60	30–40	20–25	10
Fecal (mL/kg/day)	10–20	10–20	10	–	–
Total	90–140	110–160	80–110	50–75	50

Table 265.3
Fluid requirements in newborns (mL/kg/day)

Birth weight (g)			
	<1,000 g	1,000–1,500 g	>1,500 g
Day 1	(80)[a] 90–100	(70)[a] 80–100	65–80
Day 2	(80)[a] 90–100	(70)[a] 80–100	65–80
Day 3	110	100–120	110
Day 4	140	140	140
> Day 5	150	150	150

[a]Recent trends are to mildly restrict fluid in the first few days to prevent fluid induced morbidities

Maintenance fluid can also be calculated on an hourly basis as follows:

– Weight less than 10 kg	= 4 mL/kg/h
– Weight greater than 10–20 kg	= 40 mL/h for first 10 kg of body weight plus 2 mL/kg/h for any increment of weight over 10 kg
– Weight greater than 20–80 kg	= 60 mL/h for first 20 kg of body weight plus 1 mL/kg/h for any increment of weight over 20 kg, to a maximum of 100 mL/h, up to a maximum of 2,400 mL daily

Appropriate fluid management will provide in addition a vehicle for the administration of adequate calories and medications. However, the total estimated need of fluid must be frequently readjusted considering other losses as mentioned before (*Table 265.5*). Additional information from hemodynamic monitoring, daily body weight, and frequent clinical examination including electrolyte monitoring is essential for a proper fluid management.

Maintenance electrolyte requirements follow the same principle applied for fluid and is estimated based upon caloric energy expenditure method. Sodium and chloride basic requirement is 2–3 mEq/100 mL of water per day and potassium 1–2 mEq/100 mL of water per day. The sodium requirement may need frequent adjustment during parenteral fluid management as ongoing physiological and pathophysiological precesses can lead to hyponatremia especially when hypotonic solutions are in use.

Fluid Management in Dehydration

A wide variety of causes leading to dehydration in small infants and children are to be considered (i.e., diarrhea, vomiting, prolonged fever, poor intake, and any condition where there is a rapid loss of body fluids). Children have the

Table 265.4
Maintenance fluid estimation by the caloric expenditure and surface area method

Maintenance fluid by caloric expenditure method	Maintenance fluid by surface area method
For children ≤10 kg = 100 mL/kg/24 h	1,500–1,700 mL/m^2
For children 10–20 kg = 1,000 mL + 50 mL/kg/24 h for each kg over 10 kg	1,500 –1,700 mL/m^2
For children 20–80 kg = 1,500 mL + 20 mL/kg/24 h for each kg over 20 kg	1,500–1,700 mL/m^2

Table 265.5
Estimated water losses in children and their replacement

Water losses in children	Caloric expenditure method
Urine output	45–55 mL/100 cal (surface area method: 1,000–1,200 mL/m^2)
Insensible	35–45 mL/100 cal (surface area method: 400–600 mL/m^2)
Fever	Increase insensible water loss by 7–10 mL/kg/day for each degree rise in temperature > 37.2°C
Tachypnea, nonhumidified	Add to maintenance l0%–30%
Marked agitation	Add to maintenance l0%–(30%)
Colostomy and iliostomy	Additional fluid to be added equal to losses
Humidified inspired gases and ventilation	May lead to fluid overload due to a decrease in insensible water loss by 20%
Oliguria	Insensible water loss + urine output ± persisting deficit/excess
Anuria	Insensible water loss is decreased to 25 mL/100 calories
Specific losses	
Upper GI	1/3–1/2 NS with KCl 20 mEq/L
Chest tube drains and dressings	Isotonic NS ± protein and RBCs as estimated losses

ability to compensate for acute fluid losses if volume loss does not exceed 15–20%. Signs and symptoms of varying degrees of dehydration are outlined in *Table 265.6*.

The most common type of dehydration in children is isotonic dehydration (i.e., serum sodium 130–150 mmol/L). Other types such as hypotonic and hypertonic dehydration occur less frequently.

The clinical findings in a patient with dehydration may vary, reflecting the type of dehydration present (*Table 265.7*). Fluid losses from different compartments (ECF and ICF) depend on serum osmolarity (Osm/L) and the acuity of dehydration. Dehydration for less than 2–3 days results in fluid loss primarily from the ECF (75–80%). However, dehydration for more than 3 days will result in 60% loss from ECF and 40% from ICF. Equal fluid losses from both compartments are encountered when the duration of the dehydration exceeds 7 days (for management, see below).

Dehydration Management

With severe dehydration (shock), restoration of the intravascular volume is a priority to ensure return of adequate intravascular volume and avoiding tissue damage. The rehydration and stabilization process is best divided into phases (*Table 265.8*). The first phase is devoted to restore the intravascular volume. As needed, the patient should receive isotonic fluid boluses of 20 mL/kg of normal saline (NS) or Ringer's lactate which may exceed 60–80 mL/kg in severe hypovolemic shock status. Should the patient be in shock secondary to bleeding, blood should be given when available to restore the circulation and oxygen delivery. The result of this initial therapy will be reflected in improved vital signs, increased urine flow, and improved state of consciousness.

In mild-to-moderate dehydration with stable hemodynamic and good perfusion, fluid resuscitation as

Table 265.6
Clinical signs and symptoms of dehydration in children

Degree of dehydration			
Clinical signs and symptoms	**5–10%**	**10–15%**	**Over 15%**

outlined in the first phase may not be necessary. In the following 8-h post-resuscitation, the second phase is aimed to partially restore the ECF deficit as well as to partially correct the acid–base status. Treatment in the remainder of the first 24 h (the third phase) is aimed at restoration of ECF, ICF, and acid–base status to normal. Following this initial period, further correction is achieved by ongoing parenteral and oral (if tolerated) hydration and replacement of additional losses (the fourth phase).

Calculating the amount of fluid deficit depends on an accurate assessment of the degree of dehydration and

Table 265.8
Phases of response to dehydration management

Phase	Therapeutic plan	Clinical response
First phase: (resuscitation phase) Restoration of vascular volume	20 mL/kg D5W 0.9% NS or D5 water Ringer's lactate over 30 min; may repeat 10–20 mL/kg	Improved vital signs
		Increased urine flow
		Improved state of consciousness
Second phase: first 8 h Partial restoration of ECF deficit and acid-base status	50% of deficit fluids + 50% maintenance daily fluids	Stabilization of vital signs
		Improved urine flow
		Partial restoration of normal acid–base status
Third phase: The following 16 h (8–24 h) Restoration of ECF, ICF, and acid–base status	50% of deficit fluids + 50% maintenance daily fluids	Gain in body weight
		Fall in BUN (50% in 24 h)
		Sustained urine flow
		Improved electrolytes
Fourth phase: (24–48 h) Total correction of acid–base, electrolytes, and volume	Ongoing parenteral ± oral hydration maintenance fluids and replacement of ongoing losses	Sustained gain in body weight
		Normal electrolytes

BUN blood urea nitrogen, *D5W* 5% dextrose in water; *ECF* extracellular fluid

previous recent weight if available. The fluid deficit can be easily calculated by multiplying the estimated dehydration by the weight of the child. For example, if the estimated dehydration is 7% and the weight of the child is 10 kg.

$$\text{Fluid deficit} = 7 \times 10 = 70\,\text{mL/kg or}$$
$$\text{Total deficit} = 70 \times 10 = 700\,\text{mL}$$

The calculated fluid deficit is added to the maintenance fluid, aiming for a correction over 24–48 h.

Isotonic Dehydration

In isotonic dehydration, the type of fluid solution recommended to be given is isotonic crystalloid. Normal saline or Ringer's lactate is the isotonic solution of choice for resuscitation in pediatrics. In case of significant dehydration with hypovolemic shock, resuscitation with fluid boluses of 20 mL/kg of NS should be initiated. Further boluses up to 60–80 mL/kg may be necessary. On the other hand, the management of mild-to-moderate isotonic dehydration with the administration of NS and electrolytes is a straightforward procedure. Modifying the fluid management during the course of treatment in the presence of ongoing losses or electrolyte imbalances may be necessary depending on the patient clinical condition. The use of hypotonic or hypertonic crystalloid solutions for emergent volume replacement therapy is never recommended in pediatric patients as it can result in serious complications, including dysnatremias, cerebral edema, and, in children with significant hyponatremia, cerebral demyelination (see "Hypotonic Dehydration"). After initial fluid resuscitation, standard solutions such as 5% dextrose water and one-quarter or one-half normal saline to cover for the fluid deficit and maintenance is started. After assuring good kidney function and urine output, 20 mEq KCL per liter is added to the infusate.

Hypotonic Dehydration

The causes of hypotonic dehydration are mainly from excessive salt loss or excessive water intake (primary polydipsia). It is most frequently observed in children with hypovolemia as a consequence of abnormal gastrointestinal losses and represents a relative excess of water in relation to sodium. However, other pathologies causing hyponatremia such as impaired water excretion resulting from advanced renal failure or from persistent release of inappropriate antidiuretic hormone (ADH), excessive use of diuretics, adrenal insufficiency, hypothyroidism, and water intoxication should be ruled out. Most patients with hyponatremia appear asymptomatic as the development of hyponatremia happens gradually and may only show subtle neurological abnormalities. However, when

significant hyponatremia is present (serum sodium less than 120 mEq/L), it is frequently associated with seizure and can lead to cerebral edema. The initial treatment in such conditions typically consists of rapid correction to a sodium level which can prevent or stop hyponatremic-induced seizure. Treatment with hypertonic saline (3% NaCl) may be necessary (every 2 mL of 3% saline contain 1 mEq of sodium). The desired serum sodium level to protect from hyponatremic-induced seizure and evolving cerebral edema is 125 mEq/L and should be achieved within 3–4 h at a rate not to exceed a rise in serum sodium of 2 mEq/L per hour. Risk of morbidity from delayed therapy in this case is greater than the risk of complication from rapid correction. The following correction after reaching a safe sodium level of 125 mEq/L is a slow correction of the hyponatremia via administration of isotonic saline if volume depletion is present, otherwise fluid restriction if the syndrome of inappropriate antdiuretic hormone secretion (SIADH) is present. Fast and/or aggressive correction of severe hyponatremia has major side effects and can lead to severe and irreversible neurological disorder called osmotic demyelination. Therefore, correction should not exceed 10–12 mEq/L in the first 24 h. In patients with SIADH, isotonic saline may worsen the hyponatremia and fluid restriction or the use of vasopressin receptor antagonists (e.g., tolvaptan) is in this case the appropriate management.

Hypertonic Dehydration

In hypertonic (hypernatremic) dehydration, the circulating volume is relatively preserved at the expense of the ICF. As a result, the degree of dehydration is difficult to assess. Serum sodium level in hypertonic dehydration is usually 150 mEq/L or higher. Conditions with hypernatremic dehydration result usually from a deficit of free water and are often associated with high intake of salt, inadequate intake (especially in breast-fed infants), and/or with the ingestion of boiled milk. However, the most common loss of free water is observed during gastroenteritis illnesses with diluted and watery osmotic diarrhea (most common form of diarrhea illness in children). In contrast to secretory diarrheas, the isosmotic diarrheal fluid has a sodium concentration only between 40 and 100 mEq/L, which is less than the serum sodium concentration leading to loss of free water and consequently to hypernatremic dehydration. Other causes leading to hypernatremic dehydration are increased insensible water losses and diabetes insipidus. If the patient is hemodynamically unstable, fluid resuscitation as described previously is given. Slow rehydration over 48 h, allowing a gradual decrease in sodium serum level between 10 and 12 mEq/L/day (0.5 mEq/L per hour) is the appropriate management. Rapid correction of the hypernatremia should be avoided since this may result in seizures and cerebral edema. The estimated free water needed to lower a serum sodium level of 150 mEq/L or higher by 1 mEq/L is about 4 mL/kg distributed over 48 h.

Fluid Management in Trauma Patient

Traumatized children may suffer from significant hemorrhage due to their injuries. Once ventilation and oxygenation are established, evaluation and management of circulation are the next priorities. Significant blood loss can lead to hypovolemic shock with the consequence of hypoperfusion and multiple organ failure. Controlling active bleeding, establishment of a secure access (peripheral venous access, central line, or intraosseous access), and

Table 265.9
Blood volume deficit and estimated blood/fluid requirement

Percentage of blood volume deficit	Blood volume deficit per kg body weight	Symptoms	Fluid replacement (3:1 rule)[a]
15%	10 mL/kg	Minimal tachycardia, no changes in respiratory rate, pulse pressure blood pressure, CRT	Crystalloid
15–30%	10–20 mL/kg	Tachycardia, tachypnea, decreased pulse pressure, increased CRT, decreased urine output	Crystalloid
30–40%	20–30 mL/kg	Shock, tachycardia, tachypnea, hypotension, oliguria, depressed level of consciousness	Crystalloid and blood
>40%	30 mL/kg	Profound hypotension, tachycardia, tachypnea, anuria, profound depression of consciousness, cold pale skin	Crystalloid and blood

[a]The 3:1 rule (three-for-one) rule is an empirical strategy of fluid management in acute hypovolemic shock due to hemorrhage where most patient require 3 mL of a crystalloid solution for each 1 mL of blood loss

Table 265.10
Estimated fluid requirement in burns for the first 48 h

Formula	Fluid	First 24 h	Second 24 h
Parkland/Baxter	Colloid	0	As indicated to maintain urine output 20–80 mL/kg/24 h
	E-lyt solution (Ringer's lactate)	4 mL/kg/% BSAB, 50% in the first 8 h, the rest 50% in the next 16 h	1/2 to 2/3 of the first 24 h requirement
	Glucose water	0	Add D5W solution as needed for hypoglycemia
Carvajal/Griffith and Galveston	Colloid	12.5 g/L in the main resuscitation fluid	As indicated(optimal albumin level $\geq$ 2 g/dl with colloid osmotic pressure $\geq$ 15 mm Hg)
	E-lyts solution (Ringer's lactate)	5,000 mL/m^2 BSAB Calculating BSAB is by multiplying the percent burn and the BSA + 2,000 mL/m^2 BSA	1,500 mL/m^2 BSA + 3750 mL/m^2 BSAB
	Glucose water	0	Add D5W solution as needed for hypoglycemia

BSA body surface area, *BSAB* body surface area burned

fluid resuscitation are essential to maintain tissue perfusion and avoid complications of shock (Table 265.9). Patients sustaining hemorrhage of 10% to as high as 30% of estimated blood volume may be resuscitated with crystalloid at the rate of 3 mL for every 1 mL blood lost. Blood transfusion may not be necessary at this stage. The response to this initial bolus of fluid determines further management. If blood pressure returns to normal with improved tissue perfusion, maintenance fluid is continued and hemodynamic parameters are monitored at frequent intervals. However, should the child remain hemodynamically unstable after the second fluid bolus, blood transfusion is indicated. Whole blood is preferable to packed red blood cells for preserving coagulation function. The first bolus of blood is usually 20 mL/kg. Subsequent volumes of blood administrated are based on magnitude of blood loss. Arterial blood pressure and central venous pressure (CVP) monitoring for management of severely volume compromised children are recommended.

Fluid Management in Burn Patient

The aim of fluid resuscitation in burned victims is replacement of existing deficit of fluid, electrolytes, and proteins. Compromised children several hours post burn are most likely suffering burn shock with or without associated injuries. Management of circulation is the priority after securing the airway and providing sufficient oxygenation. Conditions with hypovolemic shock should be aggressively treated as highlighted earlier. Calculation of fluid requirements thereafter is based on the BSA and the estimated body surface area burned (BSAB). Heart rate, urine output (1–2 mL/kg/h for children below 30 kg and 0.5–1 mL/kg/h for those greater than 30 kg), capillary refill time, and blood pressure are the parameters to monitor for adequate tissue perfusion. The most commonly used formulas to calculate the fluid requirements in burn children are the Parkland, Galveston, and Carvajal formulas (Table 265.10). Parkland formula is the most used formula (4 mL/kg per percent BSAB, adding maintenance fluid for children below 5 years of age). Galveston and Carvajal formulas (5,000 mL/m^2 per percent BSAB plus 2,000 mL/m^2 per day for maintenance requirements) use the BSA for calculating the fluid need and adding colloids in the first 24 h post burn. However, these formulas used to determine fluid rates provide an estimate of the initial requirements. Observational evidence indicates that they often underestimate the volume of fluid required for adequate resuscitation. For this reason, proper estimation of fluid requirements and monitoring the result of the fluid management is essential. Appropriate body proportion charts corrected to age with wound mapping, proper estimation of body surface area BSA, and BSAB are very important information used in fluids calculation to prevent errors during fluid resuscitation in the first 24 h. Excessive administration of fluid can be as detrimental as administration of insufficient volume during the resuscitation stage.

266 Acute Respiratory Failure

Khalid K. Bshesh · Manal Alasnag

Introduction

The human respiratory system is a complex entity that requires both neurologic and mechanical forces to work in a complementary fashion. The signal for initiating a breath starts in the respiratory center located in the medulla oblongata and travels through a network of nerves to stimulate the muscles of respiration. Any abnormality, whether mechanical or neurologic in this relatively complex system, may lead to respiratory failure (*Table. 266.1*).

The primary function of the respiratory system is gas exchange: oxygenation and carbon dioxide clearance. Failure of the respiratory system is failure in one or both of these gas exchange functions. Clinically acute respiratory failure is defined as arterial partial pressure of oxygen (PaO_2) < 60 mmHg or arterial partial pressure of carbon dioxide (PCO_2) > 50 mmHg. Respiratory failure may thus be classified as hypoxemic respiratory failure or hypercarbic respiratory failure.

Hypoxemic respiratory failure is also referred to as type I respiratory failure. Patients with this pathology present with PaO_2 less than 60 mmHg but a normal or even low $PaCO_2$. Clinically, the patient is tachypneic as the hypoxemia stimulates the respiratory centre to initiate breaths. The underlying pathology is usually acute failure of oxygenation at the level of the alveoli secondary to pneumonia or pulmonary edema. The alveolar spaces are obliterated by fluid, inflammatory cells and debris, or atelectasis.

Hypercarbic respiratory failure is type II respiratory failure. In addition to a raised $PaCO_2$, patients are usually hypoxemic. This type of failure is seen in patients with severe airway obstruction. A relatively common example is severe acute asthma exacerbation.

In the management of respiratory failure, it is also useful to differentiate between acute and chronic pathologies. Acute failure usually develops and progresses rapidly. There is very little, if any, compensation by the body buffering systems. This results in respiratory acidosis. The arterial blood gas pH is below 7.35, and the bicarbonate is normal.

On the other hand, if the respiratory failure is chronic, the body buffering systems are able to compensate. The renal compensation becomes evident as the serum bicarbonate level increases in proportion to the level and duration of the $PaCO_2$. The arterial blood gas pH is usually normal or only slightly decreased. To establish chronicity, however, other evidence of long-standing hypoxia and hypercarbia should be present. A full blood count may reveal polycythemia, while an echogardiograph may show elevated right ventricular and pulmonary arterial pressures. It is not uncommon for patients with chronic respiratory failure to present with acute decompensation. In the pediatric age group, the most common scenario is a child with a neuromuscular disorder who presents acutely secondary to aspiration or infectious pneumonia.

Pathophysiology of Acute Respiratory Failure

As described above, respiratory failure develops if any part of the respiratory system is disturbed either directly or secondary to hypoperfusion as in shock states.

In hypoxemic respiratory failure, the alveolar spaces are obliterated by fluid, inflammatory cells and debris, or atelectasis. This results in areas that are not ventilated while their pulmonary blood flow may be relatively normal. Therefore, a ventilation-perfusion (V/Q) mismatch produces hypoxemia. The management in such cases targets the underlying pathology and should include treating the infection and recruiting the collapsed lung segments.

The other mechanism that leads to hypoxemic respiratory failure is the presence of intrapulmonary or intracardiac shunts. Deoxygenated blood bypasses the ventilated alveoli. Severe hypoxemia result and will be refractory to simple oxygen therapy. This mechanism contributes to the development of respiratory failure in pulmonary hypertension and in cases of excessive alveolar distending pressures on mechanical ventilation.

On the other hand, hypercarbic respiratory failure may be better understood as a result of disequilibrium between supply and demand. The body's demand on the work of breathing exceeds its capacity. There is an increased demand on the work of breathing when the

Disorders of the peripheral nervous system and respiratory muscles	Muscular dystrophy
	Myasthenia gravis
	Guillian–Barre syndrome

body's basal metabolic rate increases with any infection, exercise, and especially in haemodynamic shock states. In such conditions, there is an increase in oxygen consumption. There may be an increased demand on the work of breathing to clear carbon dioxide in cases of poor respiratory effort, bronchospasm or atelectasis. Respiratory muscle fatigue leads to respiratory failure. Patients with neuromuscular disorders or depression of the central nervous system decompensate rapidly and usually benefit from early ventilator support.

Acute Respiratory Distress Syndrome (ARDS)

Although initially admitted as cases of bronchiolitis or pneumonia, some patients deteriorate rapidly. Respiratory failure in the form of acute respiratory distress syndrome (ARDS) remains a challenge to modern intensive care medicine.

ARDS was first described in a case series published in 1967. This included 12 adult patients with hypoxemia refractory to oxygen therapy, decreased lung compliance, and diffused lung infiltrate on chest radiograph. In 1988, a four-point lung injury scoring system was developed to quantify respiratory distress. This was based on PaO_2/FiO_2 ratio, PEEP, the static lung compliance, and degree of lung infiltration on chest x-ray. However, one of the main problems with this system was its inability to predict outcome in the early stage of the disease. In 1994, the North American-European Consensus Conference published an internationally accepted clinical definition of ARDS. The consensus definition recognized that the severity of clinical lung injury varied. So patients with less severe hypoxemia ($PaO_2/FiO_2 \leq 300$) would be at one end of the spectrum and were considered to have acute lung injury (*ALI*), whereas patients with more severe disease ($PaO_2/FiO_2 \leq 200$) have acute respiratory distress syndrome (*ARDS*). The definition also required that the onset be acute, with bilateral pulmonary infiltrates on CXR and without evidence of left atrial hypertension (PAWP $\leq$ 18 mmHg).

Unfortunately, the simplicity of such a definition ignored factors that influence the outcome, such as the underlying cause and whether other organ systems are affected. In 1988, a prospective observational study published and concluded that the underlying diagnosis has significant bearing on outcome. Mortality from respiratory failure was related to associated disease rather than the severity of initial gas exchange. So patients who develop ARDS secondary to sepsis have a worse outcome than patients whose respiratory insult is the primary pathology.

Studies that have used the consensus definition for ARDS have reported higher annual incidences. The National Institute of Health Acute Respiratory Distress Syndrome Network estimates the incidence as 75 per 100,000. Approximately 10–15% of ICU patients and 20% of mechanically ventilated patients meet the definition criteria. Large trials suggest that the overall mortality of ARDS ranges from 34% to 58%. Mortality increases with age from 24% for patients 15 through 19 years of age to 60% for patients 85 years or older. Some reports suggest that the trend is a decline in overall mortality, possibly attributed to more effective treatments for sepsis, changes in ventilation strategies, and improvement in the supportive care of critically ill patients. However, mortality rate varies with the underlying cause, and most patients die of multiorgan system failure rather than isolated respiratory failure. Factors that predict the risk of death at the time of diagnosis include chronic liver disease, nonpulmonary organ dysfunction, sepsis, and advanced age.

The mechanism of acute lung injury can be either direct (pneumonia, aspiration, inhalation, emboli, near drowning) or indirect (sepsis, trauma, multiple blood transfusion, cardiopulmonary bypass, burns). Sepsis is associated with the highest risk of progression to acute lung injury or ARDS. The presence of multiple predisposing conditions increases the risk, as in patients with chronic lung disease.

Normal lung function requires dry, patent alveoli, and appropriately perfused capillaries. Acute lung injury occurs as the result of inflammatory injury to the alveoli. The exudative phase is characterized by the release of pro-inflammatory cytokines such as TNF, IL-1, IL-6, and IL-8. Neutrophils are recruited to the lungs, where they release toxic mediators such as proteases. In turn, these damage the capillary and alveolar epithelium. Impaired neutrophil apoptosis in the early stages of ARDS augments this process. The result is that air spaces are filled with bloody, proteinaceous edema fluid and debris from degenerating cells; functional surfactant is also lost as type II cells are damaged, resulting in alveolar collapse. This exudative phase could resolve completely with no sequelae or progress to the fibrosing alveolitis (proliferative phase).

In the fibrosing alveolitis phase, there is persisting hypoxemia, increased alveolar dead space, and further decreased lung compliance. Right heart failure may develop secondary to pulmonary hypertension precipitated by obliteration of the pulmonary capillary bed. Chest x-rays show linear streaky opacities, demonstrating the evolving fibrosis (*Fig. 266.1*). Recovery is characterized by gradual improvement of the hypoxia and lung compliance. Radiographic abnormalities resolve completely, and in most patients, pulmonary function returns to normal. However, the degree of histologic resolution of fibrosis is not known. Severe disease and prolonged ventilation are associated with the greater risk of persistent pulmonary function abnormalities.

The pathology of acute lung injury results in significant physiological derangements, including impaired gas exchange, pulmonary hypertension, and decreased lung compliance. Hypoxemia is due to ventilation-perfusion mismatching and physiologic shunting, whereas increase in physiologic dead space interferes with CO_2 clearance. Pulmonary hypertension occurs in up to 25% of ARDS patients. Contributing factors include hypoxic vasoconstriction and vascular compression by positive pressure ventilation. Decreased lung compliance is characteristic of ARDS. The low compliance is due to non-aerated lung rather than changes in the pressure-volume characteristics of residual functioning lung units.

Understanding the pathophysiology of ARDS was enhanced as CT scans changed the "view" of ARDS. There was a shift from the notion of a homogeneously heavy and stiff lung to the concept of the "baby lung," with non-homogenous densities and a much reduced normally aerated tissue at end-expiration. It is well documented that respiratory compliance correlated well with the amount of normally aerated tissue, not the amount of non-aerated tissue. ARDS lung is thus small, not simply stiff. The amount of non-aerated tissue correlated with the degree of hypoxemia, shunt fraction, and pulmonary hypertension. It was also noted that when CT scans were done in prone position, the densities were redistributed in the dependent lung. The "baby lung" is therefore not a discrete anatomical structure.

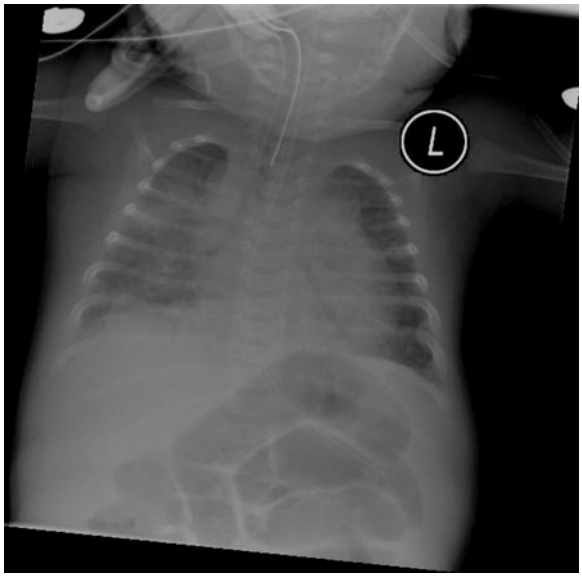

Figure 266.1
X-Rays

The understanding of ARDS evolved further with the concept of "sponge lung." In 1993, the ARDS disease process was described as involving the whole lung parenchyma, so that edema is evenly distributed from the sternum to the vertebra, not a simple gravitational distribution. The increased lung weight due to accumulation of edema raises the hydrostatic pressure which is transmitted through the lung, thus producing a "superimposed pressure." This pressure squeezes gas out of the dependent lung regions. In order to keep the most dependent lung regions open, PEEP must be higher than the superimposed pressure. Inevitably, this leads to overdistension of regions with lower superimposed pressure.

The result of overdistension is ventilator-induced lung injury (*VILI*). The lung skeleton is composed of two fiber systems linked at the level of the alveoli. An axial system is anchored to the hilum and runs along branching airways down to alveolar ducts. The peripheral system, anchored to the visceral pleura, goes centripetally down to the lung acini. The anatomical units of this system are the extensible elastin ("spring") and the inextensible collagen

("string"). The limits of lung distension are dictated by the inextensible collagen. The fibers of the lung skeleton develop an internal tension equal to but opposite to the pressure applied; this is "*stress*." Barotrauma results as stress increases, exceeding the properties of collagen fibers. The internal tension is also associated with elongation of fibers from resting position; this is "*strain*." Volutrauma is the result of increased strain without reaching the levels of physical rupture. Alveolar overdistension added to the repeated collapse and reopening of alveoli leads to activation of mechanosensors; consequently, cytokines are produced and the inflammation cascade is initiated. The pulmonary cytokine response is coupled with a systemic cytokine response, thus contributing to multiorgan failure.

Other factors that contribute to VILI include preexisting lung disease and high inspired oxygen concentrations. Oxygen causes lung injury in ARDS by forming oxygen-free radicals. In addition, high concentrations of inspired oxygen cause rapid deinflation of well-ventilated alveoli, which reduces their volume and increases the risk of collapse. Therefore, more consideration is given to arterial oxygen saturations rather than arterial oxygen tension in ARDS, as tissue oxygenation is primarily dependent on oxygen delivery.

To minimize VILI and prevent disease progression, lung-protective ventilation strategies have been proposed: limiting tidal volumes, maintaining plateau pressures to less than 35 cm H_2O, reducing inspired O_2 concentrations, and maintaining high PEEP.

The NIH Acute Respiratory Distress Syndrome Network compared traditional tidal volume (12 ml/kg) and lower tidal volume (6 ml/kg) in 861 patients. In the lower tidal volume group, plateau pressure did not exceed 30 cm H_2O. Mortality was reduced by 22% in the group treated with lower tidal volumes (31% versus 39.8%).

In addition to low tidal volumes, specialists advocate the "open-lung" approach. Most protocols included raising the level of PEEP above the lower inflection point on the pressure-volume curve for each patient to optimize lung recruitment. However, reliable measurement of the lower inflection point on the pressure-volume curve is technically difficult. Using recruitment maneuvers followed by a PEEP $< P_{inf}$ but above the closing pressure on deflation limb, the lung can be ventilated at optimal compliance.

Recruitment occurring over the entire respiratory cycle can improve oxygenation, but can cause significant barotraumas and cardiovascular instability. Based on literature available, prone positioning and sufficient PEEP appear to be the safest and most effective recruitment maneuvers. Prone positioning, though safe and efficient, has no beneficial effect on morbidity and mortality. Moreover, the effect on oxygenation is usually short lasting and depends on the type and phase of underlying lung disease.

A more recent NIH Acute Respiratory Distress Syndrome Network ventilation trial suggested that in patients with ALI/ARDS who receive mechanical ventilation with a tidal volume of 6 ml per kg and an end-inspiratory plateau-pressure limit of 30 cm H_2O, clinical outcomes are similar whether lower or higher PEEP levels are used.

On the other hand, the benefit of PEEP in pulmonary and extrapulmonary ARDS was examined. At PEEP levels of 0 cm H_2O, both groups had similar respiratory elastance ($\Delta P/\Delta V$) and end-expiratory lung volumes. Increasing PEEP in those with extrapulmonary ARDS correlated with significant lung recruitment while increasing PEEP in those with pulmonary ARDS resulted in minimal lung recruitment. Investigators concluded that the two groups presented different pathologies: Patients with pulmonary ARDS had consolidated lungs while extrapulmonary ARDS resulted in alveolar edema. This would explain the different responses to PEEP.

High-Frequency Oscillation Ventilation (HFOV) appears to incorporate all the lung-protective strategies discussed. Greater lung recruitment is achieved with very small tidal volumes avoiding high peak pressures, while higher end-expiratory lung volumes prevent both overdistension and collapse. Pediatric ARDS patients demonstrated improved oxygenation on HFOV. Unfortunately, defined criteria for transition to HFOV are lacking.

The clinical application of HFOV has been studied in a large multicentre sample of pediatric patients with respiratory failure. Lack of improvement on HFOV was associated with further deterioration, necessitating the use of extracorporeal membrane oxygenation (ECMO), while improvement of oxygenation with HFOV was associated with an increased likelihood of survival. Patients with preexisting lung disease had significantly more days of conventional ventilation before HFOV was initiated, required ECMO more frequently, and had a nonspecific increase in mortality compared to those without prior respiratory pathology.

ECMO could support gas exchange in patients who fail on conventional ventilation techniques. A prospective randomized trial involving 90 patients with severe ARDS found no difference in survival between ECMO-treated and conventionally managed patients. Only four patients in each group survived. Several explanations have been offered. Primarily, ECMO was used as rescue therapy in patients with very poor prognosis. The earlier provision of this form of support may have changed the results.

It was also stressed that similar mechanical ventilation techniques were used in both groups. Therefore, neither group was completely protected from VILI.

As discussed earlier, respiratory failure is not a primary cause of mortality in most nonsurviving ARDS patients. Persistent respiratory failure prolongs ICU stay, which leads to inevitable complications such as nosocomial infections and multiple organ dysfunction syndrome. Uncontrolled inflammation is fundamental in the pathophysiology of ARDS. Persistent inflammation and fibrosis are strongly correlated with poor outcome as are low levels of anti-inflammatory cytokines. Agents that suppress inflammation and promote repair have been studied.

The overall consensus is that there is a possible role for corticosteroids in the later, fibroproliferative phase of ARDS. This phase is clinically characterized by fever, purulent secretions, and new pulmonary infiltrates without evidence of infection. However, data from an NIH ARDS Network trial (2004) suggests no mortality advantage.

Similar lack of sufficient supportive data appears to bring into question the benefit of surfactant and nitric oxide as therapeutic agents used in ARDS. Both therapies tend to produce a temporary improvement in oxygenation but without significant effects on outcome. Treatment with synthetic surfactant has no effect on oxygenation, the duration of mechanical ventilation, or survival. Nitric oxide decreases pulmonary vascular resistance without affecting systemic blood pressure and improves oxygenation by redistributing pulmonary blood flow toward ventilated lung units. Nitric oxide tends to be added on when there is sufficient evidence for pulmonary hypertension in patients with ARDS. However, its relatively high cost and the lack of evidence for significant benefit have made it less popular on pediatric intensive care units.

In outlining the management for a patient with ARDS, one must remember to *first do no harm*. The aim is to provide adequate oxygenation without inducing morbidity from oxygen toxicity, haemodynamic compromise, barotraumas, or alveolar overdistension. Consideration for the underlying etiology must be made, as it brings more insight to the ARDS disease process. For patients with refractory hypoxemia, it is reasonable to consider modes of treatment which have not demonstrated an improvement in mortality according to available literature to date. This may be especially true in pediatric ARDS patients, as much of the literature is based on adult studies. So are there special factors unique to pediatric ARDS. The answer imposes itself: yes. It is known that pediatric physiology is sufficiently different. Unfortunately, though acknowledging this, much of the literature does not include pediatric patients.

267 Mechanical Ventilation

Omar M. Hijazi

Also called positive pressure ventilation, after initiating the trigger by the machine or the patient, inspiration starts, and a predetermined mixture of gas is pushed into the patient's trachea. The ventilator stops pushing the gas mixture into the patient's airway once predetermined volume, time, or pressure is reached. During exhalation, gas leaves the patient's airway into the machine. The flow of gas from the patient stops when the positive end-expiratory pressure (PEEP) is reached. Mechanical ventilation can be life saving. Sound knowledge in mechanical ventilation, is vital for health-care providers taking care of critically ill children. Although when used properly mechanical ventilation can help us save lives, it is not risk free.

Indications for Mechanical Ventilation

Indications for endotracheal (ET) intubation and mechanical ventilation include: respiratory failure; whether hypoxic respiratory failure (type I), or hypercapnic respiratory failure (type II) or both, loss of upper airway protective reflexes, apnea, need for paralysis as in operative procedures, need for high doses of anticonvulsants and anxiolytics that may compromise oxygenation and ventilation as in the treatment of status epilepticus, need to control of pH and $PaCO_2$ as in patients with head injury and increased intracranial pressure (ICP), breathing muscle fatigue secondary to increased work of breathing, patients who are in shock and poor oxygen delivery, and to help decrease the after load for left ventricle heart failure.

Mechanical ventilation can be used to give full support as in paralyzed patient, or partial support to decrease work of breathing. Mechanical ventilation should not be delayed till the patient decompensates. Unplanned, emergent endotracheal intubation can be risky. The decision to intubate and mechanically ventilate a patient depends mainly on clinical judgment. Many factors will be taken into account including the patient's general condition, level of consciousness, work of breathing, patient's progress, blood gases, and the need for high oxygen supplement.

Advantages of Mechanical Ventilation

The main advantages of endotracheal intubation and mechanical ventilation are improvement in oxygenation and ventilation secondary to improved ventilation perfusion matching, and decrease work of breathing. Work of breathing can increase secondary to increase demand as in sepsis, acidosis, or secondary to abnormal lung or chest wall compliance, or increase airway resistance. In patients with left ventricle dysfunction, positive pressure ventilation will decrease the left ventricle transmural pressure and decrease left ventricle after load. However, right ventricle dysfunction may get worse with positive pressure ventilation. Positive pressure ventilation can decrease the systemic venous return and increase pulmonary vascular resistance (PVR) if not used properly.

While one should not wait for a patient with severe respiratory distress to collapse and intubate him or her on emergency basis, one should not rush to intubate patients that can be managed without invasive positive pressure ventilation. Intubation and mechanical ventilation are not risk free. Unprepared patient with borderline hemodynamics can go in cardiopulmonary arrest during intubation. Furthermore, during intubation the patient can develop aspiration, abdominal distension, pneumothorax, and hemodynamic instability. Noninvasive ventilatory support should be tried first if applicable.

Modes of Mechanical Ventilation

Mode refers for the mechanism of inspiratory support. There is no clear evidence to support the use of certain mode. The mode selection is based on the clinician and the institution preference. Neonatal units have tendency to use the pressure limited, time-cycled ventilation. In general, pediatric critical care units tend to use volume-cycled ventilation. However, some pediatric critical units prefer pressure limited time-cycled ventilation. Studies comparing volume- versus pressure-cycled ventilation did not

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_267,

show a significant difference between the two in regard to work of breathing, oxygenation, and mortality. Patients ventilated with pressure-cycled ventilation had lower peak inspiratory pressure (PIP), better patient ventilator synchrony, and more homogeneous gas distribution, while patients ventilated with volume-cycled ventilation had guaranteed minimal minute volume.

There are three types of breaths for a patient who is on mechanical ventilator. These are mandatory, assisted, and spontaneous breaths. Mandatory breaths are initiated and fully supported by the ventilator, assist breaths are initiated by the patient and are fully supported by the ventilator, and spontaneous breaths are initiated by the patient and can be supported by the ventilator. In assist mode of mechanical ventilation, the patient-triggered breaths are completely supported by the ventilator. However, in pressure support mode whether as solo mode or in combination with other modes like synchronized intermittent mandatory ventilation (SIMV) with pressure support, the clinician will decide how much support will be given to the patient-initiated breaths. In pressure support, the support is usually not complete and patient-triggered breaths that are supported by the pressure support will generate a smaller tidal volume (TV) compared to the mandatory breaths.

Volume-Cycled Ventilation

In volume-cycled ventilation, the clinician will define the tidal volume (TV), respiratory rate (RR), inspiratory (I) time, peak flow rate, flow pattern, positive end-expiratory pressure (PEEP), and fraction of inspired oxygen (FiO_2). In volume-cycled ventilation, the inspiratory flow ends after delivering the preset tidal volume. In this mode of mechanical ventilation, airway pressures, peak inspiratory pressure (PIP), plateau pressure, and mean airway pressure (MAP) depend on ventilator and patient factors. Ventilator factors include inspiratory time, peak flow rate, and tidal volume. Peak inspiratory pressure (PIP) increases with increasing flow rate and tidal volume, and decreasing inspiratory time. Patient's related factors include lung compliance, chest wall compliance, and airway resistance. Volume-cycled ventilation can be delivered using the control mode ventilation (CMV), assist control ventilation (ACM), intermittent mandatory ventilation (IMV), and synchronized intermittent mandatory ventilation (SIMV).

Control Mode Ventilation (CMV)

In this mode, the clinician determines the minute volume that the patient is going to receive. This is done by determining respiratory rate (RR) and tidal volume (TV). The clinician will also determine positive end-expiratory pressure (PEEP), fraction of inspired oxygen (FiO_2), flow pattern, and inspiratory to expiratory (E) time ratio. This mode of ventilation is given to a patient who does not trigger the ventilator. Usually the patient is heavily sedated, paralyzed, and very sick. Furthermore, this mode is also given to patients who need high respiratory rate. If the clinician elected to give the patient short inspiratory time, the peak inspiratory flow will be high and will increase the peak inspiratory pressure (PIP). While giving longer inspiratory time will allow the ventilator to deliver the same tidal volume with lower flow rate decreasing the PIP. Should the patient try to initiate breath in control mode, the ventilator will not assist the patient.

Assist Mode

In assist mode, the clinician determines the lower minute volume, FiO_2, flow rate and pattern, PEEP, and I:E ratio. The lower minute volume is set by setting ventilator rate and tidal volume. Minute volume is the product of tidal volume and respiratory rate. In this mode should the patient trigger the ventilator, the ventilator will give support to the patient-initiated breath. This support will be in the form of a full breath with the same tidal volume as the ventilator mandatory breaths.

Intermittent Mandatory Ventilation (IMV) Mode

Intermittent mandatory ventilation like assist mode allows the patient to initiate breaths to increase the minimal minute volume (TV $\times$ RR) that is set by the clinician. However, in this mode the patient-initiated breaths (spontaneous breaths) will not be supported by the ventilator. So, the tidal volume of each patient-initiated breath will depend on the patient's age and health.

Synchronized Intermittent Mandatory Ventilation (SIMV) Mode

In synchronized intermittent mandatory ventilation, the ventilator breaths are in synchrony with the patient's breathing. In IMV and SIMV, the amount of support given to the mechanically ventilated patient is variable. It can give full support. Full support is achieved by setting the ventilator at high respiratory rate above which the

patient will not have spontaneous breaths. On the other hand, the support can be partial or minimal by setting the ventilator on very low rate. Unless the patient is having a major problem with oxygen delivery and the clinician objective is to paralyze the patient, and direct the precious limited oxygen supply to the vital organ, one should not allow the ventilator to take over the full work of breathing since this may lead to deconditioning of the patients' breathing muscles. If one did not train the patients' breathing muscle, deconditioning can take place in few days. This will prolong weaning the patient from mechanical ventilator. SIMV mode is different from control mode in that the ventilator will work in synchrony with the patient. For example if the patient initiated a breath at the same time allocated for a ventilator breath, the ventilator will not give its breath and will allow the patient to take his or her own breath, the ventilator will not start inspiration while the patient in the beginning of exhalation. Pressure support is usually added to SIMV mode to give support to the patient-initiated breaths. However, the support in SIMV and pressure support will be partial support. Since SIMV will allow the ventilator to work in harmony with the patient, it is used much more common than control mode in awake, non-paralyzed patient.

Pressure Regulated Volume Control (PRVC)

PRVC is the most commonly used ventilator mode in some pediatric critical care units. In this mode of mechanical ventilation, the ventilator is capable of control of the inspiratory time and flow rate. So, based on the tidal volume pressure profile from previous breaths, the ventilator will adjust inspiratory time and flow rate to deliver the tidal volume with smaller rise in the plateau pressure.

Pressure-Cycled Ventilation

Can be in two forms; pressure control and pressure support ventilation (PSV). In pressure control mode, the ventilator will deliver a preset pressure above the PEEP at a preset rate and for a preset I:E ratio. The ventilator will stop pushing gas into the patient's trachea, once the PIP is reached. Inspiration ends once the preset inspiratory time is over. By then, exhalation starts, gas leaves the patient to the ventilator until PEEP pressure is reached. In this mode, the peak inspiratory pressure (PIP) and pressure above the PEEP (PAP) are fixed. However, the tidal volume delivered will vary based on the patient's lung and chest wall compliance, and airway and tubing resistance. If the patient was having good lung compliance at the time of setting the ventilator that got worse over time, then the tidal volume given by the ventilator will decrease. The same will happen if the airway resistance increased. This will lead to decrease minute volume and increased $PaCO_2$. While, if the airway resistance and/or the lung and/or chest wall compliance improved, the ventilator will deliver a higher tidal volume that may lead to volutrauma. Pressure-cycled ventilation can be delivered using the same modes used to deliver volume-cycled ventilation. The difference is that tidal volume is fixed in volume-cycled ventilation and pressure above the PEEP is fixed in pressure-cycled ventilation.

Pressure Support Ventilation (PSV)

Pressure support ventilation (PSV), flow-limited ventilation, is a new mode of mechanical ventilation. Pressure support ventilation can be pressure or flow triggered. Pressure support can be the only support given to the patient by the ventilator or it can be in combination with other modes of support like SIMV with pressure support, and/or CPAP (continuous positive airway pressure) with pressure support. In pressure support ventilation, the clinician sets the plateau pressure, while the patient controls the rate, inspiratory time, and expiratory time. The inspiration ends and expiration starts when the inspiratory flow falls to predetermined value, usually less than 25% peak flow rate. The tidal volume will be variable. Since the rate and trigger for PSV are initiated by the patient, PSV does not guarantee a minimal minute volume. Thus, if the patient develops apnea or received paralysis or heavy sedation, PSV will not give the patient the needed support. PSV when added to SIMV gives support to the patient-triggered breath and is thought to improve weaning from the ventilator. Adding PSV to the patient-triggered breaths helps the patient overcome the resistance of the endotracheal tube and the ventilator tubing.

Starting Setup

Adjusting TV, PEEP, PAP, RR, Inspiratory (I) and Expiratory (E) Times

If the health-care provider of the critically ill child decided that the patient needs support for his or her breathing, then based on the patient's condition and health-care provider's experience and the institution's resources, the following points should be tackled: Starting invasive

endotracheal intubation and mechanical ventilation or by noninvasive like nasal-CPAP, if invasive mechanical ventilation to be used, is one going for volume- or pressure-cycled ventilation? What pressures or tidal volume should one use to maintain good ventilation? How much PEEP should one start with? What I and E time and I:E ratio will this patient need? Which is better for this patient, full support (high rate) or partial support (low rate)? What rate should one start with? Should one paralyze this patient or let him or her share the work of breathing. Why did this patient need the ventilatory support and how can one help free him or her from the ventilator? How and when should one start weaning from the ventilator?

Setting the Mode

According to the patient's condition and the operator experience, the mode of ventilation will be chosen. In many pediatric intensive care units, volume mode is the default mode. Pressure regulated volume control (PRVC), a hybrid mode, is the most commonly used mode for mechanical ventilation in pediatric age groups in some centers. Pressure mode is usually chosen when the lung compliance is poor, patient needs high pressures on volume mode for oxygenation, and/or there are problems in ventilation secondary to large leak around the endotracheal tube.

Noninvasive Versus Invasive Mechanical Ventilation

Noninvasive mechanical ventilation can help one avoid the invasive mechanical ventilation complications. CPAP (continuous positive airway pressure) can be applied using nasal cannula, nasopharyngeal tube, and face mask. It can help in patients who are in distress due to heart failure and lung collapse.

Noninvasive positive pressure ventilation delivered through face mask is contraindicated in patients who are vomiting, having lot of secretions, and with depressed mental status.

Setting the Tidal Volume (TV) in Volume Mode, or Pressure Above PEEP (PAP) in Pressure Mode

Tidal volume is usually based on the patient's age, weight, and lung pathology. At bedside, one will titrate up the TV or PAP on the ventilator till there is good but not excessive chest excursion. On blood gases, the minute volume is good, if the pH and $PaCO_2$ are at our target range. The usual tidal volume in the pediatric age group is 8 $\pm$2 ml/kg. Newborn babies usually need much smaller tidal volume starting by 4 ml/kg and titrate as needed. In patients with sick lungs and poor compliance, smaller tidal volume is used. The use of small tidal volume is proven to improve the outcome of patients with acute respiratory distress syndrome (ARDS). While titrating up the tidal volume, auto-PEEP and plateau pressure should be monitored. If the patient developed auto-PEEP more than 5 and/or plateau pressure more than 30 cmH_2O, the tidal volume should be decreased. Large tidal volume can lead to barotraumas and volutrauma. In volume-cycled ventilation, the clinician sets the tidal volume and it is fixed. In pressure-cycled ventilation, the clinician sets the pressure above the PEEP (PAP), delivering fixed pressure and variable tidal volume depending on patient and ventilator variables.

Setting the Trigger

The patient can trigger the ventilator through either pressure or flow triggering. In pressure triggering, the ventilator will give the support if the patient inspiratory effort generated a pressure in the system in excess of the triggering pressure. For example, a patient on the ventilator with trigger pressure of -3 cm H_2O and a PEEP of 4 cm H_2O, should drop the pressure from +4 down to –3 cm H_2O (a change of 7 cm H_2O) for the ventilator to recognize that the patient is trying to breath, so the ventilator will give the preset support. The trigger is usually set at -2 to -4 cm H_2O. Making the trigger too much negative as -9 cm H_2O may exhaust the patient. Setting the trigger at positive or 0 cm H_2O, makes the trigger very sensitive may lead to over triggering. In flow triggering, the ventilator will be triggered if the flow returning to the ventilator is lower than the flow sent by the ventilator to the circuit.

Setting the PEEP

The PEEP, positive end-expiratory pressure, is needed to recruit the lung, to open the lung and keep it open, improve oxygenation, wean FiO_2, and decrease the lung edema. The usual PEEP that one starts with in a normal lung is between 2 and 5 cm H_2O. Lungs with poor compliance, lungs that have tendency to collapse need higher PEEP. While higher PEEP may help recruit collapsed alveoli improving oxygenation, improper use of high PEEP may decrease right ventricle output (decrease preload and increase pulmonary vascular resistance), decreasing

cardiac output and oxygen delivery. On the pressure volume curve, the PEEP should be above the lower inflection point (pressure). Lower inflection pressure is the pressure below which the lung will collapse. Collapsed lung will develop hypoxic pulmonary vasoconstriction increasing the pulmonary vascular resistance. This will increase right ventricle after load and will also decrease oxygen delivery. Clinically, one would increase the PEEP until the patient's oxygen saturation is in the 90% with fraction inspired oxygen (FiO_2) $\leq$ 40%. High PEEP may over distend the alveoli increasing the pulmonary vascular resistance by capillary tamponade. In general, patients with increased intracranial pressure, bronchial asthma, hypovolemia (decreased right ventricular preload), and high pulmonary vascular resistance (PVR) do better with low PEEP. While patients with white stiff lungs need high PEEP to open the lung and keep it open. The lowest pulmonary vascular resistance correlates with lung volume at functional residual capacity (FRC). If the lung volume decreases below FRC, the PVR is going to increase secondary to collapse-induced hypoxic pulmonary vasoconstriction. However, if the lung was inflated over the total lung capacity, PVR is going to increase secondary to pulmonary capillary tamponade. So, to help the right ventricle, to improve flow across the pulmonary vascular bed, to improve cardiac output the PEEP should be high enough to maintain FRC and low enough to avoid lung over inflation.

Setting the Respiratory Rate (RR)

Setting the respiratory rate is influenced by many factors. The younger the patient, the higher the rate he or she needs. The average starting range is around 30–40 breaths/min for newborn, 20–30 breaths/min for child, and 12–20 breaths/min for adolescent. The sicker the patient is, the higher rate he or she will need. Patients who need full support on the ventilator will be given higher rate compared with those who need partial support. A patient with poor lung compliance, who is given small tidal volume, will need higher ventilator rate compared with a patient who has normal lung compliance. Patients who have asthma with increased airway resistance, normal lung compliance (increased time constant), and auto-PEEP will need low rate on the ventilator. Once one has the blood gases results, the rate will be optimized according to the patient's needs. The higher the rate, the more support is given to the patient. Giving full support (high rate) will help the patient's fatigued muscle recover and help optimize oxygen delivery in patients with oxygen debt. However, full support even for as short as 3 days, can lead to deconditioning of the breathing muscles, alkalosis, and shift to the left in oxygen dissociation curve. Low rate that is not meeting the patient needs will not allow the patient's breathing muscle to recover, and will not help the patient optimize oxygen delivery.

Setting the Inspiratory and Expiratory Times (I, E, Respectively)

The inspiratory and expiratory times are set based on the time constant of the patient's lung. Time constant is the product of lung compliance (C) and airway resistance (R). The higher the compliance and the resistance, the longer is the time constant. The longer time constant is, the longer time the lung will take to recruit and derecruit. Sixty-three percent of the recruitable lung volume is recruited after one time constant, 99% after five time constants. Usually, the inspiratory time is set at three to five time constants. Different areas of the lungs have different compliance and resistance. In lung disease, as in pneumonia, collapse, and obstructive airway disease, the variability in time constant is more apparent. The time that is needed to recruit an area of the lung may over distend another area in the same lung. Patients with obstructive airway, like patients with status asthmaticus, need long I and E times. These patients have good lung compliance and increased airway resistance. This increases their lung time constant. Since the main problem in patients with airway obstruction that is more apparent during exhalation, these patients need longer E time. The usual I and E times ratio to start mechanical ventilator with, is based on the patient's pathology and the targeted I:E ratio. The usual starting I:E ratio is 1:2, so a newborn patient who is intubated for apnea, with healthy lungs, with initial respiratory rate of 40/min, then the cycle time is 1.5 s (60 s per minutes/40 breaths per minute), the I time will be 0.5 s, E time will be 1 s, and I:E ratio will be 1:2. On the other hand a 16-year-old ventilated for severe status asthmaticus with severe air trapping will be given low respiratory rate like 12/min, giving a cycle time of 5 s, if I time is set at 0.8 s, this will give the patient long expiratory time of 4.2 s and I:E ratio of 1:5. If such a patient with bronchospasm is not given a long enough expiratory time, he or she will develop air trapping and auto-PEEP. To detect auto-PEEP check what is the setup PEEP (e.g., it is 4 cm H_2O), then press on expiratory pause and look at the pressure (let say it was 7 cm H_2O), this tells one that there is auto-PEEP, that the patient cannot exhale all the air that he or she is given during inspiratory phase, and that the E time is not long enough. Normally the PEEP and

the expiratory pause pressures should be equal. In such a patient with auto-PEEP, the patient can be helped by giving longer E time, smaller tidal volume, and/or improve the airflow by optimizing the bronchodilator therapy.

Setting the Fraction Inspired Oxygen

In general, when starting mechanical ventilation for a patient with respiratory failure one starts with FiO_2 of 100%. As soon as the patient achieves target saturation, the FiO_2 should be weaned. If the patient saturation failed to reach our target, and the lung looks white (under recruited) on the chest X-ray, PEEP should be increased as needed to wean the FiO_2. High FiO_2 can worsen atelectasis, and damage the lung airway and parenchyma. In sick lungs, the usual target oxygen saturation is 85–90% and target $FiO_2 \leq 40\%$.

Monitoring Lung Compliance

Monitoring the lung compliance for a patient on mechanical ventilation gives the health-care provider a good idea about the patient's lung condition, patient's progress, and the need to escalate or wean the mechanical ventilation support. Compliance (C) is change in volume (ΔV) over change in pressure (ΔP). In calculating the compliance, one takes into account the exhaled tidal volume. There are two lung compliances. These are the dynamic and static lung compliances. Dynamic compliance is calculated by dividing exhaled tidal volume (TV) over the difference between the peak inspiratory pressure (PIP) and the PEEP. So, dynamic compliance equals TV/ (PIP-PEEP). Static compliance is calculated by diving exhaled TV over the difference between inspiratory pause (plateau) pressure and PEEP. Inspiratory pause pressure is measured by pressing on the inspiratory pause knob on the ventilator and checking the pressure. For example, a 1-year-old is connected to mechanical ventilator. He is on PRVC mode. Ventilator rate is 20/min. Inspiratory tidal volume is 110 ml. Exhaled tidal volume is 100. The ventilator reads 18 cm H_2O for PIP, 16 cm H_2O for inspiratory pause pressure, and 4 cm H_2O for PEEP. Then for this patient the dynamic compliance is 100 ml/(18–4) cm H_2O and the static compliance is 100 ml/(16–4) cm H_2O.

Monitoring a Patient on MV

The management of a sick patient who needs ventilatory support does not end by intubating the patient's trachea and connecting him or her to the mechanical ventilator. The patient's condition and the patient's lung dynamics do change with time and the setup that may suite the patient now may not suite him or her few hours later. It is a teamwork in which nurses, respiratory therapists, and physician are involved in.

Securing the Endotracheal Tube

Orotracheal route is the most commonly used way for intubating the trachea in children. Nasotracheal intubation, though can give more stability to the endotracheal tube, is associated with complications like nasal ulceration and sinusitis. After intubation, verifying that the ET tube in the trachea, and that the ET tube tip is in the right position which is 1 cm above the carina, the endotracheal tube should be secured so it does not move in or out. There are many ways to secure the ET tube. If adhesive tape is going to be used secure the tube, it should be waterproof tape so it does not peel off in contact with the patient's secretions. To avoid accidental extubation, the bedside nurse and the respiratory therapist should check and document the ET tube position periodically. Most accidental extubation incidents take place when the patient is given bath or being weighed. Health-care providers are advised to avoid head dorsiflexion while serving the intubated patient. With dorsiflexion, the ET tube will move up and this may leads to accidental extubation. A rough way for estimating the level of the ET at the level of the gums is three times the size of the tube. So, for a 4 kg newborn intubated with size 3.5 ET, the tube level at the gum would be at 10.5 cm. Another way for older children is age in years plus 10. So, for a 5-year-old child the tube can be secured initially at 15 cm. Later the position can be checked in the chest X-ray and tube positioned to be around 1 cm above the carina.

Assure That the ET Tube Is Patent

The endotracheal tube should be patent. There are certain indicators that may indicate that the tube is completely or partially occluded. For example, an increase in the peak inspiratory pressure in volume mode or a decrease in the tidal volume in pressure mode may indicate partial tube obstruction. Kinked tube can give the same picture of ET tube occlusion. Suction of the ET tube should be done periodically as needed under sterile technique by the nurse and the respiratory therapist. Certain patients need special preparation before and during ET tube suction. Patients with pulmonary hypertension for example can have severe

desaturation during suction. Before suction of these patients, the patient may need sedation, analgesia, and paralysis. Preoxygenation and installing lidocaine in the ET can also help. Patients with increased intracranial pressure also need special care before and during suction of ET tube. If not done properly, ET tube suction can lead to cough, patient irritation, and further increase in the intracranial pressure leading to serious complications like brain herniation.

Leak Around the Endotracheal Tube

The size of the endotracheal tube is estimated by the formula (age in years + 16)/4. In preparation for intubation, it is good to prepare tubes that are 0.5 mm above and below the calculated size. A good size tube should go into the vocal cord into the cricoid ring easily. After intubation, one should look for air leak around the endotracheal tube. There should be some air leak around the ET tube. Having no air leak at airway pressure of $\geq$25 cm H_2O will increase the risk of mucosal injury and subglottic stenosis. In such scenario, the endotracheal tube cuff should be deflated or the tube should be changed to smaller size as the patient's condition allows. However, too much leak can compromise ventilation and oxygenation. In such case with big leak, one will inflate the balloon if the ET tube was cuffed, or change the ET to a bigger size. Air leak around the endotracheal tube changes with the patient's condition. Edema around the tube will decrease the leak. Worsening lung compliance or airway resistance will increase the leak. Checking for air leak should be part of the daily monitoring of intubated and mechanically ventilated patient. Checking for air leak around ET tube is also a part of preparation for extubation. If there is no leak, one should plan to prevent and treat complications like post-extubation stridor or need for reintubation.

Synchrony Between the Patient and the Ventilator

In a patient who is not paralyzed, who is breathing while on the ventilator, it is important that the patient and ventilator breaths are synchronized. If not, the patient gets agitated and this may increase the patient's oxygen consumption, risk of having ventilator-associated volume or barotraumas, and prolong duration of mechanical ventilation. At the bedside, patient ventilator asynchrony is evident as ventilator fails to initiate a breath after being triggered by the patient. Ineffective triggering may account for 88% of asynchronous breaths. In some patients, the asynchrony is due to highly sensitive trigger. This can be ameliorated by decreasing the sensitivity, others due long inspiratory time that can be overcome by increasing the flow to get the tidal volume with shorter inspiratory time.

Ventilator Humidifier

In spontaneous inspiration, the inhaled air is filtered, humidified, and warmed mainly in the nose. By intubating the patient's trachea, the inhaled air is not getting the advantages of going through the nose. To overcome this problem, a humidifier is attached to the mechanical ventilator. Inhaled air goes through the humidifier to get humidified and warmed. The usual humidifier temperature is set around 35°C. Should the patient be hypothermic, the humidifier temperature can be increased to 39–40°C to warm the patient up. On the other hand in a patient who is febrile, the humidifier temperature can be decreased to 33–34°C to help control the patient's fever. Humidifier temperature less than 33°C will give less humidity to the inhaled air, thickening the patient's secretions leading to mucous plugs, airway occlusion, and lung collapse. Furthermore, dry cold air is irritant to the airway and can lead to bronchospasm especially in a patient with reactive airway disease.

Weaning from Mechanical Ventilator

As soon as the patient is connected to mechanical ventilator, one should start planning for weaning the patient from this machine. As mentioned in the beginning, while mechanical ventilator can help us save lives, this is not risk free. Mechanically ventilated patients are at risk of ventilator-associated lung injury, ventilator-associated pneumonia, and breathing muscles deconditioning. Mechanical ventilator lung injuries can be related to high volume, volume trauma (volutrauma); high pressure, pressure trauma (barotrauma); atelectasis (atelectetrauma); high inspired oxygen concentration; oxygen toxicity; and cytokine release. These mechanical ventilator–associated traumas should be prevented. The target is not optimal blood gas. Our target is to take from the lung as much as it can give us with the least possible ventilator-associated lung damage. To decrease the risk of breathing muscle deconditioning, the patient should not be on full support for long time. The risk of breathing muscle deconditioning increases if the ventilator takes over the work of breathing for $\geq$72 h from the patient. Patients treated with muscle relaxants in combination with steroids like patients with bronchial asthma are at risk of developing critical illness neuromyopathy. The risk increases with the

use of aminoglycosides, diuretics, and electrolytes imbalance. It is preferable to give the muscle relaxant as needed rather continuous infusion in such patients. Should the patient's condition mandate continuous muscle relaxant infusion, the infusion should be held periodically and the health-care provider should assure and document that the patient is moving while off paralysis. One of the measures that helps us titrate the dose of muscle relaxant is to check for train of four. A nerve stimulator gives four electrical stimuli (train of four) applied in series stimulating a peripheral nerve like the ulnar nerve. If the patient is having no response to this series (0/4), the muscle relaxant should be held and the patient should be reassessed clinically and by the nerve stimulator. The target is to prevent the patient from fighting the ventilator. One do not have to have (0/4) response to achieve that. When following the paralyzed patient for mechanical ventilation a response of (2–3/4) is usually adequate. This level of response indicates that the patients' muscles are relaxed enough to facilitate mechanical ventilation.

High Frequency Oscillatory Ventilation (HFOV)

HFOV is the most commonly used type of high frequency ventilation in the pediatric critical care units. In this form of ventilation, the ventilator plays an active role during inspiration and expiration. The ventilator piston pushes air in during inspiration, and it sucks it out from the patient during expiratory phase. The tidal volume in this mode of ventilation is much smaller than the dead space. HFOV used to be offered for patients who are on high pressures on conventional ventilation or patients who fail conventional ventilation. Nowadays, the patient does not have to fail conventional ventilation to justify using HFOV. In many pediatric and neonatal critical care units, HFOV is used along with conventional ventilators as a standard of care for patients who need mechanical ventilation. Compared to conventional mechanical ventilation, HFOV uses higher mean airway pressure. Since the damping effect is higher in HFOV compared to conventional MV, the alveoli are more protected with HFOV. Some patients have better oxygenation and ventilation while on HFOV compared to conventional ventilation. However, there are no clearcut guidelines for which patients do better on HFOV. To start the patient on HFOV, the clinician has to define the following: the mean airway pressure, the power or delta-P, the frequency, and the FiO_2. The mean airway pressure on HFOV is started at 2–4 cm above the mean airway pressure on the conventional mechanical ventilator. FiO_2 started usually at 100% and weaned keeping oxygen saturation around our target usually in the 90–95% range. If the patient desaturate when the FiO_2 is weaned down, and the lung is showing signs of de-recruitment, the mean airway pressure should be increased by 1–2 cm H_2O, to help recruit the lung and wean the FiO_2. Our target is to reach the MAP that will achieve O_2 saturation in the target area with FiO_2 in the safe area ($\leq$40%). Delta-P or the power, which reflects the change in the pressure between inspiration and expiration, is age dependent. The usual staring delta-P is 40 for newborn, 45 for infants, and 50 for older children and teenagers. By looking at the patient, a good delta-P will make the patient shake down to mid-thighs. Delta-P reflects ventilation, and if the patient is having problem washing out CO_2, but with good saturation, the delta-P should be increased. However, if the patient is having inadequate oxygenation and ventilation the MAP would be increased to improve lung recruitment. The frequency in HFOV ranges between 6 and 12 Hz. The starting frequency also is age and size dependent. The usual starting frequency is 12 Hz for newborns, 9 for infants, and 7 for older children. Increasing the frequency on HFOV shortens the inspiratory time giving a smaller tidal volume. This leads to CO_2 retention. Thus, in contrary to conventional mechanical ventilation if the patient is having a problem with CO_2 retention after optimizing the delta-P and MAP, the frequency should be decreased rather than increased. As the patient's condition improves, our target is to wean the FiO_2 to $\leq$40%, then wean the MAP to teens, and then to switch him or her to conventional mechanical ventilation. Patients, who are having lot of secretions that need frequent suction of their endotracheal tube, are not good candidates for HFOV. With suction, the patient will have lung de-recruitment leading to transient desaturation and CO_2 retention. Recruitment takes time on HFOV. To overcome this problem, it may be helpful to increase the MAP by 2 cm after suction to enhance recruitment and to go back to the base line MAP once the O_2 saturation goes back to base line. Patients with borderline hemodynamics may not tolerate HFOV. Before staring HFOV for such patients, the intravascular volume should be optimized.

Permissive Hypercapnia

First described by Wung in neonates treated for persistent fetal circulation, permissive hypercapnia is a strategy in which the clinician will accept higher $PaCO_2$ and lower pH in order to minimize the ventilator-associated lung injury.

This strategy was also described in patients mechanically ventilated for bronchial asthma and acute respiratory distress syndrome (ARDS).

Inverse Ratio Ventilation (IRV)

Inverse ratio ventilation is a strategy that is used to improve oxygenation in patients who failed to respond to other measures like optimizing the PEEP and FiO_2. In this strategy, inspiratory time will be increased to exceed the expiratory time. This leads to increase in mean airway pressure, and potentially improving recruitment and oxygenation. This strategy can be applied for patients who are on volume- or pressure-cycled ventilation. Inverse ratio ventilation may improve oxygenation. However, there is no clear evidence that it improves duration of mechanical ventilation, ICU length of stay or mortality. Because IRV is uncomfortable, patients who are on inverse ratio strategy need deep sedation or paralysis.

Mechanical Ventilation in Different Case Scenarios

Mechanical Ventilation for Patients with Bronchial Asthma

Patients with bronchial asthma can develop severe asthma exacerbations. In some patients, the attacks will be so severe that the patients do not respond to the conventional treatment for such attacks. These patients may get exhausted, lethargic, and develop respiratory failure. Since endotracheal intubation and mechanical ventilation in a patient with bronchial asthma is surrounded with complications, such measures are to be avoided as much as possible. Most of the morbidity and mortality for patients with severe status asthmaticus who were sick enough to need mechanical ventilation are related to intubation and mechanical ventilation. As they need intubation, patients with asthma can be dehydrated secondary to increase insensible loss through hyperventilation, and vomiting and decrease intake. The high doses of beta 2 agonist that these patients are receiving increase vascular capacitance and decrease systemic vascular resistance. To compensate for the relative intravascular volume depletion and beta 2 agonist–induced vasodilatation, the stressed body of these patients releases lot of epinephrine and norepinephrine, which helps increase their cardiac output and their vascular resistance to maintain their perfusion pressure. While preparing such patients for endotracheal intubation, these patients are medicated with anxiolytics, narcotics, and muscular relaxants. Narcotics and anxiolytics suppress the stress-induced release of catecholamines. The muscular relaxants lead to decrease venous return by abolishing the muscle pump effect and changing the intrathoracic pressure during inspiration from negative to positive; these factors lead to sudden drop in the venous return, systemic vascular resistance, and cardiac output and may lead to cardiac arrest if the patient is not well prepared. So, intubating a patient with severe status asthmaticus is to be avoided if possible, to be done by the most experienced health-care provider, patient is to be prepared with good IV access, and reviving circulation by giving fluids (fill the tank) before giving the drugs needed to facilitate endotracheal intubation.

The main problem in bronchial asthma is air trapping. The patient's main problem is in the expiratory phase. Airway diameter is smaller during exhalation and exhalation is usually passive. Patients with bronchial asthma have normal lung compliance and increased airway resistance. So, the time constant in bronchial asthma is increased. To facilitate air exchange in these patients, inspiratory (I) time and expiratory (E) time should be adequate. The usual I:E time ratio that a patient with bronchial asthma needs is 1:3–1:5. To allow good I time that is 3–5 time constant and longer E time these patients need low rate on the ventilator. Patients with bronchial asthma can be ventilated using volume or pressure modes. This is based on the operator experience and comfort. In many critical care units, volume mode is the default mode. PRVC is the most common mode that is used for our patients in general and patients with status asthmaticus are no exception.

Patients with bronchial asthma can be difficult to ventilate and may need muscle relaxants. Usually, these patients are on systemic steroids and if given muscle relaxants, they should be given the smallest dose to help the patient not to fight the ventilator. The bedside nurse should check for the train of four responses. To help decrease the risks of mechanical ventilation and muscle relaxant in such patients, both should be weaned as soon as possible.

Positive end-expiratory pressure (PEEP) is usually applied to the mechanical ventilation strategy for patients with asthma. No PEEP for such patients can lead to increased micro atelectasis increasing ventilation perfusion mismatch which is the most common cause of low saturation in these patients. High PEEP and auto-PEEP can increase air trapping and CO_2 retention. Usually one starts with low PEEP in range of 2–3 for these patients and follows their progress. These patients if not given enough

time during exhalation will develop auto-PEEP. Auto-PEEP is the difference between the expiratory pause pressure and the setup PEEP. Patients with auto-PEEP can be helped with increasing expiratory time, decreasing tidal volume, and/or bronchodilators.

Beta 2 Agonists for Mechanically Ventilated Asthmatic

Beta 2 agonists are essential medication for the treatment of status asthmaticus. To decrease their side effects, these medications are best given by inhalation route. This can be done by metered inhaler puffs or by nebulizer. Both methods are effective in treating patients with severe bronchial asthma exacerbation. However, if the respiratory therapist did not account for the flow coming through the nebulizer, the patient can have excessive flow and develop pneumothorax. In general, in our ICU it is preferred to give these medications to our mechanically ventilated patients by metered dose inhaler (as puffs). In very sick asthmatic with poor air exchange, the beta 2 agonist can be given through the IV route.

Setting the Humidifier for a Patient with Asthma

Some of these patients have thick dry secretions that may obstruct the air worsening the lung collapse. Dry cold air is well known to be irritant to these patients' irritable airway. Thus, the humidifier by warming and humidifying the inhaled gas mixture can be of great help in the treatment of these patients.

Helium Oxygen Mixture and Asthma

Helium oxygen gas mixture can be given to patients with bronchial asthma attach. This can be given for ventilated and non-ventilated patients. The advantage of this mixture is that decreasing the density of the inhaled gas will change the flow of gas mixture from turbulent to linear flow. This will facilitate the gas flow to the lower airway. However, for this gas to be effective and to have low density the helium to oxygen ration has to be high. The best combination is 20% oxygen and 80% helium. If the patient's condition mandate giving high concentration of oxygen $\geq$30%, this mixture will be less effective. Some clinicians will argue that in patients with severe bronchospasm with poor air entry, giving helium will help deliver the medications to the lower airway and improve the patient's condition.

Mechanical Ventilation for Patients with Head Injury and/or Increased Intracranial Pressure (ICP)

There are few points that are worth mentioning in regard to endotracheal (ET) placement and mechanical ventilation in such patients. In preparation for endotracheal intubation, special care should be applied for the stability of the cervical spines while opening the airway. Head tilt chin left to be avoided. Jaw thrust can be applied. While preparing drugs for tracheal intubation, one should not use drugs that increase intracranial pressure (ICP) as succinylcholine and ketamine. Once their circulation is revived, these patients need drugs to help decrease risk of escalating the increased ICP. These drugs include short acting painkillers like fentanyl, anxiolytics like midazolam, anesthetic like lidocaine, non-depolarizing muscle relaxant like vecuronium, and short acting barbiturate as pentothal.

Ventilator setup for patients with increased ICP: Both volume and pressure modes can be used. In our institution volume mode is used. PRVC is our first choice. Ideally, these patients need a ventilator setup that gives the patient good oxygenation with $FiO_2 \leq 40\%$, a PCO_2 between 35 and 38 mmHg with the lowest possible mean airway pressure. So, for these patients PEEP should be the lowest that gives target O_2 saturation with $FiO_2 \leq 40\%$. I time around 0.5–1 s, I:E ratio 1:2, and tidal volume the lowest that gives good chest excursion by inspection and target CO_2 in blood gases. The rationale behind this strategy is to decrease the intrathoracic pressure to enhance the venous return from the head while maintaining good oxygenation and ventilation. This will help decrease ICP and improve the cerebral perfusion pressure (CPP). CPP equals the difference between the mean arterial pressure (MAP) the force pushing the blood into the cranium and intracranial pressure (ICP) or central venous pressure (CVP) whichever is higher. High mean airway pressure which is a reflection of tidal volume or pressure above the PEEP, the PEEP, I time and I:E ratio, increases the resistance for the venous drainage from the head into the thoracic cavity increasing the intracranial pressure and decreasing the cerebral perfusion pressure.

Patients with increased intracranial pressure need also to be covered with sedation, analgesia as needed to tolerate the endotracheal tube and the mechanical ventilator. Muscle relaxants are to be added, if sedation and analgesia

failed. Muscle relaxant will make it difficult to follow the clinical neurostatus progression of the patient. As mentioned above, using the muscle relaxants and taking over the work of breathing from the patient for long time can lead to deconditioning of the breathing muscles. So this should be used as needed and the patient should be monitored with train of four.

To help avoid increase ICP crisis, these patients need to be well prepared for endotracheal suction and/or any irritating or painful procedure. Before extubating such patients, the clinician should assess their capability to protect the airway.

Mechanical Ventilation and Cardiac Function

During spontaneous inspiration, the diaphragm goes down and the ribs rise up to be horizontal increasing the intrathoracic volume. This decreases the intrathoracic and increases the abdominal pressure, increasing the venous return, increasing right ventricle preload, shifting the interventricular septum to the left, increasing the pulmonary vascular capacitance, decreasing left ventricle preload, and increasing left ventricle transmural pressure. The left ventricle transmural pressure is the difference between systemic pressure and intrathoracic pressure. For example, if the systolic pressure was 100 and the intrathoracic pressure was −15, then the transmural pressure is 115. So, the arterial systemic systolic pressure is lower during inspiratory phase. If the patient is in respiratory distress and has to create more negative pressure during inspiration, then the gradient in the systolic pressure is going to be wider between inspiration and expiration. If the difference is more than 10 mmHg, this is called pulsus paradoxus. In general, the right ventricle output is better and the left ventricle output is worse with increasing the negative intrathoracic pressure.

Once the patient is connected to positive pressure ventilation, the pressure gradient that drives the venous return to the right atrium is decreased decreasing the right ventricle preload. Positive pressure ventilation that pushes the lung volume above the functional residual capacity (FRC) will increase the right ventricle after load. On the other hand the left ventricle transmural pressure will decrease. If the patient's main problem was left ventricle failure, his or her intravascular volume, the preload for both ventricles was adequate, then, positive pressure ventilation will improve his or her left ventricle function, and improve his or her cardiac output. However, if the patient was hypovolemic, his or her intravascular volume is depleted, positive pressure ventilation will decrease the preload for the right ventricle, decreasing the cardiac output. In general, left ventricle likes positive pressure ventilation. Right ventricle does not like positive pressure ventilation.

268 Infections in the PICU

Tavey Dorofaeff · Hadi Mohseni-Bod · Peter N. Cox

Introduction

Effective control of infections starts at the community level, outside the hospital. There are a number of important initiatives that, although simple and not necessarily intensive care related, have the greatest impact on the outcomes of infections. These include provision of adequate and age appropriate foods, breast feeding, drinkable water, provision of mosquito nets and shelter, avoidance of overcrowding, sanitization, and prevention of disease by vaccination. These are basic needs and requirements of mankind as a basis of good health. They are attainable in the largest cities or the most remote areas.

Infections are one of the commonest causes of mortality in the pediatric intensive care unit (PICU), with a mortality of up to 50%, depending on the origin of the infection.

Infections in the intensive care unit can be divided into those that occur outside the hospital (community acquired) and those that occur within the walls of the hospital and beyond 48 h of admission (nosocomial). Preventive measures give the most benefit, both outside and inside the hospital. Good hand washing, good respiratory care practice, and judicious use of antibiotics are examples of effective interventions that reduce the rate of nosocomial infections.

Sepsis comprises up to 25% of admissions to a typical pediatric intensive care unit. Shock and management of septic shock are discussed elsewhere in this text. However basic principles of management are the same and are not, and should not be, limited to the intensive care unit. Treatment should commence as soon as the recognition of any septic process is underway be it in the field, the clinics, emergency departments, or on the wards.

In the community, on the hospital wards, and in the PICU, timely identification of illness and access to skilled healthcare personnel are crucial steps limiting the development of organ dysfunction and failure. Early identification means early resuscitation and early treatment. This may be hours or in some cases days prior to the admission to the PICU. This early recognition and intervention gives the patient the greatest chance of surviving a significant infection.

Organization of this Chapter

1. "Catalog" of important microorganisms and diseases they cause in the PICU
   (a) Bacteria
   (b) Fungi
   (c) Viruses
2. Significance of viral infections in the PICU
   (a) Viral epidemics and pandemics
   (b) Viral infections of regional importance
      (i) Dengue fever
      (ii) Viral hemorrhagic fevers
3. Parasitic infections in the PICU
   (a) Malaria
4. Shock syndromes in the PICU
   (a) Staphylococcal toxic shock syndrome
   (b) Streptococcal toxic shock syndrome
   (c) Necrotizing soft tissue infections
5. Anatomical distribution of infections in the PICU
   (a) Upper airway infections
      - Epiglottitis
      - Croup
      - Tracheitis
   (b) Lower respiratory tract infections
      - Community-acquired pneumonia
      - Bronchiolitis
   (c) Cardiac infections
      - Myocarditis
      - Infective endocarditis
      - Infectious pericarditis
      - Wound infection after cardiac surgery
   (d) CNS infections
      - Purulent meningitis
      - Encephalitis
      - ADEM
      - Guillain-Barre syndrome
      - Botulism
6. Infection in the immunocompromised host
   (a) Neutropenia
   (b) Cellular immune deficiency
   (c) Humoral immune deficiency
   (d) Complement deficiency
   (e) Human stem cell transplant (HSTC) patients

   (a) Blood stream infections
   (b) Central venous access line infections
   (c) Ventilator associated pneumonia (VAP)
   (d) Urinary tract infections (UTI)
   (e) Wound infections
8. Infection control principles in the PICU
9. Summary

Catalog of Important Microorganisms in the PICU

Medically Important Bacteria in the Pediatric Intensive Care Unit

Crucial to the management of any serious infection in the Intensive care unit and elsewhere is the *early* use of *appropriate* antibiotics. Early identification of most bacteria is almost universally by the way of a Gram stain. This can be performed in any microbiology lab, in the field, or a clinic that is suitably equipped.

Though references such as the "Red Book" (American Academy of Pediatrics) give invaluable information on the appropriate antimicrobial therapy for a given microbe or infectious syndrome, there is no substitute for a well informed, up-to-date infectious diseases physician or microbiologist. They are able to provide information on local isolates, patterns of sensitivity, and best management practices for a large variety of infections.

The majority of the bacteria listed below will be referenced elsewhere; they are highlighted to reflect their frequency of identification in the PICU. Additionally, the immunocompromised host will be at risk from a number of opportunistic infections that will be discussed later in this chapter.

Gram-Positive Cocci

Staphylococcus aureus. Pneumonia, disseminated infection/multi site (bone, heart, lungs, CSF), toxic shock syndrome, central venous line (CVL) infection

Staphylococcus epidermidis. CVL infections

Streptococcus pyogenes (Group A Streptococcus). Bacteremia, septicemia, necrotizing fasciitis, toxic shock syndrome

Streptococcus agalactiae (Group B Streptococcus). Early/late onset group B sepsis in neonates

Enterococcus faecalis. Urinary tract infections/VAP (Ventilator Associated Pneumonia)

Streptococcus pneumoniae (Pneumococcus). Bacteremia, septicemia, pneumonia, meningitis

Gram-Positive Rods

Clostridium tetani. Wound-related tetanus, neonatal tetanus in the developing world

Clostridium botulinum. Flaccid paralysis (Botulism)

Clostridium perfringens. Gangrene/sepsis/toxin mediated disease

Clostridium difficile. Antibiotic associated diarrhea, pseudomembranous colitis

Corynebacterium diphtheriae. Diphtheria in unvaccinated

Listeria monocytogenes. Sepsis and meningitis in neonates and immunocompromised

Gram-Negative Cocci

Neisseria meningitidis (Meningococcus). Septicemia, meningitis

Neisseria gonorrhoeae (Gonococcus). Neonatal conjunctivitis, pelvic inflammatory disease, occasionally disseminated infections and involvement of the joints

Gram-Negative Rods

E. coli, Klebsiella pneumoniae, Enterobacter cloacae, Serratia marcescens, Proteus Sp. (e.g., *P. vulgaris, P. mirabilis*), *Bacteroides fragilis.* Urinary tract infection, sepsis (esp. neonates and debilitated), CVL infections, Ventilator Associated Pneumonia (VAP), meningitis in neonates.

Haemophilus influenzae (*type A, B and non-typable*). Otitis media, pneumonia, epiglottitis, and meningitis in the unvaccinated

B. pertussis. "Whooping Cough" in older children, necrotizing/calcifying pneumonia, and cardiovascular collapse in neonates

Pseudomonas aeroginosa, Burkholderia cepacia, Stenotrophomonas maltophilia. Pneumonia/chronic infection/colonization of cystic fibrosis patients and patients with a tracheotomy, VAP

These bacteria have a tendency for multiple antibiotic resistances.

There are a number of other medically significant bacteria that only periodically present in the pediatric intensive care unit. These bacteria are prevalent in some regions and not elsewhere. They will not be discussed further in this chapter.

Fungi (of Importance in the PICU)

Classification

- Yeasts (e.g., *Candida* or *Cryptococcus* sp.)
- Molds – filamentous fungi (e.g., *Aspergillus* sp. and *Trichophyton* sp.)
- Dimorphic fungi – yeasts in tissue but grow in vitro as molds (e.g., Histoplasmosis)

Candida. C. albicans has the highest incidence in the critical care environment followed by *C. parapsilosis*, *C. tropicalis*, *C. glabrata*, and *C. Krusei*. Localized and systemic infections in neonates and immunocompromised children. Any organ can be involved: mucous membranes, larynx, esophagus, brain, eyes, lungs, heart, kidneys, liver, and spleen.

Aspergillus. A. fumigatus is the most common species in invasive aspergillosis, followed by *A. Flavus*, and *A. Nigra*. Localized and systemic infection in immunocompromised children (particularly post stem cell transplant and in children with AML); in the skin, subcutaneous tissues, nasopharynx, lungs, brain, and virtually any other organ.

Endemic Mycosis (Histoplasmosis, Blastomycosis). Pneumonitis, hepatosplenomegaly, fever in children with T-cell dysfunction and in those with HIV infection.

Coccidioides immitis. Pneumonia, meningitis in children with T-cell dysfunction and in those with HIV infection.

Cryptococcus neoformans. Pneumonia, meningitis in children with T-cell dysfunction and in those with HIV infection.

Viruses (of Importance in the PICU)

Human Herpes Viruses

1. Herpes Simplex Virus (HSV, types 1 and 2)
   (a) Systemic infection in the neonate with shock and coagulopathy and severe liver failure
   (b) Encephalitis, hepatitis
   (c) Local (mouth, esophagus, larynx, lungs, heart, liver, kidneys, CNS) or systemic disease in organ and stem cell transplant and immunocompromised patients
2. Cytomegalovirus (CMV)
   (a) Congenital infection in the neonate with systemic involvement
   (b) Localized (liver, lungs, heart, kidneys, GI, CNS, eyes) or systemic infection in solid organ and stem cell transplant as well as immunocompromised patients
3. Epstein-Barr Virus (EBV)
   (a) Infectious mononucleosis
   (b) Burkitt's lymphoma, X-linked Lymphoproliferative disorder (XL-LPD), post transplant lymphoproliferative disorder (PTLD)
   (c) Localized (liver, heart, lungs, kidneys, GI, CNS) or systemic infection in solid organ and stem cell transplant and immunocompromised children
4. Varicella-Zoster Virus (VZV)
   (a) Chickenpox and its complications [pneumonia, encephalitis, meningoencephalitis, soft tissue necrotizing infections (caused by streptococcus and staphylococcus and associated with chickenpox)]
   (b) Disseminated Herpes Zoster in immunocompromised children

Parvovirus

1. Hydrops fetalis in the neonate
2. Aplastic crisis in patients with sickle cell anemia
3. Bone marrow failure
4. Myocarditis

Enteroviruses

1. Coxsakie (A and B), and echovirus
   (a) Myocarditis, pericarditis
   (b) Meningitis
2. Poliovirus (types 1 to 3) bulbar poliomyelitis

Adenovirus

1. Upper respiratory infection, pertussis-like syndrome, pneumonia, pharyngoconjunctival fever
2. Acute hemorrhagic cystitis
3. Hepatitis, meningoencephalitis, myocarditis
4. Localized (liver, heart, lungs, kidneys, GI, CNS) or systemic infection in organ and stem cell transplant and immunocompromised children

Hepatitis Viruses (A, B, C, D, E)

Fulminant hepatitis

Retroviruses

HIV/AIDS

Bunyaviridae and Arenaviridae

1. Hemorrhagic fever
2. Encephalitis

Togaviruses and Flaviviruses

1. Dengue
2. Yellow fever
3. Encephalitis

Rhabdoviruses

Rabies

Filoviruses

Marborg and Ebola hemorrhagic fevers

Orthomyxoviruses

Influenza A (H1N1, H2N2, H3N2, $H_{SW}N1$, H5N1), and Influenza B and C

1. Upper respiratory infection; croup, pneumonia, ARDS
2. Encephalitis

Paramyxoviruses

- Measles (pneumonia, croup, encephalitis, subacute sclerosing panencephalitis(SSPE))
- Parainfluenza (bronchiolitis, pneumonia, croup)
- Mumps (parotitis, encephalitis, meningoencephalitis, orchitis, pancreatitis)
- RSV and Human Metapneumovirus (bronchiolitis, pneumonia, ARDS)

Coronaviruses

SARS (severe acute respiratory distress syndrome)

Significance of Viral Infections in the PICU

It is likely that viral infections have been underestimated both in their frequency and the degree of morbidity they cause. Indisputably, in the modern day, HIV (Human Immunodeficiency Virus) is one of the most significant viral pathogens worldwide, particularly in Africa and developing nations that do not have the available resources to prevent spread among the community and more importantly maternal infection of the newborn. This leads to a range of morbidities as discussed in the immunocompromised section of this chapter.

Viral infections are mostly diagnosed clinically on the basis of history and physical examination as well as the regional prevalence of viral diseases. There are a number of ways to test for the presence of a particular virus from either patient blood or other body fluids. These are: tissue culture, serology and seroconversion, immunoflouresence, and PCR (Polymerase Chain Reaction). Only two of these are of any use to the intensivist: PCR and Immunoflouresence. The turnaround time for viral culture and serum serology is inefficient in the critical care context.

Respiratory Viruses (Respiratory Syncytial Virus, Influenzae, Adenovirus, ParaInfluenzae, and Human Metapneumovirus) are the main contributors to viral disease in the PICU, as they are in the general pediatric population. In the PICU the majority of patients that develop significant degrees of illness are those who have significant comorbidities. Conditions such as ex-prematurity, chronic lung disease, neuromuscular diseases, and congenital heart disease are probably the most common of these.

Herpes Virus family, particularly herpes simplex virus (HSV), is the next important contributor to the burden of viral disease. All members of this family (HSV, EBV, CMV, and VZV) can cause serious infections in the neonate and in immunocompromised children.

Viral Epidemics and Pandemics

All services that treat the acutely unwell child (and adult) are at risk of being overwhelmed in an epidemic. National and regional planning needs to be undertaken prior to the advent of any serious infection where ever possible. (Examples are SARS -Severe Acute Respiratory Syndrome,

or H1N1 "Swine Flu.") This is encapsulated in the worldwide pandemic planning taking lessons from the SARS epidemic and the last major (in terms of mortality) influenza epidemic, the "Spanish Flu" that was prevalent from 1918 to 1920.

At a hospital or an organizational level the concept of "surge strategy" is used. This is an organization based contingency plan to deal with large numbers of patients admitted simultaneously (i.e., mass trauma casualties or epidemics). In the case of influenza (or SARS) this is relevant to the intensive care in that there is a finite capacity of any unit to provide mechanical ventilation. In addition to this, the institution is responsible for the protection of health care workers who are at high risk to contract an infectious illness and become a patient themselves. This would further increase the burden of illness and has the potential to limit available human resources.

Regional Viral Infections

The prevalence of HIV in the general population and, in particular, in children in many developing countries poses significant stress on limited resources. Hopefully, with more effective preventive programs to control vertical transmission of the infection and with availability of affordable anti-HIV medications, the quality of care for HIV-infected children will improve and the need for intensive care will diminish.

Regional or local experience is crucial in the management of many infections. Dengue fever and viral hemorrhagic fevers, which are of more global importance, will be reviewed in more detail.

Dengue Fever

Dengue infections, caused by the four antigenically distinct dengue virus serotypes (DEN1, DEN2, DEN3, DEN4) of the family Flaviviridae, are the most important arbovirus diseases. Dengue is the most widely distributed mosquito-borne viral infection of humans, affecting an estimated 100 million people worldwide annually. Dengue hemorrhagic fever usually occurs in children, with peaks in incidence at 7 months of age (with dengue-immune mothers), and at 3–5 years of age (during a second infection with a new serotype). It is spread throughout the tropical and subtropical zones between 30°N and 40°S where environmental conditions are optimal for viral transmission by *Aedes* mosquitoes, principally *Aedes aegypti*. The disease is endemic in SE Asia, the Pacific, West Africa, the Caribbean, and the Americas.

Global warming, by increasing the range of Aedes mosquito, has the potential to lead to more widespread disease.

WHO has classified the severity of dengue infection on the basis of a combination of clinical and laboratory findings (presence of hypotension and shock, tourniquet test, lowest platelet count, plasma leakage represented by high hematocrit level) in to:

- Dengue fever
- Dengue hemorrhagic fever
- Dengue shock syndrome (DSS)

Severe Dengue (Dengue Hemorrhagic Fever and Dengue Shock Syndrome)

1. Increased vascular permeability and "plasma leakage" leading to shock is the hallmark of severe dengue infection in children. High or progressively rising hematocrit is often a sign of plasma leakage. A drop in platelet count to 100,000/mm^3 or less usually precedes a rise in hematocrit. Tachycardia, a narrow pulse pressure (<20 mmHg), prolonged capillary refill time, and cold extremities herald impending shock if appropriate treatment is not rapidly initiated. Hypotension is usually a late sign. Shock often occurs on day 4–5 of illness. Early onset shock (day 2 or 3) suggests very severe disease.
2. Bleeding; skin or mucosal, GI bleeding.
3. Hepatitis; RUQ tenderness and jaundice.
4. Encephalopathy; lethargy or restlessness, coma, seizures.

Management of Dengue Shock Syndrome (DSS)

Treatment is supportive; there is no specific treatment for dengue infections. The only effective treatment in DSS is timely, aggressive fluid resuscitation. There is no evidence that colloids are superior to crystalloids. With appropriate use of fluid resuscitation in DSS, the mortality has dropped from 10% to <0.2%. Steroids have not been shown to be effective. There may be a role for intravenous immunoglobulin (IVIG) or plasma exchange in severe dengue infections. Hypoglycemia and hyponatremia should be avoided and rapidly corrected if present. A platelet count of less than 20,000, or less than 40,000, with associated bleeding warrants platelet transfusion. Ventilation should be supported as needed by noninvasive or invasive mechanical ventilation. If ascites or pleural effusions (which are not uncommon due to vascular leak) cause hemodynamic

or ventilatory compromise, the collection should be drained. Renal dysfunction may need hemofiltration/dialysis.

Viral Hemorrhagic Fevers

Viral Hemorrhagic Fever is a loosely defined category that includes infections from a host of viruses leading to similar clinical syndromes and sharing a similar severity of illness. Otherwise, these viruses are different from each other with regard to their reservoir hosts, geographic distribution, and taxonomy. Risk factors for exposure also vary among these infections and hence the control methods are geared to specific infections and their causative agents and intermediate hosts. In endemic areas diagnosis is by and large clinical and is confirmed by serological tests and viral PCR or culture. There are vaccines developed for some of these viruses.

As a group, the treatment for these infections in the PICU is mainly supportive and includes measures to:

- Optimize hemodynamic state and treat shock
- Monitor and control brain edema and intracranial hypertension
- Support ventilation and gas exchange with noninvasive or invasive ventilation
- Treat coagulopathic state if symptomatic
- Provide renal replacement therapy if needed; monitor and optimize glucose and electrolyte levels

Exhaustive discussion of this topic is beyond the current chapter, so the most important ones are briefly mentioned here.

Yellow Fever

Yellow fever is endemic in tropical Africa between 15°N to 10°S and in parts of Central and South America between 10°N and 40°S. In the life-cycle of this virus, in different parts of the world, mosquitoes (*A. aegypti*, *Haemagogus*, *and Sabethes*), monkeys, and people are involved; however, epidemic mosquito-borne human-to-human transmission can occur.

After an incubation period of 3–10 days, fever, headache, malaise, nausea and vomiting, and musculoskeletal pain occur suddenly. Initially, the clinical signs may include conjunctivitis, flushing of the skin, and relative bradycardia. In about 10% of cases the illness deteriorates with development of shock, systemic toxicity, GI bleeding, renal dysfunction, liver failure and jaundice, encephalopathy, and systemic bleeding. This latter picture is associated with a high mortality rate (30–50%).

Differential diagnosis includes other viral hemorrhagic fevers, viral hepatitis, leptospirosis, malaria, typhus, typhoid fever, brucellosis, rickettsial disease, and some intoxications.

Therapy is supportive and these patients may need intensive care admission for hepatic, renal and circulatory failure.

WHO has recommended routine childhood vaccination in endemic areas (for children >4 months of age). Vector control is important in highly populated areas to reduce the risk of epidemic transmission.

Lassa Fever

Lassa fever causes as many as 300,000 cases and 5,000 deaths each year in West Africa and is a leading cause of maternal and fetal deaths. The virus is carried by *Mastomys huberti* and *Mastomys erythroleucus*, the rodent reservoirs whose infectious excretions are the source of human infections in West Africa.

In adults and children, early illness includes fever, malaise, headache, and musculoskeletal pain. These nonspecific symptoms progress over 4–5 days to include pharyngitis, cough, chest pain, diarrhea, and vomiting. In endemic areas, a purulent pharyngitis, with conjunctivitis, head and neck edema, and mucosal bleeding are highly specific signs of Lassa fever.

In severe cases, the illness may be complicated by hypovolemic shock, encephalopathy, respiratory distress caused by laryngeal edema, pleural effusions, or pneumonitis. Liver failure, systemic and GI/GU bleeding, and myocarditis can occur. Mortality is between 15% and 30%. There are anecdotal reports of the use of intravenous ribavirin in critically ill children with Lassa fever but treatment is mainly supportive.

Lassa fever has been transmitted from person to person during hospitalization. Universal exposure precautions should be observed as well as contact and droplet precautions.

Congo-Crimean Hemorrhagic Fever (CCHF)

CCHF is caused by a nairovirus (family Bunyaviridae), and is transmitted by *Hyalomma* ticks and by contact with infectious body fluids. The geographical distribution of the Hyalomma ticks covers Africa, the Middle East and Mediterranean areas, Eastern Russia, and West Asia.

The incubation period is from 2 to 9 days. Illness onset is abrupt and nonspecific, with fever, chills, rigors, intense headache, and generalized muscle pain. Onset of bleeding

in the skin, mucous membranes, and the GI tract usually occurs after 3–6 days of illness. Hepatitis, liver failure, circulatory failure, shock, and ARDS can ensue with mortality in up to 30% of cases.

Treatment is mainly supportive. The virus is sensitive in vitro to Ribavirin, and this agent has been used in management of CCHF with variable success (WHO). The value of immune plasma from recovered patients for therapeutic purposes has not been demonstrated, although it has been employed on several occasions (WHO).

Patients with suspected or confirmed CCHF should be cared for by staff using added droplet and contact precautions.

Hemorrhagic Fever with Renal Syndrome (HFRS)

HFRS is caused by Old World Hantaviruses (family Bunyaviridae). The reservoirs are small rodents, and humans are infected percutaneously or by direct exposure. Clinical illness has an abrupt onset with fever, severe musculoskeletal pain, renal failure, systemic and GI bleeding, circulatory failure, and shock. This form of the disease is more common in Asia and Eastern Europe.

In Hantavirus pulmonary syndrome (HPS) (mainly seen in the Americas), within 12–24 h of onset of symptoms, most patients develop some degree of hemodynamic instability and pulmonary edema accompanied by hypoxemia to full blown ARDS. Petechiae of the head and neck are common but overt hemorrhagic symptoms are not. Treatment is supportive and in those who survive, recovery is usually rapid.

When given early in the course of illness, intravenous ribavirin has improved survival rate in HFRS but not in HPS. Steroids reduce the severity of the symptoms but do not increase the survival rate.

Parasitic Infections in the PICU

Malaria is singled out here because it is the most significant parasitic disease in humans with an estimated 500 million infections annually that result in 1–3 million deaths. The majority of these deaths are in children younger than 5 years of age and most are in Africa. In developed countries malaria is the most common cause of febrile illness with no localizing signs in travelers returning from developing countries. The most important aspects of severe malaria are reviewed, which, for the most part, is caused by *Plasmodium falciparum.*

Severe Malaria

Indicators of severe and complicated falciparum malaria and prognostic signs (World Health Organization 2000)

Cerebral malaria	Unrousable coma (GCS < 11/15), with peripheral *P. falciparum* parasitemia after exclusion of other causes of encephalopathy
Severe anemia	Hgb < 5 g/dl in the presence of parasitemia >10,000 per ml
Respiratory distress	Pulmonary edema, ARDS, labored "acidotic" breathing
Renal failure	UOP < 0.5 ml/kg/h (<400 ml/24 h in adults), and a serum creatinine >265 micromole/l (>3 mg/dl)
Hypoglycemia	Whole blood glucose <2.2 micromole/l (40 mg/dl)
Shock	
Coagulopathy	Bleeding and/or lab evidence of DIC

Complicated Malaria

Impaired consciousness of any degree, prostration, jaundice, intractable vomiting, parasitemia >2% in nonimmune individuals. Levels of parasitemia should be interpreted in the light of immunity.

Patients with complicated malaria should be managed as severe malaria, i.e., with parenteral antimalarials even though they do not necessarily meet the criteria of severe disease. For details of management, review Chap. 101, "Malaria".

Cerebral Malaria

The World Health Organization defines Cerebral Malaria as unrousable coma in the presence of *P. falciparum* parasitemia when other causes of encephalopathy have been excluded. The precise etiology of cerebral malaria is not certain. Most likely it is caused by sequestration of infected erythrocytes. This condition has a high mortality that likely results from brain micro vascular ischemia, infarction, and secondary cerebral edema.

Cerebral malaria is a medical emergency that requires:

1. Supportive care:
   (a) Continuous monitoring of vital signs.

(b) Monitoring of serum electrolytes and glucose and correction of the abnormal results with appropriate therapy.
(c) Seizures are frequent and will require suppression with anticonvulsants.

2. Specific Parenteral Malarial therapy: Detailed discussion of anti malaria treatment is reviewed in Chap. 101, "Malaria".

   Parenteral quinine remains the first line treatment for severe falciparum malaria. Intravenous administration of this drug requires monitoring of the ECG and cardiac function. For travelers returning from Southeast Asia where quinine resistance is common, advice regarding the use of intravenous artesunate should be sought from specialist centers.
3. Extracorporeal therapy: For severe parasitemia exchange transfusion may be required. Renal replacement therapy may be necessary in those presenting in advanced shock and multiorgan system failure (MOSF).
4. Management of intracranial hypertension: Please read the section on raised intracranial pressure in bacterial meningitis later in this chapter, as the management is similar.

Sepsis Syndromes

For a detailed discussion on Sepsis, and the diagnosis and management of shock, please review the appropriate chapters (Chap. 61, "Bacterial Sepsis and Shock"). Toxic shock and necrotizing fasciitis are two particular sepsis syndromes that require a special reference.

Toxic shock syndrome (TSS) is caused by two bacteria: *Staphylococcus* and S*treptococcus.*

Staphylococcal Toxic Shock

S. aureus is a Gram-positive coccus that is grouped in clusters. It is responsible for a number of infections ranging from skin sepsis, pneumonia, and joint infections to endocarditis. Phage transformed *Staphylococcus* produces a toxin that initiates a syndrome known as toxic shock syndrome (TSS). This came to light in the 1980s with the "Menstrual Shock" syndrome. A non menstrual form was also identified. This was associated with *Staphylococcus* sepsis at surgical sites, skin or joint infections, and with staphylococcal pneumonia.

This syndrome is said to be "superantigen" mediated. The toxin proteins produced by the *Staphylococcus* are able to "cross-link" the T-cell receptor without being processed by an antigen presenting cell (APC). This leads to an uncontrolled cascade of cytokines and immune system up regulation. At the level of the capillary this leads to inflammation and increasing permeability with secondary organ dysfunction (renal impairment, cardiac, pulmonary, and liver dysfunction). Clinically this is manifested by skin erythema, tachycardia, hypotension, hypoxia and other critical organ dysfunction. Initially this is subtle but rapidly develops into multi organ dysfunction. See the table below for the criterion upon which a diagnosis of Staphylococcal toxic shock is made.

Treatment consists of recognition of the process, draining any collections of pus, and debridement, if that is appropriate. At the same time initiation of large volume fluid resuscitation, inotropic support and support of failing lungs with oxygen and ventilation if needed. Anti-staphylococcal antibiotics should be administered (this includes an antibiotic to cover for methicillin resistant *Staphylococcus*). Clindamycin being an anti-ribosomal antibiotic (50S bacterial Ribosome) has a theoretical advantage in reducing the amount of toxin produced prior to antibiotic induced death of the bacterium. Intravenous immunoglobulin (IVIG) is a treatment for severe toxic shock that is progressing to multi-systems dysfunction. It has a proven efficacy in toxic shock in reducing the mortality of severe disease. This is thought to be via two general mechanisms. The first is by binding directly to the toxin. The second is by its immuno-mediatory properties.

Staphylococcal Toxic Shock Syndrome (Case Definition from CDC)

Major criteria (all required)

1. Fever $\geq$38.8°C
2. Hypotension (orthostatic or shock)
3. Rash (erythematous early and desquamative later)

Minor criteria (any three required)

1. Gastrointestinal: vomiting or diarrhea
2. Muscular: severe myalgia or CPK $\geq$2x upper limit of normal
3. Mucous membranes: vaginal, oropharyngeal, or conjunctival hyperemia
4. Renal: urea or creatinine $\geq$2x upper limit of normal, or urinalysis with $>$5 WBC per high-power field
5. Hepatic: total bilirubin, AST or ALT $\geq$2x upper limit of normal
6. Blood: platelet count $<$100,000/µl
7. CNS: disorientation or change in level of consciousness without focality, noted when fever and hypotension are absent

And

1. Absence of other explanations
2. Blood cultures negative (except for *S. aureus*)

Streptococcal Toxic Shock

Streptococcal toxic shock is a syndrome that is analogous to staphyloccal toxic shock syndrome in that it is a superantigen mediated toxin related dysfunction of the immune system. Group A beta-hemolytic *Streptococcus* is most commonly associated with streptococcal toxic shock syndrome. Clinical presentation is very similar to staphylococcal toxic shock. See table below.

Treatment consists of appropriate antibiotics. Clindamycin is used for antimicrobial and antitoxin producing properties as previously mentioned. IVIG here too has a role in reducing the mortality of severe disease. Intensive care therapy consists of fluid resuscitation (large volume) and support of organ dysfunction (inotropes, ventilation, renal replacement therapy).

Streptococcal Toxic Shock Syndrome (Case Definition from CDC)

Hypotension or shock, plus any two of the following:

1. Scarlet fever rash
2. Abnormal liver function tests
3. Renal insufficiency
4. Disseminated intravascular coagulopathy (DIC)
5. Acute Respiratory Distress Syndrome (ARDS)
6. Soft tissue necrosis

Definite: preceding requirements + isolation of group A streptococcus from a normally sterile body site

Probable: preceding requirements + isolation of group A streptococcus from a non sterile body site

Necrotizing Soft Tissue Infections

Necrotizing soft tissue infections are aggressive soft tissue infections that cause extensive necrosis, and include necrotizing cellulitis, fasciitis, and myonecrosis.

The following clinical findings may be present:

- Erythema or discolored skin
- Tense edema
- Discolored/gray wound discharge
- Blister
- Ulcer
- Skin necrosis
- Crepitus

Also the following systemic signs may be present:

- Local pain and tenderness out of proportion to physical findings
- Pain or tenderness that extends past the margin of apparent affected skin area
- Fever
- Persistent tachycardia
- Diaphoresis
- Change in sensorium
- Hypotension

Necrotizing Fasciitis is a *surgical emergency*. It is caused by a number of organisms:

Group A beta-hemolytic *Streptococci* and other streptococci, *Staphylococcus, Clostridium, Pseudomonas, Klebsiella, Serratia, Neisseria, Escherichia, Morganella, Proteus, Shigella, Vibrio, Salmonella, Pasturella, Enterobacter, Corynebacterium, Cryptococcus, Fusobacterium, Peptococcus, Eikenella, Bacteroides.*

The most common causative agent is group A Streptococcus. Pathologically it is characterized by micro angiopathic thrombosis and necrosis along superficial and deep fascial planes. The illness is associated with a breach of the integument. This can be by superficial infection, surgery or trauma. Non steroidal anti-inflammatory drugs are implicated in the pathogenesis. In children there is an association with Varicella (Chickenpox) infection. Clinically the lesions appear either pale or have violaceous discoloration, often edematous, and there may be crepitus from gas forming bacteria. *Pain and tenderness in excess of that expected is a feature.* The concern for the intensivist is the physiological decompensation that can lead to rapid cardiovascular collapse. Broad-spectrum (and appropriate) antibiotics are indicated, and mechanical ventilation and cardiovascular support may be needed. Urgent and wide surgical debridment of the affected areas is indicated. In cases of streptococcal necrotizing fasciitis there may be additional benefit from human immunoglobulin (IVIG) therapy. Though this has not been subjected to clinical trials, given the high mortality rate of necrotizing fasciitis and the biologically plausible consideration that IVIG could neutralize the effects of streptococcal superantigens, its use can be justified.

Other treatments that have been used are:

- Vacuum-assisted wound closure (particularly in patients who have had large wound debridement)
- Hyperbaric oxygen (anecdotal evidence)

Anatomical Location of Infections in the PICU

Upper Airway Infection

The child, especially the infant, presenting with upper airway obstruction (UAO) demands immediate attention. Acute inflammation of the upper airway is of greater importance in small children because of the smaller diameter of the airway, hence the greater degree of obstruction from a similar amount of inflammation (resistance changes inversely to the fourth power of the radius of the airway).

The following signs and symptoms are particularly worrisome:

- Inspiratory AND expiratory stridor
- Active expiration (use of the rectus abdominis muscle when exhaling)
- Apnea or irregular breathing
- Increasing tachycardia (if no intervention is done tachycardia may be followed by decreasing heart rate which is usually a pre-arrest sign)
- Hypoxemia (late sign)
- Change in neurological status (becoming increasingly inconsolable and restless, or a child who "stops fighting" and becomes fatigued and hypotonic)

There are many scoring systems for severity of the UAO in children. The following is one suggested by Downes et al. in 1980. Of note there is no mention of the neurological status in this scoring system. Level of alertness and consolability of a small child are very important indicators of the severity of the UAO.

Score			
	0	1	2
Stridor	None	Inspiratory	Inspiratory and expiratory
Cough	None	Hoarse cry	Bark
Retractions and nasal flaring	None	Flaring and suprasternal retractions	Flaring, and suprasternal, subcostal, intercostals retractions
Cyanosis	None	In air	In 0.4 FiO_2
Inspiratory breath sounds	Normal	Harsh, with wheezing or rhonchi	Delayed

Immediate management of acute severe stridor outside the PICU, independent of underlying cause:

- Keep the child and the parent as calm as possible. Do not separate the child from parent.
- Give the parent an oxygen mask to hold near the child's face.
- Call for help urgently from someone with expertise in airway management (usually an anesthesiologist).
- Give nebulized epinephrine (IM epinephrine if airway obstruction is due to anaphylactic reaction). (Skip nebulized epinephrine if you suspect epiglottitis.)
- Do not send the child to the radiology department for a lateral x-ray of the neck.
- Do not administer any sedative medications to the patient.
- Do not do attempt to draw blood for investigations.
- Place ECG monitoring leads and pulse oximetry probe without disturbing the child.
- Do not attempt to place an IV line (obviously you would place an IV/IO access if the child has already had a respiratory or cardiac arrest).
- The airway expert will decide to take the child to the OR for intubation, or transfer to the PICU.

In children, there are many causes of acute UAO, including infections (viral, bacterial) such as infectious mononucleosis, croup, epiglottitis, tracheitis, peritonsillar abscess, retropharyngeal abscess, diphtheria. Noninfectious causes include foreign body, severe allergic reactions, acute angioneurotic edema, airway burn, trauma, and post-extubation in the PICU.

There are many causes of chronic/recurrent UAO. In the history there may be chronic/recurrent symptoms. These patients may become symptomatic acutely (often with a viral respiratory infection) mimicking acquired acute upper airway obstruction. Examples are: choanal atresia, laryngotracheomalacia, vascular ring, laryngeal web, subglottic stenosis, subglottic haemangioma, vocal cord palsy, recurrent angioneurotic edema.

In this section the infectious causes of UAO are addressed to.

The more common infectious etiologies that may present with severe UAO in children are:

- Croup or viral laryngotracheobronchitis
- Bacterial tracheitis
- Epiglottitis

Croup or Laryngotracheobronchitis

Viral croup is the most common form of UAO in children 6 months to 6 years of age (mostly 6 months to 2 years)

and is more common in the autumn and early winter. The site of obstruction is the subglottic area. Obstruction is caused by inflammation and edema.

The most common viral etiology is parainfluenza, but influenza, enterovirus (coxsakie and echovirus), RSV, adenovirus, paramixovirus, rhinovirus, and HSV can cause a similar clinical picture. Human Metapneumovirus has been implicated in a few reports. In immunocompromised children, *Candida sp.* can cause a similar presentation.

Diagnosis

There is a prodrome of mild fever and URI symptoms for 1–2 days before the onset of stridor. The stridor is characteristically harsh, dry, high pitched, and inspiratory. A "barking" or "seal-like" cough is prominent and usually worse at night. These children do have a voice, though hoarse, and they do not have trismus, dyphagia, or significant drooling.

Management

Children with stridor at rest should be admitted for observation, while those with severe UAO should be admitted to a PICU. Up to 15% of children with croup require hospitalization. Usually no investigations are needed.

Administration of steroids (oral route is as good as intramuscular) in the emergency room has decreased the rate of hospitalization. Hospitalized children with croup should receive a short course of oral or intravenous steroids (an example of a regimen is: Dexamethasone 0.6 mg/kg IV/PO as an initial dose followed by 0.15 mg/kg q 6 h IV/PO). Inhaled nebulized epinephrine 1:1,000 solution (0.5 ml/kg, up to 5 mg) reduces the severity of obstruction and stridor. This can be repeated as required. The child must be observed for at least 2 h after a dose of nebulized epinephrine as the effects are transient.

The decision on when to intubate a child with croup is a clinical one. If, despite maximum medical treatment there is not a clinical improvement or perhaps deterioration, a decision to intubate should be made or at least considered. A gentle and smooth intubation, using a tube one size smaller than usual for the age of the child, should be performed by a skilled and experienced practitioner. These children are at risk of accidental extubation and need proper securing of the ETT, skilled nursing care, and adequate sedation only once the airway has been secured.

Most clinicians extubate the child 2–6 days later, when an audible air leak has developed around the ETT and fever has settled.

Epiglottitis

Epiglottitis, or acute bacterial supraglottitis, is a bacterial infection of the laryngeal inlet, and is usually caused by *H. influenzae* type b (Hib). With "classical" Hib epiglottitis, the peak age of involvement is 2–3 years of age. Since the introduction of the Hib vaccine, the incidence of this disease has fallen dramatically, but the vaccine does not offer 100% protection. Also, other organisms like *S. aureus*, *S. pneumoniae*, group A + B *Streptococcus,* and *N. meningitidis* have been implicated as causative agents. The incidence of these latter organisms is higher in adolescents and older children.

Noninfectious causes of epiglottitis have been described in the following conditions:

Kawasaki's disease, Stevens-Johnson Syndrome, airway burn, caustic ingestion, post-radiotherapy, angioneurotic edema, trauma (including trauma from intubation), leukemia, and lymphohistiocytosis. Granulomatous states can cause a more chronic picture (sarcoidosis, TB, or Wegener's granulomatosis).

Diagnosis

As fewer and fewer physicians have seen even one case of epiglottitis, it is important to have a high index of suspicion in any febrile child with UAO.

The following signs are highly suspicious of epiglottitis:

- Usually there are no prodromal signs and symptoms.
- A few hours of high fever and tachypnea.
- Pain with swallowing, hence drooling is common.
- Reluctance to speak.
- The child looks ill, with circumoral pallor, and a "toxic" appearance.
- There is minimal or no coughing.
- Stridor is low-pitched and muffled, more like a snore.
- Child prefers to sit forward in the tripod position with mouth open and is reluctant to move his head or neck.

Management

If you have suspicion (on clinical grounds) that a child may have epiglottitis:

- Do not make the child lie down.
- Do not separate the child from parent.
- Do not examine the throat.
- Do not place an IV cannula.
- Do not order a lateral x-ray of the neck.
- Do not order any blood work.
- Do not transport a child with epiglottitis between hospitals unintubated.

- The child should be accompanied by an expert in difficult airway management to the operating room for examination under anesthesia and securing airway if needed.

The technique for induction of anesthesia is beyond the scope of this chapter. Generally the inhalational method is performed in the sitting position (position of comfort for the child), and once the child loses consciousness intravenous access is secured and the rest of the monitoring is applied. Laryngoscopy and intubation is only attempted after adequate depth of anesthesia has been obtained.

Blood cultures and a swab from the inflamed epiglottis should be sent and a 3rd generation cephalosporin should be given once an IV is in place. When back in PICU, accidental extubation can have disastrous consequences. Skilled taping of the ETT, nursing care, and adequate anaelgesia/sedation cannot be over emphasized.

Usually after 12–48 h of intravenous antibiotics the patient can be safely extubated, once the fever has subsided and presence of a leak is documented and the child is able to swallow (The child is not drooling). Some practitioners prefer to reevaluate by direct laryngoscopy with the patient deeply sedated or anesthetized.

If the causative organism is proved to be Hib, in families with siblings under 4 years of age or families with an immunocompromised child, prophylaxis with Rifampicin should be provided.

Bacterial Tracheitis

Bacterial tracheitis is characterized by profuse purulent secretions or sometimes by pseudomembrane formation in the tracheal lumen. The median age of the patient is 5 years. *S. aureus* is the most common etiology, though other Gram-positive and less commonly Gram-negative microorganisms might be causative. In immunocompromised children *Candida* and *Aspergillus* can cause tracheitis.

Diagnosis

These children usually have a high fever, they look toxic, and the stridor characteristically is high pitched and composed of both inspiratory and expiratory components. Cough is usually prominent and they may have dysphonia or aphonia. Drooling can be seen with bacterial tracheitis. These patients are at risk of airway obstruction. They require appropriate antimicrobial therapy, observation, and intubation by experts if warranted.

Lower Respiratory Tract Infection

Community-Acquired Pneumonia

Community-acquired pneumonia (as opposed to nosocomial or hospital acquired pneumonia) is a common pediatric diagnosis that leads to admission to hospital for intravenous antibiotics and supportive respiratory therapy. Pneumonia means inflammation of the lung parenchyma caused by infection and the diagnosis is made clinically in a febrile child with respiratory signs and symptoms who has evidence of consolidation on CXR.

Blood cultures frequently fail to reveal the infecting organism in pneumonia. Tracheal aspirate, or more reliably, bronchoalveolar lavage (BAL) and on occasions lung biopsy are required. Children with immunodeficiency or malignancy undergoing therapy are a common example of where BAL and/or lung biopsy may be necessary.

Etiology

Viral

- RSV
- Influenza A, B, C
- Parainfluenza types 1–4
- Human metapneumovirus
- Adenovirus
- Others: Rhinovirus, CMV, VZV, Enterovirus, HSV, Measles

Bacteria-typical

- *S. pneumoniae*
- *S. aureus*
- *H. influenzae*
- *S. pyogenes* (group A streptococcus)
- Enteric Gram negatives (*Klebsiella, E. coli, P. aeroginosa*)

Bacteria-atypical

- *Mycoplasma pneumoniae*
- *Chlamydia pneumoniae*
- *Legionella pneumoniae*

Bacteria-mycobacteria

- *Mycobacterium tuberculosis*

S. pneumoniae and *S. aureus* are the most important bacterial pathogens in children with pneumonia

who need intensive care admission. As a general rule, truly focal disease, confined to a single lobe, is more likely to be due to bacteria. An ill child with unilateral pleural effusion most likely has *S. pneumoniae* or *S. aureus* pneumonia.

Pathophysiology

Routes to acquire infection:

- Inhalation of infected particles (most common)
- Aspiration
- Hematogenous

Invasion of the lower respiratory tract with viruses and bacteria leads to inflammatory changes characterized by migration of neutrophils into the alveoli. Together with alveolar macrophages they provoke the production of inflammatory exudates and cellular debris that lead to consolidation of the lung parenchyma. The surrounding areas can be affected by atelectasis.

Indications for PICU Admission

- SpO_2 <90% in high concentrations of inspired Oxygen (>60% FiO_2)
- Excessive work of breathing which may lead to exhaustion
- Shock and hemodynamic instability
- Change in neurological status (agitation or alteration of the level of consciousness)

Reasons of failure to respond to treatment on the pediatric ward or as outpatient:

- Development of an empyema or less commonly a lung abscess
- Underlying lung disease such as: bronchopulmonary dysplasia (BPD, in ex-premies), cystic fibrosis, inhaled foreign body, tracheobronchomalacia or post tracheal surgery, or infected congenital lung cyst
- Diagnosed or undiagnosed immunodeficiency states (primary, HIV, leukemia)
- Children with neuromuscular diseases, weakness, or spasticity such as muscular dystrophies, myasthenia, spinal muscular atrophy, or cerebral palsy
- Inappropriate antibiotics, inappropriately low dose or resistant bacteria
- Non bacterial pneumonia (viral pneumonia or alternative pathogen such as Tuberculosis)

Once the culture results (BAL, blood culture, sputum culture) and sensitivities are known the therapy should be tailored to the antibiotic sensitivities of the causative organism(s).

Complications

- Empyema. More commonly seen with *S. pneumoniae* and *S. aureus* pneumonia. Generally a chest drain is needed. The use of fibrinolytics and surgery are areas for debate and local advice from thoracic or general surgeons and physicians from the respiratory and infectious diseases services should be sought.
- Lung abscess. With *S. aureus*, *S. pneumoniae*, Group A streptococcus, *K. pneumonia*, *P. aeroginosa*, anaerobic organisms, and Aspergillus. If there is no rapid response to intravenous antibiotics, early percutaneous drainage under CT guidance and a prolonged course of intravenous antibiotics is indicated.
- Pneumatocele, pneumothorax and "air leak," with *S. aureus* or necrotizing lung infections. May need chest drain(s). If possible, wean positive pressure to spontaneous ventilation.
- HUS associated with *S. pneumoniae* pneumonia. These children are usually very sick, younger, and may have associated meningitis. Majority of them need temporary renal replacement therapy while in the PICU.

Bronchiolitis

Bronchiolitis is a seasonal viral infection of the lower respiratory tract that mainly affects infants. The usual cause is respiratory syncytial virus (RSV), although influenza, parainfluenza, adenovirus, and human metapneumovirus can cause a similar syndrome. In young infants, *Chlamydia* and *B. pertussis* can cause respiratory illness with a more prolonged course that initially may resemble bronchiolitis. 20–25% of infants with bronchiolitis may have a secondary bacterial infection.

Infants with bronchiolitis have fever, cough, difficulty in feeding, and, on occasion, audible wheezing. On examination bronchiolitis is a syndrome characterized by respiratory distress, hyperinflation of the chest, and wheezes with fine inspiratory crackles heard on auscultation.

Apnea may occur even before onset of clinically significant respiratory distress, especially in ex-premature

and very young infants. Though not common, neonates may present with hypothermia and a sepsis like syndrome. The following groups are at increased risk of severe infection:

- Ex-premature infants and neonates
- Infants with congenital heart disease
- Infants with immune deficiency
- Infants with neuromuscular disease

Pathophysiology

The virus causes direct damage to the respiratory epithelium with resultant inflammation, increased secretions, small airway obstruction. Areas of hyperinflation and atelectasis exist simultaneously throughout the lung. This leads to ventilation and perfusion (V/Q) mismatch and hypoxia. Hyperinflation flattens the diaphragm and makes breathing less efficient.

Management Outside the PICU

- Hydration and nutrition: nasogastric feeding (if the infant does not seem to need immediate ventilatory support), intravenous fluids.
- Oxygenation: suction the nasal and nasopharyngeal airways frequently and provide supplemental oxygen via nasal cannulae or head box to keep SpO_2 >90%.
- Drugs: "Routine" use of bronchodilators (salbutamol, ipratropium, and epinephrine) is not recommended. In practice, the response to a single dose of nebulized Salbutamol should be evaluated and continued only if improvement is observed.
- Ribavarin has NOT been shown conclusively to improve the outcome.
- Antibiotics are not routinely recommended, except with bacterial super infection.
- Steroids are not indicated.

Do not over hydrate the child; there are reports that up to one third of these infants have hyponatremia due to excessive levels of ADH.

Indications for Transfer to PICU and Respiratory Support

- SpO_2 < 90% despite high concentrations of supplemental O_2 (> 60%)
- Apnea or irregular respiratory effort
- Excessive work of breathing leading to exhaustion (inability to settle or paucity of spontaneous movement)

Guidelines for Respiratory Care in Infants with Bronchiolitis

Should they require respiratory support, many of these infants can be managed with noninvasive continuous positive airway pressure (CPAP) at 4–8 cm H_2O. This reduces the work of breathing and improves oxygenation. Suction to maintain patency of airways is of crucial importance. If the saturations remain low and/or the infant continues to have frequent apneas despite providing noninvasive ventilatory support intubation of the trachea is indicated.

- Intubation is usually required for several days.
- Inadequate humidification and inadequate tracheal suctioning cause endotracheal tube blockage or lung atelectasis followed by increasing pressure and FiO_2 requirements.
- As a general rule, the best ventilatory mode is one that assists spontaneous respiratory efforts; keep the child's own respiratory and coughing efforts by providing enough comfort (sedation) and pressure support.
- PEEP or CPAP (initially at 4–6 cm H_2O) may reduce the work of breathing.
- Apply enough peak inspiratory pressure (PIP) to achieve visible chest excursions and if higher pressures (>30 cm H_2O) are needed, let the $PaCO_2$ gradually rise to 75–80 mmHg with arterial pH > 7.2 (permissive hypercapnia).

Particular issues in infants with congenital heart disease and bronchiolitis:

- Infants with left to right shunts have more frequent viral and bacterial respiratory infections, and have higher morbidity and more prolonged course with bronchiolitis.
- Infants with palliated single ventricle physiology and those with limited cardiac output (for example severe valvar aortic stenosis) have high morbidity and mortality with bronchiolitis.
- Bronchiolitis and other viral respiratory infections in infants with congenital heart disease lead to operative delays and increasing complications post cardiac bypass surgery (e.g., pulmonary hypertension). In any infant with RSV bronchiolitis and congenital heart disease awaiting surgery, it is suggested to wait for 2–3 weeks before proceeding with bypass and surgery.

The American Academy of Pediatrics has specific recommendations on prophylactic monthly injection of RSV monoclonal antibody in "at risk" infants during the cold season. However, the use of this approach has only been shown to aid a small number of patients.

Cardiac Infections in the Pediatric Intensive Care Unit

This section reviews:

- Myocarditis
- Infective endocarditis
- Infectious pericarditis
- Wound infection after cardiac surgery

Myocarditis

Myocarditis is an inflammatory disease of the heart muscle characterized in its active phase by cellular infiltrates and myocardial necrosis. However myocarditis can have cellular infiltrates with little or no myonecrosis. Most cases of myocarditis are thought to have a viral etiology; however, viruses are infrequently isolated. The most common viral causes include the enterovirus family particularly coxsackievirus B and adenovirus. Other viral causes are influenza, CMV, HSV, parvovirus, rubella, varicella, mumps, HIV, and EBV. Myocarditis has a number of other non viral etiologies, some infective and some not. They include bacteria, rickettsia, fungi, protozoa, pharmaceuticals, toxins, and connective tissue/autoimmune disorders.

Typically viral myocarditis begins as a systemic viral illness with flu-like symptoms. As the virus infects the myocytes the immune system is up regulated and CD4 T-helper cells and CD8 cytotoxic T cells are stimulated along with proinflammatory cytokines. Persistence of the viral RNA and production of NO by the myocytes have been linked to myocardial tissue damage.

Myocarditis can present in a number of ways:

- Out of hospital cardiac arrest/sudden death
- Cardiogenic shock (May mimic sepsis)
- Congestive heart failure (increasing dyspnea, lethargy)
- Dysrhythymias – bradycardia, tachycardia

Whilst sepsis and hypovolemic shock are more common than cardiogenic shock from myocarditis, it should always be in the differential. Sometimes acute "decompensation" of these children is heralded by abdominal distension and vomiting. Teenagers may complain of a feeling of "impending doom" or severe chest discomfort.

Clinically, signs of tachycardia/tachypnea, gallop rhythm, hyperdynamic precordium, and displaced apex are often present. Hepatomegaly and in older children elevated Jugular Venous Pressure (JVP) are usually present. Crackles on auscultation are often present in the chests of older children.

Chest x-ray (CXR) may show an enlarged heart, pulmonary venous congestion, alveolar edema, Kerley B lines, and in some cases pleural effusions. In acute myocarditis the heart may often look normal in size on the CXR. A 12-lead ECG is useful to assess underlying rhythm, assess for ischemia and for the subtle ECG changes that are sometimes evident with myocarditis; ST-T changes, reduced QRS voltage, widened QRS.

Echocardiography is absolutely necessary to assess structure and function of the heart and to assess for a pericardial effusion. Involvement of appropriate specialists is important – cardiologists, intensivists, and cardiothoracic surgeons work cooperatively to manage and stabilize these patients.

Treatment of myocarditis is largely supportive. Immunomodulation using steroids, intravenous immunoglobulin, and immunosuppressive agents is controversial. Identifying any modifiable contributors, i.e., toxins and drugs, is of crucial importance. Supportive therapy for heart failure associated with myocarditis ranges from diuretics and afterload reduction, addition of inotropic support to placing the patient on mechanical circulatory support. Dopamine and Dobutamine increase contractility but also heart rate and myocardial oxygen consumption. Milrinone is an intravenous phosphodiesterase inhibitor that improves contractility and at the same time, reduces the afterload. Enoximone is an oral phosphodiesterase inhibitor that is available in Europe, but not in North America. Levosimendan is a calcium sensitizer and improves contractility. It has limited availability world wide.

Positive intrathoracic pressure, given noninvasively via a face mask (CPAP), reduces LV afterload and may improve cardiac output in the setting of LV dysfunction.

Failed medical therapy or deteriorating function will usually indicate the need for extracorporeal support and ultimately heart transplantation. Mechanical support (ECLS, "Berlin" heart) is frequently used as a "bridge" to recovery or transplant.

Endocarditis

For a complete review of endocarditis review the Cardiology chapter in this book. The major reasons a child with endocarditis may need admission to PICU are:

1. Congestive heart failure due to worsening valvar regurgitation
2. Congestive heart failure with abrupt onset due to valve apparatus rupture/perforation, or dehiscence of a prosthetic valve
3. Systemic to pulmonary artery shunt obstruction
4. Arrhythmia
5. Renal failure
6. Embolic events to
   (a) Brain
   (b) Heart
   (c) Lungs
   (d) Bowel
   (e) Extremities

Infectious Pericarditis

For a complete review of pericarditis and tamponade, please review the Cardiology chapter in this book.

Acute inflammation of the pericardium in a previously healthy child has usually been assumed to be viral. In most cases a causative agent is not detected (hence the term "idiopathic" pericarditis). An upper respiratory infection usually precedes the onset of symptoms by 10–14 days. The reported viral pathogens include coxsackievirus, adenovirus, RSV, varicella, hepatitis B, HIV, and post influenza vaccine.

Primary infectious pericarditis that may need PICU care is usually purulent bacterial pericarditis. These patients are generally toxic looking. The infection in the pericardium rarely occurs in the absence of infection elsewhere (hematogenous spread). In comparison with the viral (idiopathic) pericarditis, the incidence of tamponade and hemodynamic instability is much higher with purulent pericarditis.

S. aureus is the most common cause of purulent pericarditis. Other bacteria include *H. influenzae*, *N. meningitides*, and *S. pneumoniae*.

In developing countries, tubeculous pericarditis is a common cause of chronic constrictive pericarditis.

Treatment of Purulent Pericarditis

Therapy depends on the hemodynamic status of the patient. A toxic-looking child with physiological signs and symptoms of tamponade should be transferred urgently to the catheterization laboratory or to the intensive care unit for percutaneous drainage of the pericardial collection. Sometimes the pus in pericardium is so thick or organized (esp. with *H. influenzae*) that percutaneous drainage may not be sufficient and the child will need open surgical drainage. With tamponade physiology, administration of fluid boluses can temporarily increase the intracardiac "filling" and stabilize the patient until the definitive treatment (percutaneous or surgical drainage) is performed.

Broad-spectrum intravenous antibiotics with good antistaphylocccal coverage should be commenced promptly if purulent pericarditis is suspected.

Wound Infection After Cardiac Surgery

Surgical wound infections after cardiac surgery can be categorized as superficial (cellulitis) or deep (mediastinitis). The patient usually presents a few days after the procedure, but may occur up to 2 months after the initial operation. The important signs are erythema and induration at the surgical incision. The child may be irritable and have a mild fever. There may be a leukocytosis with "left shift" and elevated inflammatory markers such as C-reactive protein (CRP) or erythrocyte sedimentation rate (ESR). In addition to the wound erythema with or without purulent discharge there may be signs of sternal instability with "crepitus" on direct pressure over the sternum. Diagnosis nevertheless is a clinical one and relies on a high index of suspicion. The risk factors are: neonates, long cardiopulmonary bypass time, delayed sternal closure, and reexploration of the chest for postoperative bleeding. The most common organisms associated with sternal wound infections are *S. aureus*, *S. epidermidis*, *Enterococcus* species, and *Candida* species.

Antibiotic treatment should begin as soon as a sternal wound infection is suspected and a wound swab has been sent. Blood cultures should be sent from both peripheral and central venous sites whenever possible. The initial antibiotic regimen should consist of broad-spectrum Gram-positive (anti-staphylococcal) coverage, with the addition of Gram-negative coverage if the patient is septic or mediastinitis is suspected. If there is not a rapid improvement or the patient deteriorates the sternal wound may need to be surgically explored and debrided. Antibiotics should be given for 10 days to 2 weeks for cellulitis and for 4–6 weeks for deep wound infections.

Central Nervous System Infections

Purulent Meningitis

Meningitis is an inflammation of the leptomeninges of the brain. For a review of "aseptic" meningitis which also

includes viral causes of meningitis, please look at the Neurology and Infectious Disease chapters in this textbook. Suffice to mention that patients with "aseptic" meningitis are usually not as sick as those with purulent meningitis, and the CSF abnormalities are not as prominent. Patients with bacterial meningitis have a number of reasons for requiring intensive care. The most common clinical scenarios are coma and seizures.

The local inflammatory response to bacteria multiplying in the CSF involves polymorphonuclear leukocytes, the endothelium, complement, and cytokines. This results in an alteration in the cerebral blood flow and venous drainage, vascular inflammation, and obstruction to CSF flow and reabsorption. The infection within the meninges may extend to the surrounding brain parenchyma.

The commonest bacteria are *S. pneumonia*e, *N. meningitidis*, and *H. infuenzae*. In the neonatal period, the likely causative organisms are different: Group B streptococcus, *L. monocytogenes*, and Gram-negative bacilli are the commonest.

This profile will be modified depending on the local vaccination policy, socioeconomic status of the children in the area, and local/regional epidemics of disease.

None the less the intensive care management is similar:

1. Broad-Spectrum CNS penetrating antibiotics with narrowing of spectrum of antibiotic cover once results of cultures of the blood and CSF are known. Antibiotics with high CSF/brain tissue penetrance must always be used. In areas with high incidence of *S pneumonia* penicillin resistance (including the United States), empiric therapy for community-onset bacterial meningitis is both vancomycin and a 3rd generation cephalosporin.
2. Appropriate level of observation and intensive care support depending on level of consciousness and physiological derangement.
3. Management of raised intracranial pressure (ICP):
   (a) Head in the midline and at 30°, no obstruction to the jugular venous return.
   (b) Sedation and analgesia in intubated and monitored patients.
   (c) Aggressive control of fever and seizures.
   (d) Hyperosmolar agents such as mannitol and 3% sodium chloride.
   (e) In intubated patients, keep $PaCO_2$ in the low normal range (35–40 mmHg) and use hyperventilation temporarily and *only* for acute rises in ICP.
   (f) CSF drainage (via an extraventricular drain), and (rarely) decompressive craniectomy. This is usually in discussion with an infectious diseases expert and a neurosurgeon.

Acute complications of bacterial meningitis are:

- Hyponatremia (serum sodium <135 micromole/l): This is usually due to the syndrome of inappropriate secretion of antidiuretic hormone (SIADH). There is hyponatremia and low serum osmolarity without signs of hypovolemia. Hyponatremia can cause convulsions. Cerebral salt wasting is a much rarer condition that gives hyponatremia *with* signs of volume contraction. SIADH is treated by free water restriction and cerebral salt wasting is treated with sodium (either IV or PO) supplementation. In a hyponatremic child with convulsions give 3% NaCl 3–5 ml/kg intravenously. It is important to note that the change of serum sodium (and hence serum osmolarity) is of more importance in some cases than the absolute serum sodium. A sudden drop in serum sodium (greater than 0.5–1.0 micromole/h) should be treated with hypertonic saline.
- Seizures: Convulsions that occur early in the course of purulent meningitis are usually generalized and have less prognostic significance than those occurring later. Etiology of convulsions in meningitis can be any of the following: brain edema, diffuse ischemia, hyponatremia, subdural collection, sinus venous thrombosis, or focal infarction.
- Subdural effusion: This complication is seen more commonly in neonates and infants. A good practice is to measure the head circumference daily in any infant with meningitis. The diagnosis is made or confirmed by neuroimaging. If the effusion is large, or if it is associated with focal signs, convulsions, or signs of increased intracranial pressure, a neurosurgical consultation is necessary.
- Obstructive hydrocephalus: Obstructive hydrocephalus occurs when the pus (often with high protein content) in the ventricles blocks the outflow of CSF. This situation occurs more frequently in small infants and neonates.

Encephalitis

Similar to meningitis, seizures, focal or generalized signs, and coma, are common presentations. The list of differential diagnosis is long and includes: aseptic meningitis, post infectious encephalitis and noninfectious encephalopathies (metabolic, vascular, demyelinating disease, tumor).

The most frequent causes of acute encephalitis include: enteroviruses, HSV, VZV, EBV, adenovirus, influenza virus, and *M. pneumoniae*. Mumps, measles, and rubella infections are rarely seen in developed countries.

In many parts of the world arboviruses are major causes of endemic encephalitides. Tuberculosis is always high on the list of differential diagnosis in developing countries.

Diagnosis: CSF can be completely normal, but usually contains >10 leukocytes/mm^3 (mainly lymphocytes), mildly increased protein level and mildly reduced to normal glucose level. In children with HSV encephalitis, the CSF may contain red blood cells. CSF in addition to cell count, chemistry and culture should be sent for PCR for viral agents. CSF PCR can be helpful in a number of the infectious encephalopathies. For example: *M. pneumoniae*, Mycobacterium, CMV, EBV, VZV; where the organism may not be cultured from the CSF.

Brain imaging (CT or MRI) can be helpful in the diagnosis. In HSV encephalitis there may be focal edema and enhancement seen in the temporal area. This is relatively specific for HSV infection of the brain.

The electroencephalogram may show focal periodic epileptiform activity in frontal and temporal parts of the brain. This is common in HSV disease. Diffuse slow waves generalized over the cerebral cortex may also be seen. This may either represent encephalitis or be secondary to sedatives and anticonvulsants used in the PICU. The primary use of EEG is in the management of seizures.

Finally, when the etiologic diagnosis is not clear, or the patient is deteriorating despite treatment, brain biopsy may be performed.

Treatment is largely supportive. As for meningitis this consists of appropriate antimicrobial (antiviral) therapy. There should be no delay in starting Acyclovir if HSV is suspected or considered. The dose is 30 mg/kg/day for 10 days. When *M. pneumoniae* is suspected antibiotics with good penetration into the brain (ciprofloxacin, or azithromycin) should be used.

Additional management includes airway protection for coma and seizures. Medical and surgical therapies for management of intracranial hypertension, as discussed above should be adhered to.

Acute Demylinating Encephalomyelitis (ADEM)

ADEM is an acute or sub acute inflammatory demyelinating disease of the CNS (brain and spinal cord). In contrast to multiple sclerosis it is a monophasic illness. ADEM is considered a parainfectious disease and the precipitants include infection with upper respiratory tract viruses, influenza, group A streptococcus, EBV, VZV, measles, mumps, rubella, and *Mycoplasma*.

Clinical presentation may involve fevers, seizures and a constellation of neurological phenomena. Commonly these are coma, focal neurological deficits or alterations in personality and behavior. Often a recent "viral infection" is present in the history.

The lumbar puncture is done to exclude infections. CSF may have normal white cell count or mild pleocytosis (mainly lymphocytes), and mild to significant protein elevation. The cultures and PCR should be negative.

Neuroimaging is the main diagnostic tool for ADEM MRI is the modality of choice, as the CT is normal in 40% of cases. The typical MRI findings are multiple disseminated asymmetrical hyperintense lesions on T2WI and FLAIR in the white matter and basal ganglia.

The cerebrum is more involved than the cerebellum.

Treatment: (1) Continue antibiotics and antivirals until final CSF cultures and PCR results are confirmed to be negative. (2) Once infection is ruled out Methylprednisolone "pulse" dose at 30 mg/kg/day (maximum 1 g) for 3 days followed by oral prednisolone 2 mg/kg/day for 2 weeks. This is followed by a 4 weeks weaning regimen. (3) Plasma exchange or IVIG for relapsed or refractory ADEM.

Guillain-Barre Syndrome (GBS)

GBS is an immune-mediated polyneuropathy that is usually preceded by a viral or bacterial infection of the respiratory or GI tract 1–3 weeks prior to presentation.

GBS is the most common cause of acute paralysis in developed countries and is characterized by progressive, ascending, symmetric motor weakness and loss of reflexes. The sensory symptoms (extremity pain, paresthesia) and autonomic irregularities (tachycardia, bradycardia, hypertension, hypotension, arrhythmia) can be prominent. There are usually no sensory deficits in physical examination.

Infections known to precede the onset of paralysis are: CMV, EBV, VZV, *Campylobacter jejuni*, *Mycobacterium tuberculosis*, HIV, and *M. pneumoniae*. The pathogenesis involves an immune response against the infectious agent and has components that cross-react with those of the peripheral nervous system.

Diagnosis is clinical but is aided by CSF and electrophysiology testing. The CSF shows a high protein content and low/normal white cell count. This may be missed if the lumbar puncture is done early in the first week of the illness.

Electrophysiology will show decreased conduction velocity in the peripheral nerves.

Treatment: IVIG at 2 g/kg/day for 2–5 days or plasma exchange. (Two courses for mild GBS and four to five courses for severe illness.)

Corticosteroids have not demonstrated effectiveness in GBS and are not recommended.

Indications for PICU admission:

- For respiratory support
- For plasma exchange
- Autonomic instability (hypo- or hypertension, arrhythmia)

Botulism

Botulism is a toxin mediated disease caused by *C. botulinum*. Symptoms start a few hours and up to 6 days after exposure to the toxin. The cranial nerves are involved initially with difficulty swallowing, abnormal speech (abnormal cry in infants) and eye movements (ptosis). Other symptoms may include nausea, vomiting, constipation, and abdominal distension. As the illness progresses it causes paralysis of the extremities and respiratory muscles to various degrees. In infants the disease can be mild with hypotonia and constipation as the main findings. Also in infants there is sometimes a history of ingestion of honey before the onset of symptoms (Honey may contain the spores of *C. Botulinum*).

Diagnosis is made from a combination of clinical findings and electromyography. Stool for botulinum toxin or serum serology is confirmatory but takes time.

Treatment is with antitoxin to remove circulating toxin but this will not affect the toxin already present at the neuromuscular junction. Specific botulinum immunoglobulin is not readily available world wide. The cost is prohibitive for a lot of countries and the cost-benefit analysis is only favorable for those patients requiring mechanical ventilation. Penicillin and Metronidazole are given to eradicate the source of toxin production. Aminoglycosides and steroids should not be given as they may worsen the neurosmuscular transmission defect and increase muscular weakness. If the source of the *C. Botulinum* is a wound (i.e., wound botulism) then it will need surgical debridement.

Indications for admission to PICU:

- Respiratory support
- Autonomic instability

Infections in the Immunocompromised Child

Children are increasingly surviving diseases that until recently were considered untreatable. There are more potent, intense chemotherapy regimens being used and increasingly there are more patients who undergo solid organ and stem cell transplants. These treatments and interventions particularly with immunosuppressants, though frequently successful, leave patients at considerable risk for severe infections.

Neutropenia

Neutropenia is defined as the absolute neutrophil count (ANC) [ANC = PMN + band count] $<1{,}000/mm^3$, and is generally associated with cancer and its treatment. The risk of infection is particularly high with:

- Rapid drop in ANC
- ANC $< 100/mm^3$ (profound neutropenia)
- Prolonged neutropenia

Fever in neutropenic patients is defined as an oral/tympanic membrane temperature $>38°C$ in two repeated measurements over a 4 h period or one measurement above 38.5°C. The portals of entry of infectious agents are usually: the oral mucosa, the gut, the upper/lower respiratory tract, and central vascular lines. The most common organisms are Gram-positive cocci (*S. aureus*, *S. epidermidis*, *and Strep. viridans*), Gram-negative bacilli (*E. coli*, *K. pneumoniae*, *P. aeroginosa*), and fungi (*Candida*, *Aspergillus*).

Recently the spectrum of pathogens has begun to change, with the emergence of more Gram-negative and fungal infections. This is likely due to an increase in resistant pathogens in the face of the use of very broad-spectrum antibiotics, intensity of therapy (high-dose chemotherapy and stem cell transplant) and prolonged neutropenia. The single most important risk factor for fungal infection is the duration of neutropenia.

It is standard of practice to start antibiotics for a child with ANC < 500 who is febrile. Initial empiric therapy for febrile neutropenia consists of a β-lactam antibiotic and an aminoglycoside, plus a glycopeptide if a coagulase negative staph or enterococcus is suspected or isolated, if the child is in shock, has an endoprosthesis or a vascular tunnel infection. If patient has a history of Arabinoside-C administration and has severe mucositis *Strep viridans* infection is highly suspected and vancomycin should be added. If perianal

tenderness is present add anaerobic coverage (Metronidazole or clindamycin).

After 4–5 days of fever and neutropenia adding an antifungal is the usual practice of most oncologists.

Cellular Immune Dysfunction

Infants with a severe combined or T-cell immune deficiency usually present early in the first few months. Defects in cell-mediated immunity can result from congenital disorders such as DiGeorge syndrome, severe combined immunodeficiency disease (SCID) and Wiskott–Aldrich syndrome. They can be secondary to lymphomas, immunosuppressive medications or chronic illness. Acute viral infections such as measles and pertussis are also known to decrease a patient's cell-mediated immunity.

Typical infections are *Pneumocystis jiroveci* pneumonia (formerly *carinii*), CMV pneumonitis, RSV pneumonitis, disseminated enteroviral infection, and invasive fungal infection. Patients are highly susceptible to infections with intracellular organisms such as *Salmonella*, *Listeria*, mycobacteria, herpes family viruses (CMV, EBV, and HSV), as well as fungi and protozoa. In older children and those with secondary immunodeficiencies, these infections tend to be reactivated disease.

Children with chronic mucocutaneous candidiasis and chronic granulomatous disease typically present early in life with recurrent candida and staphylococcal infections.

Neonates with adhesion molecule deficiency usually present with delayed separation of the umbilical cord stump, increased polymorphonuclear count, and increased incidence of bacterial infections.

Humoral Immune Dysfunction

Children with primary humoral immune deficiency usually present between 6 months and 5 years of age. The onset is consistent with the time when the level of placentally transferred maternal antibodies (IgG) has declined. These defects as well as complement deficiency and asplenia are more commonly associated with infections by encapsulated microorganism such as *H. influenza*, *N. meningitides*, and *S. pneumoniae*.

Although patients with these conditions are mainly susceptible to bacterial infections involving the upper and lower respiratory tract, they can have protracted diarrhea with *Giardia* or echovirus.

Complement Deficiency

Defects in the late complement component (the "attack" component, C5-9) are prone to recurrent *Neisseria* infections. Children with early complement defects usually have autoimmune and rheumatologic manifestations. Fulminant meningococcemia is also associated with properdin deficiency (alternative complement pathway).

Hematopoietic Stem Cell Transplant Patient (HSCT)

HSCT is now an established treatment for a host of immunologic, metabolic, hematological, and neoplastic disorders. The "stem cells" may be obtained from the patient (autologous). Alternatively from an HLA-compatible related or unrelated donor (allogeneic). There is little risk of acute or chronic Graft Versus Host Disease (GVHD) with autologous HSCT. Currently there are three sources for stem cells: bone marrow, peripheral blood, and umbilical cord blood. Generally with the umbilical cord stem cell transplant the speed of engraftment is lower, but so is the risk of GVHD. With peripheral blood stem cell transplant engraftment occurs faster but the risk of GVHD is also higher. With bone marrow stem cell transplant the speed of engraftment and the risk of GVHD is somewhere between the other two sources.

With unrelated umbilical cord blood and T-cell depleted bone marrow or blood stem cell transplant, the risk of graft failure is higher.

There is a higher risk of infection with occurrence of GVHD, and with graft failure.

The conditioning regimens used to prepare the patients generally consists of high-dose chemotherapy with or without regional or total body irradiation. Post transplant, there is a period of pancytopenia and though the neutrophil count usually normalizes after 3–4 weeks it is not unusual for these patients to need red cell or platelet transfusions for much longer.

The risk of infection is influenced by rapidity of myeloid recovery and the rate of lymphoid reconstitution. The speed of restoration of adequate immune function is highly variable. The stem cell source, HLA compatibility, purging or T-cell depletion of the graft prior to transplant, and severity of GVHD are important factors.

In the early post-transplant period (first 100 days), transplant centers employ prophylactic measures to reduce the risk of infection. These measures vary between different centers, and include:

- Prophylactic antibiotics (for PCP, candida, HSV, CMV)
- Administration of IVIG
- Environmental precautions (isolation and barrier nursing)

In the early post-transplant period, patients are most susceptible to infections caused by both Gram-negative and Gram-positive organisms and by fungi. There is a higher risk of CMV pneumonitis in patients with GVHD (largely due to the need for immunosuppressive treatments). CMV negative recipients who receive transplant from a CMV positive donor are at highest risk for CMV pneumonitis.

Children who have undergone HSCT and are admitted to PICU have a particularly poor prognosis. Pneumonia, mechanical ventilation, and the need for renal replacement therapy are especially poor prognostic factors. Those with septic shock and line sepsis have the best prognosis. In addition to bacteria, the most commonly isolated organisms are CMV, RSV, adenovirus, candida, aspergillus, and PCP. In a recent report from Great Ormond Street Hospital in London, UK, only 56% of these patients survived to discharge.

Solid Organ Transplant Patient (SOT)

Similar to children who have received HSCT, children receiving solid organ transplants are prone to infections before and after the transplant. The main differences are:

1. Patients after solid organ transplants are usually less immunosuppressed than HSCT patients and are not at risk of immune reconstitution syndrome and its associated inflammatory and infectious complications. However they are at risk of surgery-related complications and postsurgical infection issues (wound infection, bacteremia, atelectasis/pneumonia, urinary tract infection).
2. Infection of the transplanted organ due to latent or colonizing organisms present in either the donor or recipient can lead to invasive widespread disease in the immune suppressed post-transplant recipient. An example of this is the child with cystic fibrosis colonized with *Pseudomonas* species; those colonized with *B. cepacia* are particularly at risk of developing resistant infection post lung or combined heart/lung transplants.
3. Children receiving solid organ transplants are at risk of reactivation of latent infections, such as CMV. But, unlike HSCT patients who most commonly present with CMV pneumonitis in recipients of solid organ transplants the CMV disease depends on the sites where the virus is latent and on the organ that has been transplanted. Lung, heart/lung, and liver transplant patients are most vulnerable to systemic disease. CMV infection can precipitate rejection and increase vulnerability to other infections such as fungal infections.
4. EBV-associated post transplant lymphoproliferative disorder (PTLD) is a potentially fatal complication of solid organ transplant. The risk of PTLD is higher in children who were EBV seronegative prior to the SOT. EBV-related infection in SOT patients may present in several different ways: asymptomatic or nonspecific viral syndrome, mononucleosis syndrome, and PTLD. The latter can have a spectrum from fever, lymphadenopathy and diarrhea to full blown lymphoma. Tissue biopsy is necessary to establish the diagnosis of PTLD. The mainstay of therapy consists of decreasing immunosuppression. Chemotherapy and biological treatments (such as anti-CD20 monoclonal antibodies) have been used.

HIV Infection in the PICU

The most common reason children with HIV/AIDS are admitted to the PICU is respiratory distress. Septic shock and CNS involvement (encephalopathy, encephalitis, and meningitis) are other common conditions leading to admission. In addition to the bacteria, viruses and mycoplasma that cause infections of the lower respiratory system in the non-HIV patient, there are a number of other opportunistic infections and inflammatory conditions to consider in the HIV-infected patient. These are commonly:

- *Pneumocystis jiroveci*
- CMV pneumonitis
- Tuberculosis
- Fungal infections
- Lymphoid interstitial pneumonitis (LIP)
- Immune reconstitution inflammatory syndrome (IRIS)

Most infants with respiratory failure will not have a previous diagnosis of HIV infection when they present. In non-endemic areas, especially during the colder season, such infants would be diagnosed and treated initially as cases of bronchiolitis. The possibility of an underlying immune deficiency and or AIDS should be considered in any infant who responds poorly to treatment or who has risk factors. These include failure to thrive, history of recurrent chest infections, hepatosplenomegaly, adenopathty, severe persistent oral thrush, or abnormal neurological signs.

In sub Saharan Africa, TB and other bacterial pneumonias were common in both HIV-infected and uninfected children who presented with respiratory failure. However *Pneumocystis* and CMV pneumonitis occurred almost exclusively in infants who were HIV-infected.

Pneumocystis jiroveci

The majority of cases of *P. jiroveci* pneumonia present in the first 6 months of life. Usually these children are quite hypoxemic. High fever is uncommon compared with bacterial pneumonia. There is a diffuse, bilateral air space or interstitial involvement on the chest x-ray. Occasionally there is a "ground glass" appearance. In an HIV positive patient with bilateral diffuse parenchymal or interstitial infiltrates on CXR, the development of pneumothorax is suggestive of *P. jiroveci* infection.

Diagnosis is by bronchoalveolar lavage (BAL). Even if a child develops *Pneumocystis* while on prophylactic therapy, high-dose intravenous trimethoprim/sulfamethoxazole should be started. Prophylaxis may have failed because of poor compliance. If one suspects drug resistance then other agents should be used (Pentamidine, Dapsone). Methylprednisolone at 2–4 mg/kg/day divided in four doses should be administered in moderate to severe cases (practically all children with *pneumocystis* who are admitted to PICU) for 5 days and then tapered.

Untreated, it is universally fatal. With proper therapy the mortality is less than 10%. The risk factors for mortality are the severity of respiratory failure and the severity of immunosuppression.

Lymphoid Interstitial Pneumonia (LIP)

LIP in children with AIDS is associated with increased risk of lower respiratory tract infections including bronchiectatsis. This condition can produce severe ventilation/perfusion mismatch and hypoxemia but may also be asymptomatic. The CXR shows diffuse infiltrates and hilar lymphadenopathy persisting for >2 months despite antibiotic therapy. Usually CXR changes are worse than clinical symptoms. LIP can be related to EBV infection or to an exaggerated immunological response to inhaled or circulating antigens or both. Steroids have been used in the treatment of symptomatic LIP.

Tuberculosis

Coexistence of HIV and TB accelerates the course of both of these infections. The risk of miliary and extra pulmonary TB is higher in children with AIDS and the course is more likely to be severe and rapid. A child with HIV infection is five to ten times more at risk of active TB. In countries with high prevalence of tuberculosis, the WHO suggests BCG vaccination of ALL neonates at birth but NOT in any child/infant with clinical AIDS.

For treatment of TB, please refer to the chapter in this book.

Mycobacterium Avium Complex (MAC)

MAC can produce a systemic illness in children infected with HIV that is characterized by fever, chronic diarrhea, abdominal pain, malabsorption, lymphadenopathy, and obstructive jaundice. MAC usually would not present with significant lung disease in these children.

Immune Reconstitution Inflammatory Syndrome (IRIS)

IRIS occurring weeks after the initiation of specific anti-HIV treatment may on occasion be severe enough to cause respiratory failure warranting admission to the ICU, though it can also indicate latent or incipient mycobacterial disease. This (IRIS) is a diagnosis of exclusion and requires a BAL and possibly a transbronchial biopsy. Management is usually with corticosteroids.

Other than sepsis and respiratory failure, the other conditions that may bring the child with AIDS to the intensive care unit are (to name the more common ones):

- CNS infections (bacterial, Mycobacterium, fungi, Cryptococcus, viruses, and rarely CNS Toxoplasmosis), acute HIV encephalopathy
- HIV-related cardiomyopathy
- Severe diarrhea and shock due to cryptosporidium or other microorganisms
- Liver failure due to infections or drugs
- Complications of antiviral medications such as acute pancreatitis, acute liver failure, Stevens–Johnson Syndrome

An important aspect of care for these children in the PICU for the staff is risk of exposure to body fluids and of needle stick injury. Universal exposure precautions should be strictly adhered to. It is imperative that all staff be aware of the guidelines and procedures after exposure to biological fluids in their institutions and seek advice from the Occupational Health Department immediately if exposed.

Brief Review of Antifungal Agents in the PICU

As increasing numbers of immunocompromised children with fungal and viral infections are admitted to the pediatric intensive care units, common antifungal and antiviral medications that are used against these infections are briefly reviewed. For a complete review of these topics, the reader is referred to chapters on individual fungal and viral infections in this book.

Increasingly systemic fungal infections have become more significant in morbidity and mortality of immunocompromised patients in intensive care units. Factors that have been associated with this increase are:

- Use of more potent and broad-spectrum antibacterial agents
- Prolonged and severe neutropenia
- Prolonged and severe immune dysfunction (primary or secondary)
- Having central venous lines and invasive devices
- Total parenteral nutrition (TPN)

The most common fungal pathogens causing systemic illness in critically ill children are *Candida* and *Aspergillus* species. In recent years there has been an increasing importance of uncommon fungal pathogens such as non-*albicans Candida* species, *Fusarium* species, *Trichosporon* species, and dematiaceous fungi.

In an immunocompromised patient with a positive fungal culture from a central venous line, current guidelines strongly advocate removal of the line.

Traditionally with invasive Candidiasis, amphotericin B (AMB) has been the first-line drug to use. However, intravenous flucanozole and itraconazole could be considered. In non-neutropenic patients positive for *C. albicans* (but not other Candida species) fluconazole is as effective as AMB. In empirical treatment of prolonged febrile neutropenic patients (>4–5 days) AMB should be started. Clinical trials have shown that liposomal preparations of amphotericin B (L-AMB) have similar, but not better, efficacy compared with conventional AMB preparations. Some authors recommend a liposomal preparation of amphotericin as a preferred first-line treatment. Unfortunately, high cost can be prohibitive in many parts of the world. In general, the L-AMB agents cause less fever, rigors, nausea, and vomiting. They are also less nephrotoxic.

Voriconazole, a second generation triazole, can be used for empirical treatment of febrile neutropenic patients in place of L-AMB. In patients with invasive aspergillosis it has been shown that initial therapy with voriconazole leads to a better response and improved survival with fewer side effects.

Echinocandins such as caspofungin have been used in combination with AMB or voriconazole in more resistant cases of invasive aspergillosis with persisting fevers. Micafungin and Anidulafungin are two other agents in this family.

Antifiungals (old and new) have a large potential for side effects and drug–drug interactions. Clinicians need to be aware of the specific profiles of the drugs they use from this antimicrobial family.

Brief Review of Antiviral Agents in the PICU

Below are the common agents likely to be used in the intensive care unit. HIV drugs have not been discussed. Please refer to the chapter on HIV for more detailed discussion of these agents.

There are two main groups of antiviral agents:

1. Inhibitors of viral replication

Agent	Virus	Side effects
Acyclovir, Valcyclovir	HSV, VZV	Kidneys, CNS
Ganciclovir	CMV, HHV-6	Bone marrow, kidneys
Foscarnet	HSV, VZV, CMV, HHV- 6	Kidneys, CNS, liver
Cidofovir	Adenovirus, CMV, HSV, VZV, HHV-6	Kidneys
Ribavarin	RSV, Adenovirus, HCV, Lassa fever virus	Teratogenicity (risk for pregnant staff), hemolytic anemia, deposition in the ventilator circuit in ICU

2. Inhibitors of viral assembly and release

Oseltamivir, Zanamivir	Influenza A, Influenza B

Nosocomial Infections in the PICU

The Pediatric Intensive Care Unit, by its nature, cares for critically ill children. To facilitate this, a number of devices are used that breach the body's normal defense mechanisms. For example, endotracheal tubes to facilitate mechanical ventilation obstruct secretion management hence secretions need to be suctioned; central venous lines (CVL) breach the skin and provide a conduit for bacteria into the blood; Urinary catheters provide conduits for bacteria from the perineum to the internal urinary structures (bladder and kidneys). On top of this, patients may be debilitated medically, nutritionally compromised, victims of traumatic injuries or post operative patients with wounds that can potentially become infected. It is not surprising then that a large number of patients requiring Intensive care acquire some form of nosocomial infection. The frequency of various nosocomial infections in PICU in a review of the US hospitals was 13.9 per 1,000 patient days. The corresponding figure in the neonatal intensive care units was 14.1 per 1,000 patient days. Between the

various types of nosocomial infections in pediatric intensive care units, blood stream infections had the highest incidence, followed by lower respiratory infections and urinary tract infections.

A basic mandate of medicine is "Primum non nocere" – first do no harm. While it is inevitable that some patients may acquire nosocomial infections, these infections cause significant morbitiy and mortality. The overall mortality attributable to the various nosocomial infections within the PICU has been estimated to be between 10% and 15% and infections acquired in the PICU are associated with an increased risk of death, with a relative risk of 3.4.

It is widely appreciated that these infections can be minimized by a number of simple interventions, most important of which is hand washing; "Clean Hands Save Lives." In a review of the related literature between 1990 and 2002, it was shown that between 11% and 48% of nosocomial infections could have been prevented.

Blood Stream Infections

Blood stream infections are common. Not surprisingly they are most common in those patients who are the most debilitated, receiving mechanical ventilation and have central venous lines in situ for longest time, urinary catheters and other artificial surfaces. The spectrum of infections also has a predictable frequency. Gram +ve infections are the most common bacteremias (whether or not associated with a central line) followed by Gram −ve and then fungi. Typically fungi are found in those patients on TPN or long term, broad-spectrum antibiotics and immuosuppressed.

Gram +ve Bacteria	Gram −ve Bacteria	Fungi
Coag Neg Staph (CONS-S. Epidermidis)	*Pseudomonas aeruginosa*	*Candida albicans*
S. aureus	*Escherichia coli*	
Streptococcus sp.	*E. cloacae*	
Enterococcus sp.	*Enterobacter sp.*	
	Klebsiella sp.	

Central Venous Catheter Associated Infection

Central venous lines (CVL) are used to provide secure intravenous access for administration of medications such as vasopressors and inotropes, to monitor pressures, blood oxygen saturations, and for intravenous nutrition. In a survey of PICU's in the United States the rate of CVL infection was 7.6 per 1,000 catheter-days. In neonates the corresponding figure was 11.3 per 1,000 catheter-days. In Europe the CVL infections occurred at a rate of 10.9 infections per 1,000 catheter-days.

Measures taken at time of insertion of the CVL significantly reduce the incidence of infection. Strict aseptic technique (gowns/gloves/mask and wide sterile field), use of Chlorhexidine (as opposed to povodine/iodine), and minimal trauma (use of ultrasound and experienced operators) are all very important factors at the time of insertion. Chlorhexidine disks topically placed upon the skin at the insertion site and antibiotic impregnated lines are used by some units but not proven to be of value.

Cuffed and tunneled lines such as Hickman lines, Port-A-Cath lines and PICC (peripherally inserted central catheter) have a significantly lower rate of infections than standard central lines that are inserted in the intensive care. Where long term therapy >1 week is required consideration should be undertaken to the insertion of one of these types of lines.

Site of insertion is important. The femoral vein is easy to cannulate with fewest insertion complications. However, it is more likely to become infected and thrombosed. It is good as a temporary line but early consideration should be given to removing and/or repositioning access.

To prevent central line infection minimization of the "opening" of the line on a daily basis is important. Asepsis on line ports prior to use (with alcohol or Chlorhexidene) is critically important.

Ultimately to reduce infection rates lines should be kept for the *briefest* time possible. Difficulty of insertion and type of ongoing therapy come into this cost-benefit analysis.

When there is a suspicion that a central venous line has become infected then blood cultures should be drawn from the line and from a peripheral puncture. Broad-spectrum antibiotics that cover the bacteria above (Vancomycin and Gentamicin for example) should be commenced. The line should be removed if at all possible. An attempt to sterilize the line may be made in the circumstances where the line is "precious" and not easily replaced. This can involve alternate infusion of antibiotics through all lumens and the use of antibiotic "locks."

Ventilator Associated Pneumonia (VAP)

This is defined as a respiratory infection that occurs 48 h post admission for mechanical ventilation. The

respiratory infection is defined by: fever/hypothermia, crackles on physical exam, new respiratory infiltrates on CXR, deteriorating ventilatory status (tachypnea), cough, deteriorating gas exchange, elevated or depressed white cell counts. This may or may not be in the presence of bacterial isolates from a sterile respiratory sample (i.e., BAL). There are age specific criteria for the diagnosis of VAP.

The CDC has produced a document that lists the specific criteria. This can be found at:

http://www.cdc.gov/ncidod/hip/NNIS/members/pneumonia/Final/PneumoCriteriaV1.pdf.

The incidence of VAP in the PICU is 6–11.6 per 1,000 ventilator-days. The diagnosis of VAP is challenging and controversial. There are a number of simple interventions to reduce the incidence of VAP.

They are:

1. Elevate head of the bed to 30°
2. Ventilator tubing:
   (a) Dependant positioning of ventilator tubing to avoid aspiration
   (b) Removal of excess condensate
   (c) Limit frequency of Tubing change unless required
3. Suctioning:
   (a) Limiting amount of saline lavage when suctioning
   (b) Sterile technique (Gloves and sterile catheter) + (gowns/masks and eye wear for protection of staff)
4. Mouth care: frequent mouth cares with Chlorhexidene-based wash
5. Feeding:
   (a) Early institution of feeding
   (b) Avoidance of gastric over distension
   (c) Limiting use of antacid therapy to high risk patients (i.e., burns, head injury)
6. Avoid/limit antibiotic therapy to minimize chance of colonization with antibiotic resistant flora

Urinary Tract Infection (UTI)

Urinary tract infection is directly proportional to the length of time that a Foley catheter is in place. Frequently, patients are on antibiotics that will suppress urinary infections. However, virtually all intensive care patients with urinary catheters will acquire urinary sepsis if their stay is prolonged. More than 90% of hospital acquired UTI's occur in catheterized children. The best intervention (as with central lines) is early removal of the catheter. When strict measurement of urinary output is not needed and the likelihood of urinary retention (due to illness or drugs) is not an issue then catheters should be removed. Intermittent catheterization can be considered as an intervention to avoid a permanent Foley catheter where retention is an issue in a longer term patient.

If an ICU patient develops fever or unexplained sepsis then it is mandatory that a urine specimen be sent for microscopy and culture. This is especially important in the patient with a catheter. If urinary sepsis is proven then consideration for catheter removal should be given. Broad-spectrum antibiotics that cover the spectrum of bacteria listed above should be commenced. Antibiotics should be specifically weighted to cover the Gram-negative bacteria as these are most common.

Wound Related Infection

Surgical Site infections are a less frequent infection but none the less important source of infectious morbidity.

If a wound is "dirty" or contaminated such as a traumatic soiled wound or contaminated peritoneum from perforated appendicitis then broad-spectrum antibiotics should be commenced in high dose. At the same time, appropriate surgical management should be undertaken to deal with the contaminated wound. The surgical team will usually offer guidance on this issue.

If a wound is "clean," for example a surgical incision, the surgical team will generally have a preference for antibiotic prophylaxis. Commonly a second generation cephalosporin will be used. This should be given at time of the operation and for a defined and limited time thereafter. Prolonged prophylaxis has been shown not to prevent inevitable wound infections and promotes emergence of multiple antibiotic resistances.

For wounds that become infected in the intensive care unit, swabs should be taken of any discharge. Surgical review should be initiated and the wound dressed (with frequent changes). Appropriate antibiotics should commence. Opening of the wound and drainage/debridement of infected tissue is the responsibility of the managing surgical team.

Infection Control Principles

All Intensive Care Units should have the ability to isolate for airborne and body fluid infectious organisms. Simple hand washing is very important (before and after examining patients or attending the bed side). Where this is not

practical an alcohol-based hand gel can be used. From simple hand washing a graduated appropriate degree of isolation and infection control processes should be undertaken, i.e., gowns, gloves, respiratory protection – masks with increasing filtering ability to full respirators.
