Familial Primary Hypomagnesemia due to selective defect of Mg^{2+} absorption in small intestines presents with generalized hypocalcemic-hypomagnesemic seizures by 3–8 weeks age. It does not respond to calcium but does to magnesium. Prompt diagnosis and treatment with magnesium prevents permanent neurological impairment. Urinary magnesium/creatinine ratio after an IM dose of Magnesium sulfate (normal = 1.5 mmol/mmol) helps to distinguish whether the defect is a renal tubular leak or a selective defect in intestinal absorption of Mg^{2+}.

Hypomagnesemia is also a cardinal finding in Gitelman Syndrome in association with hypocalciuria and hypokalemic alkalosis.

Treatment

Acute/symptomatic deficiency is treated using IV or deep IM Magnesium sulfate as discussed in the section on treatment of hypocalcemia. Long term supplementation of Magnesium is with oral Magnesium-L-Aspartate. Magnaspartate® powder 6.5 g/sachet provides 10 mmol of Mg^{2+}. It can be dissolved in water. The starting dose in children 1 month–2 years is 0.2 mmol/kg 3 times daily. Half a sachet (5 mmol) dissolved in 100 ml of water daily in children aged 2–10 years and 1 full sachet (10 mmol) daily in 200 ml water is used in children >10 years. Doses are adjusted as required.

Familial Hypercalciuric Hypocalcemia = Hypocalcemia with Normal PTH

The combination of hypercalciuria with hypocalcemia and normal PTH is reflective of an abnormality of Calcium-Sensing Receptor (CaSR).Activating mutations of the CaSR are usually inherited autosomal dominant or sporadic. There is an inappropriately suppressed PTH; in other words a lowered set-point for PTH secretion, i.e., a small fall in plasma calcium, is unable to stimulate the CaSR to signal PTH release. This heterozygous gain of function mutation of CaSR is also called Familial Hypercalciuric Hypocalcemia.

Clinical Features

Presentations range from asymptomatic to severe. Most common symptoms are polyuria and polydipsia even at normal plasma calcium levels due to increased renal calcium excretion. The urine calcium/creatinine ratio is >0.3 mmol/mmol.

Bartter syndrome is a genetically heterogeneous disorder characterized by deficient renal reabsorption of sodium and chloride, and hypokalemic metabolic alkalosis with hyperreninemia and hyperaldosteronemia. Hypocalcemic patients with deficient parathyroid hormone secretion, characteristics of Bartter

syndrome, and activating mutations of the CASR gene have been described.

Treatment

Most patients have mild asymptomatic hypocalcemia and require no treatment. Severe, symptomatic hypocalcemia necessitates cautious use of calcium and vitamin D as treatment may exacerbate baseline hypercalciuria resulting in nephrocalcinosis and renal insufficiency. Several patients have been treated successfully with PTH therapy, averting hypercalciuria and renal failure. More data are needed before its use can be recommended in practice.

Drugs that antagonize the extracellular calcium-sensing receptor (i.e., calcilytic agents), in trials stimulate endogenous PTH, are a promising alternative for disorders with intact but hypofunctioning parathyroid glands.

Hypocalcemia with High PTH suggests vitamin D deficiency/impaired metabolism (discussed later) or pseudohypoparathyroidism (PHP).

Pseudohypoparathyroidism (PHP)

There are several types Ia, Ib, Ic, II, and also pseudopseudohypoparathyroidism (PPHP). The prototype variant Type Ia is eponymous as Albright's Hereditary Osteodystrophy.

Definition

These patients have clinical and biochemical features consistent with hypoparathyroidism but with raised PTH levels and do not respond to exogenous parathyroid hormone (lack of urinary cAMP and phophaturic response to PTH infusion).

Biological resistance to PTH is present and causes hypocalcemia due to impaired mobilization of calcium from bone and reduced intestinal absorption of calcium. Plasma levels of Phosphate are high.

PHP is twice as common in females as males. The commonest genetic mutation is in the GNAS1 gene (Chr20q3.2). Inheritance is autosomal dominant. The resistance to PTH is caused by a defect in G-protein, a ubiquitous protein required for functional cyclic AMP production. Plasma membrane–bound hormone receptors communicate with the catalytic unit of adenylate cyclase through the interaction of a pair of guanine nucleotide binding regulatory proteins (G-proteins). There are many G-proteins, some of which are stimulatory (Gs) or inhibitory (Gi). Patients with PHP type Ia have a 50% reduction in G-stimulatory protein alpha (GSα) in all tissues due to a variety of mutations in the GSα gene.

Clinical Features

As expected patients with PHP Ia display partial resistance to several other hormones and may present with short stature, hypothyroidism, hypogonadism, mental retardation, subcutaneous calcifications, ovulatory, gustatory, and auditory dysfunction. Characteristic dysmorphology includes large head, round facies, obesity, short stature, short neck, and short 4th metacarpals and metatarsals. They tend to grow below the 9th percentile but have blunted pubertal growth spurt. Symptoms and signs of hypocalcemia such as muscle spasms, tetany, etc., can be present. This constellation of developmental and somatic defects is referred to as Albright's Hereditary Osteodystrophy (AHO). Not all features are seen in every patient as there is enormous phenotypic variability. Characteristic hand changes evolve gradually and may not be apparent before the age of 4 years. Shortening of the fourth (and fifth) metacarpals causes short digits, recognized as dimpling over the knuckles of a clenched fist (Archibald sign). Shortening of the distal phalanx of the thumb is identified by the increased ratio of the width of the nail to its length (so-called murderer's thumb or potter's thumb).

In PHP type Ib hormone resistance is confined to only PTH receptors. The biochemical picture is identical to PHP type Ia; however, there are none of the phenotypic features. Mild TSH resistance may be found. Some patients have features of hyperparathyroidism bone disease suggesting that bones respond to PTH. It may be inherited dominantly from an affected mother but sporadic cases are usual.

PHP Ic is rare and involves multiple hormone resistance and phenotypic features of AHO but normal Gsα activity. The defect may be in other components of the receptor-adenylate cyclase system or in mutations in exon 13 affecting only the Gsa–receptor interaction.

PHP type II is a clinically heterogeneous syndrome with no clear genetic basis. The molecular defect is unknown. There is resistance to PTH action but phenotypic features of AHO are absent. The pathophysiology is poorly understood. There may be normal cyclic AMP response but an absent phosphaturic response to PTH. Hypocalcemia, decreased bone mobilization response to

PTH, and decreased serum 1,25-dihydroxyvitamin D are the prominent features of PTH resistance.

Pseudopseudohypoparathyroidism (PPHP) is genetically similar to PHP type Ia. The GNAS-1 gene on Chr20q3.2 displays imprinting. If the maternal abnormal gene is functional it results in PHP Ia, while paternal transmission leads to PPHP. The imprinting is also tissue specific. Only the maternal gene is expressed in the kidneys; thus renal resistance to PTH is only seen in PHP Ia and never in PPHP. PPHP patients express the AHO phenotype but have normal serum calcium levels and have no other evidence of hormone resistance. Some patients may have other affected family members who also have hormone resistance and are diagnosed as PHP Ia.

Investigations

Serum calcium is low. Serum phosphate levels are elevated. Elevated serum concentration of PTH in a hypocalcemic patient suggests either a form of PHP or secondary hyperparathyroidism. An assessment of skeletal and renal responsiveness to PTH is done by measurement of changes in serum calcium, phosphorus, cAMP, and calcitriol concentrations and in urinary cAMP and phosphorus excretion after administration of the biosynthetic N-terminal fragment of PTH. Evaluation of other endocrine functions: thyroid function tests gonadotropins, testosterone or estrogen levels, and growth hormone and insulin-like growth factor-1 axis. X-ray hand may show shortening of the bones (the distal phalanx of the thumb and the third through fifth metacarpals) and small areas of soft tissue calcifications/ossifications. CT scanning may reveal calcification of the basal ganglia. Analysis of the *GNAS1* gene helps identify the specific genetic defect in patients with PHP type 1a while methylation studies help to identify PPHP.

Treatment

Severe symptomatic hypocalcemia is initially treated with intravenous calcium. Oral calcium with calcitriol (0.25–0.5 μg/day) or Alphacalcidol dose (15–50 ng/kg/day) is the mainstay of treatment. The goals of therapy are to maintain serum total and ionized calcium levels within the reference range to avoid hypercalciuria and normalize PTH levels. This is important because elevated PTH levels in patients with PHP could cause increased bone remodeling and can lead to hyperparathyroid bone disease.

Hypocalcemia of Renal Failure

The hypocalcemia of renal failure is mainly due to hyperphosphatemia. Impaired synthesis of 1,25-dihydroxyvitamin D plays a less important role. Hyperphosphatemia alters calcium and phosphate ion solubility products, and calcium deposition in soft tissue may occur. Hyperphosphatemia inhibits lα-hydroxylase activity in the kidney. 1,25-dihydroxyvitamin D deficiency impairs intestinal absorption of calcium. This also results in increased PTH secretion. Secondary hyperparathyroidism from long-term hyperphosphatemia is usually associated with renal insufficiency. Ectopic calcification in tissues may occur, including blood vessels, skin, periarticular tissues, and cornea (band keratopathy).

Other causes of hyperphosphatemia include: use of phosphate-containing enemas or overzealous use of oral phosphate; vitamin D administration; transcellular shift of phosphorus from cells into the extracellular fluid compartment is seen in tissue destruction or increased metabolism, e.g., in acute leukemia, lymphomas; and following chemotherapy for large bulky tumors lead to a rapid release of cellular phosphorus causing a "tumor-lysis-syndrome." Rhabdomyolysis and severe intravascular hemolysis may lead to a similar syndrome.

Hypocalcemia and tetany may occur if serum phosphorus rises rapidly.

Treatment should be directed toward the hyperphosphatemia in order to correct the hypocalcemia.

Medications causing hypocalcemia include oral, rectal, or parental phosphate preparations; drugs that inhibit bone resorption – mithramycin (plicamycin), bisphosphonates; and calcitonin. Hypocalcemia due to bisphosphonates can be prolonged. Anticonvulsants – phenytoin or Phenobarbital – also cause hypocalcemia. Hypocalcemia occurs in patients undergoing exchange transfusions and plasmapheresis with citrated blood. Radiographic contrast dyes that contain the calcium chelator; ethylenediaminetetra-acetic acid (EDTA); Gadolinium administered for MRI imaging; and chemotherapeutic agents, e.g., combined use of 5-fluorouracil and leucovorin, lead to hypocalcemia. Cisplatinum induced hypocalcemia is secondary to hypomagnesemia.

Rickets and Osteomalacia

Definition

Since the primary action of vitamin D is the uptake of calcium from the intestine and its subsequent deposition

as bone mineralization the main effect of vitamin D deficiency is failure of bone mineralization.

Rickets is the failure of mineralization of growing osteoid tissue. Osteomalacia is the general term for failure of bone mineralization; "rickets" is used in growing children, while osteomalacia is used in adults when bones have stopped growing.

Defective bone matrix mineralization can be caused by either calcium or phosphate deficiency and so we have Calcipenic (hypocalcemic) rickets and Phosphopenic (hypophosphatemic) rickets. Rickets can also be due to primary defects in local bone processes (e.g., hypophosphatasia)

Calcium deficiency is rarely primary nutritional deficiency in the UK (but not so in developing countries). Calcium deficiency secondary to disorders of vitamin D metabolism is more common. Phosphorous deficiency (e.g., due to increased renal phosphate clearance as in X-linked Hypophosphatemia) is uncommon.

Etiology

Causes of calcipenic rickets (i.e., rickets caused by a deficiency of vitamin D or defect in its metabolism or action): Deficiency of vitamin D is most common worldwide and accounts for up to 95% cases. The deficiency may be due to deficient intake vitamin D in diet or lack of effective exposure to sunlight (reduced synthesis of vitamin D by skin) or deficient absorption, e.g., celiac disease, pancreatic insufficiency, short gut syndrome, etc.

Impaired metabolism of vitamin D is the next most important cause and includes (a) impaired C-25 hydroxylation in liver disease and (b) impaired C-1 hydroxylation in kidneys due to renal failure or Type 1 Vitamin D Resistant Rickets (XLD inherited deficiency of 1α hydroxylase enzyme; also called vitamin D dependent rickets).

Target organ resistance to 1,25-dihydroxyvitamin D results in Type 2 Vitamin D Resistant Rickets.

Enhanced metabolic breakdown of vitamin D by P450 hepatic microsomal enzyme induction (anticonvulsants) can also cause rickets.

Epidemiology

Incidence of symptomatic vitamin D deficiency in children <5 years age in the UK is 7.5 per 100,000 children per year. There are notable ethnic differences within the UK. Black African or African-Caribbean children have an incidence of 95, South-Asian 38, and white ethnic origin 0.4 per 100,000.

Clinical Features

Clinical Features include bone deformity, bone pain, pathological fractures, frontal bossing, craniotabes (posterior flattening of the skull), bow legs (genu varum), knock knees (genu valgum), widening of wrists, bowing of arms, "Rachitic rosary" (beading of costochondral junctions of ribs), Harrison's sulcus' (an indentation in the lower chest wall), weakness (proximal myopathy), hypotonia, and protuberant abdomen.

Delayed walking and dentition, poor appetite, and growth failure are nonspecific features. As previously mentioned signs of hypocalcemia are rare.

Radiological Features

Thin bones with wide irregular cupped and poorly mineralized metaphyses are best seen at the growing ends of long bones, e.g., in X-rays of wrist and knee. Apparent widening of the joint space is a result of absence of epiphyseal calcification. Bone deformity and sometimes greenstick fractures are seen. Chest radiographs show the costochondral thickening. Osteopenia is a feature of calcipaenic rickets but not seen on x-rays in phosphopenic rickets. Looser's zones are lines of pathological fractures.

Vitamin D Deficiency: Stages and Clinical Signs

1. Stages of vitamin D deficiency
   Stage I
   25-OH-D level decreases, resulting in hypocalcemia and normal phosphate levels; 1,25-dihydroxyvitamin-D may increase or remain unchanged
   Stage II
   25-OH-D level continues to decrease; PTH acts to maintain calcium through demineralization of bone; the plasma calcium normalizes with hypophosphatemia; slight increase in the skeletal alkaline phosphatase
   Stage III
   Severe 25-OH-D deficiency with hypocalcemia, hypophosphatemia, and increased alkaline phosphatase; bones have overt signs of demineralization
2. Clinical signs of vitamin D deficiency
   - Dietary calcium absorption from the gut decreases from 30–40% to 10–15% when there is vitamin D deficiency
   - Low concentrations of 25-OH-D trigger the release of PTH Rickets/Osteomalacia and osteopenia seen
   - Abnormal immune function with greater susceptibility to acute infections and other long-latency disease states (see below)

3. Potential latent disease processes associated with vitamin D deficiency
   - Dysfunction of the innate immune system is noted with vitamin D deficiency Immuno-modulatory actions may include
     - Potent stimulator of innate immune system acting through Toll-like receptors on monocytes and macrophages
     - Decrease threshold for long-latency diseases such as cancers (including leukemia and colon, prostate, and breast cancers), psoriasis, diabetes mellitus, and autoimmune diseases (e.g., multiple sclerosis, rheumatoid arthritis, systemic lupus erythematosis)

Investigations: Plasma calcium, phosphate and magnesium, alkaline phosphatase, albumin, creatinine, serum PTH level, and plasma level of 25-OH vitamin D. Serum should be stored for 1,25-Di-OH vitamin D. Urine investigations: calcium, phosphate, and creatinine. X-ray of wrist + hand (or knee + chest in infants and toddlers).

The 3 main groups of Rickets can be biochemically distinguished.

Treatment of Nutritional Deficiency Rickets

Treatment for rickets is vitamin D administered over several months or in a single dose. Both calcitriol and alphacalcidol bypass the natural physiologic controls and are potentially toxic.

Gradual method: Ergocalciferol liquid (1 ml contains 3,000 units) is used in small children. Dose: children <6 months give 1 ml daily; in children 6 months–12 years give 2 ml daily. Ergocalciferol tablets of 250 μg (10,000 units) and 1.25 mg (950,000 units) are also available. Vitamin D treatment is given daily for 6–8 weeks (sometimes longer) until healing is well established and the alkaline phosphatase concentration is approaching the reference range. Adherence to daily treatment over weeks is essential. Single-day treatment (also called Stoss therapy) vitamin D in a total dose of 15,000 mcg (600,000 U) is administered in a single day in 4 or 6 divided oral doses. An intramuscular injection (Cholecalciferol or ergocalciferol 7.5 mg equivalent to 300,000 units) can be given as a single dose of 600,000 units. Vitamin D given as this large dose is well tolerated and stored in the body to be gradually released over many weeks. The single-day therapy avoids problems with compliance. It is helpful in differentiating nutritional rickets from XL-Hypophosphatemic rickets. In nutritional vitamin D deficiency rickets, the phosphorous level rises in 96 h and radiographic healing is visible in 6–7 days. Neither happens with XLD Hypophosphatemic rickets.

Maintenance supplement after the rickets is healed as 400 units daily vitamin D is needed. In patients with chronic intestinal malabsorption or liver disease higher therapeutic doses up to 40,000 units daily may be needed. If severe deformities have occurred, orthopedic correction may be required after healing. Most of the deformities correct with growth.

Other types of calcipaenic rickets:

Vitamin D–Resistant Rickets Type I (VDRR 1)

Also known as Vitamin D–dependent rickets (type I) and as vitamin D pseudodeficiency (PDDR) this disorder results from an inherited deficiency of 1α-hydroxylase that converts 25(OH) cholecalciferol to 1,25-dihydroxycholecalciferol (1,25-dihydroxyvitamin D) in the kidney. Inheritance is autosomal recessive; the gene locus is 12q13.3. Clinical findings are similar to those seen in nutritional rickets. Serum levels of 1,25-dihydroxyvitamin D are low. These patients develop rickets despite receiving vitamin D at the recommended preventive doses. Treatment: oral calcitriol (0.5–1.5 mcg/day). These patients may also respond to high doses of vitamin D (5,000–10,000 U/day).

Vitamin D–Resistant Rickets Type II (VDRR 2)

Also known as receptor defect rickets and as type II vitamin D–dependent rickets and Hereditary 1,25-dihydroxyvitamin D–resistant rickets (HVDRR) this results from an autosomal recessive inherited abnormality in the calcitriol receptor, causing an end-organ resistance to the vitamin. HVDRR can be lethal in the perinatal period. The clinical features appear in early infancy and consist of all the musculoskeletal symptoms and signs of nutritional rickets with very severe hypocalcemia and usually normal phosphate levels. Alopecia is an associated feature, although a variant without alopecia has been reported. Serum levels of 1,25-dihydroxyvitamin D are typically elevated. Several mutant forms of receptor defect rickets are known, with a wide range of phenotypic severity and response to treatment. Calcitriol is the treatment. Some patients are totally resistant to therapy. Patients without alopecia appear to respond better to treatment with calcitriol. Some patients benefit from intravenous calcium (400–1,400 mg/m^2/day) followed by

oral therapy with high doses of calcium (with risks of nephrocalcinosis, hypercalciuria, nephrolithiasis, and cardiac arrhythmias). Patients with mutations in the ligand-binding domain (LBD) region of the receptor are more likely to respond to high-dose vitamin D treatment than patients with mutations in the DNA-binding domain (DBD) region of the receptor.

Hypophosphatemic Rickets

Primary (Inherited) forms include X-linked (dominant) Hypophosphatemia (XLH), Autosomal Dominant Hypophosphatemic Rickets (ADHR), Autosomal Recessive Hypophosphatemic Rickets (ARHR), Hereditary hypophosphatemia with hypercalciuria (HHRH), McCune-Albright syndrome, and Fanconi syndromes.

Secondary hypophosphatemic rickets are due to oncogenic and drug-induced nephrotoxicity (e.g., ifosfamide toxicity). Some mesenchymal tumors release FGF-23 which causes phosphaturia and cause hypophosphatemic osteomalacia.

Inherited Hypophosphatemic Rickets

X-linked hypophosphatemia (XLH) is an X-linked dominant disorder characterized by growth retardation, rickets/osteomalacia, hypophosphatemia, and renal defects in phosphate reabsorption and vitamin D metabolism (defective 1α hydroxylation). XLH is caused by mutations in the phosphate-regulating endopeptidase gene (PHEX, locus Xp22.2-p22.1). The mutated PHEX gene allows accumulation of the peptide encoded by FGF-23 causing unregulated renal phosphate leak. Defective osteoblast function contributes to the pathology. XLH presents in toddlers with bowed legs, bent femurs, waddling gait, and short stature. Family history is important. Recurrent dental abscesses are frequent. Asymptomatic neonates may have low phosphate levels. Normal ranges of serum phosphate vary with age: newborns, 1.61–2.52 mmol/L; 1 month–1 year, 1.23–2.0 mmol/L; 1–10 years, 1.16–1.81 mmol/L; and after 10 years and in adults, 1.0–1.65 mmol/L.

Other inherited forms of hypophosphatemic rickets include:

Autosomal recessive form (ARHR) – mutations in the dentin matrix acidic phosphoprotein (DMP1) gene (locus 4q21), a nuclear protein that regulates the expression of osteoblast-specific genes.

Autosomal dominant form (ADHR) – mutation occurs in the gene encoding a member of the fibroblast growth factor family, FGF23 (locus 12p13). Mutations at the furin cleavage site prevent the processing of a fibroblast-growth-factor peptide (encoded by the gene FGF-23), into fragments, leading to the accumulation of a "stable" circulating form of the peptide which inhibits renal Pi reabsorption.

X-linked recessive form – mutation in the CLCN5 gene (locus Xp11.22, which encodes a voltage-gated chloride channel) that leads to defective apical endocytosis of PTH and 25-hydroxyvitamin D, resulting in hyperphosphaturia and hypocalciuria.

Hereditary Hypophosphatemic Rickets with Hypercalciuria (HHRH) is caused by mutation in the sodium-phosphate co-transporter gene SLC34A3 at locus 9q34.

A variety of hypophosphatemic rickets with hyperparathyroidism is caused by a translocation at locus 13q13.1 that results in an increase in plasma alpha-klotho and FGF-23 levels.

In Tumour-Induced Osteomalacia (TIO) a similar mechanism exists wherein ectopic overproduction of FGF-23 overwhelms its processing and degradation by PHEX, leading to the accumulation of FGF-23 products in the circulation that inhibit renal Pi reabsorption.

Investigations: X-rays in hypophosphatemic rickets show changes of rickets like wide splayed metaphyses but not the osteopenic changes like cupping and fraying. Diagnosis is made by laboratory investigations: low serum phosphate, moderately elevated alkaline phosphatase, normal serum PTH, 25 OH vitamin D, and 1,25-dihydroxyvitamin D. Normal urine calcium excretion and a low% TRP and TmP/GFR are the keys to diagnosis.

Treatment

The primary objectives of treatment are to prevent bone deformity and orthopedic surgery, normalize growth and activity, and avoid complications. Short stature can be improved if treatment is started early by ~2 years. Phosphate replacement: 70–100 mg/kg/day needs to be given 4–5 divided doses because each dose will be excreted in about 4–5 h. Preparations available in the UK include Phosphate Sandoz 500 mg tablet and Joules solution 28 mg/ml. (K Phos Neutral 250 mg capsules are available in the USA.) Alfacalcidol (1α cholecalciferol):10–50 ng/kg/day (maximum 1 μg/day). One Alpha Drops contain 2 μg/ml (1 drop is equivalent to 100 ng). One Alpha capsules is 250 ng strength. Injection (2 μg/ml) is also available. Alternatively Calcitriol (1,25-dihydroxyvitamin D) can be used in a dose of

15 ng/kg/day (maximum 250 ng/day). Each capsule contains 250 ng of the medication.

The balance between the phosphate and Alphacalcidol needs meticulous monitoring. Serum phosphate is a poor index; alkaline phosphate is not sensitive enough. Monitoring is by growth and clinical assessments with serum PTH and calcium levels and urine calcium/creatinine ratio. Serum PTH should be normally monitored at least every 6 months. Elevated serum PTH with normal serum calcium indicates the need to increase alphacalcidol dose and/or to reduce phosphate supplementation. Hypercalciuria and/or elevated serum calcium with normal serum PTH suggests reduction in alphacalcidol dose. If both serum calcium and serum PTH indices were to be elevated, it suggests tertiary hyperparathyroidism, and if confirmed (repeat serum chemistry), parathyroidectomy may be necessary. Ultrasound of kidneys is done 2 yearly. About half the patients will develop some nephrocalcinosis but most will have normal renal functions.

Renal Rickets

Fanconi syndrome is a disorder of proximal renal tubular transport characterized by phosphate, amino acids, glucose, bicarbonate, and uric acid wasting. Tubular phosphate reabsorption via the sodium-phosphate cotransporter is impaired. Additionally there is defective endocytotic reabsorption of vitamin D – vitamin D–binding protein complex. Acid–base regulation is affected. These three factors are responsible for the pathogenesis of bone mineralization defects.[25] The disorder may be inherited or acquired.

Lowe disease (Oculocerebrorenal syndrome) *OCRL1* gene (locus Xq26.1) and Dent disease – Dent disease type 1 *CLCN5* gene (locus Xp11.22) and Dent disease type 2 *OCRL1* gene (locus Xq26.1) – all cause X-linked hypercalciuria, hypophosphatemia, nephrolithiasis, and rickets.

Cystinosis, a lysosomal storage disorder of cystine transport protein, cystinosin (mutations of CTNS gene locus 17p13), and tyrosinemia (fumaryl acetoacetase/fumaryl acetoacetate hydrolase deficiency, FAH gene locus 15q23–q25) are other inherited conditions included in this group of conditions with renal phosphate wasting along with aminoaciduria and glucosuria.

Distal renal tubular acidosis, through phosphate wasting, may also cause rickets.

Renal osteodystrophy. In end-stage renal disease, renal 1-hydroxylase is diminished or lost, and excretion of phosphate is defective. This leads to low levels of 1,25-dihydroxyvitamin D, hypocalcemia, and failure of osteoid calcification. This is the only type of rickets with a high serum phosphate level. It can be adynamic (a reduction in osteoblastic activity) or hyperdynamic (increased bone turnover). See also ❯ "Hypocalcemia of Renal failure."

Acquired Fanconi syndrome results from various toxins, including heavy metals (mercury, lead) and drugs (cisplatinum, ifosfamide).

The clinical picture varies with age and cause and includes severe hypophosphatemic rickets, failure to thrive, and metabolic acidosis. Treatment is by managing the underlying cause (when possible) and vitamin D therapy (or calcitriol).

McCune Albright Syndrome (MAS)

McCune Albright syndrome (MAS) is defined as the association of 2 out of following 3 features: polyostotic fibrous dysplasia (PFD), precocious puberty, and café au lait spots. Other endocrinopathies coexist. MAS is due to a postzygotic activating mutation of the GS alpha gene in the affected tissues. Hypophosphatemic rickets is a potential complication that may worsen the bone disease associated with PFD. The hypophosphatemia is usually mild and secondary to excessive urinary phosphate leak induced by fibroblast growth factor 23 (FGF-23), so PTH levels remain normal. Severe hypophosphatemia is rare in MAS and, if untreated, results in severe clinical rickets and short stature. Treatment is vitamin D and phosphorus supplements. Patients with must be monitored closely for hypercalcemia and secondary hyperparathyroidism.

Hypercalcemia

Definition

Serum calcium level > 2.62 mmol/l (normal 2.12–2.62 mmol/l) OR ionized calcium Ca^{2+} level > 1.31 mmol/l (normal 1.16–1.31 mmol/l).

Clinical Manifestations of Hypercalcemia

Asymptomatic hypercalcemia: verify that the blood result is not a laboratory error. The most common reasons for falsely elevated serum calcium levels are hemoconcentration and elevated serum albumin levels. Acidosis increases the level of ionized calcium (but not total calcium) by changing plasma protein binding. A high intake of phosphate may also falsely elevate the serum calcium level.

Symptoms and signs vary depending on whether the hypercalcemia is of acute onset and severe (>3 mmol/l) or whether it is chronic and relatively mild. Patients generally tolerate higher serum calcium levels if the elevation is gradual; most patients are symptomatic at levels about 3.5 mmol/l. In either case the major manifestations affect gastrointestinal, renal, cardiac and central nervous and musculoskeletal systems.

Investigations

Serum/Plasma Calcium, Phosphate, Parathyroid hormone, Parathyroid hormone related peptide (PTHrP), 25 hydroxyvitamin D and 1,25-dihydroxyvitamin D. Urine for Calcium/Creatinine ratio and to assess renal tubular function (bicarbonate, pH, amino acids).

In the neonate, in addition to calcium, determine serum protein, phosphate, and PTH levels as well as the levels of maternal calcium and maternal PTH. Serum calcium levels from father, siblings, and other family members may also be helpful, e.g., in NSHPT both parents may have mild and asymptomatic familial hypocalciuric hypercalcemia (FHH). In a baby with hypercalcemia, the serum PTH level should be <10 pg/mL. A definitive diagnosis of hyperparathyroidism is confirmed by a PTH level >50 pg/mL.

Interpreting blood biochemistry: When PTH is high or inappropriately normal, consider hyperparathyroidism, familial hypocalciuric hypercalcemia, secondary hyperparathyroidism, and, rarely, malignancy. High PTH levels usually indicate primary hyperparathyroidism if the urine calcium/creatinine ratio is high while low urine calcium/creatinine ratio indicates FHH, which can be confirmed with DNA sequence analysis for *CASR* gene. When PTH is suppressed, the possible causes are malignancy, granulomatous disease, iatrogenic causes, adrenal insufficiency, thyrotoxicosis, and vitamin D intoxication. Low PTH levels usually indicate hypervitaminosis D if 25-hydroxyvitamin D and 1,25-dihydroxyvitamin D levels are high and indicate malignancy if they are low. If malignancy is suspected, evaluate accordingly and also check for high PTHrP level.

Etiology and Pathophysiological Mechanisms of Hypercalcemia

Neonatal Hypercalcemia

Transient neonatal hypercalcemia secondary to transient hyperparathyroidism is induced by a hypocalcemic feto-maternal environment. Mothers with hypoparathyroidism, pseudohypoparathyroidism, or vitamin D deficiency transfer low amounts of calcium to their fetuses. Fetal hypocalcemia induces a secondary hyperparathyroidism in the fetus that persists for several weeks after birth leading to hypercalcemia. It is often mild and asymptomatic, usually with serum calcium levels around 2.8 mmol/l picked up during blood investigations for other reasons. If asymptomatic it does not need further investigation or treatment. It is useful to check maternal parathyroid calcium and vitamin D status.

Neonatal Severe Primary Hyperparathyroidism (NSHPT) seen with homozygous inheritance of CaSR mutation (or in compound heterozygotes with little functional CaSR), presents within a week of birth and is characterized by severe life-threatening hypercalcemia, hypermagnesemia, increased circulating PTH concentrations, massive hyperplasia of the parathyroid glands, and relative hypocalciuria. Skeletal abnormalities including demineralization, craniotabes, widening of the metaphyses, osteitis fibrosa, and fractures may occur. Serum PTH levels are very high. Though the course of NSHPT can be self-limited, aggressive medical management is first indicated in all patients of NSHPT and prompt surgical intervention including total parathyroidectomy with immediate or delayed parathyroid autotransplantation should be performed. Postoperatively these infants develop "Hungry Bone Syndrome" needing large replacements of calcium for which a central access is desirable. PTH levels return to normal 2–4 days after surgical treatment.

Absorptive Hypercalcemia

Absorptive Hypercalcemia – inappropriately high absorption of dietary calcium from the gut is seen in Williams syndrome, Idiopathic Infantile Hypercalcemia (IIH), subcutaneous fat necrosis (of the newborn), vitamin D toxicity, and granulomatous disease. In Williams syndrome (a sporadic multisystem disorder with "elfin facies," supravalvular aortic stenosis, and hypercalcemia usually due to a microdeletion of chromosome 7q11.23, which represents a continuous gene deletion that includes the elastin gene (ELN)) hyperabsorption of calcium begins a few months after birth and spontaneously resolves between the ages of 2–4 years. A similar pattern is seen in Idiopathic Infantile Hypercalcemia but without other features of Williams syndrome. The mechanism is not understood but infants and toddlers have symptomatic hypercalcemia and most also have elevated levels of serum

1,25-dihydroxyvitamin D. Treatment is usually needed. Investigations in absorptive hypercalcemia show: elevated serum calcium, 1,25-dihydroxyvitamin D, and urine ca/creatinine ratio (valid only after the age of 1 year). Serum Phosphate is normal or mildly raised. 25 hydroxyvitamin D is normal while serum Parathormone is low.

Subcutaneous fat necrosis: Symptomatic hypercalcemia occurs at 3–6 weeks age, usually in a term infant with perinatal hypoxia who develops violaceous nodules on the back, buttocks, and thighs with thrombocytopenia. Hypercalcemic symptoms are subtle, vomiting and failure to thrive may be confused as resulting from perinatal hypoxia. Hypercalciuria and nephrocalcinosis occur. Hypercalcemia is due to excessive conversion of 25 hydroxyvitamin D to 1,25-dihydroxyvitamin D by the macrophages.

Granulomatous disease: Extra-renal production of 1,25-dihydroxyvitamin D occurs in various cell (tumor cells, macrophages, granulomatous cells). This alone or in conjuction with lymphoid cytokines is responsible for the hypercalcemia.

Vitamin D toxicity: due to overdoses of vitamin D (or analogues), e.g., during Stoss therapy or regular supplementation. Levels of 25 hydroxyvitamin D and 1,25-dihydroxyvitamin D are both elevated.

Childhood Hypercalcemia

Hypercalcemia due to increased bone resorption occurs in (1) prolonged immobilization, (2) hyperparathyroidism, (3) familial hypocalciuric hypercalcemia, and (4) endocrine disorders associated with increased bone resorption but without excess PTH production such as Hyperthyroidism, Hypoadrenalism, and Jansen's Metaphyseal Chondrodysplasia.

Hypercalcemia associated with childhood malignancies such as non-Hodgkin or Hodgkin lymphoma, Ewing sarcoma, Neuroblastoma, Langerhans cell histiocytosis, Rhabdomyosarcoma with metastases and ovarian small cell carcinoma in adolescents *and* Renal tumors with rhabdoid histology in infants.

The pathophysiologies responsible for oncological hypercalcemia are three. (1) Due to osteolytic secondaries causing bone destruction. (2) Due to elevated Parathyroid hormone related peptide (PTHrP): 50–90% of patients with solid tumors (squamous cell carcinomas of various tissues especially lung, renal cell carcinoma, bladder and ovarian carcinoma, pheochromocytoma and pancreatic islet-cell tumors) and hypercalcemia and 20–60% of patients with hematologic malignancies (non-Hodgkin's lymphoma, chronic myeloid and lymphoblastic leukemia, adult T cell leukemia/lymphoma (ATL), and multiple myeloma) have elevated circulating PTHrP. (3) Due to substances other than PTHrP. Tumor cells produce several bone resorbing substances besides PTHrP: proteases which facilitate tumor cell progression through unmineralized matrix, cytokines, eicosanoids, and growth factors (e.g., EGF) which can act on osteoblasts to increase production of cytokines such as Macrophage-Colony Stimulating Factor and RANKL and to decrease production of osteoprotegerin (OPG). Receptor activator of NF-κB ligand (RANKL) binds to its receptor RANK in osteoclastic cells, and increases production and activation of multinucleated osteoclasts which can resorb mineralized bone. Osteoprotegerin (OPG) also known as osteoclastogenesis inhibitory factor (OCIF) blocks RANK-L and inhibits the production of osteoclasts.

Parathyroid hormone related peptide (PTHrP): In 1941 Albright, observed that hypophosphatemia should not accompany hypercalcemia if the tumor was simply causing osteolysis. He suggested that the tumor might be secreting a substance which hypercalcemic and phosphaturic, which lead to the concept of "ectopic" PTH production. However neither PTH nor PTH-mRNA be detected in these patients. Bioassays subsequently identified PTH-like bioactivity in both blood and tumor extracts which lead to identifying a novel protein called PTHrP (1988 by Broadus et al.). PTH(1–34) and PTHrP(1–34) act similarly at the PTH receptor type 1 (PTH-R1) to raise blood calcium, phosphorus, reduce renal calcium clearance, and inhibit tubular reabsorption of phosphate. PTHrP has important physiological roles in fetal life for active transplacental transport of calcium. PTHrP also acts as an endocrine, autocrine/paracrine, and intracrine hormone that regulates epithelial-mesenchymal interactions during the formation of the mammary glands and during lactation regulates the mobilization and transfer of calcium to the milk. PTHrP is critical in the intraosseous phase of tooth eruption where it acts as a signaling molecule to stimulate local bone resorption. Without PTHrP, the bony crypt surrounding the tooth follicle will not resorb, and therefore the tooth will not erupt. It regulates endochondral bone development by maintaining the endochondral growth plate at a constant width.

Endocrine disorders causing Hypercalcemia can do so with or without elevated PTH levels. Those that do so without elevated PTH include: (1) Hyperthyroidism, increased triiodothyronine directly increases bone turnover and resorption. The liberated calcium suppresses PTH release so that 1,25-dihydroxyvitamin D levels are reduced and renal calcium reabsorption is diminished.

Therapy of the hyperthyroidism reverses the hypercalcemia. (2) Hypoadrenalism causes hypercalcemia by an unclear mechanism. Elevated ionized Ca^{2+} suppresses PTH and 1,25-dihydroxyvitamin D. Treatment of hypoadrenalism with replacement glucocorticoids and restoration of intravascular volume corrects the hypercalcemia. (3) Jansen's Metaphyseal Chondrodysplasia (JMC) is a very rare disorder that results from ligand-independent activation of the PTH-R1 due to activating mutations. Levels of PTH and PTHrP are low. The mutation leads to auto-activation of the PTH-R1 signaling. Short limbed dwarfism with disorganized metaphyses and normal epiphyseal plates with hypercalcemia, hypophosphatemia and elevated urinary calcium, phosphorus, and cyclic AMP are seen. There is no known treatment although bisphosphonates have been tried. Endocrine conditions with elevated PTH are hyperparathyroidism of various types.

Hyperparathyroidism

Etiology

Primary hyperparathyroidism is due to enlargement of one or more of the parathyroid glands (adenoma). It is rare in children; the typical patient being an elderly female. In primary sporadic hyperparathyroidism PTH is generally overproduced by a single parathyroid adenoma. There is net increase in plasma calcium and decrease in plasma phosphate. Urine calcium/creatinine ratio is high. 25 hydroxyvitamin D level is normal. Bone loss manifested by discrete lesions including subperiosteal bone resorption of the distal phalanges, osteitis fibrosa cystica characterized by bone cysts and "brown tumors" (i.e., collections of osteoclasts intermixed with poorly mineralized woven bone), and pathological fractures. Severe skeletal manifestations reflect uncontrolled disease and are seen in <2% adults with parathyroid adenoma. Nephrocalcinosis/nephrolithiasis occurs in 20% patients.

Primary Familial Hyperparathyroidism occurs in four situations.

Multiple Endocrine Neoplasia, Type I (MEN1) Syndrome: Autosomal dominant, with tumors of the parathyroid glands (80–100%), anterior pituitary (usually prolactinomas), and pancreatic islets. The mutation affects MENI gene (locus 11q13) which encodes the nuclear protein, menin.

Multiple Endocrine Neoplasia Type II (MEN2) Syndrome: MEN2A is characterized by medullary thyroid carcinoma (MTC, calcitonin-secreting) bilateral pheochromocytomas and hyperparathyroidism which result from activating mutations in the receptor tyrosine kinase (RET) proto-oncogene (locus 10q11.2).[27] MTC and pheochromocytomas have high malignant potential and common. Hyperparathyroidism is milder and less frequent (5–20%). The treatment of parathyroidism in MEN is surgical.

Hyperparathyroidism – Jaw Tumor Syndrome: an autosomal dominant disorder characterized by early onset of single or multiple cystic parathyroid adenomas and fibro-osseous jaw tumors which lack osteoclasts and therefore differ from "brown tumors." Mutations occur in tumor suppressor gene, HRPT2 (locus 1q25–q31), which encodes the protein parafibromin. Renal lesions like benign cysts, hamartomas and Wilms tumor are associated.[28] Due to a high malignant potential surgical removal is indicated.

Familial Hypocalciuric Hypercalcemia (FHH): is due to an autosomal dominant inactivating mutation in the Calcium sensing receptor (CaSR) gene (locus 3q13.3–q21). In heterozygotes the kidney CaSR has diminished ability to detect plasma calcium leading to enhanced renal tubular reabsorption of calcium and magnesium i.e. hypercalcemia and hypermagnesemia. Parathyroid gland CaSR also inadequately senses plasma calcium so mild hyperplasia occurs and "normal" levels of PTH are secreted despite the hypercalcemia which is mild to moderate. In patients with co-existing vitamin D deficiency FHH may be masked. Parathyroidectomy should not be done; the renal defect is not correctable.

Secondary Hyperparathyroidism is when persistent hypocalcemic states, e.g., renal failure induces a parathyroid hyperplasia with secondarily elevated PTH.

Tertiary Hyperparathyroidism – occasionally secondarily elevated PTH levels persist even after removal of the primary cause, e.g., renal transplant. This then causes hypercalcemia and may need parathyroidectomy.

Investigations

Blood: Calcium, PTH and 1,25-dihydroxyvitamin D – elevated. Phosphate low. Urine: high Calcium/creatinine ratio. Localization of parathyroid adenoma(s)/ectopic location can be done by Ultrasonography of neck and Tc99-labeled Sestamibi scan.

Management of Hypercalcemia

Acute Hypercalcemia

Hydration is the initial step using isotonic saline (3 L/m^2). Hydration helps decrease the calcium level through

dilution and increase renal calcium clearance. Calciuresis with Loop diuretics (e.g., frusemide) can be used with hydration to increased calcium excretion and lower serum calcium levels within 24–48 h. Thiazides are contraindicated because they increase tubular reabsorption of calcium. Regular (6–8 hourly) monitoring of serum calcium, phosphate, urea, creatinine, and sodium, magnesium, potassium during diuresis is essential. Bisphosphonates inhibit bone resorption. Pamidronate (Aredia) (dose 1–1.5 mg/kg, maximal adult dose 90 mg) lowers serum calcium levels over a period of days to months. Repeat dosing is based on a further rise in serum calcium levels and should not be done more than once a month. Fever, musculoskeletal discomfort, and vomiting are common side effects as is hypocalcemia. Glucocorticoids are useful in hypercalcemia caused by vitamin D toxicity, certain malignancies (e.g., multiple myeloma, lymphoma), sarcoidosis, and other granulomatous diseases. They are ineffective in patients with solid tumors or primary hyperparathyroidism. Hydrocortisone (2.5 mg/kg IV qds) or prednisolone (2 mg/kg, maximum 40 mg/day) reduce non-renal alpha-1-hydroxylase activity and 1,25-dihydroxyvitamin D–induced calcium absorption from the gut. Dialysis is needed in patients with kidney failure. Calcitonin: subcutaneous or intramuscular (2–6 mcg/kg every 6 h) works within hours to decrease skeletal reabsorption of calcium and inhibits renal reabsorption. Effects are limited to initial 2–3 days because of tachyphylaxis. Serum calcium reduces by only 0.5 mmol/L. Adverse effects include nausea, cramping, abdominal pain, and flushing. It use is now largely supplanted by bisphosphonates. Cinecalcet hydrochloride (Sensipar) is a calcimimetic that resets the configuration of the CaSR making it more sensitive to serum calcium. Primarily indicated for chronic renal disease and secondary hyperparathyroidism its efficacy has been substantiated in adults but there are no large pediatric studies. It may prove valuable in children with FHH.

Management of Absorptive Hypercalcemia: Stop all vitamin D supplements and restrict dietary calcium intake to <1/4th of the recommended intake for that age. A special low calcium and low vitamin D formula milk may be used to feed infants with Williams syndrome and IHH (e.g., Locasol® which contains no vitamin D and calcium <7 mg/100 ml). Standard infant feeds contain 50–90 mg of calcium/100 ml. Avoid hard water and use clothing and sunscreen crèmes to reduce exposure to sunlight. Glucocorticoids may be used for short periods.

Monitoring blood biochemistry and clinical status is important as the conditions are self resolving over 2–4 years. This includes (1) aim to normalize the serum calcium levels and (2) keep urine calcium/creatinine ratio <75 (mmol/mmol). Monitor BP and avoid iatrogenic rickets due to overzealous restriction of calcium in diet. Dentist input is important as enamel hypoplasia can occur as well as annual ultrasonography to monitor nephrocalcinosis.

Serum PTH remains suppressed during the hypercalcemic phase of illness. When PTH begins to rise again, it may mark the end of this phase of the illness (in Williams syndrome and IHH) and a slow and cautious withdrawal of restrictions with vigilant monitoring of clinical and biochemical parameters.

Surgery: Parathyroidectomy is indicated in hyperparathyroidism due to adenoma(s). Preoperative investigations include imaging to localize the tumor, parathyroid arteriography, and intraoperative selective venous sampling. Early referral to an experienced parathyroid surgeon is necessary.

Osteoporosis in Children

Definition

Osteoporosis literally means "porous bones"; these bones are fragile and can easily fracture. NIH consensus (2001) definition: Osteoporosis is a condition characterized by reductions in bone strength, leading to an increased risk of fractures. World Health Organization (WHO) classification defines osteoporosis as a systemic skeletal disease characterized by low bone mass and micro-architectural deterioration of bone tissue with a consequent increase in bone fragility and susceptibility to fracture, which typically involves the wrist, spine, or hip. Limitations to WHO definition: (1) This definition is based on bone densitometry, in Caucasian adults, on epidemiological data. It is unsuitable for use in children. (2) The relationship between bone density and fracture risk in children is currently unknown. It is therefore not possible to define thresholds below which fracture risk increases. (3) Bone density measurements in children are affected by body size. Current methods of bone densitometry are based on area and not volume; thus, a child who is short for age will have smaller bones and so the areal bone density measured will be less than that for the mean for that age, leading to an inappropriate diagnosis of osteoporosis.

International Society for Clinical Densitometry statement on Fracture Prediction and Definition of Osteoporosis (2007): Fracture prediction should primarily identify children at risk of clinically significant fractures, such as

fracture of long bones in the lower extremities, vertebral compression fractures, or two or more long-bone fractures of the upper extremities.

The diagnosis of osteoporosis in children and adolescents should *not* be made on the basis of densitometric criteria alone.

The diagnosis of osteoporosis requires the presence of both a clinically significant fracture history and low bone mineral content or bone mineral density.

A clinically significant fracture history is one or more of the following: (a) long-bone fracture of the lower extremities, (b) vertebral compression fracture, and (c) two or more long-bone fractures of the upper extremities

Low bone mineral content or bone mineral density is defined as a BMC or areal BMD Z-score that is less than or equal to −2.0, adjusted for age, gender, and body size, as appropriate.

Etiology

Primary Osteoporosis

Primary Osteoporosis – due to an intrinsic bone abnormality (usually inherited) is subdivided in three groups: (1) Osteogenesis imperfecta (OI): 1 in 10,000 to 100,000 births. Osteogenesis imperfecta (OI) is a disorder of congenital bone fragility caused by mutations in the genes that encode type I procollagen (i.e., COL1A1 and COL1A2). Subtypes of OI: Type I – mild forms, Type II – extremely severe, Type III – severe, Type IV – undefined. (2) Idiopathic juvenile osteoporosis (IJO) occurs in children from the ages of seven to the early teens. It is extremely rare, affecting less than 100 children in the UK. Allelic polymorphisms in low-density lipoprotein receptor–related protein-5 (LRP5) gene (locus 11q12–13) have association with osteoporosis.(3) Osteoporosis pseudoglioma syndrome: very rare genetic syndrome due to heterozygous loss of function of gene encoding low-density lipoprotein receptor–related protein-5 (LRP5) (locus 11q13.4).

Secondary Osteoporosis

Secondary osteoporosis – occurs due to the following factors acting singly or in combination. (1) Conditions with elevated inflammatory cytokines like juvenile idiopathic arthritis (JIA), Crohn's disease, and systemic lupus erythematosis. (2) Conditions with reduced mobility such as cerebral palsy, spinal cord defects or injury, head injury, spinal muscular dystrophy, and other neurodisability states. (3) Long-term, high-dose oral corticosteroids inhibit osteoprotegerin and stimulate osteoclast activity. (4) Delayed puberty or pubertal arrest due to a primary endocrine disorder or secondary to effects of chemotherapy, radiotherapy, or iron overload causes poor bone development. (5) Low body weight as in anorexia nervosa or undernutrition are associated with poor bone development. In many secondary osteoporotic conditions several of the above factors coexist, e.g., in JIA there may be a combination of inflammatory cytokines, glucocorticoids, immobilization, undernutrition, and delayed puberty.

Clinical Presentation of Osteoporosis

Recurrent long bone fractures due to low impact injuries. Mild forms of OI and osteoporosis secondary to immobilization present this way. Distal femur and proximal tibia are the commonest sites. Some may be flagged up as possible non-accidental injury. Vertebral compression fractures may be asymptomatic and get diagnosed by a spinal x-ray or cause back pain, spinal deformity, and potential loss of height. JIO, OI, and osteoporosis secondary to poor nutrition, prolonged immobilization, or post chemotherapy manifest as vertebral compression fractures. A high index of suspicion in children with disorders which predispose may lead to investigation for secondary osteoporosis. A family history is often a pointer, but occasionally the diagnosis of OI in a child leads to the identification of other affected family members.

Prevention of Osteoporosis

Calcium and or vitamin D deficiency should be treated appropriately, but their routine supplementation is not recommended. One study showed that calcium carbonate supplementation of adolescent boys increased skeletal growth, resulting in greater stature and bone mineral acquisition, but whether this reflects a change in the tempo of growth or an effect on skeletal size that persists into adulthood is unclear. There is no good evidence to support their use to prevent secondary osteoporosis, especially corticosteroid induced. Hypogonadism treated with the appropriate hormone replacement therapy improves bone density. Growth hormone has been shown to increase bone thickness in JIO but there is no good evidence to recommend its use to prevent osteoporosis. Increased physical activity improves BMD but this may be challenging in children with neuromuscular disabilities. A small double-blind, placebo-controlled clinical trial of intravenous pamidronate administered for 3 consecutive days repeated at 3-month intervals for 1 year to treat

osteopaenia in nonambulatory children with cerebral palsy found it to be safe and efficacious. Current data are inadequate to support the use of bisphosphonates in children to treat reductions in bone mass/density alone. More research is needed to define appropriate indications for bisphosphonate therapy and the optimal agent, dose, and duration of use in pediatric patients.

Treatment

Bisphosphonates are analogues of pyrophosphates. First generation bisphosphonates (Etidronate and Clodronate) form ATP analogues and inhibit ATP-dependent enzymes. They get incorporated into hydroxyapatite and shorten the life span of osteoclasts reducing bone resorption. Second generation bisphosphonates (Pamidronate, Alendronate, Zoledronate) are nitro-bisphosphonates that inhibit the enzyme farnesyl diphosphate synthase and protein prenyltion. They decrease serum calcium in 2–4 days with a peak effect at 4–7 days. Bisphosphonates particularly etidronate and pamidronate have been used in children with hypercalcemia due to a variety of causes including immobilization, leukemia, hyperparathyroidism, and subcutaneous fat necrosis in children. Bisphosphonate use in children in other diseases associated with pathological effects on the skeleton, that is, osteopathy; and in conditions associated with soft tissue calcification, that is, calcinosis have been shown to be beneficial. However data regarding lowest effective dose and frequency as well as long term safety (some bisphosphonates stay in the bones for several years) in children is yet to be established.

Bisphosphonates are currently the treatment modality with most evidence of benefit, however this evidence falls short of recommending their use in routine clinical care. Pamidronate has been the most studied bisphosphonate in secondary osteoporosis. Benefits include increased bone density, reduction in fracture frequency and relieving pain associated with vertebral compression fractures. The latest Cochrane review of the results of the controlled studies justifies use of bisphosphonates in the context of pediatric clinical trials. The favorable short-term profile of bisphosphonates and preliminary positive effects on BMD and pain reduction may justify their use on compassionate grounds in severe cases where there is clinical evidence for bone fragility that significantly impacts patient quality of life. Bisphosphonates in OI for at least 2 years have shown that there is increase in cortical and trabecular bone width and trabecular number in long bones. Similar benefits to lumbar spine bone density and reduction in fracture risk are also noted.

The management of osteoporosis remains multidisciplinary with inputs from radiologists, surgeons, physiotherapists and occupational therapists, and community pediatrician coordinating with a pediatrician with expertise in bone diseases.

382 Disorders of Puberty

Nicola A. Bridges

Introduction

Puberty occurs in most animal species, and it is the means by which immature animals are protected from having to reproduce until they reach sufficient size, or the environment is appropriate. Human puberty is under the control of neuropeptides that suppress development until an appropriate time, which is determined by size and nutrition. Normal puberty occurs over a wide age range, but the pattern of development in males and females is very predictable.

Normal Puberty

Historical evidence of various kinds (e.g., records of military recruits and choirboys) confirms that the age at which puberty occurs has decreased through the centuries. The trend for younger age of pubertal onset over time is probably related to improved health with fewer infectious diseases and better nutritional status during childhood. The age of development has continued to decrease in developed countries during the twentieth century, but there is some evidence that this trend has started to slow. There is also evidence that the age of onset of puberty in girls has changed more than the age of menarche. A study looking at girls and boys attending office pediatricians in the USA suggested that African American girls appeared to mature earlier than white American girls. There also appears to be a genetic influence over pubertal timing, with correlation between time of menarche in twins, and in mothers and daughters.

The hypothalamo-pituitary gonadal axis is active antenatally with a flare of activity in the immediate neonatal period (sometimes called "minipuberty"). There is a fall in activity during the first few years of life, although even in mid-childhood there is some activity with occasional gonadotropin pulses. The secretion of the gonadotropins, luteinizing hormone (LH), and follicle-stimulating hormone (FSH) is stimulated by gonadotropin-releasing hormone (GnRH) produced in the hypothalamus (see *Fig. 382.1*). GnRH is secreted by neurons within the hypothalamus and passes into the blood vessels of the hypothalamo-pituitary portal system. GnRH is secreted in pulses and as a result the secretion of LH and FSH is pulsatile. There is a gradual increase in the number and amplitude of LH and FSH pulses in the years before puberty. Kisspeptin, a neurotransmitter which is made within the hypothalamus, appears to be an important factor in the change in activity in the years before the onset of puberty. Kisspeptin (encoded by the gene KiSS-1) was originally described as a factor in controlling metastasis but subsequently found to be involved in the onset of puberty. The receptor for kisspeptin (called GPR54) is located on the surface of GnRH secreting neurons and stimulates GnRH secretion. Activation of the kisspeptin receptor has been demonstrated to initiate pubertal development in animal models. Kisspeptin appears to be an important factor controlling the timing of the onset of puberty. Expression of kisspeptin and GPR54 is influenced by leptin, which may be one of the routes by which nutrition has an influence over pubertal onset.

Gonadotropin secretion stimulates gonadal growth, and an increase in sex steroid secretion. Pulsatile LH and FSH are secreted mainly at night in prepuberty and early puberty. Single blood samples for gonadotropins and sex steroids taken during the day in early puberty may show low (prepubertal) levels. In puberty, LH concentrations are higher than FSH, and this distinguishes pubertal development from some other forms of sexual precocity such as premature thelarche, and thelarche variant (see below) where FSH levels are greater than LH. As changes in gonadotropin secretion progress, sex steroid concentration eventually becomes high enough for secondary sexual characteristics to develop – this is counted as the start of puberty although endocrine changes precede this by several years. With progress through puberty, both the amplitude of gonadotropin pulses and the time over which they occur increase, with gonadotropin pulses occurring over the whole 24 h by late puberty. Sex steroid feedback controls gonadotropin secretion. Sex steroids act on receptors in the hypothalamus and pituitary, and reduce the amplitude and frequency of gonadotropin pulses. In gonadal failure, there is no sex steroid feedback, and

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_382,

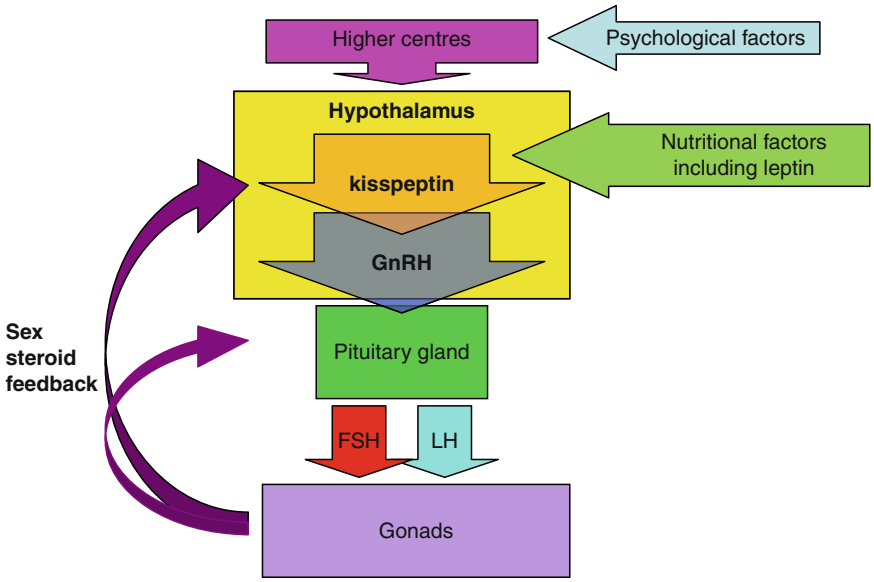

Figure 382.1

LH and FSH levels become elevated with rapid pulse frequency (hypergonadotropic hypogonadism).

In females, the first sign of puberty is usually breast development and in males, testicular enlargement with an increase to 4 ml testicular volume defined as the start of puberty. In normal male puberty, testicular development is accompanied by pubic hair growth and genital development, and in female puberty, breast and pubic hair development progress together, with menarche occurring at Tanner breast stage 4 or 5. In girls, there is progression in the appearances at pelvic ultrasound. The ovaries show a gradual increase in follicular activity in the years before puberty and then increase in size as puberty progresses. The uterus is cylindrical in shape prepubertally. Changes in the shape of the uterus commence with the onset of breast development; there is an increase in length and width and the uterus becomes pear shaped. The endometrium becomes thicker, with at least 5 mm of endometrium usually needed for menstruation to occur. The pattern of development in males and females is preserved whatever age the development occurs. The same pattern of progress is seen in children with central precocious puberty, and if progress does not follow this pattern the diagnosis is not likely to be centrally mediated precocious puberty. If, for example, menarche occurs very early in puberty or male genital development without testicular enlargement, this is abnormal even if it is happening at the normal age for puberty.

The Pubertal Growth Spurt

Sex steroids stimulate skeletal growth independently but also stimulate increased growth hormone (GH) secretion from the pituitary. Individuals with no GH secretion have a pubertal growth spurt, although it is reduced. The pubertal growth spurt in girls commences at the start of puberty (breast stage 2–3) and in boys not until testicular volume of 10–12 ml is reached. As pubertal growth occurs, there is skeletal maturation and the bone age advances. At the peak height velocity, bone age can advance by up to 2.6 bone age years per chronological year. At the end of puberty epiphyseal fusion occurs, with those in the peripheral skeleton fusing first, so that bone age in the hand will be mature before growth has stopped. The last part of growth in height is in the spine, with the last epiphyses to fuse in the pelvis. In girls growth slows after menarche, with 4–5 cm left at this point, and in boys growth slows when they reach full maturity (15–25 ml testicular volume). A single case report of a man with an inactivating estrogen receptor mutation has demonstrated that bone age maturation and epiphyseal fusion is estrogen mediated, even in males. This individual was found to be still growing in adult life with a prepubertal bone age despite being fully mature in puberty. He also had severe osteoporosis, demonstrating the role of estrogen in the acquisition of mature bone density, even in males. Bone density increases during puberty and maximum

levels are reached a few years after the completion of growth. Since it decreases with age after this, one of the aims of pubertal induction is to achieve optimum bone density because of concerns that reduced bone density at the end of puberty may contribute to later fracture risk. The increment in height gained during puberty is greater in those who start earlier, compensating for the age of onset of puberty. Individuals with slightly early puberty do not lose out in terms of height and those with pubertal delay do not gain adult height because of their delay.

Abnormalities of Puberty

Concerns about puberty are a very common reason for referral to pediatric services. Many abnormalities of puberty go unreported or unnoticed, and referral patterns vary, so the true prevalence of pubertal disorders is not known. Most abnormalities of puberty are related to timing – secondary sexual characteristics too early, or puberty too early or too late. In addition, pubertal boys may present because of gynecomastia, or girls because of delay in menarche or the development of hirsutism.

Delay of Puberty and Pubertal Failure

Definition/Classification

Most individuals with pubertal delay are healthy individuals who are at the extreme of the normal range and will go on to develop without problems (see *Table 382.1*). Many boys referred with pubertal delay come with concerns about height; a boy who has been among the shorter ones during childhood will start to feel increasingly left behind if he is late in puberty and his peers have had their pubertal growth spurt. Investigations are aimed at identifying those for whom pubertal delay is the presenting feature of an underlying medical condition, and the small number who have a permanent defect interfering with pubertal development.

Table 382.1
Causes of pubertal delay or pubertal failure

Pubertal delay
Idiopathic-constitutional delay in growth and puberty
Nutritional including anorexia nervosa
Chronic disease
Inflammatory bowel disease and other gastrointestinal disorders
Sickle cell disease
Cystic fibrosis
Associated with genetic syndromes
Noonan syndrome
Prader–Willi syndrome
Pseudohypoparathyroidism
Pubertal failure or arrested puberty
Gonadal disorders – *hypergonadotropic hypogonadism*
Turner syndrome
Klinefelter syndrome
Gonadal failure related to chemotherapy
Testicular failure related to orchitis
Undescended testes
Biosynthetic disorders of sex steroids
Autoimmune gonadal failure
Hypothalamo-pituitary disorders – *hypogonadotropic hypogonadism*
Developmental defects (septo optic dysplasia, multiple pituitary hormone deficiency)
gonadotropin or GnRH deficiency (including Kallman syndrome)
Tumors, for example, craniopharyngioma, germinoma, glioma, pituitary adenomas including prolactinoma
Langerhans cell histiocytosis
After CNS trauma
Iron overload related to transfusion
After CNS infection

Etiology

Pubertal delay is more common in individuals with a range of chronic diseases (such as inflammatory bowel disease, cystic fibrosis, poorly controlled asthma, or sickle cell disease). A number of genetic conditions (such as Noonan syndrome, Prader–Willi syndrome, and pseudohypoparathyroidism) are associated with pubertal delay. Anorexia nervosa can present with pubertal delay or with arrest of pubertal development, and pubertal delay has been reported in female athletes in intensive training. Boys presenting with pubertal delay frequently report delay in their father or brothers, suggesting an inherited tendency.

Epidemiology

The majority of those referred for pubertal delay are boys; the problem appears to be more common in boys and for social reasons boys may be more likely to seek medical input. The commonest cause of gonadal failure in girls is Turner syndrome, which has an estimated prevalence of 50 per 100,000 female births.

Pathogenesis

Pubertal failure, either not starting to develop in puberty at all or failing to complete pubertal development, can be related abnormalities of the pituitary or hypothalamus, or gonadal factors. Developmental defects of the pituitary, which result in multiple pituitary hormone deficiencies can include gonadotropin deficiency. Usually, other pituitary hormone deficiencies will have presented earlier in childhood, for example, ACTH or GH deficiency. These defects may be associated with structural abnormalities of the pituitary, and for a proportion of these there are demonstrated genetic causes (see Chap. 385, "Disorders of the Posterior Pituitary").

Causes of hypogonadotropic hypogonadism without other pituitary hormone defects include mutations in the GnRH gene, the genes for LH, and in the receptor for Kisspeptin. However, the majority of individuals with hypogonadotropic hypogonadism have no genetic defect demonstrated. In Kallman syndrome, failure of the migration of GnRH neurons along the olfactory nerves in embryonic life causes hypogonadotropic hypogonadism, and abnormal development of the olfactory nerves results in absent sense of smell or a limited sense of smell. Several different mutations have been demonstrated to cause Kallman syndrome. The commonest is a mutation in the X-linked gene KAL1, with autosomal forms of Kallman syndrome caused by mutations in the fibroblast growth factor receptor 1 (FGFR1), prokineticin-2 gene (PROK2), the G protein–coupled prokineticin receptor-2 gene (PROKR2), chromodomain helicase DNA-binding protein 7 (CHD7), and the fibroblast growth factor 8 gene (FGF8). Some individuals with clear clinical features of Kallman syndrome do not have any of these mutations. X-linked Kallman syndrome can be associated with unilateral renal agenesis and mirror hand movements (bimanual synkinesia). Kallman syndrome was previously thought to always cause permanent hypogonadotropic hypogonadism, but it has been found that surprisingly a proportion of individuals with clear clinical features of Kallman syndrome go on to have partial or full pubertal development, which can occur well into adult life.

Damage to the hypothalamo-pituitary axis because of trauma, infection, radiotherapy, or surgery can cause pubertal failure, and is likely to result in loss of other pituitary hormone secretion as well as LH and FSH. Iron overload related to regular transfusion for hemoglobinopathies without adequate chelation (or with poor adherence to chelation) can result in pituitary hormone deficiencies. Gonadotropin defects are usually the first to develop in this situation, so failure to develop in puberty can occur without signs of other pituitary hormone deficiencies.

In boys, anorchia, undescended testes, orchitis, or torsion of the testes can result in gonadal failure. Gonadal failure can occur in both sexes secondary to chemotherapy, radiotherapy, or autoimmune disease. Autoimmune gonadal failure that presents prepubertally or in puberty may be associated with one of multiple autoimmune endocrinopathy syndromes; other autoimmune disorders and autoantibodies are usually present. The commonest cause of ovarian failure is Turner syndrome. Ovarian failure unrelated to Turner syndrome frequently has no demonstrable cause.

Approximately 50% of individuals with Turner syndrome have 45 XO karyotype, and the rest other karyotypes including isochromosome Xq, and mosaic karyotypes (e.g., 45 XO/46XX mosaicism). Over 80% of girls with Turner syndrome have retained their maternal X chromosome. A small proportion (7–12%) will have Y chromosome elements within their karyotype. This group has a significant risk of developing gonadoblastoma, which can be prevented by gonadectomy. Accelerated loss of ovarian follicles in Turner syndrome results in ovarian failure, which often occurs before puberty. Up to 20% of girls with Turner syndrome make some progress in puberty; in the majority, development will not be completed but some will have menarche, and pregnancies have been reported in Turner syndrome. Girls with the classical physical features of Turner syndrome, or a well recognized association like coarctation of the aorta, are the most likely to be diagnosed in early childhood. Many are not diagnosed until they present with pubertal delay, amenorrhea, or early menopause. Typically, those with late diagnosis have less obvious physical features and the diagnosis should be considered in any girl with pubertal delay and short stature.

Pathology

In pubertal failure related to abnormalities of the hypothalamus or pituitary both gonadotropin and sex steroid levels are low (hypogonadotropic hypogonadism).

In pubertal failure secondary to failure of sex steroid production, gonadotropin levels are elevated because of failure of feedback to the pituitary and hypothalamus from sex steroids (hypergonadotropic hypogonadism).

Clinical Manifestations

Significant factors in the medical history include any long-term medical condition, even if it is now resolved, and

anything that suggests an undetected underlying condition, for example, diarrhea, chronic abdominal pain, or headaches. Height and weight should be plotted and pubertal stages noted. The degree of pubertal delay should be allowed for when assessing growth. An individual with pubertal delay will continue to grow at a prepubertal rate until they start their growth spurt and will fall in centile position, because growth standards compare them to children with normally timed puberty. Examination should look for wasting or any other feature of a chronic disease. Healthy individuals with mild delay of puberty and a typical growth pattern may not need investigations. Further investigations in pubertal delay are indicated if pubertal delay is associated with short stature; there is a history suggesting an underlying chronic disease, or a risk factor for gonadal failure such as previous chemotherapy or undescended testes. Investigations should be considered if the individual is a long way out of the normal range (e.g., over 16 years), although there is no evidence to support any age limit for investigation.

Diagnosis

Investigations include markers of chronic disease and malabsorption (including celiac antibodies) and thyroid function tests. Single blood samples for LH and FSH are only likely to be helpful in the exclusion of gonadal failure, when they will be elevated. Low levels of LH, FSH, and sex steroids on a single sample cannot distinguish between a central defect causing hypogonadotropic hypogonadism and pubertal delay. Because of the diurnal variation in these hormones, the levels can be very low during the day in individuals who have already started to develop in puberty. A GnRH stimulation test can give more information on hypothalamo-pituitary gonadal function, but may not indicate future progress. A completely absent gonadotropin response to GnRH suggests a central defect but this can change with time. A stimulated LH and FSH in the prepubertal range fits with pubertal delay, but does not give an indication of when or if progress will happen. In gonadal failure, there is an exaggerated gonadotropin response to GnRH stimulation.

If there are concerns about height, an X-ray for bone age should be performed. Bone age remains prepubertal (12–13 years) until development starts, whatever the chronological age. Because the increment in growth achieved at puberty gets smaller with age, individuals who present very late prepubertal and with a prepubertal bone age may actually have very little growth to come. Pelvic ultrasound in prepubertal girls can confirm normal anatomy and may demonstrate ovarian activity with follicular development. Some follicles are seen throughout childhood and their appearance does not necessarily indicate that puberty will start soon. Uterine changes (increase in size with change to a pear shape and endometrial thickening) do not occur until breast development has started. MRI of the hypothalamo-pituitary area should be performed in any individuals where there is any suspicion of a central lesion, if the investigations suggest hypogonadotropic hypogonadism, there is an elevated prolactin level or puberty appears to have started and then stopped. MRI should be considered if there are no signs of puberty in someone well over the normal pubertal age range. In Kallman syndrome, the abnormal olfactory nerves may be visualized at MRI.

Treatment

General Care (Nonspecific Treatment)

Any individual with a central defect or gonadal failure, where it is known that spontaneous puberty is unlikely to occur spontaneously, will need treatment to induce pubertal development and should be given information about their need for long-term therapy and likely prospects for fertility. Most individuals with pubertal delay do not need any treatment and can be reassured that they are likely to have a problem of timing, which will resolve itself. For individuals with mild pubertal delay and no obvious risk factors, the chances of an underlying defect are very small, but monitoring for a period of time will confirm that they have a normal growth pattern and that they go on to develop with time.

Specific Treatment

Any child who is not going to develop spontaneously in puberty should be given treatment to induce pubertal development at an age in keeping with their peers. Studies in Turner syndrome have demonstrated no advantage in delaying pubertal induction beyond the normal age, and there is no evidence that delaying pubertal induction in other causes of pubertal failure increases adult height. These individuals will need treatment to give normal pubertal growth and development and then in most cases must continue with sex steroids as adults to maintain development and bone density (see *Table 382.2*). Endocrine status can change, particularly for those who appear to have a central defect and all individuals should be reassessed at the end of growth and development.

If investigation suggests pubertal delay but the individual is significantly delayed, they may benefit

Table 382.2
Treatment to induce pubertal development

Male
Sustanon 50 mg im every 4 weeks for 6 months then Sustanon 100 mg im every 4 weeks for 6 months then Sustanon 100 mg im every 3 weeks for 6 months then Sustanon 100 mg im every 2 weeks, increasing this dose if necessary to get adult serum testosterone levels Adult maintenance: continue with Sustanon, 3 monthly im depot testosterone, or testosterone patches or gel
Female
Ethinyloestradiol 2 μg or 2.5 μg oral daily for 6 months then Ethinyloestradiol 5 μg oral daily for 6 months then Ethinyloestradiol 10 μg oral daily for 6 months then Ethinyloestradiol 15 μg oral daily for 6 months then Ethinyloestradiol 20 μg oral daily for 6 months Adding in progestogen as norethisterone 5 mg/day or levonorgestrel 30 μg/day for 7 days out of every 28 days when dose of ethinyloestradiol is 10–15 μg or the first vaginal bleed occurs Adult maintenance: continue with ethinylestradiol as above, low-dose oral contraceptive pill, or HRT preparations (oral or patch)

psychologically from treatment to induce puberty. Doses of sex steroids the same as those given to induce puberty (*Table 382.2*) should be given, and treatment stopped when spontaneous puberty occurs (usually after 3–6 months).

Testosterone as Sustanon is the most widely used formulation to induce male puberty. This is suspended in peanut oil and an alternative should be used in allergic individuals. Oral testosterone undecanoate and testosterone patches have been used to induce puberty but evidence supporting this is quite limited. In girls, oral ethinyloestradiol is the most commonly used preparation, although other oral and topical estrogen formulations have been used. Ethinyloestradiol is started at a low dose and gradually increased (*Table 382.2*). Cyclical progesterone should be given when the ethinylestradiol dose is 10–15 μg or as soon as a vaginal bleed occurs. Ethinyloestradiol given on its own will result in a thickened endometrium with erratic bleeding. Treatment to induce puberty should be monitored by measuring height and weight and reassessing pubertal stages at 3–4-month intervals. The need for long-term treatment should be reassessed at the end of puberty.

Prognosis

Pubertal delay can cause significant psychological upset. In the longer term, final height and bone density are normal in pubertal delay. Individuals with permanent defects will require long-term sex steroid replacement. For women with Turner syndrome, there is evidence of long-term psychological benefit from pubertal induction at an appropriate time. As well as optimizing final height, estrogen therapy in Turner syndrome is aimed at inducing normal uterine growth and bone density. Studies in adult women with Turner syndrome suggest that they may not attain normal adult uterine dimensions, and this may impact on the success of fertility treatment by ovum donation. Adult women with Turner syndrome also have an increased risk of low bone density and increased fracture risk.

Premature Development of Secondary Sexual Characteristics: Sexual Precocity or Premature Sexual Development

Definition/Classification

The conventional definition of sexual precocity is the appearance of any secondary sexual characteristic before 8 years in a girl and before 9 in a boy (see *Table 382.3*). Following studies in the USA confirming earlier development in normal children, it was suggested by the American Paediatric Association that puberty before 6 years in African American girls and before 7 in girls and boys of other ethnic groups should be regarded as precocious. This new definition has not been universally adopted.

Etiology

The majority of children presenting to medical attention with secondary sexual characteristics too early are not actually progressing in true puberty, and have premature thelarche, premature adrenarche, or variations of these conditions. A small proportion of those with sexual precocity are developing in true puberty and have the endocrine and physical changes seen in normal puberty occurring at an abnormally early age (central precocious puberty). Sex steroid–secreting or gonadotropin-secreting

Table 382.3
Sexual precocity

Premature thelarche Thelarche variant and slowly progressing precocious puberty Premature adrenarche or exaggerated adrenarche Premature menarche
Central precocious puberty
Idiopathic central precocious puberty – no underlying defect Congenital or acquired CNS disorders: Hydrocephalus Neurofibromatosis CNS neoplasms, for example, hypothalamic hamartoma, optic nerve glioma After CNS infection, trauma, or irradiation Secondary to previous elevated circulating sex steroids, for example, congenital adrenal hyperplasia or peripheral precocity
Peripheral precocious puberty
Autonomous gonadal function: McCune–Albright syndrome Testotoxicosis Familial testotoxicosis Congenital adrenal hyperplasia Sex steroid–secreting or gonadotropin (HCG)-secreting tumors Autonomous ovarian follicular cyst Hypothyroidism Exogenous steroids

tumors, or autonomous sex steroid production (peripheral precocious puberty) are rarer causes of sexual precocity.

Epidemiology

Many cases of sexual precocity clearly do not present to medical attention, and the prevalence of different forms of sexual precocity reported in case series varies considerably, probably because of differences in referral patterns.

Premature Thelarche

Definition/Classification

Premature thelarche is isolated breast development without progress in puberty. Typically, it occurs in girls under 1 year, and may be one sided and fluctuate with time. Development stops as the child gets older (2–3 years) although a small amount of breast tissue may persist. Older girls can present with breast development which may be accompanied by some pubic hair growth; they may either not progress at all or make very slow progress into puberty. This pattern of development is either described as thelarche variant or slowly progressive central precocious puberty.

Pathogenesis

Endocrine studies in premature thelarche show gonadotropin pulsatility which differs from that seen in puberty, with FSH levels higher than LH.

Clinical Manifestations

If the history and examination for a girl presenting with breast development is typical of premature thelarche, further investigations may not be needed. However, breast development may be the first feature in someone who will go on to develop central precocious puberty, so a period of follow-up of growth and development is necessary to confirm a diagnosis of premature thelarche.

Exaggerated or Premature Adrenarche, Also Called Premature Pubarche

Definition/Classification

The premature development of pubic hair without progress in puberty is called premature adrenarche, exaggerated adrenarche, or premature pubarche. Presentation is typically between 5 and 9 years; hair growth gradually progresses and is often accompanied by the development of axillary hair and an "adult" body odor.

Epidemiology

There appears to be an ethnic variation in rates of presentation. Girls are in the majority of those referred; there may be a sex difference but also the problem may go unnoticed in boys.

Pathogenesis

The development is associated with adrenarche, which is the maturation of adrenal sex steroid production which

occurs in late childhood in normal children. The term "exaggerated adrenarche" is sometimes also used because the development is often occurring at the normal age for adrenarche, and so is not actually premature. There is an increased risk of developing premature adrenarche if a child was of low birth weight.

Clinical Manifestations

Most children with premature adrenarche have no underlying endocrine defect. Investigations should be performed to exclude an underlying adrenal problem such as late onset congenital adrenal hyperplasia or an androgen-secreting tumor.

Pubic hair development occasionally presents in infants. It is thought that this is a different clinical entity from premature adrenarche although the cause is not known. Reported series have demonstrated no underlying endocrine pathology, although investigations should be done to exclude adrenal defects, as in older children.

Central Precocious Puberty

Definition/Classification

In central precocious puberty, all the physical and endocrine changes of true puberty occur too early, including the pubertal growth spurt.

Etiology

The majority of children with central precocious puberty are girls, and in most (over 80%) there is no obvious underlying cause. Approximately 15% of those with central precocious puberty are boys, and most of these have an underlying pathology.

Pathogenesis

Central precocious puberty can be caused by a variety of CNS lesions including tumors, which may not all be directly (see *Table 382.3*) related to the hypothalamo-pituitary area. Hypothalamic hamartoma (see *Fig. 382.2*) results in an abnormal pattern of gonadotropin secretion with an exaggerated LH response to GnRH testing. The tumor can also result in developmental delay, and an unusual form of epilepsy called gelastic

Figure 382.2

epilepsy (where the seizure is said to resemble laughter). Most hypothalamic hamartomas associated with central precocious puberty are small and not associated with neurological defects. Hypothalamic hamartomas are benign and usually do not increase in size after diagnosis. The MRI appearances are characteristic but repeat scan is of value in confirming the diagnosis for a lesion where biopsy is almost always not possible.

Raised intracranial pressure in the neonatal period related to hydrocephalus causes a decrease in the age of pubertal development and increased incidence of precocious puberty. This occurs even if intracranial pressure has been maintained at a normal level after the neonatal period by a ventricular shunt. The elevated intracranial pressure, even for a short period appears to permanently "reset" the hypothalamic clock. A similar effect can occur if there is a period of raised sex steroid concentration in childhood. There is an increased risk of central precocious puberty in congenital adrenal hyperplasia if there has been a period of time where the androgen levels have not been adequately controlled because the diagnosis has not been made or adherence to treatment is poor. The risk remains even if treatment brings the androgen levels down to normal. For the same reason, central precocious puberty can occur in children who have originally presented with peripheral precocious puberty or after treatment of a sex steroid–secreting tumor. The prevalence of central precocious puberty is increased in girls adopted in early childhood from developing countries. The reason for this is not known. There is speculation that it is related to rapid catch-up growth with change in environment.

Central precocious puberty has also been described because of activating mutations in the receptor for kisspeptin, GPR54.

Clinical Manifestations

A significant proportion of children with sexual precocity present with a clinical picture which does not fit exactly into one of the diagnostic labels described above. Children presenting with apparent premature adrenarche can subsequently start to progress in true puberty. The pace of development of girls with thelarche variant or central precocious puberty can vary considerably. If investigations exclude underlying pathology, following the child for a while to monitor the pace of development can be useful in this situation.

Premature Menarche

Definition/Classification

Premature menarche is the occurrence of periods without any other signs of puberty.

Etiology

The endocrine cause of this phenomenon is not known, although abnormal gonadotropin secretion has been reported.

Clinical Manifestations

Long-term follow-up suggests that this is a benign condition. Since there is no test to confirm premature menarche, the diagnosis requires exclusion of other causes of recurrent vaginal bleeding such as foreign body, tumors, and trauma.

Peripheral Precocious Puberty: Autonomous Sex Steroid Production

Definition/Classification

In testotoxicosis and McCune–Albright syndrome, gonadotropin receptors are activated without either gonadotropin production or gonadotropin binding to the receptors. Sex steroids are produced autonomously by the gonads.

Pathogenesis

Sex steroid secretion in the gonads is normally stimulated by LH and FSH binding to specific membrane-bound receptors. Sex steroid concentrations are normally controlled by LH and FSH secretion, and LH and FSH concentrations regulated by feedback by sex steroids on the pituitary and hypothalamus. Testotoxicosis is caused by mutations of the LH receptor, which result in continuing activation of the receptor without LH binding. The problem is inherited in an autosomal-dominant fashion, but is only manifested in males because both LH and FSH action are required for estrogen secretion in females. In McCune–Albright syndrome, the defect is not in the LH receptor but in the second messenger related to the receptor, a G protein which is shared between a number of different hormone receptors (including TSH, ACTH, PTH, and GHRH). McCune–Albright syndrome occurs in males and females. Other hormone excess syndromes can occur because the defect has the same effect on the other receptors which share this G protein, for example, thyrotoxicosis, Cushing syndrome, and acromegaly. There are associated areas of skin hyperpigmentation with a characteristic jagged edge and bone abnormalities (polyostotic fibrous dysplasia of bone). McCune–Albright syndrome is not inherited and occurrence of the mutation as a germ cell mutation is probably not compatible with fetal survival. The defect is a somatic cell line mutation occurring during early fetal development, and individuals with McCune–Albright syndrome carry both affected and unaffected cell lines. For this reason, the syndrome is very variable and depends on which cell types carry the mutation. Polyostotic fibrous dysplasia of bone can occur without other clinical features of McCune–Albright syndrome. A proportion of girls with functioning ovarian cysts probably have a very localized form of McCune–Albright syndrome.

Clinical Manifestations

Sex steroid concentrations are not regulated by gonadotropin feedback at the hypothalamus and pituitary, and so concentrations can be much higher than normal.

Feedback by sex steroids suppresses gonadotropin secretion, and LH and FSH concentrations are very low.

The pattern of physical development can be variable and will not necessarily follow the same pattern as in centrally mediated puberty.

Congenital Adrenal Hyperplasia

Pathogenesis

In the commoner types of congenital adrenal hyperplasia, 21 hydroxylase deficiency and 11 beta hydroxylase deficiency, failure to suppress ACTH secretion results in elevated adrenal androgen levels. This occurs if the disorder is either not diagnosed or diagnosed but undertreated.

Clinical Manifestations

The elevated adrenal androgens result in rapid growth with bone age advance, pubic hair development, and hirsutism. As discussed above, individuals with congenital adrenal hyperplasia are at risk of developing central precocious puberty if they have a period with elevated androgens, either before diagnosis or related to poor compliance with medication.

Sex Steroid–Secreting or Gonadotropin-Secreting Tumors

Pathogenesis

Tumors that secrete either sex steroids or HCG are rare causes of sexual precocity. Sex steroid–secreting tumors most commonly originate in the gonads or adrenal glands, and most secrete androgens, although estrogen-secreting tumors occur. Adrenal tumors that cause Cushing syndrome usually secrete androgens, and virilization can be present as well as typical features of Cushing syndrome. Very few gonadotropin-secreting adenomas of the pituitary gland been described, but gonadotropin secretion (as HCG) has been described from tumors including hepatoblastomas, teratomas, and germ cell tumors.

Clinical Manifestations

The typical features of sex steroid–secreting or gonadotropin-secreting tumors are high sex steroid concentrations with suppressed LH and FSH concentrations, and very rapid development.

Autonomous Ovarian Follicular Cyst

Pathogenesis

Individual estrogen-secreting cysts within the ovary can present with vaginal bleeding with little or no breast development, or with a history of rapid onset of breast development or breast tenderness.

Clinical Manifestations

Pelvic ultrasound shows a single, large simple cyst within one ovary and endometrial thickening within a small uterus. Estrogen concentrations can be higher than those seen in normal puberty, and FSH and LH are suppressed. Typically, the cyst disappears after a few weeks and estrogen levels fall to prepubertal levels, and most girls do not have any recurrence.

Hypothyroidism

Pathogenesis

Hypothyroid individuals with very high TSH values also have elevated FSH concentrations because of an overlap in the stimulation pathway within the hypothalamus and pituitary.

Clinical Manifestations

Severe hypothyroidism can result in enlarged testes in prepubertal boys, and signs of pubertal development, including breast development and vaginal bleeding in girls. The development usually regresses with treatment of the hypothyroidism.

Exogenous Steroids

Pathogenesis

Most reports of sexual precocity related to exogenous sex steroids are related to contact with creams used by adults. One of the disadvantages of topical testosterone creams is that there is a risk of transfer if it is not allowed to dry completely, and virilization has been reported in children because of transfer from their fathers. The role of contact

with environmental factors in the timing of puberty is unclear. Phytoestrogens like soya have no proven role in provoking early puberty. Ingestion of soya products in children does not seem to be linked to precocious puberty, and the age of pubertal development is not reduced in countries where large quantities of soya products are eaten.

Diagnosis of Premature Development of Secondary Sexual Characteristics

The majority of children who present with sexual precocity have a self-limiting problem with no long-term sequelae. There is a balance between trying to limit excessive investigations in children who have a totally benign condition and the requirement not to miss significant pathology. Initial investigations should be guided by an assessment of the most likely source of the sex steroids, with the results of biochemical investigations likely to guide any imaging investigations.

Biochemistry

As in pubertal delay, individual tests of LH and FSH may be unhelpful because of the pulsatile and diurnal pattern of secretion. Sex steroid secretion also has a diurnal rhythm; so a low concentration of estradiol or testosterone during the day does not rule out precocious puberty. In central precocious puberty, a pubertal pattern of secretion is seen after GnRH stimulation. Typically, the stimulated LH is very high in hypothalamic hamartoma. In peripheral precocious puberty (McCune–Albright syndrome or testotoxicosis), or development related to sex steroid–secreting tumors, the gonadotropin response to GnRH will be suppressed and sex steroid concentrations very high. Pubertal concentrations of sex steroids are not seen in premature thelarche or premature adrenarche. In premature adrenarche, plasma levels of adrenal androgens (17-β hydroxyprogesterone, androstenedione, and testosterone) should be measured as a screening test for congenital adrenal hyperplasia or other adrenal pathology, either baseline or after stimulation by ACTH. Urine steroid profile should be performed if there is any suspicion of congenital adrenal hyperplasia or androgen-secreting tumor.

Imaging

Sex steroid concentrations in the pubertal range will advance bone age, and in central precocious puberty the bone age advances into the pubertal range. Bone age is not significantly advanced in premature thelarche. In premature adrenarche, a degree of bone age advance is common, but not into the pubertal range. In girls, ultrasound can help to confirm a diagnosis of precocious puberty. Uterine and ovarian development keeps pace with puberty, and so in central precocious puberty ultrasound appearances are pubertal. In premature thelarche, the ultrasound appearances remain prepubertal whatever the breast stage. In central precocious puberty, MRI of the head should be performed, if there is not an already documented lesion. A minority (10–15%) of girls with central precocious puberty have a CNS lesion, and many present with this already documented, but almost all boys with central precocious puberty will have an underlying CNS defect. If a boy with central precocious puberty does not have a CNS lesion detected, a repeat scan at an interval should be considered.

Treatment

General Care (Nonspecific Treatment)

Premature adrenarche and premature thelarche can cause considerable distress to families, but unfortunately there is no effective treatment to regress the development. Parents can be reassured that trimming pubic hair is safe and this can help if the child is embarrassed by it.

Specific Treatment

Gonadotropin-releasing hormone analogues (GnRHa) will arrest development in central precocious puberty, although they are ineffective in other forms of sexual precocity. Endogenous GnRH is secreted in a pulsatile pattern by the hypothalamus and stimulates the secretion of LH and FSH. Early studies of exogenous GnRH showed that if it is administered in a non-pulsatile pattern at a high dose, the receptors are downregulated and gonadotropin secretion is suppressed. This effect is utilized in GnRHa designed to suppress gonadotropin secretion, usually given as long-acting depot preparations (lasting 1 or 3 months). There is often an advance in pubertal stage at the start of treatment, because gonadotropin levels are stimulated before they suppress. Oral cyproterone acetate can be given for the first 4–6 weeks to control this advance. If any endometrium at all has formed, there is likely to be a vaginal bleed 4–6 weeks into treatment, and parents should be warned about this. Side effects of GnRHa are very rare; the most common are problems at the site of injection, such as irritation or scarring. GnRHa are effective in halting pubertal progress; secondary sexual characteristics are likely to regress but rarely disappear completely. After stopping treatment, gonadotropin

pulsatility takes 3–4 months to return to normal and puberty then restarts. Most girls start their periods within a year of stopping treatment. Long-term follow-up after stopping treatment has demonstrated normal fertility and bone mineral density in adult life. GnRHa are the first-line treatment for centrally mediated precocious puberty. Cyproterone acetate and medroxyprogesterone were used before the availability of GnRHa but although they have the advantage of oral administration, they are much less effective in halting puberty and have more side effects.

GnRHa treatment should be considered because of the social and psychological problems associated with central precocious puberty, and to reduce the impact on adult height. Data on the impact of GnRHa on adult height are variable. Published studies have often used individuals who have declined treatment as controls or compared adult height with height prediction at the start of treatment. Adult height predictions based on bone age have limited accuracy in untreated precocious puberty with large discrepancies between height prediction and height achieved. Treatment with GnRHa usually arrests or slows bone age advance, and because growth continues while bone age advance is arrested, the calculated height prediction inevitably increases during treatment. The true final height reached after treatment is stopped is usually less than the prediction at the end of treatment. Studies with GnRHa in central precocious puberty suggest that there is an improved adult height with treatment, but wide variations between studies mean that it is difficult to quantify this. It is not possible to give an individual child a realistic estimate of the likely height benefit from treatment. Children with a less-advanced bone age at the start of treatment have a better height outcome. For very young children with central precocious puberty, the need to treat is usually completely clear for social and psychological reasons. For children at the older end of the spectrum for precocious puberty, adult height is not likely to be significantly improved, and the disadvantages of treatment (regular injections and hospital monitoring) may well outweigh the potential advantages of stopping periods. Studies using GnRHa in children with early but not precocious puberty, or a normally timed puberty and short stature, have not demonstrated any benefit to adult height.

In peripheral precocious puberty, GnRHa are ineffective and the choice of medication is less clear. Cyproterone, which suppresses gonadotropin secretion and acts as an antiandrogen, has been widely used in this indication. More recently, aromatase inhibitors and tamoxifen have been studied as potential treatment. Suppression of pubertal development is much more difficult in this group of patients and there is no evidence that it increases adult height.

Prognosis

Short- and Long-Term Effects of Sexual Precocity

Premature thelarche and premature adrenarche do not usually affect age at true puberty. Premature thelarche has no long-term sequelae. Follow-up studies in girls with premature adrenarche have suggested that this group may be at increased risk of developing polycystic ovarian syndrome and metabolic syndrome although not all investigators have confirmed this finding.

Central precocious puberty can result in short stature, although the adult height reported in series of untreated individuals with central precocious puberty varies considerably. As discussed above, the magnitude of the pubertal growth spurt is greater in younger children, compensating for variations in the age of onset of puberty. This compensation is lost for the youngest children, who have not completed enough growth in childhood before the onset of puberty. For girls at the upper end of the age range defined for precocious puberty, there is minimal impact on adult height.

In precocious puberty, behavioral difficulties are frequently reported, and children with precocious puberty frequently require psychological input during childhood. However, these problems usually resolve and studies looking at adults whose puberty was precocious find they do not differ significantly from the rest of the population. In the longer term, fertility is normal for most girls with central precocious puberty. Early menarche does not appear to be related to early menopause. If central precocious puberty is secondary to hypothalamic hamartoma, there may be menstrual irregularity in adult life related to continuing abnormal patterns of GnRH secretion. The underlying defect also remains after pubertal growth and development has completed for those with peripheral precocious puberty such as McCune–Albright syndrome, and can result in menstrual irregularity.

Problems in Normally Timed Puberty

Gynecomastia

Definition/Classification

Approximately 50% of normal boys have a small amount of breast development during puberty. Development is often one sided and many boys complain of breast tenderness.

Pathogenesis

The cause of the development in normal boys is thought to be increased circulating free estrogen compared to androgen during pubertal development. The appearances can be made much worse by obesity. Gynecomastia usually regresses as puberty ends, although this may take several years to occur.

Any conditions resulting in an excess of estrogen or estrogen action can cause gynecomastia, including Klinefelter syndrome, estrogen-secreting tumors, ovotestis, enzyme defects such as aromatase deficiency, and exogenous estrogen-like substances (including lavender and tea tree oil).

Clinical Manifestations

A pathological cause is much more likely to be present in gynecomastia presenting in prepubertal boys, and these individuals should all be investigated. If a boy is in mid-puberty, with mild gynecomastia and no other features of endocrine disorder, they are extremely unlikely to have any pathological cause.

Diagnosis

The majority of publications about gynecomastia describe individual rare causes and there are no data to guide whether it is worth investigating boys with no risk factors for pathology. LH, FSH, testosterone assay, and karyotype (to look for Klinefelter syndrome) will exclude most likely pathological causes.

Treatment

General Care (Nonspecific Treatment)

Most boys are content with being reassured that the development is harmless and will wait for it to disappear.

Specific Treatment

Studies of medical treatments for gynecomastia have examined blocking estrogen action with tamoxifen, inhibiting estrogen production with aromatase inhibitors (e.g., anastrozole), or giving extra androgen as danazol. There have been no controlled trials, and no agent has been very effective. In addition, there is the concern that treatment would inevitably interfere with the normal hormonal changes of puberty. Surgical removal or liposuction can give good cosmetic results and should be offered if there is significant psychological distress.

Polycystic Ovarian Syndrome

Definition/Classification

Polycystic ovarian syndrome is a common cause of menstrual disorders, infertility, and hirsutism in adult women. Because it is associated with insulin resistance and changes in lipid profile, PCOS in adult women is a risk factor for type 2 diabetes and cardiovascular disease. A consensus meeting 2003 proposed that the diagnosis should be made on the basis of any two out of the following features: oligo or anovulation; hyperandrogenism, clinical or biochemical; and polycystic ovaries on ultrasound. The characteristic biochemical findings are elevated androgens (or free androgen index) with elevated LH compared to FSH. The typical ultrasound features include 12 or more follicles of 2–8 mm diameter and ovarian volume over 10 cm^3.

Pathogenesis

There are genetic factors in PCOS, and the biochemical and ultrasound features often develop during puberty. Premature adrenarche has been identified as a risk factor. Polycystic appearances at ultrasound are found in approximately 20% of all women, but only 5–10% have any other features of polycystic ovarian syndrome.

Polycystic features can be seen in prepubertal ovaries, and PCOS can present in pubertal and post pubertal girls, causing hirsutism, acne, greasy skin, delayed onset of menarche, and irregular periods or amenorrhea. If there is significant virilization (severe hirsutism or acne, clitoromegaly), other causes of elevated androgens such as late onset congenital adrenal hyperplasia or adrenal tumor must be excluded. Insulin resistance is part of the spectrum of PCOS, and measurement of fasting glucose and insulin levels or an oral glucose tolerance test should be considered in girls who are obese, have acanthosis nigricans, or a strong family history of type 2 diabetes.

Treatment

General Care (Nonspecific Treatment)

Weight loss has been demonstrated to be effective in improving the biochemical and clinical features of PCOS, and weight gain makes them worse. Adolescent girls with PCOS should be advised to try not to gain excessive weight and to lose weight if already obese.

Specific Treatment

The most frequently used medical therapies for PCOS are the antiandrogen, cyproterone acetate (often given as part of an estrogen containing oral contraceptive pill, Dianette), and metformin, an insulin-sensitizing agent. Both are effective in suppressing androgen production and giving regular periods. Metformin can help weight loss, but side effects can include nausea, gastrointestinal symptoms, and hypoglycemia. Other antiandrogen medications have been used such as spironolactone, but there is less evidence as to effectiveness. Treatment does not resolve the underlying problem, which may recur when the medication is stopped and so it is only worth offering treatment if the symptoms at the time warrant it. Changes in acne or hair growth on treatment may take 3–4 months to start, and patients should be warned about this. Hirsutism and acne can have a very significant impact on an adolescent girl's self-esteem and social skills. Treatment can make a huge difference in appropriate cases. The opinions of parents and their daughter may differ considerably as to how significant they think the problem is. Severe acne can occur in girls without PCOS, and there are a number of effective topical and oral treatments available. Cyproterone or metformin are only likely to be effective in treating acne if investigations confirm elevated androgens.

Hirsutism

Etiology

Adolescent girls who present complaining of hirsutism often have increased hair growth due to a combination of hormonal (such as PCOS) and genetic factors.

Pathogenesis

The increased hair growth related to increased androgens in PCOS is typically on the face (upper lip, cheeks, and chin), and often associated with acne, greasy hair, and other features of PCOS such as irregular periods. Increased hair on the trunk and limbs is less likely to be related to hormonal status and has a strong genetic element.

Treatment

Antiandrogen treatment will only improve hormonally mediated hair growth. Other treatment options may be more satisfactory, such as bleaching and waxing. Electrolysis or laser treatment can be helpful for severe cases and can be used in combination with medical treatments. Both treatments can only treat small areas at a time, can be expensive, and also carry the risk of hyperpigmented scarring after the treatment. A topical treatment containing eflornithine (an ornithine decarboxylase inhibitor) is effective in reducing hair growth of nonhormonal cause. The cream must be applied evenly over the affected area twice daily and is only effective as long as it is being applied, so in practice is best for relatively small areas such as the face.

Puberty in Children with Learning Disabilities

Central precocious puberty can be caused by a variety of CNS lesions, and so children with cerebral palsy and severe learning disabilities are overrepresented in this group. If a girl is likely to be unaware of their pubertal development, they may not get any benefit from treatment for central precocious puberty, and adult height may be irrelevant in children who cannot walk. If a child is not mobile, increasing weight at puberty may mean that their family has more difficulty caring for them. Parents and carers are often concerned about how girls with learning disabilities will manage periods, even if these happen at a completely normal time. For parents, pubertal development in a child with severe learning disabilities brings up complex psychological and practical concerns about how the child will manage as an adult. For girls, treatment to give regular periods or to improve heavy periods can help with managing the situation. Therapy to stop periods completely carries the risk of osteoporosis if estrogen is suppressed, and if started, it can be very difficult to stop in a child who is never going to be mature enough to deal with puberty. There are wide variations in the approach to this problem. Pubertal delay or arrest may go unnoticed for much longer in children with learning disabilities. There is frequently a concern for children with developmental delay or behavior problems (particularly boys) that treatment to induce puberty will result in more difficult behavior. There are few data to support this concern, and even for children with very severe learning disabilities, induction of puberty can bring benefits in terms of increased psychological maturity as well as normal bone density.

The Psychology of Puberty

Late Puberty

Late pubertal development can be associated with psychological distress. Treatment to induce puberty can be

helpful although there are few studies confirming a psychological benefit of treatment. For girls with Turner syndrome, induction of puberty at a similar time to their peers carries psychological benefits. There is no evidence that treatment to induce puberty with sex steroids increases behavior problems in normal children.

Early and Precocious Puberty

A study following 466 girls born in the same Swedish town in 1955 (interviewing them at 13, 15, 27, and 43 years of age) examined the effect of early menarche (before 11 years) and late menarche (after 13 years). The early maturing group was more likely to be overweight as adults than the late maturing group. At age 15–16 years, the early maturing groups were more likely to exhibit delinquent behavior, more likely to use alcohol or drugs, and had more advanced sexual experiences. Early maturing girls were less likely to have university degrees. However, assessment later on as adults aged 43 found no adverse effects of early maturation on quality of life. Other studies have confirmed an association between early maturation and conduct disorder.

The psychological impact of early development is often a great concern for the families of children with precocious puberty. Children with precocious puberty may have behavior changes related to their hormonal levels but in addition there is the impact of the response of those around them to their early development, and the social difficulties associated with appearing much older than their true age. Studies confirm satisfaction with treatment, but it is much less clear whether psychological difficulties are resolved by treatment. Investigation and treatment of precocious puberty will inevitably focus the attention of families onto their child's pubertal development in a way that would not happen with a normally timed puberty, and occasionally this manifests as distress when the treatment is stopped and normally timed puberty occurs.

383 Disorders of Sexual Development

Jamal Raza · Garry L. Warne

Definitions and Terminology

Disorders of sex development (DSD) are defined as *congenital conditions in which development of chromosomal, gonadal, or anatomical sex is atypical.* The initial determination of sex by genes directing the bipotential gonad to become an ovary or a testis is called *sex determination.* The subsequent development of the genital appearance resulting from the function of that gonad is called *sex differentiation.*

Some useful and at times confusing terminologies used over the years need to be clarified for a better understanding of the subject. *Chromosomal sex* is referred to as the sex based on the number of sex chromosomes. *Gonadal sex is* the sex according to the gonadal differentiation. *Phenotypic sex* is the sex based on the external anatomy of the genitalia. *Gender identity* is the individual's perception about his/her own gender. In some individuals, gender identity is different from the phenotypic sex. *Intersex* is a term no longer in use; it has now been replaced by the term DSD. *Ambiguous genitalia* refers to the appearance of external genitalia that are not easily classified as male or female.

Epidemiology

The reported incidence across the world is about 1:4,500 to 1:5,000 live births. This group of disorders affects approximately 85,000 children per year in the European community. Geographically, the incidence is variable. Egypt, for example, has reported a high incidence, 1:3,000.

Gonadal Differentiation

The Bipotential Gonad

In the embryo, the gonads develop in two phases. Initially, the gonad is described as "indifferent" or "bipotential." At this stage, the histological appearance of a gonad destined to become a testis is identical to the one destined to become an ovary. In the second phase, the bipotential gonad is directed into the pathway of differentiation into either a testis or an ovary.

The central portion of the intermediate mesoderm, or mesonephros, is the precursor of the urogenital ridge. Subsequently, part of the urogenital ridge becomes the genital ridge and it here that the bipotential gonad forms. The portion of the ridge lying caudal to the central portion is the pronephros; it gives rise to the adrenal cortex. The portion distal to it is the metanephros, from which the kidney develops. In addition to mesoderm, the genital ridge is also comprised of cells from coelomic epithelium which are destined to become supporting cells (either Sertoli cells in the testis or granulosa cells in the ovary). Steroid-secreting cells, which have an uncertain origin, are also present in the early gonad. They later develop into Leydig cells if the gonad is to be a testis or theca cells in cases of ovarian development.

As early as the second week of gestation, the germ cells from the primary ectoderm migrate, first into the yolk sac and then dorsally into the body wall by the sixth week. The germ cells will eventually develop into the mature gametes, i.e., spermatozoa and oocytes. The germ cell clusters come to rest on either side of the midline.

The primordial germ cells also express a number of transcription factors such as, POU5F1 (also known as octamer binding transcription factor (OCT)3/4 [OMIM No. 164177]), placental/germ alkaline phosphatase (PLAP), testis-specific protein Y encoded (TSPY), and VASA but lose expression for these markers following entry into the genital ridge. Pathologists are able to distinguish undifferentiated from differentiated germ cells by staining for these gene products, because undifferentiated germ cells express them, whereas differentiated ones do not, and the persistence of undifferentiated germ cells in a postpubertal testis is evidence that the germ cells are displaying primitive characteristics that should have disappeared, correlating with high risk of germinoma.

Differentiation of the Gonad into a Testis or an Ovary

The switch that initiates the pathway of differentiation of bipotential gonad into a testis is the expression of SRY, the *s*ex-determining *r*egion on the *Y* chromosome. This first

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_383,

occurs in cells referred to as pre-Sertoli cells, which then, under the influence of another gene, SOX9, transform into Sertoli cells.

The Sertoli cells then aggregate to form *seminiferous cords*, which increase in density and extend into the medulla of the developing testis. There they subdivide to form a network, the rete testis. Within the seminiferous cords, the Sertoli cells surrounding the germ cells are in turn surrounded by a layer of peritubular myoid cells which migrate from the mesonephros. These cells resemble smooth muscle and have contractile capability, so it is thought that they may be the means by which sperm are propelled along the seminiferous tubules of the mature testis.

Initially, the seminiferous cords communicate with the surface epithelium of the testis but lose this communication following the development of a thick fibrous capsule, the *tunica albuginea*. The seminiferous cords are solid, with no lumen, until the onset of spermatogenesis at puberty. Androgen receptor expression in Sertoli cells is very low until 5 months' gestation and increases after that; it has been suggested that spermatogenesis, being androgen-dependent, does not occur until androgen receptor expression has reached a critical level.

The testes descend to the abdominal wall by a retroperitoneal route, reaching the internal inguinal ring by 17 weeks. A long cord of gelatinous connective tissue, called the *gubernaculum* (or "rudder"), connects each testis to the bottom of the developing scrotum. There are two phases of testicular descent: the transabdominal phase and the trans-inguinal phase. The trans-inguinal phase in the rat is regulated by calcitonin gene-related peptide (CGRP), which is released from sensory endings of the genitofemoral nerve in an androgen-dependent manner and which is able to stimulate contractions in the gubernaculum.

Unlike the trans-inguinal phase, the transabdominal phase is androgen-independent. In patients with complete androgen insensitivity syndrome, whose androgen receptor gene is not expressed in any tissue of the body, the testes are usually found at the inguinal ring or in the inguinal canal, having completed transabdominal descent.

Hormone Secretion by the Fetal Testis

Müllerian inhibitory substance (MIS, also known as Anti-Müllerian hormone or AMH (gene locus 19p13.3-p13.2)) is a glycoprotein with two identical subunits that is secreted by Sertoli cells in the early phase of testicular differentiation under the influence of SOX9. MIS gene expression is regulated by SF1, GATA factors, WT1, DAX1, and FSH. MIS has the function of suppressing the development of the Müllerian ducts, which would otherwise develop into the uterus and Fallopian tubes (see ❯ Genes Involved in Sex Determination in this chapter).

Sertoli cells also secrete a second glycoprotein, Inhibin B, by a process requiring the presence of germ cells. Inhibin B has nonidentical subunits, α and β, and it is thought that the α-subunit is made by the Sertoli cells while the β-subunit is contributed by germ cells. Inhibin is an important regulator of FSH, which controls the increase in the germ cells.

Leydig cells lie in the interstitium outside the testis cords, often close to blood vessels and secrete testosterone from as early as 7 weeks. Each testis contains approximately 24×10^6 Leydig cells by the 15th week, but their numbers then decline to about 9×10^6 per testis by the time of birth.

It is now thought that *fetal* Leydig cells, which are derived from the mesonephros and which disappear within 3–6 months after birth, are a distinct population from *immature* Leydig cells, which differentiate after birth, become operative in the first year of life and persist throughout childhood, *adult* Leydig cells, which differentiate after birth from mesenchymal cells of the interstitium and become active at puberty. Unlike adult Leydig cells which can respond only to LH, fetal Leydig cells are sensitive to both luteinizing hormone and adrenocorticotropic hormone (ACTH), fetal and adult Leydig cells predominantly secrete testosterone, but immature Leydig cells are distinguished by mainly secreting androstane-3α, 17β-diol.

The differentiation and proliferation of fetal Leydig cells is regulated by two paracrine factors of Sertoli cell origin: Desert hedgehog (DHH; gene locus in the human 12q13.1) and fibroblast growth factor-9 (FGF-9). Experimental evidence suggests that exposure of the fetal testis to the antiandrogen flutamide can interfere with Desert hedgehog signaling and impair differentiation of fetal Leydig cells, thus causing abnormal testis development and sex differentiation (❯ *Figs. 383.1* and ❯ *383.2*).

Leydig cells (before and after birth) also secrete a protein hormone, insulin-like 3 (INSL3; gene locus 19p13.2), which acts on the gubernaculum during testicular descent through a cellular receptor known as leucine-rich repeat-containing G protein-coupled receptor 8 (LGR8; also known as GREAT). INSL3 is a member of the insulin-like hormone superfamily which comprises insulin, relaxin, IGF-1, and IGF-2. Maternally inherited mutations in INL3-GREAT were shown in an Italian study to account for 9.2% of boys with bilateral cryptorchidism.

After 10 weeks' gestation, the gonad separates from the developing adrenal and kidney. This process is inhibited by expression of the gene, *WNT4*. Rests of adrenocortical cells are commonly found along the line of testicular descent and

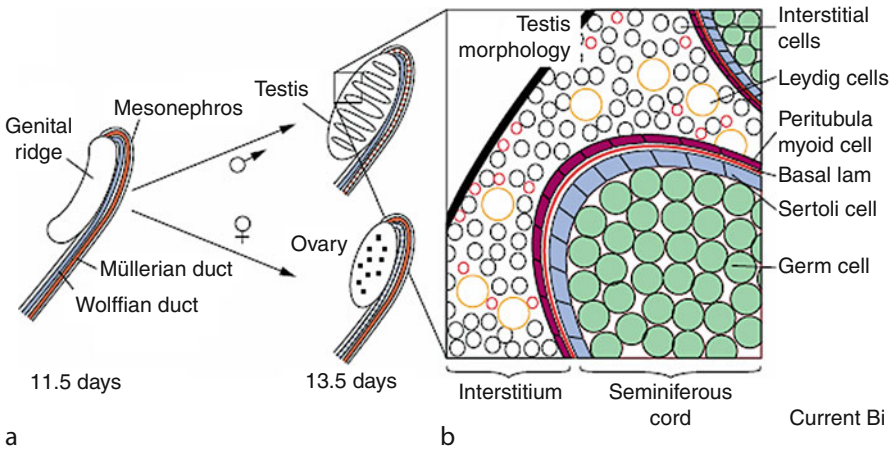

Figure 383.1
Differentiation of the internal genitalia into testicular tissue

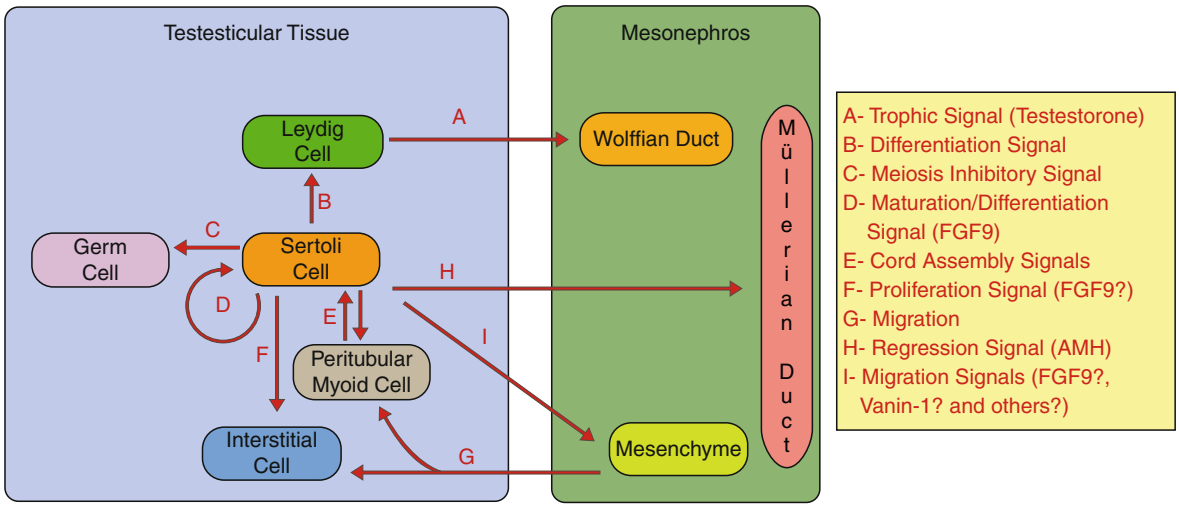

Figure 383.2
Differentiation of testicular tissue and role of migration factors

within the testis itself (surgeons are familiar with them and refer to them as "golden granules"). Under prolonged ACTH stimulation, these adrenal rests may undergo hyperplasia, particularly in men with poorly controlled congenital adrenal hyperplasia, in whom one testis (or both) may enlarge so markedly that a malignant tumor may be mistakenly diagnosed.

Development of the Human Ovary

The fetal ovary in the female develops later than the testis in the male. In the male, SRY triggers rapid testicular development, but there is no comparable factor stimulating rapid ovarian development. In the mouse, female-specific genes are beginning to show expression at the same time as *SRY* in the testis, but morphological changes are not obvious until weeks later. The cells of the sex cords surrounding germ cells develop as follicles, and oocytes are seen in the 11th–12th week. The number of primordial follicles in both ovaries (six to seven million) peaks at 20 weeks and is then reduced, by apoptosis, to only two million by term. The germ cells within the follicles all commence meiosis to create gametes by the fifth month of gestation, after which the gametes become dormant until puberty. Retinoic acid,

via stimulation of *Stra8* expression is thought to initiate meiosis. Until recently, it was believed that the number of female gametes was fixed at birth, but bone marrow has been found to contain germ line stem cells, and it is therefore possible, although as yet unconfirmed, that fresh oocytes for the ovary could be derived from this source. The fetal ovary makes no MIS until late gestation and very little estrogen. The human ovary secretes both Inhibin A and Inhibin B, but the testis secretes only Inhibin B, making Inhibin A a specific marker of the ovary after birth. In the mouse, Inhibin A is expressed in the ovaries from an early stage and increases with gestational age, but in the human, the lack of any difference between umbilical arterial and venous blood levels of Inhibin A suggests that most Inhibin A comes from the placental membranes rather than from the fetal organs.

Genes Involved in Sex Determination

Genes Expressed During Differentiation of the Genital Ridge: WT1, SF1

The following genes are expressed when the bipotential genital ridge is differentiating from the intermediate mesoderm: *WT1, SF1, SOX9, DMRT1, DHH, ATRX, TSPYL1, Gata4/Fog2, Fgf9/Fgfr2, Pod1, Pdgfr-α, Vanin-1, Tescalcin, Testatin, Dax1, Sox3, Sox8, RSPO1, WNT4,* and *DAX1.*

WT1, the Wilms' tumor suppressor gene (located at 11p13), is expressed in the less differentiated cells undergoing the transition from mesenchyme to epithelium which are both the primitive kidney and the genital ridge. A transcription factor, *WT1* has ten exons and four zinc fingers and binds to an ERG1 consensus binding sequence. At least four splice variants are known to occur. One variant results in Frasier syndrome, similar to Denys–Drash syndrome without the Wilms' tumor. The splice variants are divided into those which have the KTS tripeptide, WT1(+)KTS, and those which do not, WT1(−)KTS. In vitro experiments show that the testis determining factor, *SRY,* is strongly activated by WT1(−)KTS but not by WT1(+)KTS isoforms. The MIS gene is strongly repressed in vitro by the WT1(−)KTS isoforms, as is the androgen receptor (AR) gene promoter. At present, the relevance of these findings to what happens in vivo in unknown. The Denys–Drash syndrome, in which renal abnormalities (either Wilms' tumor or a progressive form of glomerulosclerosis, or both) and gonadal abnormalities (streak gonad with high neoplastic potential) coexist, is caused by germline mutations in WT1.

Steroidogenic factor-1 (SF-1; also called the adrenal 4-binding protein and NR5A1), is a nuclear hormone receptor, that in the rat, regulates the expression of the cytochrome P450 enzymes. It is expressed in the urogenital ridge prior to the differentiation of the gonad and is then expressed in the developing testis, but not in the developing ovary. Homozygous male and female *SF-1* knockout mice develop neither adrenal glands nor gonads. In addition, they show impaired gonadotrophic function and agenesis of the ventromedial hypothalamic nucleus. SF-1 also regulates the adrenocorticotropin receptor, the steroid acute regulatory protein (StAR), and in the pituitary, the α-subunit of the glycoproteins. Recent evidence indicates that certain oxysterols (particularly 25-hydroxycholesterol) show specific binding to SF-1 and stimulate SF-1-dependent transcription. There is evidence that WT-1 and SF-1 exert a synergistic effect on expression of the MIS gene. Mutations in SF1 have been identified in 46,XY patients with the combination of hypogonadism and adrenal insufficiency but also in 46,XY patients with gonadal dysfunction and normal adrenal function. Mutations in this gene are also found in patients with 46,XX ovarian dysgenesis and 46,XX primary ovarian insufficiency, suggesting that it plays an important part in the development of the ovary.

Genes Expressed in Male Sex Determination: SRY, SOX 9, DAX1, DMRT1, and Testatin

SRY: The Testis Determining Gene

SRY, the *s*ex-determining *r*egion of the *Y* chromosome, was cloned as the result of gene-mapping studies of Y chromosome deletions in XY females with gonadal dysgenesis and of Y-to-X translocations in XX. Mutations in *SRY* account for only 15% of cases of 46,XY complete gonadal dysgenesis, but 90% of cases of 46,XX individuals who have testes can be explained through the abnormal presence of SRY through translocation. This gene is crucial in switching the indifferent gonad into the pathway of testicular development and if *Sry is* transfected into the genome of a female mouse embryo, the gonads that differentiate are testes, not ovaries (but spermatogenesis is absent).

Another gene that is expressed in the genital ridge at an early stage is *SOX-9*. The *SOX* genes are defined by possession of the same HMG b*ox* as *SRY* and were detected by a genome-wide search for genes containing this sequence. In the developing embryo, *SOX-9* is expressed in the genital ridge and in the skeleton. Mutations in *SOX-9*

result in *campomelic dysplasia*, a severe birth defect causing bowing of the long bones (SOX9 directly regulates the type-II collagen gene) and sex reversal due to gonadal dysgenesis in 75% of XY individuals. In the mouse, high levels of *Sox9* mRNA are found in male (XY) but not female (XX) genital ridges and are localized to Sertoli cells within the sex cords of the developing testis.

DAX-1, DMRT-1, and Testatin

Duplications of DAX-1 are found in patients with X-linked 46XY DSD due to gonadal dysgenesis. DAX-1 is a member of the nuclear receptor superfamily which is expressed in steroidogenic tissues as well as in Sertoli cells, pituitary gonadotrophs, and in the ventromedial hypothalamus. Loss-of-function mutations of *DAX-1* were already known to cause adrenal hypoplasia congenita (AHC). The physiological role of DAX-1 is considered to be inhibitory to testis development through an anti-*SRY* effect. In Y-1 adrenocortical cells, DAX-1 has been shown to inhibit steroidogenesis at multiple levels, including the rate-limiting step controlled by StAR (the steroid acute regulatory protein).

The distal portion of 9p is a region implicated in human 46,XY DSD. A gene called *DMRT1* maps to that chromosomal region and is expressed only in testis. Its role in the regulation of testis differentiation has yet to be fully elucidated.

Testatin was detected using the signal peptide differential display screening technique, and it is a member of a gene family that encodes cystatins (cysteine protease inhibitors). Expression of testatin is confined, in the mouse, to fetal gonads, where it is expressed in pre-Sertoli cells during testis cord formation. These cells are believed to be the source of the testis determining factor, Sry, and testatin is expressed immediately following peak *Sry* expression. This suggests that testatin may have a role in tissue reorganization during early testis development. Testatin is also expressed in adult testis.

Genes Expressed in Female Sex Determination: RSPO1, WNT4, and β-Catenin

Two genes, Wnt4 and RSPO1, are currently considered to be candidates for ovary-determining genes. Wnt4, possibly assisted by RSPO1, opposes the action of two genes considered to promote testis development, SOX9 and FGF9. Wnt-signaling is involved in endocrine regulation and in the pathogenesis of some endocrine disorders and these actions, which are associated with expression of a transcriptional coactivator, β-catenin.

R-spondin 1 (RSPO1) has been cited as the female counterpart of the *SRY* gene. During gonadal development, both males and females have a low expression of *SOX9*, which in males is upregulated under the influence of SRY and leads to further testis development. In females, SOX9 is turned off, leading to the development of ovaries. This turning off seems to be under the influence of RSPO1. Mutations in the human RSPO1 gene give rise to an autosomal recessive syndrome of 46,XX testicular DSD. Other features of the reported phenotype include palmoplantar hyperkeratosis and increased risk of squamous cell carcinoma. Affected individuals lack Müllerian structures and have masculinized external genitalia, indicating that both fetal Sertoli cells and Leydig cells functions had been affected. Overexpression of SOX9 in females is also responsible for the masculinization seen in some cases of 46XX males.

Sexual Differentiation

The External Genitalia

The external genitalia of male and female fetuses are indistinguishable until 8–9 weeks (Fig. 383.3). Initially, the allantois, the large intestine, the postanal gut, and the Wolffian (mesonephric) ducts open into a common cloaca. At 6 weeks, the cloaca is subdivided into separate openings for the gut and the urogenital sinus. Bilateral cloacal tubercles coalesce at the anterior end of the cloaca to form the genital tubercle. This phallic structure at 9 weeks is a prominent structure resembling a penis in both sexes but it can develop into either a penis or a clitoris. The inner and outer genital folds form the lateral flanks of the urogenital sinus.

Leydig cells are first seen in the fetal testis at around 7 weeks and the effects of testosterone on the external genitalia are seen between 9 and 12 weeks. At 12–16 weeks, fetal serum testosterone reaches a peak approaching the adult male level.

Differentiation of the fetal genitalia is androgen-dependent. Furthermore, it requires dihydrotestosterone, an androgen 10–20 times more potent than testosterone because of its greater affinity for the androgen receptor. The genital tissues are rich in 5α-reductase-2, an enzyme which converts testosterone to 5α-dihydrotestosterone (DHT). Under the influence of DHT, the genital tubercle shows differential growth to become the penis and the inner genital folds fuse from posterior to anterior to enclose the penile urethra and *corpus spongiosum* (or spongy urethra). This is lined by endoderm derived from the urogenital sinus;

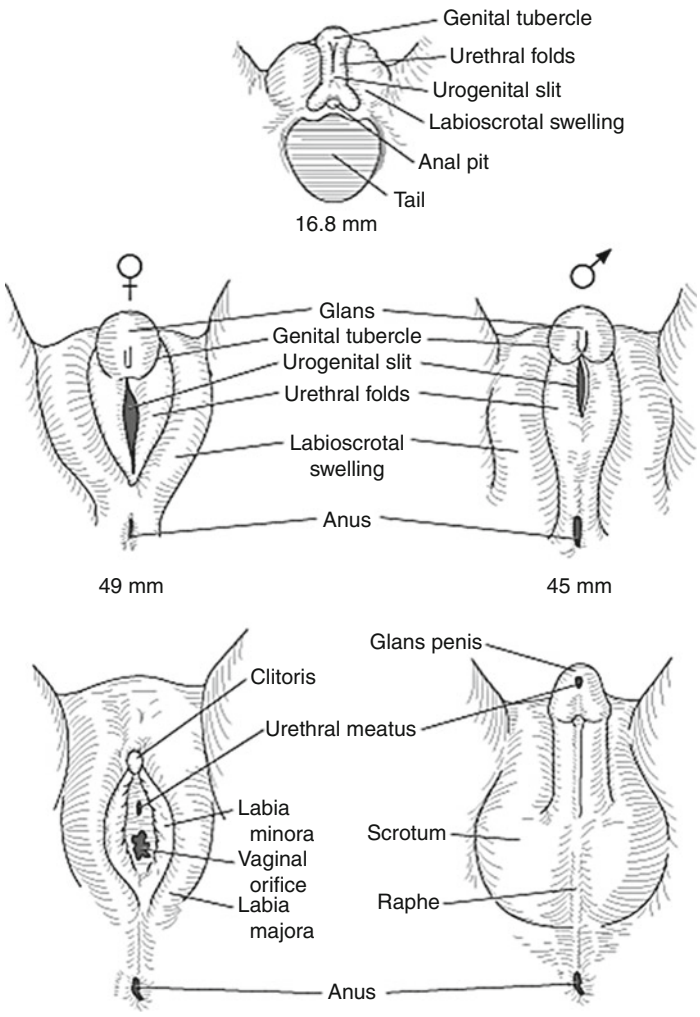

Figure 383.3
Differentiation of the external genitalia

it subsequently connects with an ingrowth of epithelium originating from the tip of the penis. At around the 12th week, the epithelium near the tip of the penis starts to invaginate in a circular fashion to create the prepuce or foreskin. This invagination divides to create two layers of epithelium which are initially adherent but later separate, allowing the foreskin to retract. (It is common for the foreskin to remain nonretractile for some years after a boy's birth.) The outer genital folds fuse to form the scrotum. This process is typically completed by 12–14 weeks and after that, the main changes are in the length of the penis.

In the female, the genital tubercle becomes the clitoris, the inner genital folds form the labia minora, and the outer genital folds, the labia majora. These changes occur in the absence of testosterone. In 46,XY individuals with complete androgen insensitivity, which is due to an inactivating mutation of the androgen receptor gene, the external genitalia are completely female, despite the presence of very high circulating testosterone levels. Feminization of the urogenital sinus commences after follicles have begun to grow in the ovaries, so a role for ovarian steroids in this process has been postulated. If the clitoris of a 46,XX female is exposed to high levels of androgen during fetal life, such as in a child with a genetic deficiency in the adrenal enzyme, 21-hydroxylase, it is possible for the urethra to be fully enclosed and reach the tip of the

phallus, just as it does in normal males. A lesser degree of androgenization will result in persistence of the urogenital sinus, so the baby is born with a single orifice on the perineum, instead of separate ones for urethra and vagina. With greater degree of virilization, the urogenital sinus is longer. Surgeons planning feminizing genitoplasty surgery on a child born with ambiguous genitalia due to a condition like congenital adrenal hyperplasia always need to make a careful assessment of the length of the urogenital sinus because the mobilization of a high junction between urethra and vagina requires great surgical skill and is potentially more damaging to the tissues than mobilization over a shorter distance.

The Genital Ducts

In the indifferent phase of embryonic development, two pairs of internal ducts – the Wolffian and Müllerian ducts – develop from the mesonephros during the seventh week (Fig. 383.4). The development of both is initially thought to be independent of the gonad. In both sexes, the *Wolffian* ducts grow caudally, penetrate the cloacal wall on the sides of a swelling called the Wolffian tubercle, and are then canalized. The ureters bud off the Wolffian ducts just behind the Wolffian tubercle on each side and connect with the metanephros (the precursor of the definitive kidney). The *Müllerian* ducts originate as a longitudinal invagination of

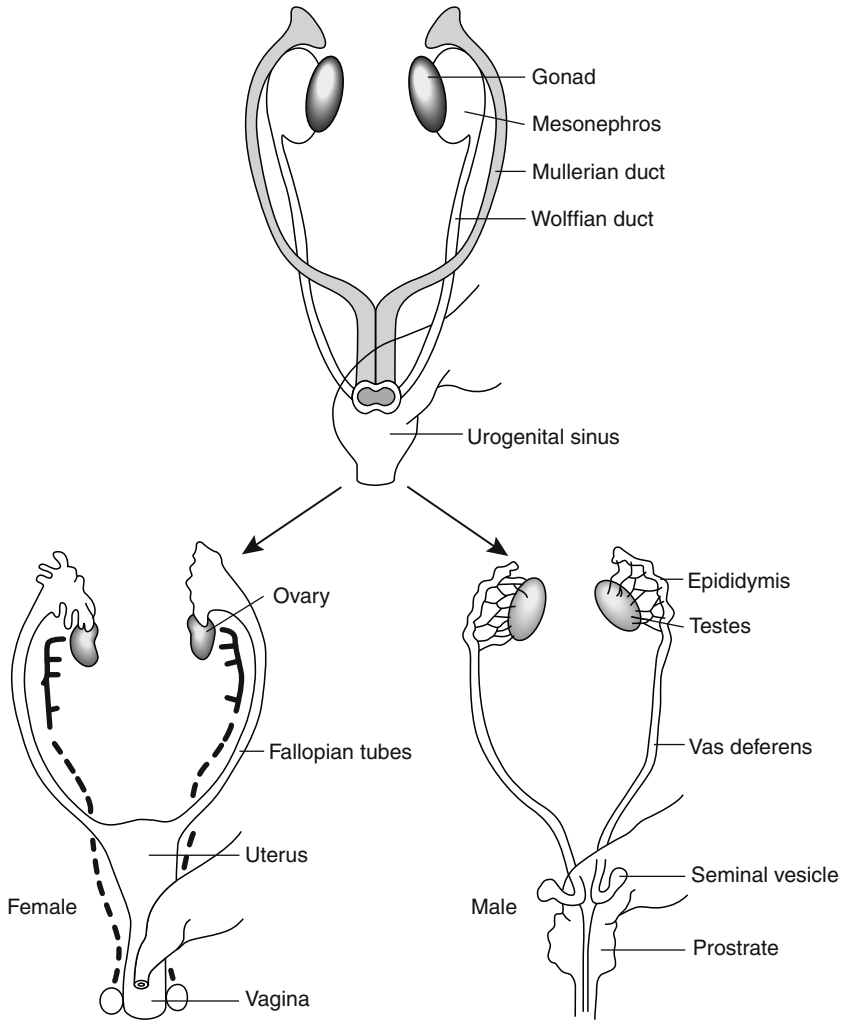

Figure 383.4
Differentiation of the genital ducts

the coelomic epithelium which grows caudally as a solid projection, lateral to, and in close apposition to, the Wolffian ducts. The Wolffian ducts precede and guide the Müllerian ducts to the urogenital sinus. At the pelvic brim, the Müllerian ducts swing medially, cross in front of the Wolffian ducts, then meet and continue migrating side by side to the urogenital sinus. They then fuse at 10–13 weeks to form the uterovaginal primordium. The uterus and vagina are recognizable by 16 weeks, but the vagina does not attain a lumen until 20 weeks. The hymen is imperforate until 20 weeks, when it breaks down. After the Müllerian ducts have been guided to their destination, the Wolffian ducts atrophy, but are represented postnatally by Gartner's ducts which open onto the vestibule. Paraovarian cysts, which are found incidentally during laparoscopy in some women, may also be of Wolffian duct origin. They are almost always benign but can be malignant.

Initially the internal ducts develop independently of the gonad, but the presence or absence of a functional testis determines the outcome once gonadal hormone secretion commences. Development of each Wolffian duct is stimulated by testosterone secreted by the Leydig cells contained in the testis of the same side. There is some direct evidence to support the hypothesis that testosterone diffuses down the Wolffian duct during sexual differentiation, the Wolffian duct enlarges and differentiates (by the third fetal month) into the vas deferens, the seminal vesicle and the epididymis. This is a direct action of testosterone that does not require the prior conversion of T to DHT. In the external genital tissues, DHT is the active androgen. The action of both T and DHT on the reproductive tract during sexual differentiation requires the presence of the androgen receptor (AR) and also involves several growth factors, particularly IGF-1 and epidermal growth factor (EGF). The cystic fibrosis transmembrane regulator gene (*CFTR*) is involved in maintaining the integrity of the vas deferens, and there are mild mutations in *CFTR* that only affect Wolffian duct differentiation without causing cystic fibrosis. The prostate gland and the bladder are both derived from the urogenital sinus. The commitment of undifferentiated stem cells to the prostate cell lineage is regulated by tumor protein p63. Formation of the lobes of the prostate and budding of the ducts is regulated by SOX9, retinoic acid, BMP (mesenchyme), and the BMP antagonist NOGGIN (postnatal ductal development). The prostatic utricle is commonly thought of as a Müllerian remnant, but this is incorrect. It, too, is derived from the urogenital sinus.

The *Müllerian, or paramesonephric, duct* develops independent of the coelomic mesoderm above the mesonephros. The part above the mesonephros gives rise to the infundibulum and fimbria of the fallopian tube; the part that runs alongside the mesonephros contributes to the ampulla and possibly the isthmus. It is argued by some writers that, in the region of the mesonephros, the Müllerian duct fuses with the Wolffian duct, and the ampulla and isthmus are Wolffian derivatives. Initiation of Müllerian duct morphogenesis from mesenchyme in both sexes requires expression of *WNT4,* a gene which is also required for ovarian differentiation the Müllerian duct can only proceed in the *absence* of any effect from MIS. The type-II MIS receptor has homology to the TGF-β/activin receptor family. In the absence of MIS, the Müllerian ducts grow and differentiate to form the two fallopian tubes and, through a distal midline fusion between the two Müllerian ducts and also involving the Wolffian duct, the uterus, and the upper vagina. This process is completed in the third fetal month. The fused portion of the Müllerian ducts connects to the expanded lower end of the urinary tract to form the *urogenital sinus.* The greater part of the vagina is derived from the urogenital sinus and only the upper portion is of Müllerian duct origin. Being of urogenital sinus origin, it is subject to the inhibitory effects of testosterone and does not develop when testosterone is actively promoting masculine development.

A point of practical significance is that an infant with a disorder of sex development who has a vagina will not have a prostate gland as well. A vagina cannot develop when there has been a marked response to testosterone, and a prostate gland cannot develop without it.

The fetal ovary does not produce MIS until late in gestation when it is secreted by the granulosa cells. MIS continues to be produced by the postnatal ovary, but by this time, the fallopian tubes, uterus, and vagina have become completely unresponsive to its effects.

In the mouse, the *Wnt7a* gene is expressed perinatally in the luminal epithelium of the uterus. Homozygous *Wnt7a-/-* knockout transgenic mice have abnormalities in the vagina (shallow fornices, vaginal concretions and epithelial inclusions in the vaginal stroma, stratified epithelium with reduced stroma and glands) and malformed oviducts. In addition, Wolffian duct remnants persist in the female reproductive tract of these animals as parovarian cysts.

Clinical Presentation of DSD

There is a range of clinical presentations for DSD:

- The infant with ambiguous genitalia
- The 46,XY female who is found to have inguinal testes (e.g., CAIS, 17α-hydroxylase deficiency)
- 46,XY Females who progressively virilize during childhood (e.g., 17β-HSD)

- 46,XY Females who develop breasts but no menses (e.g., CAIS)
- 46,XY Females with absent pubertal development (e.g., complete GD)
- Girls with absent uterus and vagina (vaginal agenesis)
- Males with hypospadias ± undescended testes
- Adolescent male with recurrent hematuria (CAH)
- Male with micropenis and adolescent gynecomastia (e.g., PAIS)
- Male with a uterus (persistent Müllerian duct syndrome)
- 46,XX male with impaired sexual development
- Male discovered to have chromosomal aneuploidy (45,X/46,XY mosaicism; 47,XXY, etc.)
- Adult male or female with an intra-abdominal gonadal tumor of germ cell origin

Classification of DSD

The present classification of the disorder places them in three major categories:

1. 46,XY DSD
   (a) Disorders of testicular development
      (i) 46,XY complete gonadal dysgenesis
      (ii) 46,XY partial gonadal dysgenesis
      (iii) 46,XY Ovotesticular DSD (formerly referred to as True hermaphroditism)
   (b) Disorders of androgen synthesis or action
      (i) Androgen biosynthetic defect
      (ii) Defect in androgen action
      (iii) LH receptor defect
      (iv) Deficiency of Müllerian inhibitory substance (MIS) or its receptor
   (c) General category
      (i) Hypospadias
      (ii) Cloacal exstrophy
      (iii) Bladder exstrophy
2. 46,XX DSD
   (a) Disorder of gonadal development (formerly called 46,XX male syndrome)
      (i) 46,XX testicular DSD (SRY translocation on X chromosome-90%)
      (ii) R-spondin1 genetic mutation
      (iii) SOX9 duplication or overexpression
      (iv) Ovotesticular DSD
   (b) Androgen excess
      (i) Fetal adrenal
         - 21α-hydroxylase deficiency
         - 11β-hydroxylase deficiency
         - 3β-hydroxysteroid dehydrogenase
      (ii) Fetoplacental
         - Aromatase deficiency
         - POR deficiency
      (iii) Maternal
         - Drugs
         - Tumors
3. Sex chromosome aneuploidy DSD
   (a) Klinefelter syndrome
   (b) Turner syndrome and its variant
   (c) Mixed gonadal dysgenesis
   (d) Ovotesticular DSD

46,XY DSD

46,XY Complete Gonadal Dysgenesis

Also known as Swyer syndrome, it represents failure of testicular differentiation at an early embryonic stage, resulting in gonadal dysgenesis. The gonads may be streaks, meaning that they contain no germ cells, or hypoplastic/dysgenetic testes. In about 15% of cases, a mutation in *SRY* is found.

Affected patients will have a female phenotype, and mostly present around puberty with reduced pubic hair, delayed breast development and primary amenorrhea. They possess normal female external genitalia with impalpable gonads. They have normal stature and lack any dysmorphic features. Raised gonadotrophins (FSH, LH) and a low basal and stimulated testosterone are found, and ultrasound is unable to pick up gonads, but usually a small uterus is found. Sex of rearing is unequivocally female and is not an issue. Gonadectomy should be carried out when the diagnosis is first established, due to the high risk of malignancy in these patients. Hormone replacement with estrogen and progesterone is required for the development of female phenotype. In the presence of uterus, pregnancy is a possibility with donor egg fertilization, but certain religious groups, e.g., Roman Catholics, orthodox Jews, and Muslims, have ethical objections to egg donation.

46,XY Partial Gonadal Dysgenesis (PGD)

In a 46,XY child without mosaicism, when there is incomplete differentiation and development of the testes and some degree of masculinization of the genitalia, the condition is labeled as Partial Gonadal Dysgenesis (previously also referred to as male pseudohermaphroditism). This may result from a heterogeneous group of chromosomal,

gonadal, and phenotypic abnormalities. Wolffian duct development depends on the amount of androgens made earlier during gestation, while regression or otherwise of the Müllerian duct depends on whether damage has occurred before the seventh week, when MIS was produced. Externally, some degree of ambiguity is mostly present; however, a male phenotype is also a possibility. Usually a smaller penile size with some chordee and a variable degree of hypospadias is found. Asymmetry of gonads, due to one gonad being palpable and the other being undescended, often gives a clinical clue to the diagnosis. The sex of rearing depends on the severity of ambiguity among other factors, but the preference is for male sex of rearing. Intra-abdominal gonads need to be removed due to high risk of malignancy if they cannot be bought down, while an inguinal gonad should be brought down and monitored periodically for any changes. Hormone replacement, if required, should commence around puberty time.

Ovotesticular DSD (OT-DSD) (OMIM #235600)

Histological presence of both ovarian and testicular tissue in one or both gonads is imperative for the diagnosis of OT-DSD. A definite requirement for an ovarian element would be at least one follicle, i.e., a large ovum surrounded by a layer of flattened cells, or better, with more cells. For testicular tissue, the requirement would be a seminiferous tubule, i.e., a tubular structure lined by at least Sertoli-like cells, and better with germ cells, although the presence of germ cells is not an absolute requirement. There may be a combination of one gonad being an ovary and the other being a testis, while both ovarian and testicular tissue may be present in the same gonad (ovotestis) on one or both sides. Ovotestis was found in about 45% in one large series. The frequency of this disorder is variable, with geographical pockets of high frequency. It is particularly prevalent in the Bantu-speaking black community in South Africa. In one cohort of 228 DSD patients, OT-DSD was diagnosed in 5.7% patients, and similar incidence has been reported elsewhere. No etiology for the disorder has been found, although about 10% of 46,XX cases have the *SRY* gene and a case report in a syndromic OT-DSD has suggested a mutation of the RSPO-1 gene. Familial cases have also been reported and both autosomal recessive and sex-limited autosomal mechanisms have been suggested.

A variable karyotype thus can be found in OT-DSD, including 46,XY, 46,XX, and a variety of mixed chimeric patterns such as 46,XX/46,XY. The commonest one is 46, XX, representing 97% of cases in Africa, 72% in North America, and over 50% in Europe. 46,XY was reported in about 7% in both series, while the chimeric pattern constitutes 41% in European series, as opposed to 21% in North America. In experimental mice, crossbreeding between similar but slightly different breeds gives rise to litters of 46,XY pups, some of which have gonadal dysgenesis while other littermates have ovotesticular DSD. This occurrence is explained by a timing mismatch between the two mouse species in the switching on of *sry*.

There are also various configurations for internal genitalia. Most classically, there is a Wolffian system on one side and a Müllerian duct system on the other. However, a combination of these may also coexist.

The external genitalia also vary in the degree of ambiguity. Usually, at least one gonad is palpable in the inguinoscrotal region. This is more often seen on the right and is often associated with an inguinal hernia. Fertility is usually not seen; however, there have been 21 reported cases of pregnancies in OT-DSD. Investigations of these individuals may include chromosomal analysis (minimum of 50 cells to be counted, to detect mosaicism), FISH for SRY (when the karyotype is 46,XX), imaging to locate the gonad (pelvic ultrasound, MRI), an hCG stimulation test to assess the testicular function, and a serum Inhibin A level to identify ovarian tissue.

The management plan for a person with OT-DSD will be an individualized one, taking into account the chromosomal type, the internal and external anatomy, the presence of functional ovarian or testicular tissue, the sex in which the person has already been raised, the availability of medical and surgical expertise, and other social and cultural factors.

Disorder in Androgen Synthesis or Action

This is further divided into:

1. Defects in testosterone biosynthesis (*Fig. 383.5*)
2. Defect in the synthesis of dihydrotestosterone (DHT), 5α-reductase-2 deficiency
3. Leydig cell hypoplasia
4. End organ resistance: Complete Androgen insensitivity syndrome (CAIS) and partial androgen insensitivity syndrome (PAIS)

Testosterone Biosynthetic Defects

A number of enzymes are involved in testosterone biosynthesis. A single enzyme deficiency may be enough to block hormone synthesis.

1. Steroidogenic acute regulatory protein (StAR protein) (OMIM 600617)
2. 3 β-HSD type-II deficiency (OMIM 201810)
3. CYP17 (17α-hydroxylase/17,20 lyase defect) (OMIM 202110)
4. CYP17 (17,20 lyase defect) (OMIM 202110)
5. P450 oxidoreductase deficiency (OMIM 201750)
6. 17 β-HSD type-III deficiency (OMIM 605573)

Congenital Lipoid Adrenal Hyperplasia

Lipoid adrenal hyperplasia is caused by a mutation in the gene regulating the steroidogenic acute regulatory protein, StAR, which is the transporter protein responsible for transferring cholesterol across the mitochondrial membrane of steroidogenic cells in the adrenal cortex and the gonad. Once inside the mitochondrion, cholesterol becomes the substrate for all of the steroidogenic enzymes. Absence of StAR results in the toxic accumulation of lipid material in the cytoplasm of adrenocortical cells and Leydig cells.

Mutation in the gene results not only in severe undervirilization but also in severe salt wasting, leading to hyponatremia, hypovolemia, hyperkalemia, acidosis, and often death during infancy, if treatment with corticosteroids is delayed. Lipoid CAH is relatively common in the Japanese, Korean, and Arab populations.

Irrespective of the chromosomal sex, nearly all reported cases have a female phenotype. The Leydig cells in 46,XY patients are also affected, leading to inadequate testosterone secretion. Most would die in infancy due to mineralocorticoid deficiency if not correctly diagnosed, but with early and appropriate glucocorticoid and mineralocorticoid treatment, patients should survive and do well.

While most 46,XY children with lipoid adrenal hyperplasia have a female phenotype, phenotypic male children with normal phenotype presenting primarily with glucocorticoid deficiency have been reported.

Interestingly, most 46,XX individuals with the mutation reach menarche and go through puberty but as well as being infertile, they experience a premature menopause and are prone enlargement of the ovaries, which become lipid-laden and cystic and which are prone to torsion. Pregnancy following IVF has been reported in this condition.

The primary defect is genetic loss of steroidogenesis that is dependent on StAR protein. There is a subsequent loss of steroidogenesis that is independent of StAR, due to cellular damage from accumulated cholesterol esters.

The adrenals are grossly enlarged with a yellowish appearance. Histology shows the classic appearance of fat laden adrenal gland.

3 β-Hydroxysteroid Dehydrogenase Type-2 Deficiency (OMIM 201810)

The two 3 β-Hydroxysteroid Dehydrogenases (3βHSD) are the enzymes responsible for the conversion of Δ^5 to Δ^4 steroids. 3βHSD type 1 is expressed in skin, breast and placenta whereas type 2 is expressed in adrenals and gonad and it is this enzyme, when deficient, that causes DSD. The type 2 gene is located at 1p13.1 and the condition is autosomal recessive.

The adrenal involvement results in salt wasting; deaths have been reported despite the steroid replacement. Some reports have also shown cases without salt loss. The diminished androgen synthesis and gonadal involvement in a male would result in variable degree of lack of virilization, ranging from a female phenotype to hypospadias. In a genetic female fetus, the accumulation of adrenal androgen (DHEA) causes overgrowth of the clitoris and partial fusion of the labioscrotal folds.

Typically, a raised level of 17-hydroxypregnenolone for the patient's age and sex is expected. Serum 17-hydroxyprogesterone may also be increased, leading to an incorrect diagnosis of 21-hydroxylase deficiency. This may result from the peripheral conversion of 17-hydroxypregnenolone by the type 1 enzyme which is present there. A raised DHEA sulfate is also found in these patients.

Hormone replacement with glucocorticoid and, as necessary, mineralocorticoid is essential. Appropriate replacement of sex hormone should be carried out around the time of puberty.

CYP17 (17α-Hydroxylase/17,20 Lyase Defect) (OMIM 202110) and CYP17 (17,20 Lyase Defect)

A member of the cytochrome p450 family of enzymes, this very rare condition is transmitted as autosomal recessive. The genetic defect is located at 10q24.3. These two conditions can coexist, or the latter can sometimes occur as a separate disorder. The deficiency of 17α-hydroxylase results in inadequate conversion of pregnenolone and progesterone to 17-hydroxypregnenolone and 17-hydroxyprogesterone respectively. The lack of cortisol leading to excess ACTH, however, results in the overproduction of deoxycortisone which causes hypokalemic hypertension.

The degree of undervirilization seen in 46,XY patients varies according to the severity of the enzyme defect, and the persistence of Müllerian structures has been reported. Analysis of urine steroids by GC-MS shows a characteristic profile. Circulating levels of DOC, 18-OH DOC, corticosterone, and ACTH are elevated, while the levels of aldosterone and PRA are reduced. Serum testosterone does not rise in response to hCG. Treatment constitutes of replacement of glucocorticoids, and this also corrects the hypertension.

P_{450} Oxidoreductase POR Deficiency (OMIM 201750)

An autosomal recessive condition with a defect in POR gene, this disorder presents with a wide range of clinical presentations. POR is a flavoprotein which plays a central role in the electron transfer in P_{450} enzymes. Although the POR reduction plays a crucial role in the 17,20 lyase reaction, there are 57 microsomal P_{450} enzymes, many of those are influenced by this defect, hence the clinical spectrum is wide. The cortisol deficiency may range from insignificant to life threatening.

Men may suffer from variable undervirilization and present with ambiguous genitalia. Females may have vaginal atresia, fused labia, large clitoris, primary amenorrhea, and large cystic ovaries.

The most severe form results in Antley–Bixler syndrome, which has a variable combination of craniofacial defects (craniosynostosis, brachycephaly, depressed nasal bridge, broad nose, cleft palate), skeletal anomalies (radiohumeral synostosis, bowing of legs, campodactyly, neonatal fractures), and urogenital anomalies (ambiguous genitalia, horse shoe kidney, ectopic kidney, hypoplastic ureters).

The diagnosis can be made by analyzing urine with GC-MS (which shows a unique steroid metabolism suggestive of impaired activity of both 17-hydroxylase and 21-hydroxylase) and confirmed with genetic analysis.

Steroid 5α-Reductase Type-2 Deficiency (OMIM 611715)

5α-Reductase-2 deficiency has been reported in many countries, especially the Dominican Republic, Turkey, India, and Papua New Guinea, but it is relatively rare in Caucasians.

This defect in androgen synthesis results in inadequate conversion of testosterone to dihydrotestosterone. As DHT is mainly involved with external appearance of genitalia, its deficiency would result in significant undervirilization. There may be a small phallus with chordee and penoscrotal hypospadias, a bifid scrotum, and a urogenital sinus.

As testosterone production is normal, the Wolffian duct develops and differentiates into the epididymis, seminal vesicle, and vas deferens, while Müllerian regression also takes place. Gonadal descent is impaired to a variable extent, and testes are found in the inguinal canal or labioscrotal folds.

A significant feature of the condition is virilization occurring at puberty, with the phallus becoming enlarged, labioscrotal folds becoming pigmented and rugose, testes enlarging and then descending into the labioscrotal folds. The hallmark investigation to diagnose the condition is the measurement of testosterone and dihydrotestosterone following hCG stimulation. In 5α-reductase-2 deficiency, the T:DHT ratio is very high (>36, as opposed to normal 8–16). The block results in high unstimulated and stimulated testosterone levels, while the DHT level remains low.

Leydig Cell Hypoplasia/Aplasia (OMIM 152790)

First described in 1976, the condition has been divided into aplasia or hypoplasia. The complete absence of Leydig cells would result in presentation similar to that of Swyer syndrome (complete gonadal dysgenesis). The cause is a defect in LH signal transduction due a mutation in the LH receptor gene.

The presentation is often a complete female phenotype with intra-abdominal gonads, rudimentary Wolffian and absent Müllerian structures. They fail to attain puberty and pubic hair does not develop. Failure of testosterone to rise with hCG stimulation is the diagnostic clue which is confirmed on histological absence of Leydig cells on testicular biopsy and an LH receptor gene defect on mutational analysis. A partial form of this disorder with lesser severity also exists.

Androgen Insensitivity or Androgen Resistance (OMIM 300068)

The effects of androgen in mediating the differentiation and development of the normal male phenotype are exerted by a single protein called androgen receptor. Defects regarding androgen resistance were noticed as early as in 1953 by John Morris; however, the receptor gene (locus Xq11-12) was not cloned until 1989. Since then, more than 400 mutations have been reported. The clinical phenotypes are variable and are divided into three types:

1. Complete androgen insensitivity
2. Partial androgen insensitivity
3. Mild androgen insensitivity

Complete Androgen Insensitivity

These may present with female genitalia with absence of Wolffian structures such as the vas deferens, epididymis, and seminal vesicles. Müllerian structures are usually absent, although a number of recent reports have found some Müllerian structures such as a Fallopian tube. At puberty, breast development may occur (due to high testosterone conversion to estradiol), but pubic and axillary hair remains absent. Failure to menstruate may be the first sign or presentation to a gynecologist, or sometimes when they operated for a suspected "inguinal hernia." The length of the vagina is usually about two third that of non-CAIS women, but sometimes it is extremely short and penetrative intercourse may be impossible without some procedure to lengthen it. Lengthening the vagina can sometimes be achieved by nonsurgical means. Localized pressure, as in repeated attempts at intercourse, can substantially lengthen a short vagina over time. Women with CAIS tend to be taller than average women. Because they have a 46,XY karyotype, they may have other X-linked conditions, such as red-green color blindness.

Partial Androgen Insensitivity

Patients with PAIS present with a variety of phenotypes. Depending on the severity of the androgen insensitivity in the tissues and even within a family, there may be substantial phenotypic variation between affected family members. More severe forms present with variable degree of ambiguity and cryptorchidism, while the less severe ones present with just clitoral enlargement, some pubic hair, and labial fusion. Wolffian structures may be partially to fully developed, but Müllerian structures are usually completely absent. Affected individuals can expect to develop gynaecomastia when they reach puberty. This differentiates PAIS from similar conditions such as 5α-reductase-2 deficiency and 17β-hydroxysteroid dehydrogenase deficiency, in which gynaecomastia is not expected.

Mild Androgen Insensitivity (MAIS)

This condition usually presents with a coronal hypospadias or a midline raphe in the scrotum. Later in puberty, they develop gynaecomastia, a high-pitched voice, sparse sexual hair, and impaired spermatogenesis and fertility.

Investigations

High testosterone and LH are found in the first 3 months and then at puberty, indicating androgen resistance. hCG stimulation reveals a high basal and higher stimulated levels of both testosterone and DHT, indicating a problem at the receptor level. High serum estrone is also found (conversion of high testosterone). MIS and Inhibin B are also present in normal amount as Sertoli cell functions remain unaffected.

Management of these children depends on the severity, age, and type of presentation. For instance, a girl diagnosed for the first time during puberty and found to have CAIS should be brought up as a girl and have the testes removed after puberty has been completed, whereas a child whose appearance is more like an undervirilized boy would generally be reared as a male with orchidopexy and hypospadias repair.

Timing of Gonadectomy and the Risk of Malignancy

Testes carrying androgen receptor gene mutations are at an increased risk of germ cell malignancies, the risk being highest in partial AIS with an intra-abdominal testis. The risk in women with complete AIS is lower. Intra-abdominal testes that cannot be brought down should be removed. Inguinal testes may be left in situ until after puberty as the risk before this time appears to be extremely low. Retention of testes in a child raised female allows spontaneous breast development to occur at puberty, but may also be associated with virilization in a child with partial AIS, and this may be unwanted. The testes in women with CAIS are the same size as in men but are in a superficial inguinal position where they may be very painful when compressed by clothing or during sporting activities. This is another reason why some women choose to have them removed (*Table 383.1*).

Persistent Müllerian Duct Syndrome (PMDS)

Mutations in the MIS gene located on the chromosome 19p 13.3 account for about half of all cases of this rare syndrome and in the other half, mutations in the MIS receptor gene are found. Clinically, it presents as

Table 383.1

Risk of type-II germinal cell tumors (GCTs) in the various categories of disorders of sex development (DSD) patients, classified into high-, intermediate-, low-, and no-risk groups

Risk group	Disorder	Malignancy risk (%)	Recommended action	Studies (n)	Patients (n)
High	GD[a] (+Y)[b] intra-abdominal	15–35	Gonadectomy[c]	12	>350
	PAIS non-scrotal	50	Gonadectomy[c]	2	24
	Frasier	60	Gonadectomy[c]	1	15
	Denys–Drash (+Y)	40	Gonadectomy[c]	1	5
Intermediate	Turner (+Y)	12	Gonadectomy[c]	11	43
	17β-HSD	28	Monitor	2	7
	GD (+Y)[c]	Unknown	Biopsy[d] and irradiation?	0	0
	PAIS scrotal gonad	Unknown	Biopsy[d] and irradiation?	0	0
Low	CAIS	2	Biopsy and Gonadectomy	2	55
	Ovotestis DSD	3	Testis tissue removal?	3	426
	Turner (−Y)	1	None	11	557
No (?)	5α-reductase	0	Unresolved	1	3
	Leydig cell hypoplasia	0	Unresolved	2	

CAIS complete androgen insensitivity syndrome, 17β-*HSD* 17β-hydroxysteroid dehydrogenase deficiency, *PAIS* partial androgen insensitivity syndrome.
[a]Gonadal dysgenesis (including not further specified, 46XY, 46X/46XY, mixed, partial, complete).
[b]GBY region positive, including the TSPY gene.
[c]At time of diagnosis.
[d]At puberty, allowing investigation of at least 30 seminiferous tubules, with diagnosis preferably based on OCT3/4 immunohistochemistry.

a phenotypic male usually along with bilateral cryptorchidism and an inguinal hernia. Leydig cell functions are usually well preserved, but azoospermia is common usually due to malformation of the *vas deferens* or agenesis of the epididymis. At operation, the surgeon finds a Fallopian tube in the hernial sac. The testes are normal, apart from perhaps being unable to secrete MIS. The anatomy is important; the vas runs down the lateral wall of the uterus, so removing the uterus removes whatever small chance of fertility there might have been.

Hypospadias and DSD

The dividing line between hypospadias and DSD is not a clear one. Hypospadias is extremely common, affecting 1:125 boys in the USA, so it would appear unreasonable to look for evidence of an underlying DSD in every case. It is usually sporadic, and some cases are found with underlying defects of the urogenital system. A careful study of a series of 32 boys presenting consecutively with hypospadias failed to detect any significant endocrine defects. Fukami et al. described a mutation in an X-linked gene, Cxorf6, in three boys with penoscrotal hypospadias and micropenis.

Currently, investigations on the following types of hypospadias patients are recommended: those with severe perineo-scrotal hypospadias; those with an undescended testis; those with micropenis; those with dysmorphic features and/or short stature suggesting a chromosomal or genetic syndrome; and those with a positive family history of hypospadias. A chromosome analysis, pelvic ultrasound, serum FSH and LH, and serum testosterone, DHT, and androstenedione would all be useful in such cases.

46,XX Testicular DSD

Some degree of masculinization is sometimes found in children with a 46,XX karyotype. This condition is clinically comparable to Klinefelter syndrome. It represents some degree of testicular determination in the gonad. It may present with ambiguous genitalia at birth or may sometimes present later in with hypergonadotrophic hypogonadism, delayed puberty, or at times with complete masculinization and infertility.

This may result from the following conditions:

1. SRY mutation: Translocation of a small segment of Y chromosome is by the commonest cause of this condition accounts for about 80% of these cases.
2. SOX9 duplication: SOX9 has been proposed as a downstream gene responsible for the actions of

SRY; thus an overexpression has recently been found to be a significant cause of this condition.

3. Ovotesticular DSD: Ovotesticular DSD would definitely result in some testicular tissue formation hence the ambiguity.
4. Another gene linked with this condition is DAX 1. Although, classically responsible for hypogonadotrophic hypogonadism, sometimes it is also one of the genes regulating the expression of SRY, thus a mutation may result in maleness in individuals with 46,XX without the SRY mutation.
5. Other candidate genes and possible mechanisms have been proposed in individuals negative for SRY and the above genes. Some familial cases have been reported, and monozygotic twins have been reported with one having ovotesticular DSD and the other 46,XX testicular DSD without any cause, suggesting a similar mechanism.

Management

Correction of genital ambiguity depends on the sex of rearing assigned after taking into consideration the exact diagnosis, the genital appearance, the presence and location of gonads, and the future possibilities.

Another major factor which is to be considered is the high risk of dysgerminoma in gonads with testicular tissue, especially if they are located intra-abdominally.

Management

46,XY DSD

Appropriate Diagnosis

The first step in the proper management of these children is to make an appropriate diagnosis as far as possible. This is often difficult as the specialized tests, especially for the genetic markers, are not available in most places. However, a near accurate diagnosis should be made with the help of available investigations.

Factors Influencing the Decision on the Sex of Rearing

Time of Presentation

There is general agreement that every child with ambiguous genitalia should be assigned as either a male or a female and named appropriately. In the past, it was thought that the decision about sex of rearing had to be made as a matter of great urgency for psychosocial reasons. Decisions were made by doctors without much discussion with parents, or vice versa, and without waiting for the results of all the investigations. While parents may find waiting difficult, it is better to assign the appropriate gender after a complete diagnostic workup and a detailed discussion with the parents. If parents bring the child having already decided the sex for themselves, they greatly limit the options regarding the medical management.

When the Sex Has Already Been Assigned

If a sex has already been assigned by the family before a physician has been consulted, especially if some time has already elapsed, the family will be very defensive about their decision. They will want to avoid the change of sex, having to give a difficult explanation to the rest of the family and friends. Also, they would fear such information to generate a lifelong stigma, isolating the parents and the child. This factor greatly compounds the difficulty of medical management.

Underlying Diagnosis

This may influence the outcome, for example, in someone with severe partial androgen resistance, and the response to endogenous testosterone or even to testosterone supplements at the time of puberty is likely to be relatively poor. On the other hand, patients with 5α-reductase-2 deficiency and 17β–hydroxysteroid dehydrogenase deficiency are likely to show much better virilization and the descent of the testes at the time of puberty.

Appearance of External Genitalia

The severity of undervirilization with a more female type of genitalia also influences the decision of sex of rearing and the final outcome. Gonads may or may not be palpable. Once a decision has been made to rear the child as male, every attempt should be made to bring the testes down into the scrotum. If intra-abdominal testes cannot be brought down, they should be removed because of the risk of cancer.

Expertise Available Regarding Surgical Correction of the Problem

Pediatric urologic surgical expertise is a highly specialized area especially in regard to patients with ambiguous genitalia. The number of available cases is also limited and a wide spectrum of malformations exists. This is a major practical problem, especially in some of the more poorly resourced countries. Lack of specialized surgeons and/or their level of comfort with which they can handle these

cases vary a great deal across the world. This then becomes a limiting factor in provision of care to these children. Even in the resource constrained environment, it is best to identify and develop specific persons in the field so that they can acquire some kind of expertise and comfort level in dealing with these complex cases.

Long-Term Issues Regarding Sexuality

Penile size and urethral orifice: As is clearly acknowledged, there is severe limitation in the way penile reconstruction can be carried out even in the most developed countries when phallic size is small. Even the hypospadias repair in severe cases may require fairly exhaustive, staged surgeries that are not always followed by the ideal results. This may carry very serious psychological issues as the boy approaches puberty.

Erection and sexual intercourse: Boys who have had surgery to correct ambiguous genitalia face very significant problems as they approach puberty. They will need skilled counseling about their capacity to marry and enjoy intimate physical relationships. Long-term outcome studies provide some encouragement. Some boys experience a major psychological impact. Their thinking is sometimes much distorted, and this problem may be much bigger than the actual physical handicap. The consultation between the parents and the physician, endocrinologist, and surgeon should take into account all findings from the initial assessment and evaluation. It is reasonable to provide the family a realistic understanding of what is going to be possible, as far as the evidence can tell us. Only after all of this can a decision about the male sex of rearing be made.

Fertility: It is often not possible in these disorders, but a clear understanding must occur on parts of parents and the child himself once he is at the age where he is able to understand.

Social Issues

In many cultures around the world, the social acceptance of an unmarried male is more than an unmarried woman. Also men in some cultures have greater opportunities to be independent financially and socially than women, regardless of marital status.

Psychological Issues Around DSD

Psychological well-being is an important part of the quality of life. This is also of utmost importance in situations like DSD, where it is not just the physical state that matters, but also the state of mind.

A recent meta-analysis reviewed previously published literature on the psychological impact and well-being of individuals with DSD. There is a great degree of variation in the outcome and the number of people suffering from psychological disorders later in their life. There have been diverse results from different studies, some showing no impact and others reporting that 40–60% were affected.

Cultural Issues and Limitations in Management

Education and Health Economics

In resource-poor developing countries with poor literacy rates, high economic burden, and poor access to health care and resources, high dependence on alternative medicine makes the diagnosis and management of these hugely complex disorders extremely difficult. With the poor health resources, the priority is with other issues like malnutrition, infectious disease, and accidents which accounts for the bulk of mortality and morbidity. Logistic difficulties in access to health care make the situation worse. Doctors and other health workers in these far-flung areas have very little in terms of continuous medical education, making their knowledge far from adequate to deal with these conditions. Reliance on expensive and relatively advance testing like chromosome analysis even for the sake of classification also becomes a constraint in populations where these tests are not available or affordable.

Traditional Values and Beliefs

Strong cultural and traditional beliefs have a strong impact, and they significantly influence the way these disorders may be managed. Patients with disorders such as DSD which are not easy to explain scientifically often fall prey to people with beliefs in myths and misconceptions. This is further compounded by taboos and unwillingness of the communities to discuss and share the information with other even medical professionals and resorting to faith healers and shrines and purveyors of magic.

Male Preference

In developing countries, high infant mortality leads to a great insecurity in the families about the survival of their children which paradoxically increase the family size. This leads to an increase in financial burden on the

already poor families; hence the greater need for males as bread winner is perceived. In countries and cultures with land holding, often boys are destined to inherit more than the girls, and look after the affairs of cultivation, etc. Thus, a son is seen as insurance for the parents, someone to look after their need in old age. Hence, the insistence on male sex of rearing often results in poor management of these disorders. In Pakistan, there are families with CAH taking their babies away when they were told about the female gender of the child, refusing point blank to raise the baby as a female and insisting that something should be done to convert this into a boy.

Summary

To summarize the management of children with 46 XY DSD, an underlying diagnosis, its impact, and factors discussed above should be considered and shared with the family. Only then a decision is made about the proposed sex of rearing for the child. Once that decision has been made, subsequent management will vary according to the sex of rearing. In cases of female, a reconstructive surgery and gonadectomy is required. This would later be followed with female hormone replacement at puberty. In sex assigned males, all effort should be made to preserve and bring the gonads down, with removal of any gonad that cannot be brought down to a location where it can easily be palpated. In addition, a reconstructive surgery (hypospadias repair) is often required. Hormone replacement at the time of puberty would depend on whether or not gonads are able to produce some androgens.

Congenital Adrenal Hyperplasia (CAH)

Certain types of congenital adrenal hyperplasia in females fall under the category of DSD. The virilizing types of CAH (classical 21-hydroxylase deficiency, 11β-hydroxylase deficiency, 3β-hydroxysteroid dehydrogenase deficiency [3β-HSD]) are, together, the most common cause of genital ambiguity. In addition, two forms of CAH (17α-hydroxylase deficiency and 3β-HSD) are capable of causing undervirilization leading to ambiguity in genetic males.

The most common cause of CAH is 21-hydroxylase deficiency, which leads to inadequate glucocorticoid and mineralocorticoid synthesis. The higher ACTH as a feedback to insufficient cortisol production then results in an excess of precursors upstream of the block, some of which are channeled into enhanced androgen synthesis. The high androgen induces masculine changes: lengthening of the urogenital sinus internally, enlargement of the clitoris and fusion between the genital folds, causing ambiguity in a 46XX infant. The virilization at times may be severe enough for the child to be assigned a wrong sex at birth.

Adrenal Steroidogenesis

Steroidogenesis pathway (◉ *Fig. 383.5*).

Clinical Features of CAH

21 Hydroxylase Deficiency

This is by far the most common defect accounting for 90–95% cases of CAH. This is further divided into three different clinical phenotypes. The term "classical" indicates an enzyme deficiency severe enough to cause genital changes at birth in the sex most likely to be affected (female in the case of the virilizing forms, male in the forms causing undervirilization). The salient features of three subtypes are presented in (◉ *Table 383.2*).

1. Classical salt-losing form
2. Classical non-salt-losing form (sometimes referred to as "simple virilizing CAH")
3. Nonclassical form (formerly called "late onset" CAH)

Salt-Losing CAH

About 75% of patients with CAH fall into category, which is the most severe form of CAH. 21-Hydroxylase enzyme activity in these patients is almost zero. The resulting mineralocorticoid deficiency then causes excessive loss of sodium in the urine and retention of potassium, leading to hyponatremic dehydration (serum sodium can fall below 100 mmol/l) and moderate to severe hyperkalemia (levels above 11 mmol/l may be seen), which can cause cardiac arrest. The baby starts to vomit, worsening dehydration, becomes listless and anorexic with persistent vomiting of every feed, blood pressure falls, and blood glucose may become very low (because cortisol is a glucocorticoid). This severe illness, called an *adrenal crisis*, typically presents toward the end of the first week of life but may be delayed for weeks or even months. Females are born with genital ambiguity and *should* be diagnosed promptly because of this and not go into adrenal crisis, but this is not always

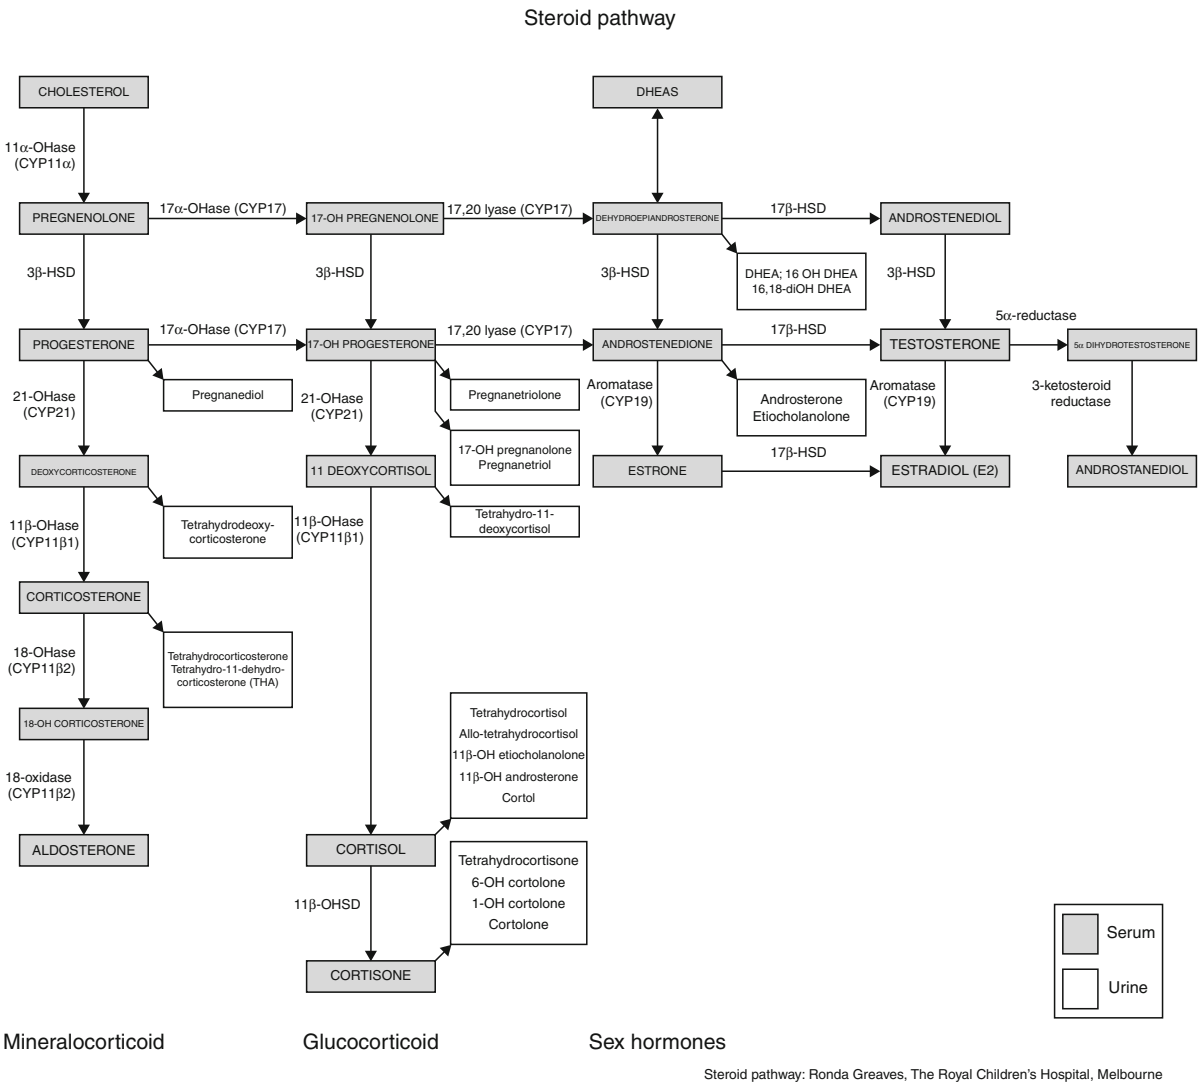

Figure 383.5
Steroidogenic pathway

the case. In males, there is no obvious genital change, and the onset of adrenal crisis, with persistent vomiting, is the first indication that there is something wrong.

Genetic Defect

21-Hydroxylase deficiency has an average gene frequency of 1:50, making CAH a relatively common autosomal recessive disorder. The gene for this disorder lies on chromosome 6 within the HLA locus. Two homologous genes exist. CYP21 is the active form and CYP21P is the inactive pseudogene. Most mutations result from the transfer of sequence between the pseudogene and the active gene, a phenomenon called *gene conversion,* but deletions, point mutations and many other types of mutation have been described.

Non-salt-Losing Form

This is the less severe variety of the disease, in that adrenal crisis is unlikely, because around 1–2% of enzyme activity is retained. Although some degree of salt wasting does occur in

Table 383.2
Characteristics of different types of congenital adrenal hyperplasia in 21-hydroxylase deficiency

	Salt wasting	Simple virilizer	Nonclassical
Frequency	1: 20,000	1:60,000	1:1,000
Enzyme activity	0%	1–2%	10–75%
Common genetic defect	236 Ile → Asp	172 Ile → Asp	281 Val → Leu
	237 Val→ Glu	356 Arg → Trp	30 Pro → Leu
	239 Met → Lys		
	8 bp deletion		
	Aberrant splicing		
Age of presentation	Newborn to 2 months	0–4 years	Child to adult, usually Puberty
Genital ambiguity	Present at birth	From birth to later	None
Somatic growth	Poor, −2 to −3 SDS below mean	Low, −1 to −2 SDS	Normal
Na	↓	N	N
K	↑	N	N
17 OH Progesterone	Markedly elevated	Moderately elevated	Normal basal level, High level in response to ACTH stimulation
Renin	↑	Normal or ↑	N

these children (as indicated by high levels of plasma rennin activity), it does not reach symptomatic levels, except perhaps in the neonatal period when renal tubular reabsorption of sodium is relatively inefficient in all infants. There will be, however, a variable degree of genital ambiguity in a 46 XX patient. If this passes unnoticed, the girl may experience progressive virilization over months or even years; the clitoris can become extremely large, linear growth and bone age advancement may be accelerated, gender behavior will be masculine, and if the condition goes on untreated for long enough, gender identity may be affected, making a girl think she is a boy. This happens commonly in resource-poor countries, and it leads to major problems for affected individuals.

Nonclassical Variety

Although not strictly falling under the purview of DSD, this variety is mentioned here for the sake of completeness of different forms. Cortisol deficiency and hence the ambiguity of genitalia is not found. However, the androgen excess manifests itself either later in childhood, in puberty or in adult life. The female patient may present with severe acne, hirsutism, male type of baldness, oligo/amenorrhea, and/or infertility.

Medical Management of 21-Hydroxylase Deficiency CAH

Glucocorticoid Replacement

The primary steroid that should be used during childhood is hydrocortisone, preferably in three divided doses, as other forms may have an adverse impact on growth. Later, when the bone age matures either prednisolone or dexamethasone may be used as replacement drug.

Dosage has been a matter of concern and controversy over the years, as it is difficult to find the right dose that will suppress the corticotrophin axis and thereby prevent the androgen excess, without incurring adverse effects of over-treatment. The currently favored dose is 12–15 mg/m^2 in two or three divided doses. The higher dose is given in the morning to mimic the circadian rhythm of steroid secretion.

Mineralocorticoid Replacement

It was previously thought that mineralocorticoid replacement was only needed by patients with salt wasting CAH, but it is now clear that it should be used even in the non-salt wasting form as it allows lower doses of

glucocorticoids to be used and this is beneficial for linear growth. Fludrocortisone is administered in a dose of 150 μg/m^2/day once daily and monitored using a plasma renin activity assay. Where a PRA assay is not available, a dose of 100–200 μg can be used, irrespective of body weight and regular arterial blood pressure monitoring would reduce the risk of overdosage. Infants are relatively resistant to the renal effects of fludrocortisone. As the child grows older, the dose actually goes down.

Children affected with salt wasting CAH should be given sodium chloride 2 mmol/kg/day along with their milk. As they grow older, they themselves develop a craving and liking for the salty food.

Stress dosing is needed to prevent adrenal crisis. As the glucocorticoids are used as replacement, this should mimic the natural responses of their hormones in the moments of stress. The usual advice is to double the dose of hydrocortisone for a short time (2–3 days) during intercurrent illnesses, especially those associated with fever or severe pain. In the surgical situation, intravenous steroids are usually required (◉ *Table 383.3*).

Table 383.3
Corticosteroid doses required during surgery in children with congenital adrenal hyperplasia

Minor surgery			
	3–10 kg	10–20 kg	>20 kg
Hydrocortisone			
Either before "nil by mouth"	25 mg PO	50 mg PO	100 mg PO
OR at induction of anesthesia	25 mg IV	50 mg IV	100 mg IV
Postoperative	Same dose six hourly until oral fluids		
Major Surgery			
	3–10 kg	10–20 kg	>20 kg
At Induction	25 mg IV	50 mg IV	100 mg IV
During surgery	1 mg/h IV infusion	2 mg/h IV infusion	3 mg/h IV infusion
After surgery	Continue IV same dose until tolerating oral fluids	Then oral dose doubled for 24 h	Then normal oral dose
Fludrocortisone	Restart as soon as tolerating oral fluids		
Intravenous fluids			
	<10 kg	10–30 kg	>30 kg
Amount of fluids	100 ml/kg	80 ml/kg	60 ml/kg
Type of fluids	5% Dextrose 0.45% Saline		

Surgical Management

Bilateral Adrenalectomy

A number of papers have discussed the option of removing both adrenal glands in patients, particularly females, who's CAH proves especially difficult to manage. The argument in favor is that abolition of adrenal androgen production eliminates androgen-related problems. Since it is no longer necessary to use suppressive doses of glucocorticoids, replacement doses can be lowered. The contrary arguments are that there is a risk of mortality and morbidity associated with surgery and anesthesia and that the irreversibility of adrenalectomy eliminates the option of further medical intervention. The authors believe that bilateral adrenalectomy does have a place, but it should be reserved for the difficult cases when all other avenues have been tried.

Genital Reconstruction

Until the mid-1960s, the treatment for an enlarged clitoris was total removal. Thankfully, this practice has now been abandoned in most places. Clitoral reduction, which can be done using a variety of different surgical techniques, is now preferred. Patient advocacy groups have seriously challenged the need for clitoral reduction, arguing that an enlarged clitoris can function perfectly well as a sexual organ when it is intact, but may not retain full sensitivity following surgery. Parents generally want to have the surgery done because they would prefer not to be reminded of the ambiguity. Patients who have not had surgery do experience discrimination; they would need emotional support during childhood and adolescence if they were asked to grow up with their original anatomy, and their families might also need support. Vaginoplasty is necessary at some stage to correct fusion of the genital folds in female patients. Those who have a uterus will menstruate and the blood needs to be able to escape. Without vaginoplasty, sexual intercourse will be impossible. The timing of the procedure varies from place to place depending upon the expertise available and the comfort level of the surgeon to carry out the procedure. However, it generally ranges from 2–4 months to 2 years on an average. Sometimes the introitus requires dilatation or minor surgery during adolescence.

Sex Chromosome Aneuploidy DSD

Klinefelter Syndrome

Although genital ambiguity is not usually a feature of Klinefelter syndrome (47,XXY or mosaic), it does occasionally occur and can be associated with gender dysphoria.

Turner Syndrome and Its Variants

Turner syndrome (monosomy X) affects one girl in every 2,500 births. Although classically the karyotype is 45,X, many patients have mosaic karyotypes such as 45,X/46,XX. The clinical features of Turner syndrome vary considerably. Some girls are severely affected, with webbing of the neck (a feature remaining after a cystic hygroma has resolved), coarctation of the aorta, gonadal dysgenesis, linear growth retardation, renal anomalies, and many other possibilities. Others, however, have a normal appearance but have growth impairment and gonadal dysgenesis. A full description of Turner syndrome and its management is beyond the scope of this chapter.

Some girls with the Turner syndrome phenotype have ambiguous genitalia, and most are found to have either 45,X/46,XY mosaicism or 45,X (+mar), meaning that a chromosomal fragment, called a marker, is present in all cells. Markers are often derived from the Y chromosome, and their presence may indicate that the girl has an increased gonadoblastoma or dysgerminoma. For this reason, when a marker is identified, it is necessary to investigate further and determine the chromosome of origin of the marker, using both X and Y probes. If Y-chromosome material is found, the streak gonads must be removed.

45,X/46,XY Partial Gonadal Dysgenesis

Of all fetuses conceived who have this karyotype, only 5% are born with ambiguous genitalia. The other 95% have a normal male phenotype, although 27% of these will have abnormal gonadal histology. The term "mixed gonadal dysgenesis" was used to refer to a patient with a streak gonad on one side and a better differentiated, but still dysgenetic, testis on the other. The term "partial gonadal dysgenesis" is now the preferred term. The condition carries a high risk of gonadal malignancy, and to manage the risk, all intra-abdominal streaks must be removed at diagnosis, as must any intra-abdominal testis that cannot be brought down. If the patient is raised female, both testes would be removed. If the patient is raised male and a scrotal testis is retained, lifelong surveillance for the development of cancer is mandatory. A biopsy after the onset of puberty is advised. The biopsy material should be sent for immunohistochemical staining with OCT 3/4 and Placental/germ alkaline phosphatase (AP) as these are markers of carcinoma in situ when positive during adolescence.

Approach to a Child with DSD

History

- Family history of ambiguous genitalia, any DSD in the family
- History of unexplained early deaths in siblings or still births
- Maternal history of drugs (especially anabolic steroids, etc.), alternative medicine like hakim, ayurvedic medicine (often contain steroids)
- Maternal illnesses like tumors, etc.
- Pregnancy: any history of virilization during pregnancy

Examination

- Any dysmorphic features, especially cleft lip, palate, limb deformity
- Complete systemic examination to look for any other system involvement especially congenital heart disease etc.

Genitailia

- Excessive pigmentation
- Phallic size: measure the stretched length from pubic tubercle to the tip of penis, age appropriate centile charts are available with standard deviation to plot the penile size
- One should also observe the presence or absence of chordae
- Urethral opening and location, any other perineal opening
- Scrotal development
- Presence and location of gonads, feeling of gonads, presence of epididymis
- Assess the degree of virilization: This is graded by either Prader stage or external masculinization score

Investigations

The first investigation is to perform the chromosomal analysis in order to classify and categorize these children

properly. However, cytogenetic testing may not be readily available in some parts of the world. Also, even if done during the first day, it can take weeks before the results come back. Thus the possibility of a salt-losing variety of DSD must immediately be covered.

1. Chromosomal analysis
2. Pelvic ultrasound: for uterus, gonads, and internal genitalia
3. Serum electrolytes to look for the possibility of hyponatremia and hyperkalemia

Further investigation may differ depending on the chromosomal type.

46 XY DSD

1. Basal or stimulated testosterone level
2. FSH/LH
3. Urine steroid profile
4. Genitogram
5. Genetic testing when required
6. Androgen receptor assay in cultured fibroblast
7. Gonadal biopsy (if required)

46 XX DSD

1. Serum 17 OH Progesterone
2. Serum 17 OH Pregnenolone
3. Serum 11 Deoxycortisol
4. Plasma renin activity
5. Serum aldosterone
6. Serum ACTH
7. Serum testosterone/androstenedione
8. Urine steroid profile
9. Genetic analysis
10. Gonadal biopsy (if required)
11. Androgen receptor mutation analysis
12. Genetic screening for gene responsible for gonadal differentiation if the above investigations fail to clinch an appropriate diagnosis

A Vignette from Pakistan

An 8 year old walked into my clinic, hailing from a remote area, after having travelled nearly a thousand miles for the consultation. She covered herself with a head scarf which covered part of her face as well, and kept sitting in clinic with her head down, avoiding to look towards me and barely speaking. She was delivered at home, no virilization was appreciated at that time, mother noticed that she started developing pubic hairs enough for her to remove by the time she was 2. A surgeon was consulted for her associated clitromegaly and down came the knife. She had her clitoral resection and then left without any treatment. When she saw me at 8, she had a clear moustache and a beard with a deep masculine voice. She was later found out to have a 46XX DSD, CAH of non salt wasting type.

This to me was the classic example of things going wrong around the management of DSD in a developing country in this day and age. Wrongly diagnosed, wrongly managed both surgically as well as medically and lack of further monitoring or follow ups, she ended in disaster, for a relatively easy to manage disorder.

Issues Regarding DSD Management in the Developing Countries

1. Medical awareness about the condition may be poor even among the health workers. The subject is not covered enough in the medical curriculum, or in the lower diploma of pediatrics, and therefore the physicians are not clear in their understanding about the subject or confident in the ways they handle them.
2. Poor accessibility to health care. In remote areas, traveling and cost both greatly limit accessibility.
3. Lack of referral system: retards the process of referral to a specialized center.
4. Poverty: limits the referral, and following medical advice.
5. Poor literacy.
6. Social taboos: already mentioned add to the misery.
7. Lack of investigation facilities: endocrine investigations being very sensitive and generally expensive are not available for a large portion of population.
8. Lack of availability of medicines: Hydrocortisone and fludrocortisone, despite being life-saving medications, are not registered in many countries. Pharmaceutical mergers and sell outs, general recession, and the products not being hugely profitable have added to the difficulty in availability, and this worsens the misery of patients.
9. Lack of expertise: Pediatric endocrinologists and trained surgeons skilled to do the job and an understanding of the subject is a rare commodity among the developing countries.

Future Directions

Dramatic changes are expected to come in the area of genetic diagnosis. As gene chip (microarray) technology develops, it will be possible to rapidly and accurately screen a patient's entire genome for mutations. Such

screening will not only simultaneously examine all of the genes currently known to cause DSD, but will also detect mutation "hot spots" in other genes which, until now, have not been implicated in DSD. In countries able to afford such technology, most patients will receive an accurate diagnosis. Will it be possible to predict gender identity any more accurately than it is done now? At present, there is very limited understanding of the factors that determine gender identity in any individual, whether affected by a DSD or not. It is possible, however, that there are centers in the brain which are permanently altered, structurally, functionally, or both, when exposed to critical levels of androgen at critical times and that these changes control gender identity. It may become possible, using a combination of functional brain imaging and genetic (or epigenetic) screening, to identify where such changes take place and what the nature of them is. This would make it possible to design hormonal and surgical treatment programs that would avoid the disastrous complication of gender identity disorder.

The broader society is starting to take an interest in the ethics and human rights aspects of medical management of DSD and this is a good thing. Medical management of DSD has been influenced far too much by the imagined need to make life-altering decisions of extraordinary importance on behalf of infants with DSD because of the "social emergency." The sense of emergency would evaporate if the broader community was well educated about DSD and more accepting of it as a variation, albeit one with serious medical implications. Parents would then be able to take more time in deciding about the sex of their baby and in weighing up the options regarding treatment. The influence of culture and belief on attitudes and decision making is a subject worthy of much more detailed analysis. Many long-term outcome studies have already been done, but they have often been very superficial and have failed to examine the issues most important to the sufferers themselves. Future studies will take into account the more exact genetic diagnosis, the broader perspectives of the community in which the patients have grown up, and outcomes in control groups. Broader and deeper comparisons of outcomes between societies with very different attitudes toward gender and sexuality will be extremely helpful.

Many resource-poor countries are currently unable to meet even the most basic needs of their citizens who have chronic medical conditions, and mortality rates are high. Survivors with DSD suffer terribly. A huge effort on the part of governments, pharmaceutical companies, and aid organizations is needed to ensure *access for all* to essential medications, such as hydrocortisone and fludrocortisone for children with CAH. Laboratory scientists can help by developing cheaper and more robust assays for steroids such as DHT, 17-hydroxyprogesterone, and androstenedione, suitable for widespread use in developing countries. Mental health service planners should continue to advocate improved access to mental health services in the world's poorest countries.

384 Disorders of the Adrenal Gland

Meena P. Desai · Nalini S. Shah

Adrenal Disorders

Disorders of the adrenal glands specifically the adrenal cortex are being recognized with increasing frequency in pediatric age group. The anatomical presence of the gland was detected in mid sixteenth century but the importance of its function was not realized upto mid-nineteenth century, till Addison's description of adrenal insufficiency. The terms *glucocorticoids* and *mineralocorticoids* were proposed by Selye in 1930s. Reichstein and Kendall shared the Nobel prize in Medicine in 1950 for detailing the structure and isolating various adrenal steroids which helped chemical synthesis of these hormones, led to better understanding of the relationship of adrenal steroids to their precursor products and their physiologic role. Based on this, both Wilkins et al. and Bartter et al. tried to treat CAH with cortisone for the first time in 1950. In past 5 decades very significant advances have been made in isolating some of the steroidogenic enzymes, understanding the pathways of steroid hormone biosynthesis, identification of the genes encoding these steroidogenic enzymes and characterizing the enzymatic errors responsible for the various inherited adrenal and gonadal disorders. Synthesis of many new potent analogs of the naturally occurring steroid hormones have augmented clinical research, and promoted their physiologic and pharmacologic uses in a variety of adrenal as well as nonadrenal systemic disorders.

Adrenal Embryology

The steroidogenic cells of the adrenal cortex and gonads have a common origin in the gonadal ridge appearing by 5–6 weeks followed by migration of adrenal cells retroperitoneally and caudal migration of the gonadal cells. The encapsulated adrenal gland with adrenal cortex of mesodermal origin and adrenal medulla consisting of chromaffin cells derived from neuroectoderm is clearly visible by 8th week of gestation close to the upper poles of the relatively small kidneys. By 9–10 weeks the cells of the fetal zone are capable of steroidogenesis.

The fetal adrenal glands at birth weigh nearly 8–9 g approximately twice the size of the adult adrenals, and function actively during fetal life with cortisol biosynthesis occurring by first trimester. The fetal adrenal cortex has two principal zones, an outer "definitive" zone responsible for the production of both mineralocorticoids and glucocorticoids and a much larger "fetal zone" generating androgenic precursors for the placental synthesis of estriol. After birth the large fetal zone involutes and disappears by 1 year of age. Full differentiation of the two outer zones is attained by 3 years of age. The zona reticularis is not fully developed until puberty.

Presence of specific nuclear transcription factors is essential for the development and steroidogenic function of adrenal glands. One such factor is DAX-1 (dose sensitive sex reversal-adrenal hypoplasia congenital X chromosome related) where loss of function mutation causes primary adrenal deficiency manifesting soon after birth and later failure of pubertal development. Mutations of DAX1 gene encoded on Xp21, cause congenital adrenal hypoplasia and hypogonadotropic hypogonadism. Mutation in transcription factor SF-1 (steroidogenic Transcription Factor −1) encoded on chromosome 9q33 causes complete adrenal aplasia with gonadal agenesis. Besides these two adrenal specific transcription factors, and genes, IGF1 and II, other factors like fibroblast and epidermal growth factors - activin and inhibin, influence adrenal development, Underdeveloped ventral medial hypothalamus also influence adrenal development.

Adrenal Histology and Physiology

The three histologically identified zones of the adrenal cortex are the zona glomerulosa next to the capsule synthesizing aldosterone, the fasciculata synthesizing glucocorticoids in the middle and the inner most, zona reticularis synthesizing adrenal androgens. The adrenal medulla is involved with synthesis of catecholamines. The three cortical zones constitute 15%, 75% and 10% of the adrenal cortex of the older child and adults. The histologic characteristics of the three zones of the adrenal cortex also differ, as regards cellular size and their arrangement, the cytoplasmic : nuclear ratio and intracellular lipid inclusions. The zona fasciculata is characterized

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_384,

by larger cell size, higher C:N ratio, higher lipid content in comparison with the other two zones. The cells are arranged in radial cords. In the inner most zona reticularis, cells are arranged in irregular anastomosing cords. Despite histologic demarcation of the three zones there is some degree of functional as well as histological overlap as shown by immunocytochemical data overlap. The zonal borders are somewhat arbitrary.

Zona glomerutosa is characteristically defined by the expression of aldosterone synthase (P450c 11As) and the absence of 17α-hydroxylase and 17,20-lyase expression (P450c17). The glomerulosa cells specific enzyme is P450c11As and has abundant angiotensin II and ACTH receptors, the later playing a permissive role for mineralocorticoid synthesis. P450c17 deficiency is associated with modest degree of glucocorticoid deficiency as corticosterone produced in excess has some degree (nearly half as potent) of glucocorticoid action. This excess of corticosterone converted to deoxycorticosterone (DOC) leads to mineralocorticoid hypertension, and salt retention along with low aldosterone levels. The zona fasciculata is the principal site associated with cortisol production and is characterized by the presence of P450c11B and P450c17 but absence of P450c11As, and relative lack of angiotensin II receptors. P450c21 deficiency is the most common defect of the zona fasciculata. The gene for P450c21 is expressed in all three zones of the adrenal cortex and can explain why its mutations can destroy all 21-hydroxylase activity leading to absence of mineralocorticoid and glucocorticoid biosynthesis. Absence or low levels of cortisol stimulate excess ACTH secretion diverting pregnenolone to the adrenal androgen pathway with androgen overproduction leading to prenatal virilization of female fetuses. Missense mutations that spare some amount of 21-hydroxylase activity manifests as non-salt wasting "simple virilizing" condition. Low levels of enzymatic activity in these patients with minimal cortisol production helps in producing near normal amounts of aldosterone.

Adrenocortical Steroidogenesis

The main pathways of adrenal steroidogenesis includes only few steroids though many have been isolated from adrenocortical tissue. The pathways of steroid biosynthesis is shown in ❯ *Fig. 384.1*.

Cholesterol uptake, storage, transport: Initial steps in adrenal steroidogenesis consist of cholesterol uptake, storage and transport of cholesterol which is the precursor and the initial substrate for all adrenocortical steroid hormones. Nearly 80% of its supply is provided by plasma low-density lipoproteins (LDLs) derived from dietary cholesterol though denovo synthesis by adrenals from acetate is possible. The cortical cells take up LDL cholesterol esters by specific cell surface receptors by endocytosis to be stored or converted to free cholesterol. The transfer (importation) of cholesterol across the mitochondrial outer and inner membrane is the initial rate limiting step in adrenal steroidogenesis. Storage of cholesterol in lipid droplets is controlled by cholesterol esterase and synthetase. ACTH stimulates esterase and inhibits synthetase.

StAR protein is synthesized by steroidogenic cells in response to trophic hormone stimulation. Steroidogenic acute regulatory protein or StAR plays an important role as a factor necessary for the rapid flux of cholesterol (from outer to inner mitochondrial membrane). It promotes acute synthesis of aldosterone following angiotensin II stimulation, of cortisol after ACTH stimulation, and of gonadal sex steroids after LH stimulation. Mutation of StAR is noted in lipoid CAH. It has a very short half life and is the main short term regulator of steroid hormone biosynthesis. Although StAR plays central role in the synthesis of steroid hormones, some steroidogenesis can occur independently.

Steroidogenic Enzymes

The generic term *cytochrome P450* (so named for pigment 450) is used for a large family members of steroidogenic oxidative enzymes consisting of about 500 aminoacids with a molecular mass of about 50 kDa with a central hememoiety. Majority of these enzymes metabolizing numerous exogenous and endogenous toxins, drugs, environmental pollutants, xenobiotics are in the endoplasmic reticulum of the liver. There are five distinctive P450 enzymes located in adrenal mitochondria, which are necessary for adrenal steroidogenesis. These are shown in ❯ *Fig. 384.1*. Two isoenzymes (P450c11B and P450c11As) of P450c11, catalyze 11β-hydroxylase, 18-hydroxylase and 18-methyloxidase activities. 17α-hydroxylase and 17,20-lyase activities are catalyzed by P450c17 located in the endoplasmic reticulum and P450c21 catalyzes the 21-hydroxylation of both mineralocorticoids and glucocorticoids. The association of cytochrome P450 with 21-hydroxylation was first demonstrated in 1965. P450aro in the endoplasmic reticulum in the gonads and few other tissues, catalyzes aromatization of androgens to estrogens.

P450scc: The *cholesterol side-chain cleavage enzyme* P450scc formerly known as 20,22-desmolase, with a molecular mass of 50 kDa, is encoded by a single gene on chromosome 15. All steroid hormone biosynthesis is

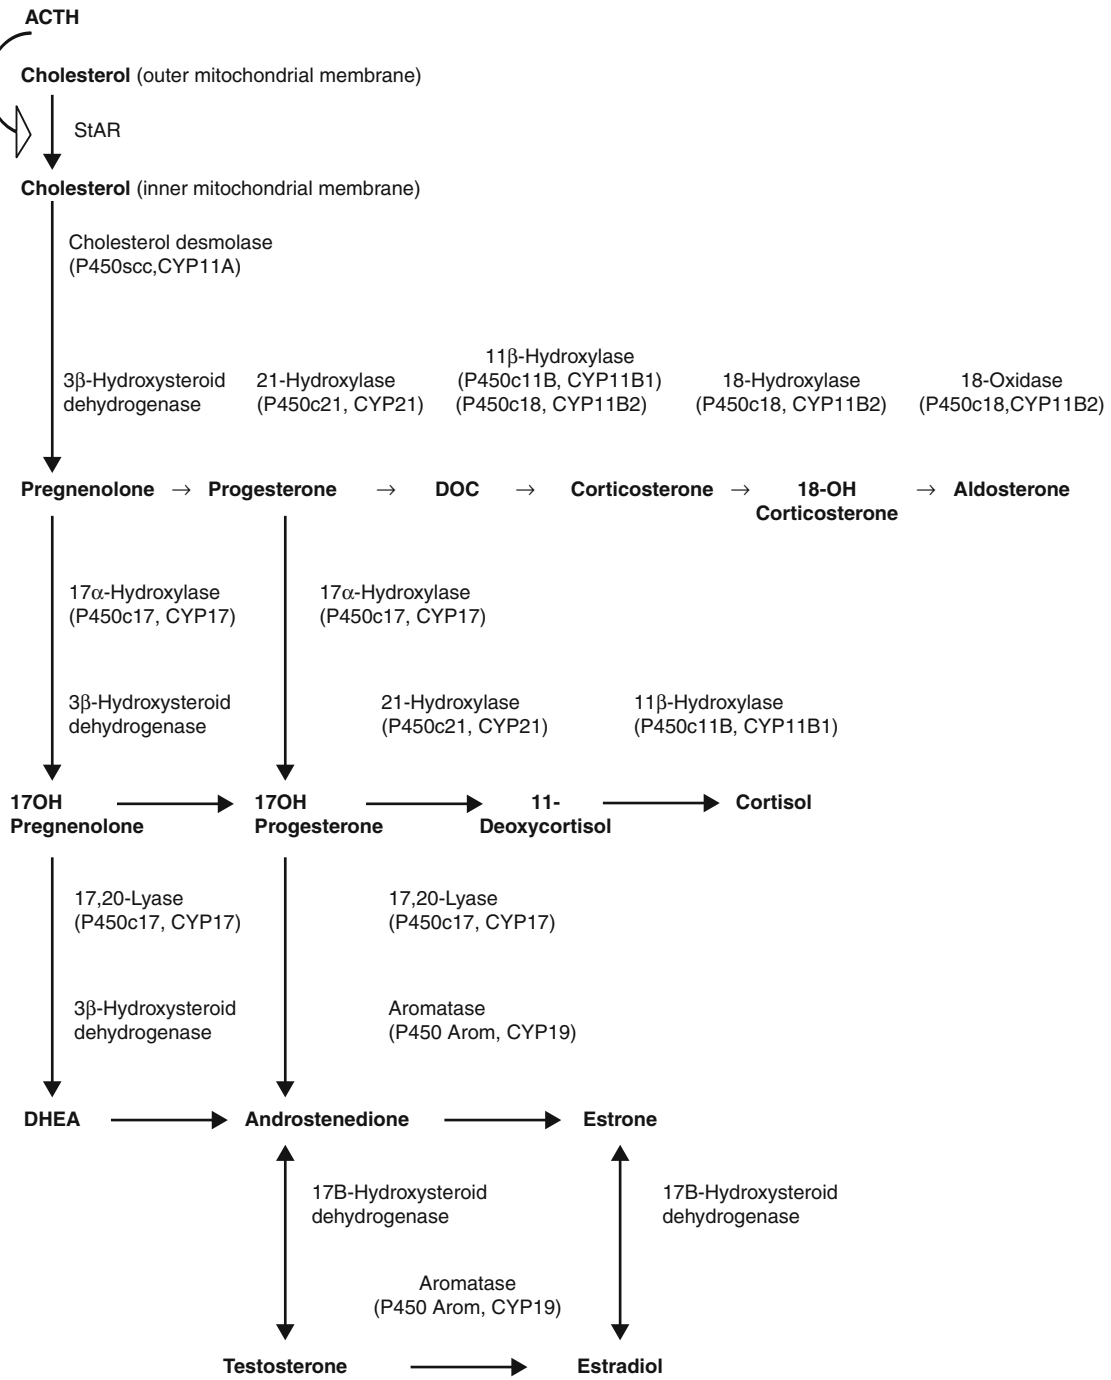

Figure 384.1

Pathways of steroid hormone biosynthesis for adrenal synthesis of mineralocorticoids (aldosterone), glucocorticoids (cortisol), and androgens (DHEA, androstenedione) arranged vertically with corresponding enzymatic activity for bioconversion as indicated. Names for the activities mediated by specific cytochromes P450 are indicated in parentheses. Dashed arrows indicate reactions which are extraadrenal primarily in gonads. P450c18mediates 11B-hydroxylase activity in the zona fasciculat to convert 11-deoxycorticosterone (DOC) to corticosterone and 11-deoxycortisol to cortisol. P450c18 mediates 11B-hydroxylase, 18-hydroxylase, and 18-oxidase activities in the zona glomerulosa for the conversion of DOC to aldosterone

initiated through the action of this one enzyme. Mitochondrial conversion of cholesterol to pregnenolone is the first rate – limiting and hormonally regulated step in the synthesis of all steroid hormones. It mediates 20α and 22α hydroxylation and scission of cholesterol side chain to yield pregnenolone at the mitochondrial inner membrane (Fig. 384.1). Pregnenolone then diffuses out of mitochondria into the endoplasmic reticulum for further processing into adrenal zone dependent adrenocortical hormones. Experimental evidence shows that deletion of the gene for P450scc, the initial step in steroidogenesis (Fig. 384.1) is incompatible with life. Rapid or acute release of cortisol into the circulation is controlled by cholesterol access to the rate limiting P450scc enzyme while as long term regulation of steroidogenesis by ACTH occurs at the level of gene transcription. Two accessory proteins, adrenodoxin reductase and adrenodoxin help in three successive oxidative reactions to cleave the C20, 22 carbon bond.

Hydroxysteroid dehydrogenases: This group of enzymes, play a critical role in both, the adrenals and the gonads. The different isoenzymes, include the 3α and 3β-hydroxysteroid dehydrogenases the two 11β-hydroxysteroid dehydrogenases, and a series of 17β-hydroxysteroid dehydrogenases.

3β-Hydroxysteroid dehydrogenase/Δ5 – Δ4 Isomerase: There are two isoenzymes of 3β HSD, encoded by separate genes. Type II enzyme catalyzing 3βHSD activity in the adrenals and gonads and Type 1 in placenta, breast and extraglandular tissues. Pregnenolone produced from cholesterol may undergo 17α-hydroxylation by P450c17 to yield 17-hydroxypregnenolone or can be converted to progesterone by 3β-hydroxysteroid dehydrogenase considered the first biologically important steroid in the pathway. A single enzyme 3-βHSD converts Δ5 to Δ4 steroids (Fig. 384.1): pregnenolone to progesterone, 17α-hydroxypregnenolone to 17α-hydroxyprogesterone (17-OHP), dehydroepiandrosterone (DHEA) to androstenedione (AD) and androstenediol to testosterone.

P450c17: This is a single enzyme with activity of two enzymes, causing 17α-hydroxylation of pregnenolone to 17-OH pregnenolone and of progesterone to 17-OHP progesterone (Fig. 384.1). The 17,20lyase activity of P450c17 converts 17-OH pregnenolone to DHEA but very little 17-OHP is converted to androstenedione (AD). The absence of this enzyme P450c17 prevents synthesis of both adrenal and gonadal steroids. The single gene for P450c17 has been cloned which localizes to chromosome 10q24.3. This deficiency is rare. To date 26 mutations have been identified.

P450c21: P-450c21 activity is localized to adrenal glands however 21 hydroxylase activity is described in extraglandular tissues in the fetus and adults. Hence, in patients with absent adrenal 21-hydroxylase appreciable concentration of 21-hydroxylated steroids may be detected in the plasma. The 21-hydroxylation of progesterone to Deoxycorticosterone (DOC) and of 17-OHP to 11-deoxycortisol is catalyzed by the enzyme (P450c21) 21α hydroxylase (Fig. 384.1). This 21-hydroxylating step is of great clinical interest as more than 90% of all cases with congenital adrenal hyperplasia (CAH) have this abnormality. This inherited genetic disease is associated with salt wasting with high mortality in early infancy if unrecognized especially in male infants. Complex problems of management are related to deficiency of glucocorticoids and mineralocorticoids (aldosterone) and diversion of precursors with formation of excess of androgenic compounds leading to virilization. There are two separate 21-hydroxylating enzymes differentially expressed in the adrenal cortical zones synthesizing aldosterone or cortisol. P450c21 characterization suggests that there is only one 21-hydroxylase encoded by a single functional gene on chromosome 6p21. This gene lies in the middle of the major HLA locus and is closely linked to specific human leucocyte antigen types.

P450c11β and P450c11AS: These two closely related enzymes encoded by tandemly duplicated genes on chromosome 8q21-22, are important for catalyzing the final steps in the synthesis of glucocorticoids and mineralocorticoids. The more abundant and classic 11β hydroxylase (P450c11β) converts 11-deoxycortisol to cortisol and 11-deoxycorticosterone to corticosterone. P450c11β involved in synthesis of cortisol is encoded by a gene CYP11β1 primarily induced by ACTH. Thus patients with disorders in P450c11β have classic 11β-hydroxylase deficiency but can still produce aldosterone, whereas patients with disorders in P450c11AS have the ability to produce cortisol but have a rare form of aldosterone deficiency (corticosterone methyloxidase deficiency). P450c11AS is found only in the zona glomerulosa where it has 11β-hydroxylase, 18-hydroxylase and 18-methyloxidase (aldosterone synthase) activities finally needed to convert DOC to aldosterone.

17B-hydroxysteroid dehydrogenase: There are several 17-βHSDs with some of these with very little 17βHSD activity. The actions of enzymes 17βHSD-III and I occur principally in the testes and ovaries while 17βHSD-II is confined to placenta, liver, and other tissues. Type I is also known as estrogenic 17βHSD and expressed in ovarian granulosa cells, where it produces estriol. 17βHSD-III is the androgenic form expressed only in testes, and associated with male pseudohermaphroditism often termed as 17-ketosteroid reductase deficiency. 17βHSD-III converts dehydroepiandrosterone (DHEA) to androstenediol, and

androstenedione (AD) to testosterone, whereas 17βHSD-I converts estrone to estradiol.

Aromatase: P450aro; A microsomal aromatase produces estrogens by aromatization of androgens. It is also expressed in extraglandular tissues especially adipose tissue which converts adrenal androgens to estrogens. At the epiphyses of the growing bones it can convert testosterone to estradiol thus accelerating epiphyseal maturation.

Steroid sulfatransferase and sulfatase play a role in hydrolyzing steroid sulfatase. In the fetal adrenal and placenta, diminished or absent sulfatase deficiency reduces the pool of free DHEA available for placental conversion to estrogen, with resulting low concentration of estriol, in maternal blood and urine. It also converts peripheral DHEA sulfate (DHEAS) to active DHEA.

11β-Hydroxysteroid Dehydrogenase converts cortisol to cortisone which is metabollicaly inactive. The interconversion of cortisol and cortisone is mediated by two isoenzymes of 11β-hydroxysteroid dehydrogenase (11βHSD), each one with oxidase and reductase activity.

The Type I (11βHSD-I) enzyme is expressed on glucocorticoids responsive tissues such as liver, testis, lung and proximal convulted tubule. 11βHSD-II catalyzes oxidation of cortisol to cortisone and prevents cortisol from overwhelming renal mineralocorticoid receptors, placenta and fetal tissues, hence it plays an important role in fetal life.

Fetal Adrenal Steroidogenesis

The Fetoplacental Unit

Fetal adrenocortical steroidogenesis begins around 6 weeks of gestation and differs from that in the postnatal gland. Major cholesterol source for steroid synthesis in the fetal adrenal gland is provided by fetal liver. The relatively low 3βHSD-II activity and high 17,20-lyase activity in the large fetal zone of the adrenal, accounts for the huge amount of DHEA and DHEAS production for conversion to estrogens by the placenta. The high sulfotransferase activity also favors conversion of DHEA to DHEAS. The DHEAS undergoes 16α-hydroxylation to 16α-OH DHEAS in the fetal liver. The placenta with its high steroid sulfatase activity uses DHEA and DHEAS as substrates for estrone and estradiol, and 16α-OH DHEAS as a substrate for estriol. Thus placental estrone and estradiol are derived equally from fetal and maternal precursors; estriol is exclusively of fetal origin. The significant amount of cortisol produced by fetal adrenals is converted to cortisone by the enzyme 11-β hydroxysteroid dehydrogenase. Towards term, adrenal cortisol secretion increases and the conversion to cortisone decreases. Aldosterone production is low in midgestation but increases near term.

Fetuses with genetic disorders of adrenal steroidogenesis can produce sufficient adrenal androgens so as to cause virilization in a female fetus. The process of masculinization of the genitalia being completed by 12th week of gestation. Prenatal treatment with oral dexamethasone given to the mother at 6–10 weeks of gestation can significantly reduce fetal androgen production and thus minimize virilization of female fetuses.

Regulation of Steroidogenesis

The Hypothalamic-Pituitary-Adrenal Axis

Cortisol Secretion

Cortisol the major secretory product of the adrenal cortex is regulated by the interaction of the hypothalamus, pituitary, adrenal glands and other neural stimuli. Hypothalamic corticotrophin-releasing factor (CRF) a 41-aminoacid peptide, synthesized by neurons of the paraventricular nucleus is the most important stimulator of anterior pituitary ACTH secretion. The same hypothalamic neurons also produce the decapeptide arginine vasopressin (AVP) also known as ADH. AVP augments CRH action. Both are secreted in the hypophyseal portal circulation in a pulsatile manner leading to pulsatile release (ultradian rhythm) of ACTH in varying amplitude through 24 h with pulses of ACTH and cortisol occurring every 30–120 min. The normal diurnal rhythm of ACTH and cortisol begins to be established by 1 year of age and often is well established by 3 years of age with ACTH peaking around the time of waking (4–6 AM) and cortisol by 8 AM. The levels are low in late afternoon and evening being lowest 1–2 h after sleep at night. The intrinsic rhythmicity of synthesis and secretion of CRF by the hypothalamus probably constitutes the basis of this diurnal rhythm as the hypothalamic content of CRF is lowest at 4 AM but this may be influenced by other factors like light/dark and feeding cycles Physical stress of severe infection, trauma, major surgery can increase the secretion of ACTH and cortisol.

Pituitary ACTH a 39-aminoacid peptide, is derived from a larger molecule, a 241-aminoacid protein known as pro-opiomelanocortin (POMC) (*Fig. 384.2*). Ectopic ACTH, in ACTH producing tumors in adults is derived from POMC precursor secreted from extrapituitary sites. This precursor peptide is also the source of (β-LPH), β lipoprotein, ACTH. β-LPH on cleavage can yield several

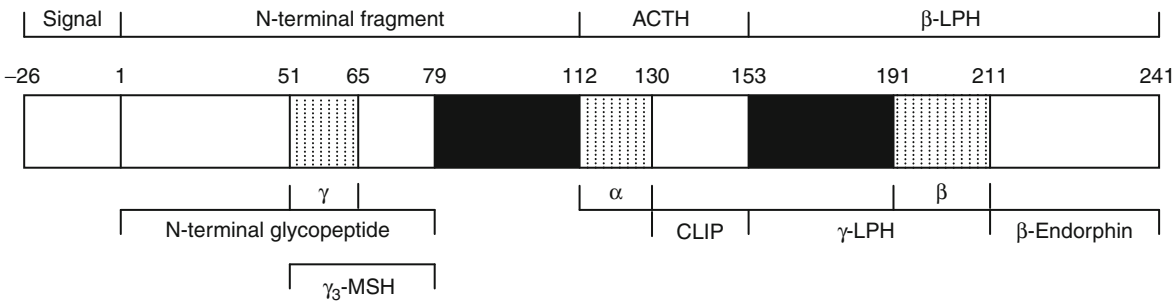

Figure 384.2

Structure of human pre-pro-opiomelanocortin (POMC). The "constant" regions α, β and γ MSH are indicated by dotted areas; the "variable" regions are represented by solid areas. The aminoacid numbers refer to the N-terminal aminoacid of each cleavage site. CLIP, Corticotrophin like intermediate lobe peptide (The numbers do not correspond exactly as in the text)

biologically active peptides, α and β melanocyte stimulating hormone, corticotrophin-like intermediate lobe peptide, (CLIP), γLPH, β and γ endorophin, and enkephalin. Cortisol has a negative feedback effect on the synthesis and secretion of ACTH, CRH and AVP. ACTH inhibits its own secretion by a feedback effect on the hypothalamus. Cortisol and other glucocorticoids cause feedback inhibition of both CRF and ACTH, and probably influence adrenal faciculata cells also. The secretion of ACTH is the result of interaction of the hypothalamus, pituitary and adrenal glands and is also affected by other neural stimuli.

ACTH acting through a G protein-coupled receptor, activates adenylate cyclase and increases levels of cyclic AMP which has short term effect varying from minutes to hours, on cholesterol transport into mitochondria by increasing expression of StAR protein. This constitutes "acute" effect or acute response of steroidogenesis to ACTH. The adrenals contain only modest amounts of steroid hormones; hence release of preformed cortisol does not contribute significantly to the acute response to ACTH. For acute responses to occur, large supply of cholesterol to mitochondrial P450scc is required. The long term or "chronic" effects of ACTH are to increase the uptake of LDL-cholesterol is expressed by stimulating the transcription of the genes encoding the enzymes for cortisol synthesis. The stimulating effect is at each step in the pathway not only at the rate-limiting step, P450scc. Part of this increased activity is achieved through the activity of protein kinase A.

Aldosterone Secretion

The rennin-antiotensin system and potassium levels are major regulators of aldosterone synthesis with ACTH having a short term effect. The rate of aldosterone synthesis is 100–1,000-fold less than that of cortisol synthesis. Renin the proteolytic enzyme secreted by the juxtaglomerular apparatus of the kidney in response to decreased intravascular volume cleaves angiotensinogen (renin substrate) produced by the liver to yield the inactive decapeptide angiotensin I. The converting enzyme in lungs and other tissues rapidly cleaves angiotensin I to its active form angiotensin II with further cleavage of II to angiotensin III. The Angiotensin II and III are potent stimulators of aldosterone the former being more potent, causing arteriolar vasoconstriction by direct action within a few seconds and aldosterone secretion within a few minutes. Increased plasma potassium also has a powerful and direct action on aldosterone synthesis and release. Aldosterone has the most powerful mineralocorticoid activity, causing renal sodium retention and potassium loss, resulting in increased intravascular volume and blood pressure. Angiotensin II functions through receptors that stimulate production of phoshatidylinositol, mobilize intracellular and extracellular calcium 2+, and activate protein kinase. This stimulates transcription of the P450scc gene independently. Phosphorylation of transcriptional regulating factors by CaM kinases, increases transcription of the aldosterone synthase (CYP1B2) enzyme required for aldosterone synthesis. Potassium ion increases uptake of Calcium 2+ with consequent hydrolysis of phosphoinositides to increase phosphatidylinositol. Thus angiotensin II and potassium work at different levels of the same intracellular second messenger pathway but the mode action of ACTH differs.

Adrenal Androgens

The regulatory mechanisms for the synthesis of dehydroepiandrosterone (DHEA) and androstenedione (AD) are

not fully understood. ACTH is the primary stimulus for adrenal androgen production. Additional factors such as a relative decrease in expression of 3β-hydroxysteroid dehydrogenase in the zona reticularis (which also continues to mature histologically till nearly 15 years of age) and increases in 17,20-lyase activity or increased cytochrome b5 expression have been implicated. DHEA and AD can peripherally be converted to testosterone however, they have little capacity to bind to and activate androgen receptors, and hence are like androgen precursors. Fetal and neonatal adrenals secrete DHEA and DHEAS in abundance but their concentration fall rapidly as the fetal adrenal zone involutes after birth. The levels remain low till onset of adrenarche (independent of puberty) around 6 years of age which precedes the onset of puberty by about 2 years. There is progressive increase in androgen secretion between the ages of 6–20 years. The trigger for adrenarche remains unknown. DHEA and DHEAS reach maximal values in young adulthood and decline till "adrenopause" in the elderly. ACTH probably plays a permissive role in adrenarche. Premature and exaggerated adrenarche has been found in association with insulin resistance and in girls with premature exaggerated adrenarche. Both these groups have higher risk for PCOs. Infants born small for gestational age may have increased risk for this syndrome.

Actions of Adrenal Cortical Hormones

Mineralocorticoids

Aldosterone is the most important mineralocorticoid and also 11-deoxycorticosterone (DOC) which is less potent. Corticosterone and cortisol have mineralocorticoid effect only when in excess. They maintain intravascular volume by promoting sodium retention and elimination of potassium and hydrogen ions in the distal convoluted tubule of the kidneys and exert some effect on the gut, salivary and sweat glands as well. In the medullary collecting duct with their permissive action they allow vasopressin to increase osmotic water flux. Mineralocorticoid receptors are found in the heart and vascular endothelium also. The mechanism of their action is unclear but is presumably due to gene expression mediated by the mineralocorticoid receptors. In response to aldosterone, levels of subunits of both the Na^+, K^+ – ATPase and the ENac (epithelial sodium channel) increase. Aldosterone also increases the expression of the sgk kinase thereby increasing the number of open sodium channels. The mineralocorticoid receptor has affinity for cortisol also. Therefore pharmacologic or genetic inhibition of the enzyme allows cortisol to occupy renal mineralocorticoid receptors and cause sodium retention and hypertension. Mineralocorticoid deficiency leads to hypotension, hyponatremia, hyperkalemia and weight loss while excess leads to hypertension, hypokalemia, sodium retention and metabolic alkalosis.

Glucocorticosteroids

Cortisol is the predominant glucocorticoid secreted by the adrenal cortex. Cortisol is essential for survival and homeostasis and has a significant impact on carbohydrate, protein, and fat metabolism. Glucocorticoids also regulate immune, circulating and renal function, and also influence growth development, bone metabolism and central nervous system activity. During stress their levels increase tenfold which enhances survival through actions on cardiac contractility and output, increase sensitivity to the pressor effects of catecholamines and other pressor hormones, as well as work capacity of the skeletal muscles and help mobilization of energy for stress.

Carbohydrat metabolism: Stimulation of gluconeogenesis by the liver is the most well known metabolic effect of the glucocorticoids. Cortisol increases the activity of enzymes needed to convert amino acids to glucose in the liver, mobilizes amino acids from extrahepatic tissues predominantly from muscle, thus increases the availability of substrates for gluconeogenesis. It increases cellular resistance to insulin in the adipocytes, muscle cells and fibroblasts, but also along with insulin enhances glycogen deposition and production in liver by stimulating glycogen synthetase and decreasing glycogen breakdown. Hence excess of cortisol can cause hyperglycemia and deficiency can cause hypoglycemia. It also decreases the rate of glucose utilization elsewhere in the body. The cumulative effect of these actions is a rise in serum glucose.

Protein metabolism: Except in the liver, cortisol reduces protein stores via decreased protein synthesis and increased protein catabolism. The actions are antianabolic. Decreased transport of amino acids into extrahepatic cells decreases the intracellular concentration with a consequent reduction in protein synthesis. Proteins already present within the cells are catabolized and amino acids are released into the circulation, leading to a rise in plasma amino acid concentration. It leads to depletion of protein stores elsewhere in the body increases plasma proteins with a concomitant increase in hepatic protein.

Fat metabolism: It promotes mobilization of fatty acids from adipose tissue, at least in part via diminished

transport of glucose into fat cells. The resultant paucity of glucose in fat cells leads to a decrease in α-glycerophosphate, which is derived from glucose and is essential for deposition and maintenance of triglycerides in these cells; in the absence of α-glycerophosphate, cells release fatty acids. This increase of plasma free fatty acids allows for increased utilization of free tatty acids for energy. Oxidation of free fatty acids in cells is also promoted by cortisol. In times of starvation or other physiological stress, this combination of increase mobilization of fats and increased oxidation of fatty acids helps to shift the metabolism of the cells from utilization of glucose to utilization of fatty acids for energy. This is important for long-term conservation of body glucose and glucose stores.

Effects of stress: Cortisol is essential for survival during times of physiological stress. There is a rapid and marked increase in ACTH secretion from the pituitary, followed by increased secretion of cortisol from the adrenal cortex. Stressors like fever, serious infection, trauma, and surgery cause an acute glucocorticoid surge.

Growth: Through its direct inhibitory effect on epiphyses, excess inhibits linear growth and skeletal maturation. This may be mediated by decrease in the levels of growth hormone and IGF-1 and increase in IGFBP-1, the binding protein and decrease in free IGF-1. Physiologic amounts are also necessary to promote normal growth and development and in the fetus and neonate, for development and differentiation of various tissues, the hepatic and gastrointestinal systems and surfactant in fetal lung. Hence it is administered to mother at risk, for premature delivery.

Cardiovascular effects: Glucocorticoids have a positive inotropic influence on the heart and promote normal cardiovascular function. It exerts permissive effects on catecholamines, angiotensin II, and arginine vasopressin (AVP), whose vaso-constricting effects maintain adequate cardiac function and vascular tone. Cortisol deficiency causes, decreased cardiac contractility and peripheral vascular tone which may cause potentially fatal systemic hypotension and cardiovascular collapse. States of cortisol excess, in contrast, are associated with hypertension.

Anti-inflammatory and immunologic effects: Glucocorticoids have anti-inflammatory effects and play a role in immune regulation. They interfere with early stages of inflammation and help resolve established inflammation. Through stabilization of lysosomal membranes, cortisol hinders the rupture of intracellular lysosomes and reduces release of proteolytic enzymes from damaged cells, decreases capillary membrane permeability, prevents leakage of plasma. However, migration of leukocytes into inflamed areas and phagocytosis of damaged cells are decreased. It inhibits synthesis of glycolipids, prostaglandin precursors, histamine, cytokines, and bradykinin and blocks their actions, thus diminishes the inflammatory process. By suppressing the immune system circulating T lymphocytes and also antibodies are decreased. These properties of glucocorticoids are utilized in the management of diseases such as rheumatoid arthritis, glomerulonephritis and to prevent rejection of transplanted organs. High levels of glucocorticoids decrease inflammatory and cellular immune responses and increase susceptibility to certain bacteria., viral, fungal and parasitic infections.

Hematological effects: Cortisol increases red blood cell synthesis and decreases circulating eosinophils and lymphocytes. Excess cortisol secretion leads to polycythemia, eosinopenia, and lymphocytopenia.

Excess cortisol causes significant atrophy of lymphoid tissue, decreases output of T cells and antibodies and reduces immunity against foreign invaders of the body hence organisms that would otherwise be easily destroyed by an intact immune system may cause overwhelming, even lethal, infections.

Effects on skin, bone and calcium: Inhibition of fibroblasts leads to bruising and poor wound healing, cutaneous atrophy, as seen with Cushing syndrome. They decrease serum calcium by decreasing intestinal absorption and renal reabsorption of calcium and phosphorus hence they are used as emergency therapy for hypercalcemia. Long term use affects osteoblasts leading to osteoporosis and decrease in osteoclastic activity leads to low bone turnover and an overall negative balance. Tendency to lower serum calcium and phosphorus levels cause secondary hyperparathyroidism with decreased bone accretion and net loss of bone mineral.

Central nervous system: The ready penetration of blood–brain barrier helps decrease CNS edema and use of corticosteroids in reducing increased intracranial pressure. Appetite is stimulated, memory concentration may be affected and emotional ability may be increased with a feeling of eruption. Both excess and deficiency states may cause depression. Excess has occasionally led to psychosis.

Androgens

The actions of adrenal androgens are mainly exerted through their conversion to active androgens or estrogens such as testosterone, dihydrotestosterone, estrone, and estradiol. Androgens are important for normal development of the male genitalia in utero. Newborns have markedly elevated levels of androgens, specifically

androstenedione, dehydroepiandrosterone (DHEA), and testosterone. Androgen levels fall within the first few weeks of life and for the most part remain low throughout prepubertal years. DHEA, begins to rise in mid-childhood approximately around 6 years of age. In some children with increased end-organ sensitivity, this rise in DHEA may manifest with benign premature adrenarche. The chief adrenal androgens DHEA and DHEAS, reach a peak in early adulthood and then decline. Beneficial systemic effects of DHEA administration have been speculated in some of the deficiency states or at an older age. Development of pubic and axillary hair during normal puberty is attributed to adrenal androgens. In adult men, less than 2% of the biologically important androgens are derived from adrenal production, whereas in women approximately 50% of androgens are of adrenal origin.

Androstenedione is the most potent adrenal androgen. It is converted to testosterone and estradiol primarily in the gonads. In the target tissue, testosterone is converted to dihydrotestosterone (DHT). Both these hormones bind to androgen receptors and facilitate major actions of androgens promoting gonadotropin regulation, spermatogenesis, sexual differentiation and maturation. They also play an important role in the pathophysiology of congenital adrenal hyperplasia, premature adrenarche, adrenal tumors, and Cushing syndrome. Diminished secretion can manifest as sparse pubic and axillary hair as in adolescents with Addison disease.

Adrenal Medulla

The physiologically active catecholamines of the adrenal medulla are dopamine, norepinephrine, and epinephrine. Catecholamine synthesis also occurs in sympathetic nerve endings, in chromaffin tissue and the brain outside the adrenal medulla. Metabolites of catecholamines are excreted in the urine, principally as 3-methoxy-4-hydroxymandelic acid (VMA), metanephrine, and normetanephrine. Urinary metanephrines and catecholamines are measured to detect pheochromocytomas of the adrenal medulla and sympathetic nervous system.

In the adrenal gland, the proportions of epinephrine and norepinephrine vary with age. In early fetal stages, thereis practically no epinephrine; at birth, norepinehprine is predominant. In adults, norepinephrine constitutes only 10–30% of the pressor amines in the medulla.

The effects of catcholamines are mediated through a series of G protein-coupled adrenergic receptors. Both epinephrine and norepinephrine raise the mean arterial blood pressure, but only epinephrine increases cardiac output. By increasing peripheral vascular resistance, norepinephrine increases systolic and diastolic blood pressures with only a slight reduction in the pulse rate. Epinephrine increases the pulse rate, decreases the peripheral vascular resistance and decreases the diastolic pressure. The calorigenic effect of norepinephrine and hyperglycemic effect are much less pronounced than are those of epinephrine.

Hypoadrenocorticism

Adrenal insufficiency can be due to congenital or acquired lesions of the adrenal cortex (primary) or involvement of the hypothalamus or anterior pituitary gland (secondary). Primary adrenal cortical insufficiency can be acute usually transient, or more often chronic, persistent, and insidious in onset. Congenital or inherited forms of primary deficiency can be due to adrenal cortical dysgenesis, inherited inborn errors of steriodogenesis due to an acquired destructive process within the adrenal glands, commonly an autoimmune adrenalitis or chronic infections. The term Addison disease indicates both an autoimmune or idiopathic cause. In secondary adrenal insufficiency, deficient corticotrophin (ACTH) secretion leads to hypofunction of the adrenal cortex, the onset being acute or insidious, based on the underlying cause.

Acute Primary Adrenal Insufficiency

Acute adrenal crisis in childhood is more frequently encountered in children with undiagnosed chronic adrenal insufficiency, when it tends to be precipitated by stress of major illness, trauma, or surgery. Very few conditions cause acute adrenal failure in infancy and childhood as listed in *Table 384.1* and briefly.

In large infants born after difficult labor or breech delivery, acute primary adrenal insufficiency can occur due to massive adrenal hemorrhage, it is uncommon with a probable incidence of 3 per 100,000 live births. Occasionally it occurs in fetal life when it may be detected as an incidental suprarenal mass on antenatal sonography. Presenting signs include an abdominal mass, shock, pallor and collapse. Unexplained jaundice or scrotal hematoma may occur. Exsanguination and death can occur. Massive adrenal hemorrhage may occur in children with meningococcemia and meningitis, (Waterhouse-Friderichsen syndrome) and can lead to shock, collapse and a comatose state. Other septicemic states may also cause a similar picture. Immaturity of the H-P axis, partial

Table 384.1
Causes of primary adrenal insufficiency

Genetic disorders	Autoimmune adrenalitis
Inborn errors of steroidogenesis	Isolated/idiopathic
Congenital adrenal hyperplasias	Autoimmune polyendocrinopathy syndrome
Lipoid (star protein mutation)	APS-Type 1 (AIRE)
21-Hydroxylase deficiency	APS-Type 2
11β-Hydroxylase deficiency	Infections/infiltration
3β-HSD type 2 deficiency	Tuberculous adrenalitis
17α-Hydroxylase deficiency	Fungal
Adrenal hypoplasia congenita	Viral – AIDS, cytomegalo
X-linked (DAX 1 gene mutation)	Hemorrhage/infarction
Xp-21 (contiguous gene syndrome)	Trauma – neonatal, postnatal
SF-1 linked (XY sex reversal)	Waterhouse–Friderichsen syndrome
ACTH insensitivity syndromes	Anticoagulants
Familial glucocorticoids deficiency	Drugs
Type 1, and type 2	Ketoconazole, aminoglutethamide, mitotane
Triple A syndrome (Allgrove's)	Medroxyprogesterone, rifampicin, dilantin
Adrenoleukodystrophy/ adrenomyeloneuropathy	
Metabolic and syndromic adrenal insufficiency	
Disorders of cholesterol synthesis/metabolism	
Wolman disease	
Smith–Lemli–Opitz	
Antley–Bixler	
Kearns–Sayre	
IMAGe	

adrenal insensitivity to ACTH, diminution of steroidogenic activity may all contribute to inappropriately low cortisol levels in neonates with RDS, sepsis or shock. Very low cortisol levels in presence of stress are indicative. Cortisol supplementation may be advisable. Child abuse and treatment with anticoagulants are other causes. Fluid and electrolyte replacement, ample doses of glucocorticoids and supplementation with mineralocorticoids can be life saving. Therapy of precipitating illness is necessary. Majority of these conditions are transient usually with complete recovery.

Chronic Primary Adrenal Insufficiency

Developmental aberrations of adrenal glands and inherited genetic conditions though congenital, may not always manifest in infancy. They cause variable degree of adrenocortical insufficiency. Acquired conditions like autoimmune adrenalitis are encountered during childhood and adolescence but are more common in adults. Various etiologic factors leading to primary and secondary form of adrenal cortical deficiency are listed in *Table 384.1* and briefly discussed.

Clinical Manifestations

Majority of clinical manifestations of chronic adrenal insufficiency are common to all these conditions with some variations based on the underlying cause and involvement of the respective zone/zones of the adrenal cortex. Symptoms vary with severity of deficiency. These patients may complain of weakness, fatigue, apathy anorexia, poor weight gain, weight loss, dehydration, vomiting, diarrhea, darkening of skin. Hypotension, hyperpigmentation (*Fig. 384.3*), hypoglycemia, rarely hyperthermia may be noted. All these manifestations are more indicative of glucocorticoids deficiency. Signs of mineralocorticoid deficiency like (hyponatremia, hyperkalemia, acidosis, and hypochloremia may not be evident during early stages. Hypotension, tachycardia, low voltage on ECG, small heart on chest radiograph, all may be indicative of significant mineralocorticoid deficiency. Low concentration of plasma cortisol stimulates hypersecretion of ACTH and other POM peptides including the various forms of MSH which brings about hyperpigmentation of skin and mucosa. This is more prominent in skin exposed to sun and on flexor surface of knees, elbows, and knuckles.

When diagnosis of primary adrenal insufficiency is suspected clinical pointers to detect the underlying causes need to be looked for, and family history of consanguinity and sibling affection should be elicited. Male infants and newborns with this disorder are often suspected as having CAH which is much more

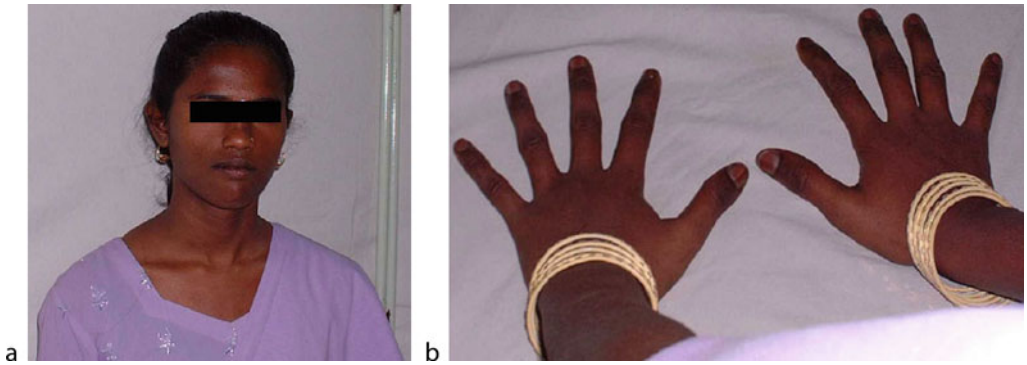

Figure 384.3
(a, b) Thirteen-year-old girl with chronic adrenal insufficiency due to glucocorticoid resistance syndrome. The figure shows a thirteen-year-old girl with gradually progressive darkening of the skin for the past 7–8 years, minimal weakness and fatigability for the past 2 years and slight delay in onset of puberty. Her hands and nails showed well marked pigmentation with pigmentation of the lips and generalized darkening of the skin. For her age, her height was within normal range. Investigations revealed low levels of cortisol, ACTH in the supra-normal range and no abnormality of the aldosterone axis, with CT adrenals showing adrenal hypoplasia. There was no past history of infective illnesses. No alacryma or achalasia. She was presumed to have isolated glucocorticoid resistance

frequently encountered. In some of these sick newborns the mild to moderately elevated 17-OHP may confuse the diagnosis. The flow chart for arriving at the underlying cause of primary adrenal insufficiency is shown in *Fig. 384.4*.

Genetic Disorders

These are inherited disorders manifesting usually at an early age due to a variety of molecular genetic abnormalities (*Table 384.1*). These disorders causing adrenal insufficiency include inborn errors of steroidogenesis leading to various forms of congenital adrenal hyperplasia, metabolic disorders like adrenoleukodystrophy (schilder disease), primary xanthomatosis (Wolman disease), cholesterol ester storage disease, hereditary unresponsiveness to ACTH, and adrenal hypoplasia congenita.

Inborn Errors of Steroidogenesis

Congenital hyperplasia due to inborn defects of steroidogenesis constitute the most common cause of adrenocortical insufficiency in infancy and childhood are discussed later. Salt wasting forms with associated deficiency of aldosterone synthesis predominate.

Adrenal Hypoplasia Congenita

Congenital adrenal hypoplasia has been associated with inactivating mutations of DAX1 and SF1 genes.

DAX-1 deficiency: This disorder has an x-linked recessive transmission and is caused by mutation of the DAX1 (NROB1) gene, a member of the nuclear hormone receptor family, located on Xp21. More than 50 mutations (nonsense, missense, frameshift) are described in patients with adrenal hypoplasia due to loss of DAX1 activity. It affects primarily boys. Usually they present with acute adrenal insufficiency in the neonatal period but onset of symptoms may be insidious and delayed until mild or later childhood or even adolescent age. Severity of presentation may vary in siblings. Histologic examination of the hypoplastic adrenal cortex reveals disorganization and cytomegaly. Puberty may not occur or its progression may be arrested due to hypogonadotropic hypogonadism. Both AHC and hypogonadotropic hypogonadism are caused by the same mutated DAX1 gene. Cryptorchidism, often noted in these boys, is probably an early manifestation of hypogonadotropic hypogonadism. In female carriers adrenal function is not compromised but delayed puberty or hypogonadotropism may occur. DAX1 may also appear as a part of contiguous gene deletion syndrome (glycerol kinase deficiency, Duchenne & Becker muscular dystrophy, chronic granulomatous disease.

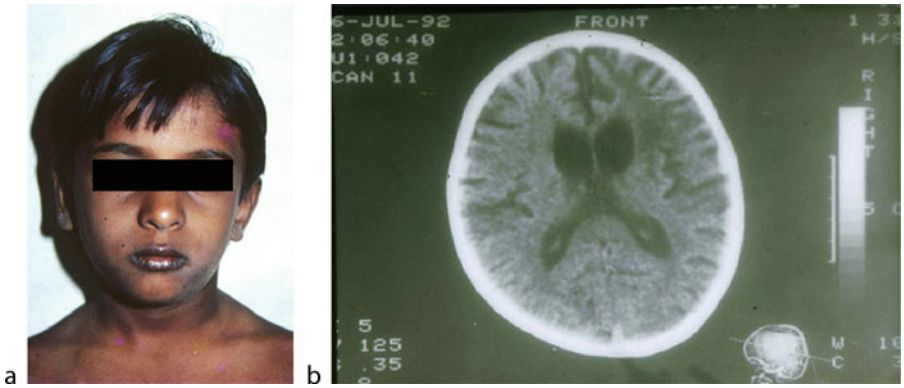

Figure 384.4
(a, b) Patient with chronic adrenal insufficiency confirmed to have adrenoleukodystrophy. A seven-year-old boy presented with gradual onset of weakness, tiredness, loss of weight, progressive darkening of skin, for 6 months. Patient was prepubertal, growth parameters equivalent to Indian average of 6-year-old boys. Generalized pigmentation of the skin, gums, tongue, lips, nails, nipples as visible in the picture. Doing well in school. Neurodevelopment normal till now. Serum cortisol was very low with ACTH in supranormal range. Health improved with corticosteroid (hydrocortisome) replacement. By 9 years of age showed scholastic backwardness, gradually progressive dementia, behavior disorder and visual difficulties. At this stage very long chain fatty acids (VLCFA) showed characteristic high levels. Lorenzo's oil introduced in therapy – progressive deterioration and death occurred by age of 13 years. Brain imaging showed cerebral demyelination. This patient had adrenoleukodystrophy presenting with cortisol deficiency as initial manifestation with CNS involvement at a later stage

SF-1 deficiency: The transcription factor SF-1 is required for adrenal and gonadal development. Very rare patients with a heterozygous mutation in SF-1 (NR5A1) may have adrenal insufficiency. Males have impaired development of the testes and may appear as females, similar to patients with lipoid adrenal hyperplasia. Some mutations of SF-1 lead to male to female sex reversal, adrenal and gonadal agenesis with GnRH deficiency and feminine differentiation of mullerian duct-derivative structures in XY fetus.

ACTH Insensitivity Syndromes

Familial Glucocorticoid Deficiency

This is an autosomal recessive disorder due to insensitivity to ACTH. Homozygous or compound heterozygous loss of function (missense or nonsense) mutations in MC2R gene have been identified in affected individuals. A number of mutations in the gene for the ACTH receptor have been described in approximately 40% of these patients. The disorder affects both sexes equally and is inherited in an autosomal recessive manner. Familial glucocorticoid resistance may be heterogenous as patients with similar findings but normal MC2R have been identified (MC2R, Type 2). A postreceptor error(s) in signal transduction is postulated. It may manifest in early infancy or early childhood. This form of chronic adrenal insufficiency is characterized by isolated deficiency of glucocorticoids markedly elevated levels of ACTH, and normal aldosterone production. Serum electrolytes and plasma renin activity are normal. Patients present with hypoglycemia, seizures, and increased pigmentation (*Fig. 384.3*) during the 1st decade of life. Linear growth is often increased due to unexplained mechanisms. Hypoandrogenemia marked by decreased pubic hair growth in females, becomes evident in puberty. There is marked adrenocortical atrophy with relative sparing of the zona glomerulosa.

Triple A (Allgrove) Syndrome

Another syndrome due to ACTH resistance causing adrenocortical insufficiency occurs in association with achalasia of the gastric cardia and alacrima. It is also known as Allgrove or ALADIN Syndrome. The adrenal zona fasciculata is absent with intact zona glomerulosa and normal aldosterone levels, hence symptoms are related to deficiency of glucocorticoids. These patients often have a progressive neurologic disorder that includes autonomic dysfunction (pupillary reflex aberrations, postural hypotension), mental retardation, deafness, and motor

neuropathy. This syndrome is also inherited in an autosomal recessive fashion, and the AAAS gene has been mapped to chromosome 12q13. The encoded protein, ALADIN belongs to a family of proteins expressed in the CNS and gastrointestinal system.

Glucocorticoid Resistance

A rare syndrome of glucocortioid resistance characterized by hypercortisolemia and hypercortisoluria without clinical signs of cortisol excess or deficiency is described. ACTH induced hyperandrogenism as well as mineralocorticoid induced hypertention and hypokalemic alkalosis can occur.

Metabolic and Syndromic Adrenal Insufficiency

This group of disorders have underlying characteristic metabolic abnormality due to specific enzyme deficiencies involved in cholesterol synthesis ultimately leading to adrenal insufficiency. Some of these disorders have associated dysmorphic features and constitute characteristic syndromes. Majority of these disorders are uncommon.

Disorders of Cholesterol Synthesis/ Metabolism

Adrenocortical hypofunction occurs in patients with disorders of cholesterol synthesis or metabolism, including abetalipoproteinemia with deficient lipoprotein B-containing lipoproteins, and familial hypercholesterolemia, with decreased or impaired LDL receptors. *Wolman disease* is a rare autosomal recessive disorder caused by mutations in the gene encoding human lysosomal acid lipase. Cholesteryl esters accumulate in lysosomes in most organ systems, leading to organ failure. During very early infancy hepatosplenomegaly, steatorrhea, abdominal distention, and failure to thrive occurs. Adrenal insufficiency and bilateral adrenal calcification are present, and death usually occurs in the first year of life. The genetic defects in patients with Wolman disease have been elucidated and the gene for lysosomal acid lipase has been mapped to chromosome 10q23.2-23.3.

Adrenal insufficiency has been reported in patients with *Smith-Lemli-Opitz syndrome* (SLOS), an autosomal recessive disorder presenting with facial anomalies, microcephaly, limb anomalies, and developmental delay due to mutations in the gene coding for sterol Δ7-reductase, mapped to 11q12-q13. Resulting impairment in the final step in cholesterol synthesis causes marked elevation of 7-dehydrocholesterol, abnormally low cholesterol, and adrenal insufficiency. Pyrooxidoreductase deficiency leads to *Antley-Bixler Syndrome*. In *Kearns-Sayre syndrome*, deletion of mitochondrial DNA is associated with myopathy, deafness, hypoparathyroidism, and adrenal insufficiency. IMAGe syndrome is associated with IUGR, metaphysieal dysplasia, adrenal insufficiency and genital anomalies.

Corticosteroid-binding globulin (CBG) deficiency and decreased cortisol-binding affinity: These disorders result in low levels of plasma cortisol but normal urinary free cortisol and normal plasma ACTH levels. A high prevalence of hypotension and fatigue has been reported in some adults with abnormalities of CBG.

Adrenoleukodystrophy (ALD)

ALD is an x-linked recessive disorder with a frequency of 1 in 20,000 male live births. It is a disorder of fatty acid transport with intracellular accumulation of very long chain fatty acids (VLCFAs more than 24 carbon or C26-hexacosanoate) as esters of cholesterol in the adrenal cortex and CNS white matter. It is associated with adrenocortical deficiency and demyelination in the central nervous system due to impaired β-oxidation in the peroxisomes (Fig. 384.4). The X-linked adrenal leukodystrophy (X-ALD) is caused by mutations in the ABCD1 gene located on Xq28, which encodes a transmembrane transporter involved in the importation of very long chain fatty acids into peroxisomes. More than 400 mutations have been described in patients with X-ALD; mutations do not correlate with phenotypes. X-ALD families may have a unique mutation with clinical phenotypes varying within families, due to modifier genes or other unknown factors. There is no correlation between the degree of neurologic impairment and severity of adrenal insufficiency.

Adrenal insufficiency often precedes progressive neurologic symptoms of spastic paraparesis severe dementia and deterioration of vision, hearing, speech, and gait, with death occurring within a few years. A milder form of X-linked ALD is adrenomyeloneuropathy (ALM), which begins in later adolescence or early adulthood. Many patients have evidence of adrenal insufficiency at the time of neurologic presentation, but Addison disease may be present without neurologic symptoms or may precede them by many years. Prenatal diagnosis by DNA analysis and family screening by very long chain fatty acid assays and mutation analysis are available. Women who are heterozygous carriers of the X-ALD gene may develop symptoms in midlife or later. In them adrenal insufficiency is rare.

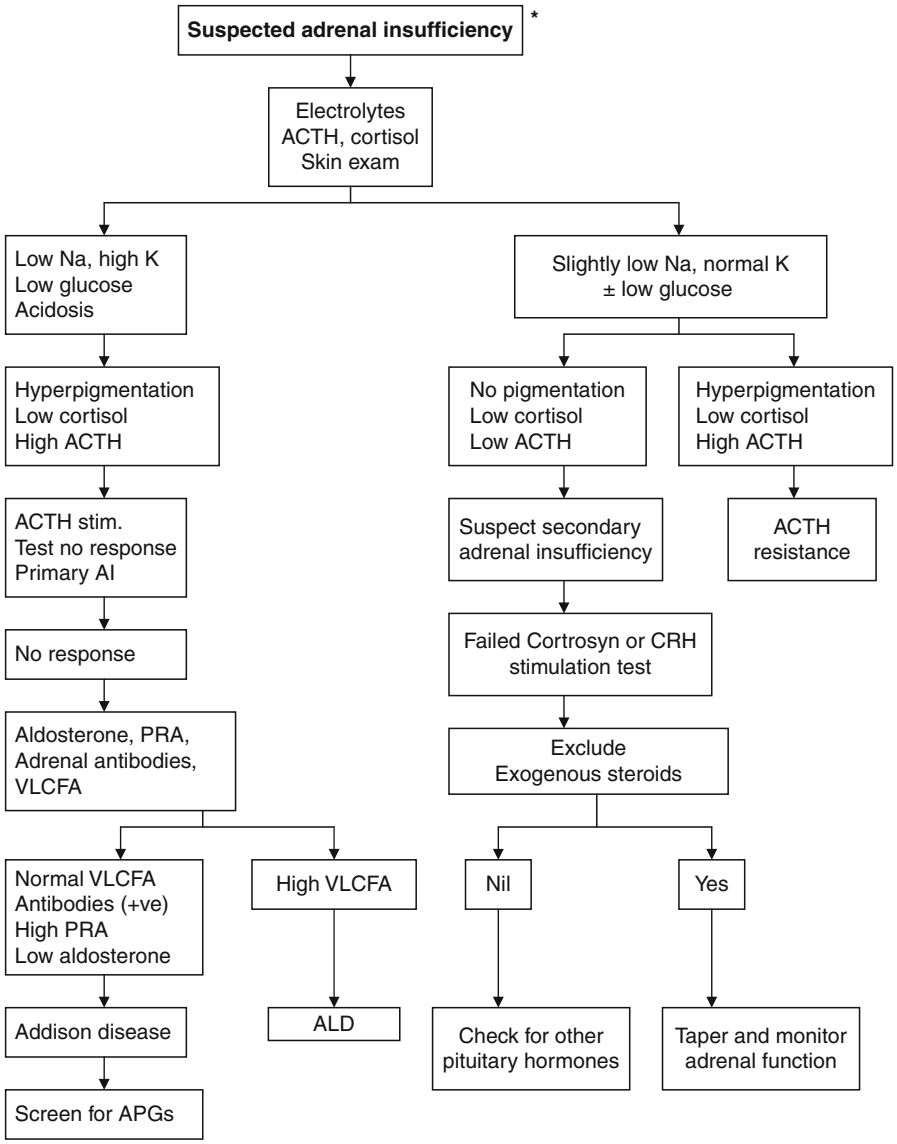

Figure 384.5
Investigative evaluation for adrenal insufficiency (AI). Precise history examination and family history help suspect AI. VLCFA – very long chain fatty acids. APG5 – autoimmune polyglandular syndrome

Neonatal ALD is a rare autosomal recessive disorder with neurologic deterioration and adrenocortical dysfunction in neonatal period or developing during infancy. Most patients have severe mental retardation and die before 5 year of age. This disorder is a subset of Zellweger (cerebro-hepato-renal) syndrome, in which peroxisomes do not develop owing to mutations in any of the several genes controlling the development of this organelle.

Autoimmune Adrenalitis

Addison Disease

The most common cause of primary adrenal insufficiency is Addison disease which is due to autoimmune destruction of the adrenal glands. The glands may become extremely atrophic, marked lymphocytic infiltration occurs but the medulla is intact. At autopsy only remnants of the glands may be seen. The incidence is approximately

1 in 20,000 and is more frequent in adults between 24 and 45 years of age with 70% of these occurring in women. It may be associated with autoimmune dysfunction of other endocrine glands as well in nearly 50% of adults.

The incidence in pediatric age group is not known. Isolated cortisol deficiency with accompanying symptoms of glucocorticoids deficiency appear first and during its clinical course, deficiency of mineralocorticoids appears. Androgen production may also be affected. Most patients have antiadrenal cytoplasmic antibodies to (CYP21) 21-hydroxylase autoantigen.

Addison disease may occur as a component of autoimmune *polyendocrine syndromes* in particular Type 1 (APS-1 or APECED) or Type II (APS-2). The components of APS-1 are mucocutaneous candidiasis with ectodermal dystrophy which is often the initial manifestation followed by hypoparathryoidism and lastly Addison disease occurring towards adolescence. Gonadal failure, alopecia, vitiligo, keratopathy, enamel hypoplasia, intestinal malabsorption, and chronic active hepatitis may be associated manifestations of autoimmune syndrome. Hypothyroidism and Type I diabetes mellitus occur in less than 10%. Adrenal failure may evolve rapidly. It is inherited as autosomal recessive condition hence screening siblings for this disorder may lead to early detection. In APS-1, autoantibodies to CYP21, CYP17 and CYP11AI enzymes are noted. There is a loss of function mutation in the affected gene in APS-1, designated as autoimmune regulator-1, (AIRE1) gene, which is a transcription factor mapped to chromosome 21q22.3. Nearly 40 different mutations are described in patients with APS-1 with 2 mutations (R257× and a 3-bp deletion) most frequent. The disease is reportedly more common among Finnish, Sardinian and Iranian Jewish people.

Addison disease may be a component of Type II autoimmune polyendocrinopathy (APS-2). Here Addison disease is associated with autoimmune thyroiditis (Schmidt syndrome) or Type I diabetes (carpenter syndrome). Some of the other manifestations may be gonadal failure, vitiligo, alopecia and chronic atrophic gastritis with or without pernicious anemia. Hypoparathyroidism and mucocutaneous candidiasis are not seen. Presence of HLA-D3 and HLA-D4 increases the risk for development of this disorder. Type 2 is associated with the same HLA markers as idiopathic autoimmune adrenalitis which could be a form of APS Type 2. It can occur at any age, less common in childhood and has higher incidence in young adults especially in middle aged females. It may occur in many generations of the same family. The overall incidence is 1.4 to 2 per 100,000 population and is transmitted as autosomal dominant trait with incomplete penetrance. Autoantibodies to the same adrenal enzymes as mentioned in APS-1 are encountered.

Secondary Adrenal Insufficiency

Dysfunction of hypothalamus and/or pituitary can cause adrenal insufficiency due to insufficient tropic hormone (CRH/ACTH) production and stimulation of the adrenal cortex (◉ *Table 384.2*). Involvement of the H-P axis can be due to idiopathic congenital developmental abnormalities (mid line lesion like septoptic dysplasia), inherited genetic (PROP1 gene) or organic forms of hypopituitarism. CNS tumors can damage the cells producing CRF and/or POMC. Cranial radiation can also affect the H-P axis. Rarely autoimmune lymphocytic hypophysitis, pituitary

Table 384.2
Etiology of secondary adrenal insufficiency

Congenital/genetic	Pituitary irradiation
Isolated ACTH deficiency	Leukemia, neoplasia
? POMC cleavage enzyme defect, POMC gene mutation	Autoimmunity, infection, infiltration
Combined pituitary hormone deficiency	Isolated or APS Syndrome
PROP-1, HESX-1, midline brain defects	Lymphocytic hypophysitis
Head trauma	Histiocytosis
Neoplasia	Tuberculosis, sarcoidosis
Pituitary tumors	Chronic glucocorticoid excess
Tumors – hypothalamic pituitary region	Exogenous more than 4 weeks
Craniopharyngioma, ependymoma, others	Endogenous – Cushing syndrome

infiltration or granuloma can cause isolated ACTH deficiency, or be associated with other tropic hormone deficiencies. Chronic suppression of tropic cells can also result from long term glucocorticoid therapy.

Idiopathic/genetic hypopituitarism is more often a disorder of hypothalamus rather than pituitary where deficient secretion of GH, gonadotropins, TSH and ACTH is related to insufficient secretion of corresponding hypothalamic hormones. ACTH deficiency is more often an associated deficiency along with deficiency of GH, gonadotropins and TSH in that order. Isolated ACTH deficiency is a rare and unusual disorder with clinical and genetic heterogeneity. It may present in infancy with hypoglycemia and seizures or later in life with failure of growth and delayed adolescence. In patients with ACTH deficiency, (either with or without deficiency of other anterior pituitary hormones) hypocortisolism may be relatively mild with no deficiency of mineralocorticoids. Adrenal reserve is compromised because of chronic understimulation of biosynthesis. Diagnosis may not be apparent unless a CRF or metyrapone test is performed to assess pituitary ACTH response and intravenous ACTH test to study adrenal reserve. Associated TSH deficiency can mask ACTH deficiency as cortisol metabolism is slowed down. An acute adrenal crisis may be precipitated if thyroxine therapy is introduced in such patients without adequate glucocorticoid cover.

CNS tumours like craniopharyngiomas can be associated with ACTH deficiency in nearly 25% of patients and the incidence may be higher with tumours such as germinomas and astrocytomas and also following surgery and radiation. Cortisol cover should be offered during therapeutic intervention and thereafter for required duration of time. Inapparent deficiency of vasopressin can also be unmasked after instituting cortisol replacement therapy for ACTH deficiency with clinical symptoms of diabetes insipidus becoming evident.

Long term therapy for steroid responsive systemic disorders can suppress the H-P-A axis by suppressing POMC gene transcription, synthesis and storage of ACTH and CRF and decrease the number of receptors for CRF in the pituitary. Considerable length of time based on the duration and dosage of glucocorticoids may elapse (6 months of more) before recovery of H-P-A axis, occurs and probably takes longer for diminished adrenal reserve to return to normal. Hence, gradual stepwise withdrawal to physiologic doses of 10 mg/m^2/day or little less is advocated. Dexamethasone used for the treatment of fetal adrenals in CAH and in preterm babies to enhance lung maturation can occasionally lead to transient hypocortisolism.

Clinical Presentation

The clinical manifestations are usually insidious in onset, gradually progressive and less severe in the secondary form. Hyperpigmentation, a characteristic feature of primary adrenal insufficiency is not seen in the secondary form of the disorder. Aldosterone secretion remains normal hence electrolytes are normal. Newborns often present with hypoglycemia. Signs related to respective hormonal deficiencies may be seen. Micropenis, neonatal jaundice, and poor growth after first year of life are suggestive of associated gonadotropin, TSH and GH deficiencies, respectively. Midface or optic nerve hypoplasia with visual impairment, wandering nystagmus or other midline defects are some of the clinical indicators of H-P axis involvement.

Management of Adrenal Insufficiency

Primary agent of choice in the management of either primary or secondary adrenocortical insufficiency is cortisol. Based on the underlying cause, long term or life long glucocortical supplementation in optimal doses will be required. Irrespective of the underlying cause, in acute adrenocortical insufficiency urgent treatment will be required. Precipitating cause should be taken care of.

In any suspected case, if the diagnosis has not been established, before administering cortisol a blood sample should be drawn for cortisol, ACTH, electrolytes, glucose, aldosterone and plasma renin activity. Depending on patient's condition an ACTH stimulation test to study cortisol response may be undertaken. Adrenal androgens and precursors like 17-hydroxy progesterone may be estimated as required. Urgent infusion with 5% glucose with normal saline (0.9%) will help correct hypoglycemia, hyponatremia and hypovalemia. Severe hyperkalemia may need treatment with intravenous calcium and/or bicarb, IV glucose and insulin or intrarectal Potassium binding resin (Kayexalate). Water soluble form of hydrocortisone needs to be given intravenously. Six hourly doses of cortisol 100 mg/m^2, or 10, 25, 50 and 100 mg for infants, toddlers, older children and adolescents respectively should be administered for first 24 h. During the ensuing 24 h doses may be reduced based on condition of the patient. High dose of hydrocortisone will also have mineralocorticoid effect. Mineralocorticoid support is given as oral fludrocortisone (Florinef) 0.05 upto 0.2 mg daily if required.

Most patients require chronic replacement therapy for cortisol and aldosterone deficiencies. Hydrocortisone is given orally 10–15 mg/m^2/24 h daily in three divided

doses. Equivalent doses (20–25% of hydrocortisone dose) of prednisone or prednisolone divided into two doses can be administered. ACTH levels may be used to monitor adequacy of glucocorticoid replacement in primary adrenal insufficiency while in CAH levels of precursor hormones can be used. A larger amount, 40–50% of the dose can be given in the morning based on individual feeling of well being or based on the morning ACTH levels if found to be in the supranormal range. The dosage of cortisol is maintained at the lower end of the therapeutic range to prevent inhibition of endogenous or GH stimulated linear growth and excess weight gain. Measurements of cortisol and ACTH help in establishing the correct dosage of cortisol.

Dose of hydrocortisone is increased 2–3 fold during acute stress of illness, or surgery. Higher doses as in treatment of acute adrenal insufficiency are required during major surgical procedures. Measurement of plasma renin activity, blood pressure, and electrolytes help in monitoring adequancy of mineralocorticoid replacement. Fludrocortisone (0.05–0.2 mg per day) is given in two divided doses and Sodium chloride to maintain eunatremia, Hypervolemia and hypertension, need to be avoided. Clinical monitoring for growth parameters like height and weight is essential. Osteoporosis can occur due to chronic glucocorticoid overdosages. DHEA replacement in older age group and adults need more study.

Underlying cause of adrenal insufficiency may need careful attention e.g., Loranzo's oil (glyceroltrioleate and glycerol trierucate) for adrenoleukodystroophy, or bone marrow transplantation or lovastatin for metabolically mediated deficiencies.

Congenital Adrenal Hyperplasia

This group of disorders with insufficient cortisol production often associated with genital ambiguity constitute one of the most common inborn errors of metabolism of the adrenal cortex, almost worldwide. The inheritance is autosomal recessive. Steroid Hormone Synthesis of all three classes of adrenal cortical hormones – mineralocorticoids, glucocorticoids, and sex steroids, has been discussed earlier. Deficiency of any one of the enzymes along the pathway (*Fig. 384.1*) disrupts adrenal cortical function and is associated with a characteristic pattern of deficiency, of one or more of the hormones with a concomitant many fold excess of precursors and/or other products along the biosynthetic pathway. *Table 384.3* refers to a brief summary of various types of CAH encountered in clinical practice. Almost 90–95% of CAH cases are caused by 21-hydroxylase deficiency (CAH-21OHD) which in its classic salt wasting form (about 75% of 21OHD) can be potentially life threatening. Inability of the adrenal cortex to synthesize adequate amount of cortisol leads to trophic hormone stimulation with increase in CRH and ACTH causing the adrenal hyperplastia. In 21-OH and 11β-hydroxylase (11β-OH) deficiencies and to a lesser extent in 3β-hydroxysteroid dehydrogenase deficiency (3β-OHD), this leads to formation of excess sex steroid precursors which are processed extraadrenally to active androgens (testosterone and dihydrotestosterone) and some to estrogens (estrone and estadiaol) (*Fig. 384.1*). In these disorders intrauterine virilization occurs in females or postnatally early virilization in males in 21-OHD and 11β-OHD. In males, with deficiency of the enzymes 3β-hydroxysteroid dehydrogenase, 17α-hydroxylase or cholesterol desmolase, inadequate androgen production leads to undervirilized genitals. Interruption of aldosterone formation interferes with sodium balance as with lipoid adrenal hyperplasia, aldosterone synthase deficiency and most cases of 21-OHD and 3β-HSD deficiencies.

21-Hydroxylase Deficiency

Mutations in the gene encoding adrenal P450c21 is most common.

Epidemiology: In most populations the incidence of classical 21-hydroxylase deficiency is 1 in 15,000–20,000 births. Approximately 70–75% of affected infants have the salt-losing form, whereas upto 30% have the simple virilizing form. Alaskan YupikEskimos have a high incidence of (1:280); so also, in natives of French island of Reunion (1:2,100), Brazil (1:7,500), and the Philippines (!:7,000). CAH is less common in African Americans compared with white children (!:42,000 vs 1:15,500) in USA. Nonclassical disease has a prevalence of about 1 in 1,000 in the general population but occurs more frequently, 1–3% in specific ethnic groups such as Ashkenazi Jews, Hispanics, and Yugoslovians.

Genetics: There are two steroid 21-hydroxylase genes – CYP21P (CYP21A1P, CYP21A) and CYP21 (CYP21A2, CYP21B) in the HLA major histocompatibility complex on chromosome 6p21.3 between the HLA-B and HLA-DR loci. CYP21 is the active gene; CYP21P is 98% identical in DNA sequence to CYP21 but is a pseudogene due to nine different mutations. More than 90% of mutations causing 21-hydroxylase deficiency are recombinations between CYP21 and CYP21P and approximately 20% are deletions. The deleterious mutations in CYP21P affect enzymatic

Table 384.3

A summary of clinical and laboratory findings in congenital adrenal hyperplasia

Enzyme deficiency	Presentation	Laboratory findings	Therapeutic measures
Lipoid congenital adrenal hyperplasia (StAR)	Salt-wasting crisis	Low/absent levels of all steroid hormones	Glucocorticoid and mineralocorticoid replacement
	Male pseudohermaphroditism	Decreased/absent response to ACTH	Estrogen replacement at age ≥12 years
			Gonadectomy of male pseudohermaphrodite and salt supplementation
		Decreased/absent response to hCG in male pseudohermaphroditism	Glucocorticoid and mineralocorticoid replacement
		↑ in ACTH and PRA	Salt supplementation
			Surgical correction of genitalia
			Sex hormone replacement as necessary
3β-HSD	Salt-wasting crisis	↑ Δ5 steroids before and after ACTH	Glucocorticoid and mineralocorticoid replacement
	Male and female pseudohermaphroditism		Salt supplementation
		↑ Δ5/Δ4 serum steroids	Surgical repair of female pseudohermaphroditism
		Suppression of elevated adrenal steroids after glucocorticoids administration	
P450c21	Classic form: Salt-wasting crisis	↑ ACTH and PRA	Glucocorticoid administration
			Surgical repair of female pseudohermaphroditism
	Female pseudohermaphroditism	↑ 17OHP before and after ACTH	
	Pre- and postnatal virilization	↑ Serum androgens and urine 17KS	
	Nonclassic form: Premature adrenarche,	Suppression of elevated adrenal steroids after glucocorticoids therapy	
	Menstrual irregularity,		
	Hirsuitism, acne,	↑ ACTH and PRA	
	infertility		
P450c11β	Female pseudohermaphroditism	↑ 11-Deoxycortisol and DOC before and after ACTH	Mineralocorticoid replacement salt supplementation
	Postnatal virilization in males and females	↑ Serum androgens and urine 17 KS	
		Suppression of elevated steroids after glucocorticoids administration	
		↑ ACTH and ↓ PRA	
		Hypokalemia	

Table 384.3 (Continued)

Enzyme deficiency	Presentation	Laboratory findings	Therapeutic measures
P450c17	Failure to thrive	Hyponatremia, hyperkalemia	Glucocorticoid administration
	Weakness	↑ Corticosterone	Surgical correction of genitalia and sex steroid replacement in male pseudohermaphroditism consonant with sex of rearing
	Salt loss	↓ Aldosterone and ↑ PRA	
			Estrogen replacement in female at ≥12 years
	Male pseudohermaphroditism	↑ DOC, 18-OHDOC, corticosterone	Testosterone replacement if reared as male (rare)
	Sexual infantilism		
	Hypertension	Low 17α-hydroxylated steroids and poor response to ACTH	
		Poor response to hCG in male pseudohermaphroditism	
		Suppression of elevated adrenal steroids after glucocorticoids administration	
		↑ ACTH and ↓ PRA	
		Hypokalemia	

ACTH adrenocorticotropic hormone (corticotrophin), *DOC* deoxycorticosterone, *hCG* human chorionic gonadotropin, *PRA* plasma renin activity, 17*OHP* 17-hydroxyprogesterone, 17*KS* 17-ketosteroids, 18-*OHDOC* 18-hydroxydeoxycroticosterone

activity when transferred to CYP21. Mutations can prevent synthesis of a functional protein or missense mutations result in amino acid substitutions with enzymes having 1–50% of normal activity. There is good correlation between disease severity and the mutations carried by an affected individual. Salt-wasting is associated with mutations on both alleles that destroy enzymatic activity completely. In compound heterozygotes, severity of the disease expression is mainly determined by the activity of the less severely affected of the 2 alleles.

Pathogenesis: This P450 enzyme (CYP21, P450c21) hydroxylates progesterone and 17-hydroxyprogesterone (17-OHP) to yield 11-deoxycorticosterone (DOC) and 11-deoxycortisol, respectively. Both cortisol and aldosterone are deficient as both require 21-hydroxylation for their synthesis. Less severely affected patients are able to synthesize adequate amounts of aldosterone but have elevated levels of androgens of adrenal origin and have simple virilizing disease. "Salt-wasting" form of this disorder is the most common form of CAH encountered in clinical practice. These two forms together constitute CAH with classical 21-hydroxylase deficiency. The salt wasting form involves nearly 75% of classical 21-OHD. Accumulation of precursor steroids occurs proximal to the enzymatic block. In 21-hydroxylase deficiency, these precursors include 17-hydroxyprogesterone and progesterone. These precursors are diverted into the androgenic pathway (*Fig. 384.1*) with the formation of excess androgenic compounds and extraadrenal conversion to testosterone. In the affected female fetus abnormal genital development begins by 8–10 week of gestation. The accumulated 17-hydroxyprogesterone shunted into the pathway for androgen biosynthesis, leads to high levels of androstenedione and ultimately to testosterone. In the male fetus this additional testosterone has little demonstrable phenotypic effect but it leads to masculinization in the female fetus. The degree of virilization ranges from mild clitoromegaly with or without partial to complete labioscrotal fusion or in extreme instances urethra traversing the enlarged clitoris. The vagina and urethra open into the common urogenital sinus (refer *Fig. 384.6*). The enlarged clitoris resembles a penis as the urethra opens below it (*Fig. 384.7*). Some affected females may be mistakenly presumed to be males with hypospadias and cryptorchidism and raised as males (*Fig. 384.7*). The internal genital organs are normal with normal ovaries (*Fig. 384.7*). Progesterone and perhaps other metabolites act as antagonists of the mineralocorticoid receptor and thus may exacerbate the effects of

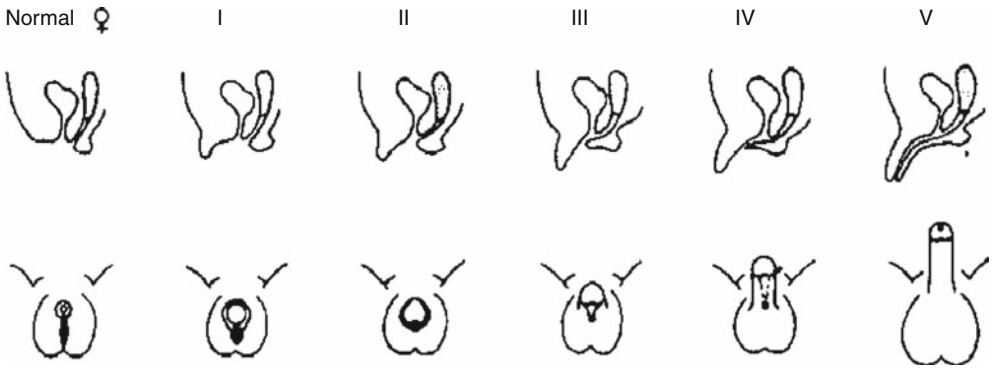

Figure 384.6
Staging system of Prader showing various stages of virlization of external genitalia. Spectrum from normal female to normal male. (*top*) – sagittal section, (*bottom*) – perineal view. This can occur either by the virlization of a normal female, as in congenital adrenal hyperplasia, or from an error in testosterone synthesis in the male

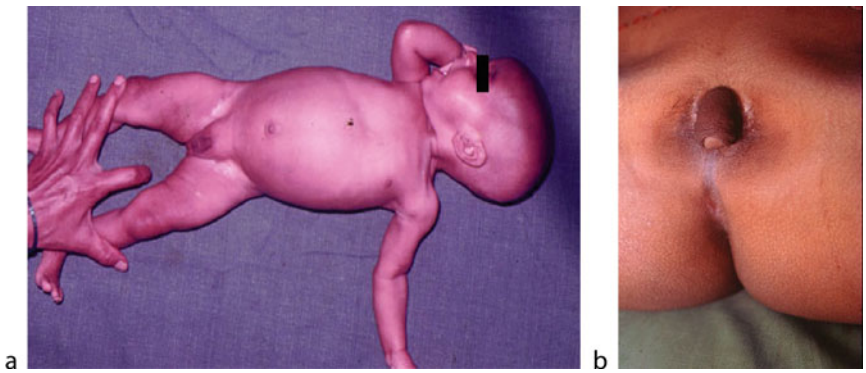

Figure 384.7
(a, b) Salt wasting CAH (21 hydroxylase deficiency) in a three-month-old girl presenting with ambiguous genetalia. This infant presented for repeated episodes of dehydration, failure to thrive and hospitalization. Examination showed genital ambiguity with slight pigmentation and a clitoral length of almost 2.5 cms, with a single opening, no palpable gonads and a single urogenital opening. 17-OHP level was very high, with low sodium and high potassium. USG confirmed presence of mullerian structures. Karyotype was 46 XX. Clinical and investigative evaluation confirmed salt wasting 21 hydroxylase deficiency. Patient showed remarkable improvement with hydrocortisone and fludrocortisone replacement

aldosterone deficiency in untreated patients. The signs and symptoms are similar to those described earlier under primary adrenal insufficiency and include progressive weight loss, anorexia, vomiting, dehydration, weakness, hypotension, hypoglycemia, hyponatremia, hyperkalemia and pigmentation. Transplacental transfer of maternal corticosteroids prevents symptoms from occurring during first 2 weeks after birth. Without treatment, shock, cardiac arrhythmias, and death may occur within days or weeks. Patients with nonclassical disease have relatively mildly elevated levels of androgens and may have signs of androgen excess developing after birth.

Prenatal Clinical Findings

The severity of virilization is usually greatest in female infants with the salt-losing form of 21-hydroxylase deficiency. Male infants appear normal at birth. Diagnosis is often delayed till signs of adrenal insufficiency develop. Many boys with this disorder may succumb before this disease is recognized. Institution of neonatal screening for this disorder has prevented many such deaths. Family history of early neonatal and infant deaths in male children or a previous female sibling with ambiguous genitalia should alert the attending physician. Genital

pigmentation in a male infant with failure to thrive and episodes of dehydration should also alert the physician.

Simple virilizing form of 21-OHD CAH can often go unrecognized in boys till signs of androgen excess appear in late infancy or early or mid childhood (◉ *Fig. 384.8*). Little attention is paid to rapid somatic growth which is often not considered abnormal. Inadequately treated children of both sexes develop signs of androgen excess. In these children signs of adrenal insufficiency with salt wasting may appear during periods of stress. Accelerated skeletal maturation leads to premature closure of the epiphyses (early cessation) results in stunted stature in adulthood. Pubic and axillary hair appear early; and acne and a deep voice may develop. The penis, scrotum, and prostate may enlarge (in affected boys); however, the testes are usually prepubertal in size and appear relatively small in contrast to the enlarged penis. Occasionally in some cases, testicular adrenal rest tumors occur. In girls the clitoris may enlarge further, breast development and menstruation may not occur unless the excessive production of androgens is suppressed by adequate treatment.

In nonclassical 21-OHD, milder signs of androgen excess may occur. In this attenuated form, cortisol and aldosterone levels are normal and affected females have normal genitals at birth. Many females and males are completely asymptomatic. Children of both sexes present with precocious pubarche and early development of pubic and axillary hair. Hirsuitism, acne, menstrual disorders, and infertility may develop later in life.

There is ongoing debate on prenatal exposure of the brain to high levels of androgens which may influence subsequent sexually dimorphic behavior in these females with preference for toys and games boys like to play. At an older age women may have decreased interest in maternal

Figure 384.8
A 2½-year-old boy presenting with sexual precocity due to non-salt wasting CAH caused by 21 hydroxylase deficiency. Presentation for gradually progressive sexual precocity, darkening of the skin and rapid growth over past 1 year. No episodes of salt wasting or dehydration, similar history in cousin brother. Height age – 5 years, testicular volume 2 mL, pubic hair growth Tanner 3, penile size (increased), Bone age – 5 years (Greulich and Pyle), Height Age – 4.5 years, 17-OHP markedly elevated, adrenal androgens and elevated testosterone. The patient was confirmed to have CAH due to non-salt wasting 21 hydroxylase deficiency

Figure 384.9
A fourteen-year-old patient referred for absence of gonads and gynaecomastia. Genital ambiguity was noted at birth but the patient was brought up as a boy (her younger sibling brought at the same time was confirmed to have non-salt wasting 21 hydroxylase deficiency). Investigations confirmed the same diagnosis in this patient. Parents and the patient were explained the underlying diagnosis. They wished to continue to raise the patient as a male, sex change to female gender was refused

roles with an increased frequency of homosexuality. However, most seem to function heterosexually with no gender identity confusion. Rearing and other postnatal psychosocial environmental factors may influence individual attitudes.

Laboratory Diagnosis

In patients with salt-losing disease cortisol and aldosterone deficiency lead to hyponatremia, hyperkalemia, metabolic acidosis, and often hypoglycemia, developing usually by 2 weeks after birth. 17-hydroxyprogesterone (17-OHP) levels are markedly elevated (>2,000 ng/dL after 24 h of age). As circulating level tends to be high during the first 2–3 days of life even normally, hence it is better to estimate it 48 h after birth. In sick or premature newborns it is often high therefore careful interpretation is necessary. Serum cortisol is usually low in salt-losing 21-OHD and often normal in patients with simple virilizing 21-OHD, but may be inappropriately low in relation to the ACTH and 17-hydroxyprogesterone levels. In addition to 17-OHP, levels of androstenedione and testosterone are elevated in affected females; testosterone levels are not helpful in affected males as testosterone levels tend to be higher during infancy. Urinary metabolites, 17-ketosteroids and pregnanetriol are elevated but are now rarely used in clinical practice. Elevated ACTH levels have limited diagnostic utility over 17-OHP. Plasma levels of renin are elevated, and serum aldosterone is inappropriately low, however, normally renin levels are high in the first few days of life. In some cases 17-OHP estimation at 0′, 30′ or 60′ min after an intravenous bolus of 0.125–0.25 mg of cosyntropin (ACTH 1–24) helps to establish the diagnosis. Nomograms help distinguish normals from patients with nonclassical and classical 21-OHD. Heterozygous carriers of this autosomal recessive disorder tend to have higher ACTH-stimulated 17-OHP levels than unaffected individuals, but significant overlap is seen in these two categories.

Differential Diagnosis

Thorough physical examination to define the anatomy of the genitals, locate the urethral meatus, palpate the scrotum or labia and the inguinal regions for testes (palpable gonads almost always indicate the presence of testicular tissue and suggests that the infant is a genetic male). Presence of other anatomic abnormalities should be excluded. Ultrasonography helps in demonstrating the presence or absence of uterus and location of gonads. A rapid karyotype (such as fluorescence in situ hybridization of interphase nuclei for X and Y chromosomes) can quickly determine the genetic sex of the infant. These studies help in determining the sex of rearing, counseling the parents and deciding future course of action. Most surgeons prefer to outline the urogenital sinus with an injection of contrast medium to formulate a plan for surgical management during infancy. ❯ *Figure 384.10* shows a flow diagram of approach to diagnosis of a newborn with CAH.

Management

Glucocorticoid replacement: This form of therapy introduced in 1950 takes care of cortisol deficiency and also suppresses excessive production of androgens by the adrenal cortex thus minimizing excessive growth, skeletal maturation and virilization. However, management of this disorder still remains difficult. Secretory rate of cortisol is around 12.5 ± 3 mg/m^2 per day but is probably substantially lower. Newborns and newly diagnosed patients often require substantially higher doses to suppress the CRH-ACTH-adrenal axis. Glucoccorticoid equivalence as compared to hydrocortisone is mentioned in ❯ *Table 384.4*. The requirement of glucocorticoids is often higher (15–20 mg/m^2/24 h of hydrocortisone daily administered orally in three divided doses) than with other causes of adrenal insufficiency. Double or triple the doses are indicated during periods of stress, such as infection or surgery. This therapy has to be continued lifelong but may not be necessary in patients with nonclassical disease unless signs of androgen excess are present. Therapy must be individualized. Growth monitoring is helpful as crossing to higher height percentiles may suggest undertreatment, whereas loss of height percentiles and excess weight gain often indicate overtreatment. Growth and skeletal maturation as well as pubertal development should be monitored periodically. Hormone levels, particularly 17-hydroxyprogesterone and androstenedione, should be measured early in the morning (beyond infancy cortisol circardian rhythm gets established) before taking the morning medications, or at a consistent time after medication dosing. Desirable 17-OHP levels are maintained in the high-normal range or little higher; low normal levels are often achieved only with excessive glucocorticoid doses.

Pubertal development and menarche occurs at the appropriate age in girls with early institution of treatment in whom good control has been achieved but can be delayed in girls with suboptimal control.

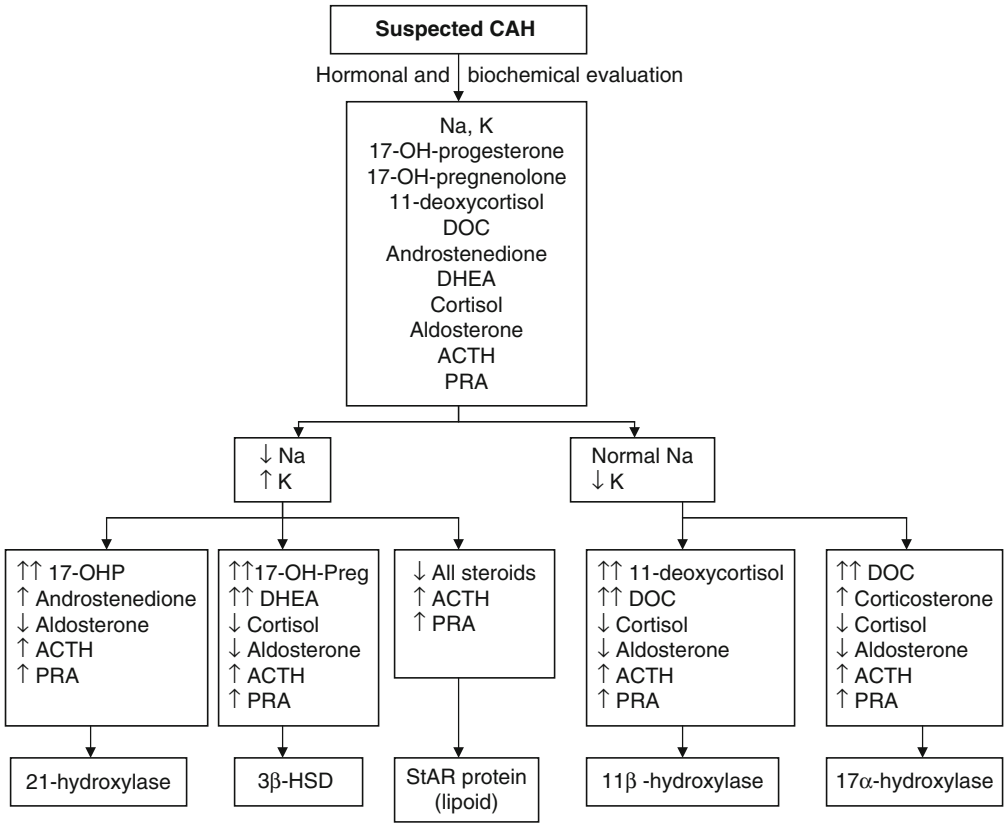

Figure 384.10

Approach to the Infant with Suspected Congenital Adrenal Hyperplasia. In genetic females (46XY) ambiguous genitalia (46,XX) is caused by 21-hydroxylase deficiency,11β-hydroxylase deficiency, and 3β-hydroxysteroid dehydrogenase deficiency. Ambiguous genitalia in genetic males (46, XY) is due to 3β-hydroxysteroid dehydrogenase deficiency and 17α-hydroxylase deficiency. Genetic males with lipoid congenital adrenal hyperplasia have a female phenotype

Children with simple virilizing disease, particularly males, are frequently not diagnosed until 3–7 year of age by which time skeletal maturation may have advanced by 5 year or more. If the bone age is 12 year or more, spontaneous gonadotropin-dependent puberty may supervene when treatment with glucocorticoids is instituted as suppression of adrenal androgen production brings about release of pituitary gonadotropins if appropriate hypothalamic maturation has occurred. Superimposed true precocious puberty may be treated with a gonadotropin hormone-releasing hormone analog such as leuprolide.

In males with inadequate corticosteroid therapy adrenal rest testicular tumors may develop, which usually regress with increased steroid dosage. Testicular MRI, ultrasonography, and color flow doppler may be helpful. Testis-sparing surgery for steroid-unresponsive tumors may be required.

Mineralocorticoid Replacement

Patients with salt-wasting disease (aldosterone deficiency) require mineralocorticoid replacement with fludrocortisone. Requirements of mineralocorticoids is higher in infancy in the first few months of life, usually 0.1–0.3 mg daily in two divided doses. Sodium supplementation (sodium chloride, 1–3 g) is often required. About 20 mg of hydrocortisone has a mineralocorticoid effect of 0.1 mg of 9α-fluorocortisol. Older infants and children are usually maintained with 0.05–0.1 mg daily of fludrocortisone. In some patients, simple virilizing disease may be easier to control with a low dose of fludrocortisone in addition to hydrocortisone even though these patients may have normal aldosterone levels. Presence of tachycardia and hypertension indicate overteatment. Serum electrolytes should be regularly monitored. Plasma renin activity helps determine adequacy of therapy. It should be maintained in or near the normal range but not suppressed.

To improve outcome additional approaches such as the use of an antiandrogen which inhibits aromatase (blocks conversion of androgens to estrogen), growth hormone with or without LHRH agonists, have been used. Adrenalectomy may be required for poorly controlled patients.

Family Education, Psychosocial Support and Genetic Counseling

As with all chronic diseases and intersex problems, family and patient (at a later age) education is extremely important. Early sex assignment is important. This is often a noncontroversial issue in this disorder. Parents and family members must understand that the disorder can be life threatening. Full implications of the diagnosis, life long optimal treatment, importance of periodic monitoring, stress management with adequate genetic counseling are all important aspects of management of these children. Chance of recurrence of this disorder is 25% with every pregnancy. Availability of antenatal diagnosis and prenatal treatment in specialized centers is explained. As they grow, full understanding of their condition must be explained to the patients. There are individuals and groups who are proponents of the patient's rights to decide about surgical procedures and suggest differing these to a later age. However, for CAH with 21-OH deficiency there is less controversy.

Surgical Management of Ambiguous Genitals

Moderate clitoromegaly often becomes less noticeable as the patient grows. In virilized females reduction clitotoplasty with partial excision of the corporal bodies and preservation of the neurovascular bundle may be undertaken between 3 and 6 months of age after discussion with parents. Vaginoplasty and correction of the urogenital sinus are usually performed at the same time which may need revision in adolescence. Confused psychosexual identity is not common in majority of cases where diagnosis and treatment is early.

In adolescent and adult females with poorly controlled 21-hydroxylase deficiency (hirsuitism, obesity, amenorrhea) bilateral laparoscopic adrenalectomy (with hormone replacement) may be superior to standard medical hormone replacement therapy.

Prenatal Diagnosis and Treatment

Prenatal diagnosis and therapy for 21-OHD in the female fetus to minimize the urogenital structural morbidity has been pursued for over past 2 decades but remains controversial. Fetal adrenal steroidogenesis begins early in gestation hence measurement of elevated 17-OHP in amniotic fluid during the second trimester has been used for antenatal diagnosis. Both, 17-OHP and $\Delta 4$ androstenedione are elevated in amniotic fluid in case of fetuses with severe salt wasting CAH. When parents are known heterozygotes, or if earlier child is affected, then HLA typing or DNA analysis of fetal amniocytes is used, if same HLA type as previous affected child is noted then fetus is affected; if one parent's HLA type is shared with index case then the fetus is heterozygous carrier and presence of both hapotypes differing from index case suggests unaffected fetus. Analysis of DNA obtained by chorionic villus sampling by 6–8 weeks to determine the sex and the genotype is very helpful in prenatal diagnosis in families with an affected child. Usually the CYP21 gene is analyzed for frequently occurring mutations, but closely linked, highly polymorphic microsatellite markers may be used if an affected child (i.e., the proband) is available for genetic comparison.

Early accurate diagnosis is essential prior to initiating prenatal treatment. In a female fetus with CAH if fetal adrenal steroidogenesis can be suppressed early (as soon as pregnancy is diagnosed) by 6–8 weeks by maternal administration of dexamethasone, virilization can be suppressed or eliminated. It is given in 2–3 divided doses of 20 ug/kg of maternal body weight (prior to pregnancy). Male fetus does not require prenatal treatment. No short term deleterious effects are observed in children exposed to this therapy. Hypertension in later life and neurotoxicity are noted in experiments on rats. Hence antenatal treatment is still considered experimental and recommended at few specialized centers. Maternal side effects of prenatal treatment have included edema, excessive weight gain, hypertension, glucose intolerance, cushingoid facial features, and severe striae.

Newborn Screening for 21-OHD

As 21-hydroxylase deficiency is the most common cause of CAH in the newborn (95% of all cases with CAH) and often remains undiagnosed in affected males who succumb to the disease early in life, screening has effectively prevented adrenal crisis in affected males. Many American states and other countries have instituted neonatal screening for the classical form of this disorder which are linked with existing neonatal screening programs. These programs analyze 17-hydroxyprogesterone (17-OHP) levels in dried blood obtained on filter paper cards by heel-stick, prick. Potentially affected infants are recalled for additional testing (electrolytes and repeat 17-OHP approximately by 2 weeks

of age by which time these infants may not yet be severely sick. To reliably detect all affected infants, the cut off 17-OHP levels for recalls are set very low resulting in a very high frequency of false-positive results. Effort is underway to set up universal standards. The predictive value is low, in premature infants. The nonclassical form of the disease is not reliably detected but that has little clinical significance. Genotyping for CYP21 might improve specificity but is not routinely available.

CAH due to 11B-Hydroxylase Deficiency

Etiology

Mutation in the CYP11B1 gene located on chromosome 8q24 causes deficiency of 11β-hydroxylase. As stated earlier CYP11B1 gene located on chromosome 8q24. CYP11B1 mediates 11-hydroxylation of 11-deoxycortisol to cortisol (*Fig. 384.1*). As 11-deoxycortisol is not converted to cortisol, levels of corticotrophin are high. In consequence, precursors – particularly 11-deoxycortisol and deoxycorticosterone – accumulate and are shunted into androgen biosynthesis (in the same manner as occurs in 21-hydroxylase deficiency). Patients are able to synthesize aldosterone normally as the adjacent CYP11B2 gene encoding aldosterone synthase is unaffected in this disorder.

Epidemiology

This disorder accounts for ~5% of cases of CAH; with a probable incidence of 1/250,000 to 1/100,000. More than 30 different mutations in CYP11B1 have been identified. It is more frequently seen in Israeli Jews of North African origin (1 in 15,000 – 17,000 live births); in this ethnic group almost all alleles carry an Arg448 to His (R448H) mutations. Affected patients present in a classical, severe form. Nonclassical milder form is rare.

Clinical Manifestations

It is unusual for these patients to manifest signs of adrenal insufficiency such as hypoglycemia or hypotension, hyponatremia, and hyperkalemia as aldosterone synthetic capacity is normal with some corticosterone being synthesized from progesterone by the intact aldosterone synthase enzyme although cortisol is not synthesized efficiently. Hypertension a consequence of elevated levels of deoxycorticosterone manifests in approximately two thirds of patients although this can take several years to develop. Interestingly, with institution of treatment with hydrocortisone, infants may transiently develop signs of mineralocorticoid deficiency. This is presumably due to sudden suppression of deoxycorticosterone secretion in a patient with atrophy of the zona glomerulosa caused by chronic suppression of renin activity. All signs and symptoms of androgen excess found in 21-hydroxylase deficiency also occur in 11-hydroxylase deficiency.

Laboratory Findings

Plasma levels of 11-deoxycortisol and deoxycorticosterone are elevated and because of deoxycorticosterone and metabolites, plasma renin activity is suppressed. Consequently, aldosterone levels are low even though the ability to synthesize aldosterone is intact. Hypokalemic alkalosis occasionally occurs.

Treatment

Hydrocortisone in doses similar to those used for 21-hydroxylase deficiency are used. Mineralocorticoid replacement is sometimes transiently required in infancy but is rarely necessary otherwise. Hypertension often resolves with glucocorticoid treatment but may require additional therapy if it is of long standing. Calcium channel blockers may be beneficial under these circumstances.

CAH due to 3β-Hydroxysteroid Dehydrogenase Deficiency

Etiology

This enzyme is required for conversion of Δ5 to Δ4 steroids (*Fig. 384.1*). Deficiency of this enzyme results in decreased synthesis of cortisol, aldosterone, and androstenedione but increased secretion of DHEA. The 3B-HSD enzyme expressed in the adrenal cortex and gonad is encoded by the HSD3β2 gene located on chromosome 1p13.1. 3β-HSD occurs in fewer than 2% of patients with CAH. Over 30 mutations in the HSD3B2 gene have been described in patients with 3β-HSD deficiency.

Clinical Manifestations

As cortisol and aldosterone are not synthesized in patients with the classical form of the disease, infants are prone to

salt-wasting crises. Lack of synthesis of androstenedione and testosterone leads to incomplete virilization in boys. Varying degrees of hypospadias may occur, with or without bifid scrotum or cryptorchidism. Postnatally, continued excessive DHEA secretion can cause precocious adrenarche. During adolescence and adulthood, hirsuitism, irregular menses, and polycystic ovarian disease can occur in females. Males manifest variable degrees of hypogonadism, although appropriate male secondary sexual development may occur. Girls are mildly virilized, with slight to moderate clitoral enlargement due to weak androgenic action of DHEA. High Δ5 to Δ4 steroid ratio in testicular effluent suggests persistent defect of 3β-HSD.

Laboratory Findings

Marked elevation of the Δ5 steroids (such as pregnenolone, 17-hydroxypregnenolone and DHEA) preceding the enzymatic block is indicative of this disorder. Elevated levels of 17-OHP may be noted because of the extra-adrenal 3B-HSD activity in peripheral tissues; these patients may be mistaken for patients with 21-hydroxylase deficiency. However, the ratio of 17-hydroxypregnenolone to 17-hydroxyprogesterone is markedly elevated in 3B-HSD deficiency, unlike the decreased ratio in 21-hydroxylase deficiency. Plasma renin activity is elevated in the salt-wasting form.

Differential Diagnosis

It has been suggested that children with premature adrenarche, or women with signs of androgen excess, with mild to moderate elevations in DHEA levels may have "nonclassical 3β-HSD deficiency." However, mutations in the HSD3β2 gene are often not found in such patients. Nonclassical form of this deficiency must actually be quite rare. The activity of 3β-HSD in the adrenal zona fasciculata and reticularis, relative to CYP17 (17-hydroxylase/17,20-lyase) activity, normally decreases during adrenarche to facilitate DHEA synthesis, and so modest elevations in DHEA in pre-teenage children or women usually represent a normal variant.

Treatment

Patients require glucocorticoids and mineralocorticoid replacement with hydrocortisone and fludrocortisone, respectively, as in 21-hydroxylase deficiency. Incompletely virilized genetic males in whom a male sex of rearing is contemplated may benefit from several injections of a depot form of testosterone early in infancy to increase the size of the phallus. They may also require testosterone replacement at puberty.

Lesions in Isozymes of P450c11

Corticosterone Methyloxidase Deficiencies

These deficiencies are uncommon. There are two distinct forms of 11-hydroxylase, P450c11β mediates the 11β-hydroxylation of 11-deoxycortisol to cortisol and that of DOC to corticosterone in the zonae fasciculata and reticularis. P450c11AS, or aldosterone synthase, is found only in the zona glomerulosa and mediates 11β-hydroxylation, 18-hydroxylation, and 18-oxidation; thus, it is the sole enzyme required to convert DOC to aldosterone.

P450c11AS, the isozyme of P450c11β is 93% identical in its amino acid sequence, is expressed exclusively in the zona glomerulosa, where it catalyzes 11β-hydroxylase, 18-hydroxylase, and 18-methyloxidase activities. Disorders of P450c11AS cause the so-called corticosterone methyloxidase (CMO) deficiencies, wherein aldosterone biosynthesis is impaired, while the zona fasciculata and reticularis continue to produce corticosterone and DOC. The absence of aldosterone biosynthesis will generally result in a salt-wasting crisis in infancy. These infants typically present with hyponatremia, hyperkalemia, and metabolic acidosis, but the salt-wasting syndrome is less severe than with 21-OHD or lipoid CAH because of the persistent secretion of DOC. Spontaneous recovery may occur with age, due to increasing sensitivity to mineralocorticoid action with advancing age. Hence, PRA is markedly elevated in affected children, it is usually normal in affected adults.

CMO type I deficiency is the result of loss of 450c11AS activity so that no 18-hydroxylase or 18-methyloxidase activity is present. CMO type II deficiency results from amino acid replacement mutations in P450c11AS that selectively delete the 18-methyloxidase activity while preserving the 18-hydroxylase activity. The distinction between CMO types I and II is not always clear.

Adrenocortical Hyper Function

Pediatric Cushing syndrome (CS) is an uncommon disorder and poses challenge in diagnosis and management. It

Table 384.4
Classification of Cushing syndrome

ACTH dependent CS	ACTH independent CS
Cushing disease (ACTH secreting pituitary adenoma)	Exogenous glucocorticoid administration
Ectopic ACTH syndrome	Adrenocortical tumors (adenoma/carcinoma)
Iatrogenic (treatment with ACTH)	Primary adrenocortical hyperplasia
	Primary pigmented nodular adrenocortical disease (PPNAD)
	Macronodular adrenal hyperplasia (AIMAH)
	McCune–Albright syndrome (MAS)

is the result of high circulating levels of glucocorticoids, either produced endogenously or administered exogenously. There is usually a delay in suspecting the diagnosis which leads to high morbidity and mortality. This disorder is best understood as ACTH dependent and ACTH independent CS. (*Table 384.4*).

Etiology

Commonest cause of hypercortisolism in children is exogenous glucocorticoid administration. Glucocorticoids are used for multiple disorders and resultant clinical picture rarely poses diagnostic dilemma. It is associated with side effects of long term glucocorticoids use namely retardation of linear growth, hyperglycemia, hypertension and osteoporosis, which needs to be addressed as a management issue.

ACTH Dependent CS

Cushing Disease (ACTH Secreting Pituitary Adenoma)

The commonest cause of endogenous Cushing syndrome in children >7 year of age is Cushing disease i.e., ACTH secreting pituitary adenomas. These adenomas are usually micro adenomas (<1 cm in diameter) and frequently show positive immunostaining for ACTH and its precursor, pro-opiomelanocortin (POMC).

Ectopic ACTH Syndrome

Ectopic ACTH secretion, accounting for 15% of CS in adults, is a rarity in children. Bronchial and thymic carcinoids and neuroendocrine tumours of pancreas predominate as etiological factors. There are case reports of association of CS with islet cell carcinoma of the pancreas, neuroblastoma, ganglioneuroblastoma, hemangiopericytoma, and Wilms tumor. Clinical manifestation of hypercortisolism may be masked by that of the underlying disorder. However in cases of bronchial carcinoids clinical picture may mimic that of CD.

ACTH Independent CS

In infants and younger children, endogenous hypercortisolism is most often caused by a functioning adrenocortical tumor, usually a carcinoma, McCune-Albright syndrome or PPNAD.

Adrenocortical Tumors

Adrenocortical Carcinoma (ACC) as a cause of CS occurs in younger individuals unlike adrenocortical adenomas in older patients. ACC is a rare malignancy with heterogeneous presentation and generally poor prognosis. Exceptionally high incidence of ACC is known to occur in southern Brazil (4.2 per million vs. 0.3 per million) related to p53 tumor suppressor gene mutation. ACC is further described under section on adrenal carcinoma.

PPNAD

PPNAD is a rare but important cause of pediatric CS. It is associated with Carney Complex, with autosomal dominant inheritance, though sporadic mutation can occur. It typically occurs in adolescence or early adulthood. The adrenal lesion shows multiple, small, pigmented, adrenocortical nodules surrounded by cortical atrophy. Diagnosis of this disorder may be difficult as it can be cyclical in nature. Apart from management of CS, patient requires

lifelong monitoring to detect associated serious lesions of Carney complex like cardiac myxoma, pituitary and testicular tumours. Germ line mutations of regulatory sub unit of R1A of protein kinase A (PRKAR1A) are present in 45% of patients and gene for the same is mapped to chromosome 17q 22–24.

McCune-Albright Syndrome

McCune-Albright syndrome as a cause of CS presents early in infancy. It is due to activating mutation of GNAS1 gene. Adrenal involvement results in constitutive steroidogenesis in adrenal nodules. Associated involvement with activating mutations may occur in gonads, thyroid, pituitary and bones. Clinical picture is determined by underlying organ involvement.

Clinical Findings

There is a large spectrum of manifestations from subclinical to overt syndrome depending on duration and intensity of excess steroid production. Distinct catabolic manifestation of hypercortisolism like fatigue, purplish striae, easy bruisabilty, proximal muscle wasting, weakness, osteoporosis and pathological fractures, are late manifestations in childhood cushing as compared to adults. Also the centripetal distribution of fat is not that marked in children. Childhood Cushing almost invariably has generalized obesity and growth retardation. The obvious dissociation between height and weight on the growth chart may be the first indication and is also specific sign of glucocorticoid excess state. Weight gain is accompanied by mooning of face and plethora. *Figure 384.11* shows classical appearance of a child with CS.

Varied degree of androgenisation in form of hirsutism, acne, and isosexual precocity, can be present. Delayed puberty, oligomenorrhoea, polycystic ovaries are other manifestations of gonadotropin axis involvement. Minerocorticoid excess due to spillover effect of excess glucocorticoid may manifest as hypokalemia, and hypertension. Cushing syndrome should be borne in mind as differential when evaluating for hypertension in a child. Other renal manifestations include microalbuminuria, glycosuria, hypercalciuria and renal calculi.

ACTH dependent cushing has generalized hyperpigmentation, more marked over the pressure areas. This may confused with acanthosis nigricans which is a marker of insulin resistance and can coexist. Glucose intolerance and insulin resistance is common in CS.

The common psychological symptoms range from emotional lability, agitated depression, panic attacks, and mild paranoia to mania. Obsessive compulsive behavior is specifically associated with childhood hypercortisolism. Learning, cognition and memory may be impaired in the diseased child. Loss of diurnal rhythm of cortisol may lead to insomnia.

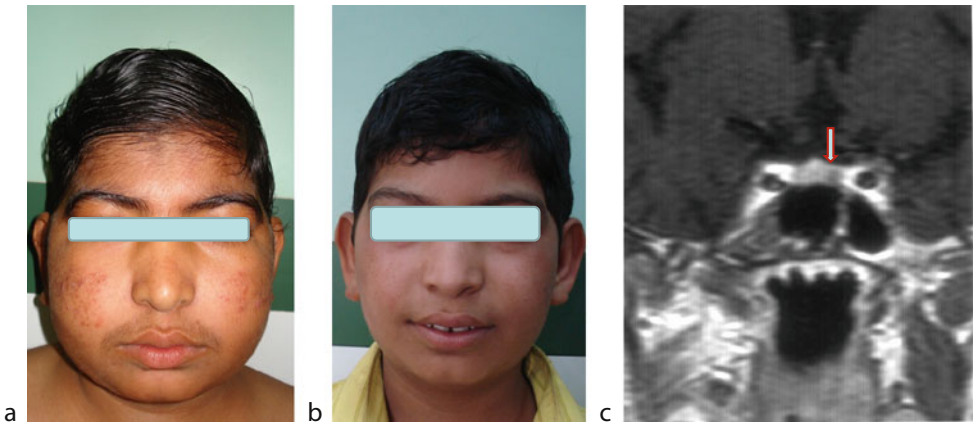

Figure 384.11
(a, b, c) Classical fascial appearance of a patient with Cushing syndrome. Thirteen-year-old boy presented with facial swelling, weight gain, abdominal striae, hyperpigmentation and growth failure. ACTH driven endogenous hypercortisolism was proven with midnight serum cortisol: 14.78 μg/dL and plasma ACTH of 112.6 pg/mL. Dynamic contrast MRI showed a pituitary microadenoma, which was excised by transsphenoidal route. There was marked reduction in cushingoid features at 3 months post surgery with basal cortisol of 2.3 μg/dL, suggestive of cure

The spectrum of clinical manifestations, at any given level of hypercortisolism varies. Progressive features and appearance of new signs increase the probability of syndrome. Duration of symptoms in all patients' ranges from 2 months to few years as diagnoses is often not suspected. Though there is clear female preponderance in adult Cushing, in children such preponderance may not exist.

Diagnosis of Cushing Syndrome

Investigations in a suspected case of hypercortisolism are done in 2 phases. Tests to establish endogenous hypercortisolism are followed by tests to localize source of endogenous hypercortisolism.

Test for Establishing Endogenous Hypercortisolism

It is very important to rule out exogenous glucocorticoid intake, before beginning any test to establish hypercortisolism. History of chronic steroid intake and suppressed basal cortisol is suggestive of suppressed hypothalmo pituitary adrenal axis secondary to exogenous steroid intake. Initial tests to prove endogenous hypercortisolism are 24 h Urinary free cortisol(UFC), late night salivary or serum cortisol, and over night or standard 2 days low dose dexamethasone suppression tests (LDDS).

In this setting goal, is to choose tests with high sensitivity. Conditions associated with hypercortisolism in absence of CS like morbid obesity, physical or mental stress, depression, and CBG excess states can give false positive results on initial screening tests. Another basic principle applied in interpreting the test is that increasing the diagnostic cut-off point, increases its specificity at the cost of reduced sensitivity.

UFC

Twenty-four hour urinary cortisol excretion is an integrated measure of the serum free cortisol concentration. Sensitivity of this test is close to 90% when upper limit of normal is used as diagnostic criteria. It needs to be ensured the collection is complete and state of high fluid intake is avoided. False negative results can occur in mild Cushing disease. One can be confident of the diagnosis in patients in whom measures of integrated cortisol production are unequivocally increased (threefold above the upper limit of normal for the assay). The cut off value for normal UFC excretion is suggested to be <72 μg (198.7 nmol)/m^2/day.

Cortisol Circadian Rhythm

Late night salivary cortisol: The most validated assays used are ELISA and LCMS. Using these two methods normal subjects will have salivary cortisol (midnight) less than 1.4 ng/mL. Various studies have reported its sensitivity as 92–100% and specificity as 93–100%. Obtaining two separate samples increases the diagnostic yield of the test. Confounding factors like oral gels with steroids, brushing of teeth, smoking at least 2 h prior etc. must be meticulously avoided. If salivary cortisol estimation is used as the test, it is important to choose a laboratory that provides a validated response range, because cortisol measurements of the same sample using different assay techniques may yield different results.

Midnight serum cortisol: Sleeping mid night sleeping cortisol >1.8 μg/dL has high sensitivity (100%). Specificity however is poor as shown in recent larges series at 20%. In patient with high clinical index of suspicion but with normal UFC and LDDS, a midnight cortisol >1.8 μg% increases the probability of Cushing syndrome. While obtaining sleeping sample it is essential to draw blood within 5 min of awakening, preferably through an indwelling catheter. Awake midnight serum cortisol cut off value used is >7.5 μg/dL for diagnosis of Cushing syndrome.

Dexamethasone Suppression Tests

Overnight 1 mg dexamethasone suppression test (ODS) consists of administration of 1.0 mg of dexamethasone at 11 PM, and measurement of serum cortisol at 8 AM the next morning. There is lack of data to interpret the performance of this test in childhood. However in adult population, at cut of 1.8 μg/dL, it gives sensitivity of 95% and specificity of 80%. Based on its greater specificity, Low dose 48 h dexamethasone suppression test is preferred, but is more cumbersome than the overnight test. In pediatric patients with weight >40 kgs, the dose of dexamethasone is 0.5 mg 6 h for 48 h. Patients with weight <40 kgs, need 30 μg/kg/day in four divided doses. Serum cortisol is measured at baseline and 6 h after the last dose of dexamethasone. *Figure 384.12* describes approach to a suspected case of CS.

In patients with high pretest probability and initial negative screening tests, further assessment preferably by an experienced person is a must. In other patients with normal test results, unless clinical signs and symptoms progress, further testing is not needed. If one of the tests is positive, further assessment for confirmation and localization are warranted.

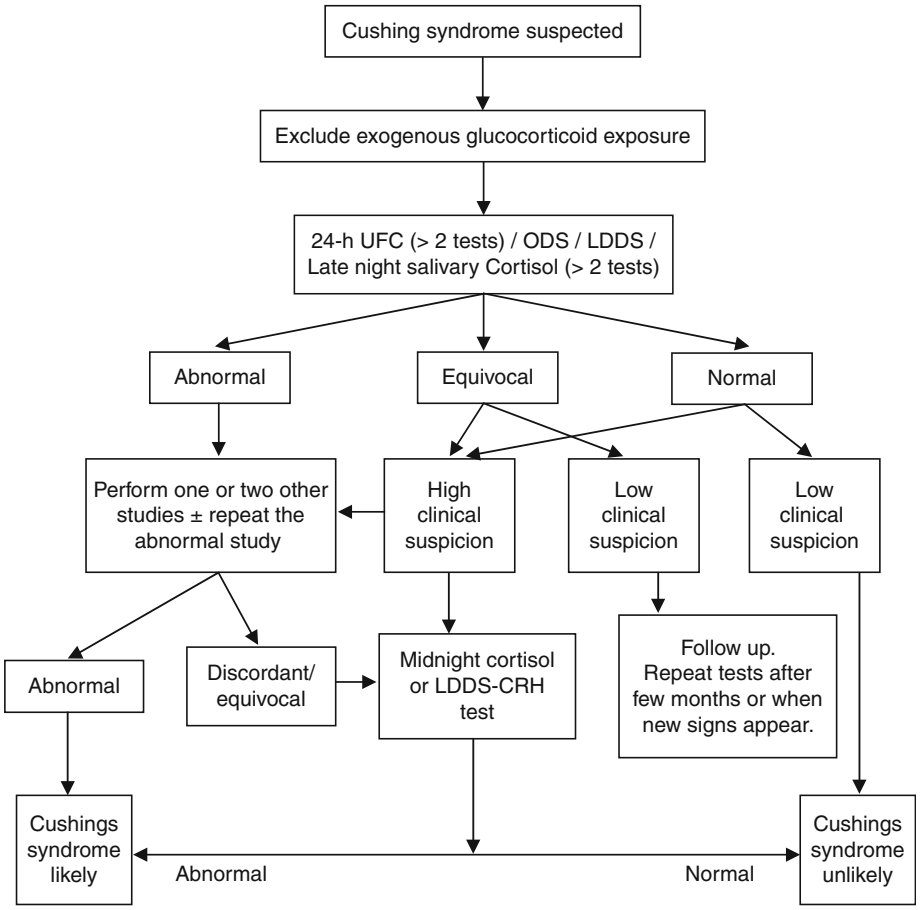

Figure 384.12

Algorithm for Investigating Patients Suspected Of Having Cushing syndrome. Interpretation of all the tests must be combined with the clinical picture. Experience is necessary to adopt the correct test and interpret the results

Localization of the Cause of Cushing Syndrome

Basal ACTH

Having confirmed the presence of Cushing syndrome, ACTH-dependent or ACTH-independent disease needs to be established. This can be done by measuring basal plasma ACTH. ACTH using immunometric assay is a useful parameter for diagnosis of adrenal Cushing syndrome, in a manner similar to suppressed TSH in Graves disease. Suppressed basal ACTH (<5 μg) is highly suggestive of ACTH independent nature of the disease. ACTH levels >15 pg/mL suggest ACTH dependent disease. Levels between 5 and 15 pg/mL are inconclusive and may need to be repeated.

Adrenal Imaging

A low plasma ACTH concentration <5 pg/mL (1.1 pmol/L) is an evidence of ACTH-independent disease and needs adrenal imaging. Most adrenal tumors are visible on MRI scan. In PPNAD, adrenals are normal in size, mostly with distinct small (<6 mm) nodules which may not be visible on the scan. Another peculiar characteristic of PPNAD is the paradoxical rise in cortisol value after dexamethasone suppression test which was classically described by Liddle. Patients with McCune-Albright syndrome may have normal adrenal glands or an adenoma. Presence of associated findings like skin pigmentation, fibrous dysplasia, hyper functioning states of thyroid/pituitary/gonads help to achieve diagnosis.

Pituitary Imaging

Plasma ACTH value >15 pg/mL (4.4 pmol/L) indicate that cortisol secretion is ACTH-dependent. Vast majority of them are likely to have corticotroph secreting adenoma. Dynamic contrast MR pituitary is the next test to be performed. The reported sensitivity of contrast MRI with spoiled gradient sequences is up to 64%. In patients with microadenoma >6 mm, the diagnosis of pituitary corticotroph adenoma can be confirmed and patients can be subjected to surgery.

Bilateral Inferior Petrosal Sinus Sampling

Failure to localize a pituitary adenoma in patients with ACTH dependent CS will necessitate invasive test like inferior petrosal sinus sampling. CRH stimulated bilateral simultaneous inferior petrosal sinus sampling is the only test which fares better than the pretest probability of lesion being in pituitary (98% vs. 85–90%). A central-to-peripheral plasma ACTH gradient of ≥2.0 before CRH administration, or ≥3.0 after CRH, is diagnostic of a pituitary source of ACTH. False negative results could be due to poor catheter placement or anomalous or asymmetric venous drainage. Lateralization of tumor is possible in up to 70% as reported in various studies. *Figure 384.13* describes an approach to localization in a proven case of endogenous hypercortisolism.

Management of Cushing Syndrome

Transsphenoidal surgery (TSS) is the preferred mode of treatment for Cushing disease. Prior to the Surgery, blood

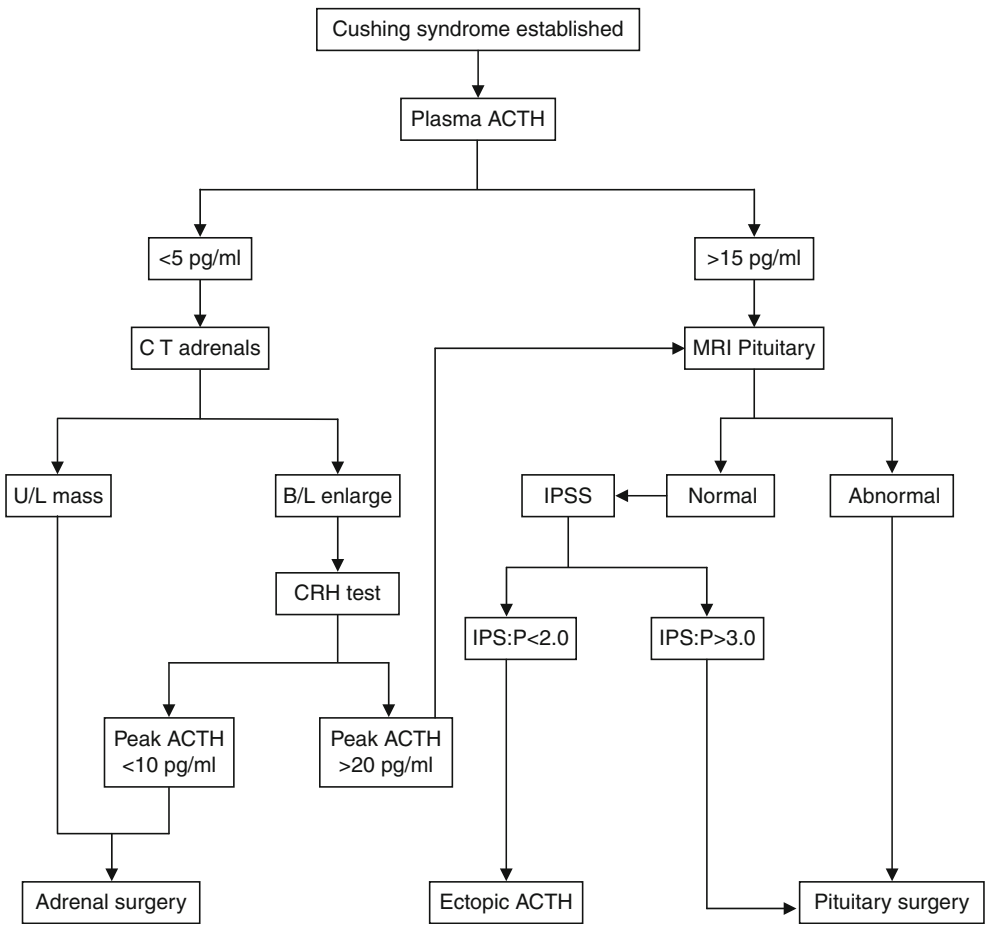

Figure 384.13

Flow chart showing approach to a patient with proven endogenous hypercortisolism. The flow chart is applied only after the state of endogenous hypercortisolism is proven. Unit with experience in IPSS may be necessary to undertake accurate localization. Correct localization is the key to success in management of patients with Cushing syndrome

pressure, plasma glucose and potassium should be stabilized and chest physiotherapy instituted to ensure early recovery in post operative period. Inhibitors of adrenal steroidogenesis (metyrapone, ketoconazole, aminoglutethimide) have been used in severe cases preoperatively to normalize circulating cortisol levels and reduce perioperative morbidity and mortality. TSS in the experienced hand results in cure rate of 80–90% with risk of mortality being, <1%. Post operative serum cortisol values of <2 μg/dL defines cure. Delayed cure up to 6–12 weeks after TSS is documented; hence additional therapeutic measures should be adopted only after documenting persistent hypercortisolism. Recurrences are treated with re-operation, pituitary irradiation, or bilateral adrenalectomy. If surgery is unsuccessful, radiotherapy is effective second line management, with majority of childhood cases achieving remission within a year. Long term risks of radiation are cognitive impairment, panhypopituitarism, increased prevalence of cerebrovascular accidents, and rarely development of secondary tumors. Adrenalectomy may lead to increased ACTH secretion by an unresected pituitary adenoma, evidenced mainly by marked hyper pigmentation; this condition is termed Nelson syndrome. Lower age at the time of adrenalectomy is an important predictive factor for the development of Nelson syndrome; hence caution needs to be observed before offering bilateral adrenalectomy as treatment option in childhood CD. Centrally acting agents like D2 receptor agonist, cabergoline and new somatostatin analog, SOM230 (paseriotide) have shown promising outcomes in recent studies. Bilateral adrenalectomy is also done in cases where ectopic ACTH secreting tumour is non localizable. Benign cortical adenomas are treated with unilateral adrenalectomy. In primary adenal hyperplasia (PPNAD, McCune-Albright syndrome or MAH) the treatment option is bilateral adrenalectomy with lifelong steroid replacement.

Even after cure is achieved, patients with CS need long term follow up, considering the fact that risk of recurrence is high and is related to length of follow up. Linear growth retardation remains a concern and it stems from continuing growth hormone deficiency with or without combined gonadotropin deficiency resulting from TSS and radiotherapy. Institution of GH therapy is warranted in patients who fail to catch up and are proven to have GH deficiency state. In addition obesity with increased risk of metabolic syndrome necessitate appropriate ongoing monitoring. Osteoporosis though uncommon in childhood CS, needs to be evaluated and treated if necessary.

Primary Aldosteronism

Primary aldosteronism (PA) comprises of group of disorders where aldosterone formation is inappropriately high, and relatively independent of the renin-angiotensin system (RAS) (see *Table 384.5*). This condition needs to be recognized as it has higher cardiovascular morbidity and mortality than the same degree of essential hypertension. Hypertension needs distinct treatment and could be even cured in many.

Table 384.5
Classification of mineralocorticoid excess states

Primary aldosteronism	Deoxycorticosterone excess
Aldosterone-producing adenoma	Congenital adrenal hyperplasia
Bilateral idiopathic hyperaldosteronism	11 β-Hydroxylase deficiency
Unilateral adrenal hyperplasia	17 α-Hydroxylase deficiency
Bilateral macronodular adrenal hyperplasia	Tumor
Familial hyperaldosteronism type I and type II	Glucocorticoid resistance syndrome
Aldosterone-producing adrenocortical carcinomas	Apparent mineralocorticoid excess (AME) state
Ectopic aldosterone-secreting tumors (e.g., neoplasms of the ovary, kidney)	Genetic
	Type 1 AME
	Type 2 AME
	Acquired
	Licorice ingestion
	Cushing syndrome

Epidemiology

The prevalence data of this rare disorder in children is not known. In adults it was earlier reported to occur in <1% of patients with mild to moderate hypertension. Hypokalemia was considered to be *sine qua non* for diagnosis. However PA is found to be causative factor in up to 10% of hypertensive adults in cross sectional and prospective studies.

Clinical Manifestations

It may be asymptomatic, as revealed on evaluation of incidentally detected high blood pressure or adrenal mass lesion. Hypertension and hypokalemia are the two major clinical findings, but normokalemic hypertension constitutes the most common presentation of the disease, with hypokalemia probably present in only the more severe cases.

Aldosterone excess leads to sodium retention, mild volume expansion, and hypertension. A steady state is reestablished due to pressure natriuresis and lack of edema is characteristic of this entity. Urinary potassium loss leads to metabolic alkalosis and hypokalemia which may be asymptomatic or manifests as polyuria, muscle weakness, intermittent paralysis and failure to thrive. Excessive secretion of aldosterone is associated with an increased risk of cardiovascular disease and morbidity, including left ventricular hypertrophy, myocardial infarction and stroke.

Laboratory Investigations

Case detection of PA is recommended in patients with moderate, severe, or resistant hypertension, hypertension with spontaneous or diuretic-induced hypokalemia, adrenal incidentaloma, or a family history of early-onset hypertension or cerebrovascular accident at a young age (<40 year). Family screening for hypertension and further evaluation is warranted in diagnosed case of primary aldosteronism.

Hypokalemia, metabolic alkalosis, mildly elevated sodium may be found. Serum calcium concentration is usually normal. Ratio of plasma aldosterone to plasma rennin activity (PAC/PRA) is the initial screening test. Drugs that affect RAS should be avoided for several weeks prior to testing. These include aldosterone antagonists, diuretics, β-blockers, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, clonidine and nonsteroidal anti-inflammatory agents. If required α-adrenergic blockers or calcium channel blockers can be used. Patient should be ambulatory for 2 h and made to sit for 15 min prior to blood collection. PAC/PRA (ng/dL per ng/mL/h) of >30 and PAC >15 ng/dL are highly suggestive of the diagnosis. Further to confirm the aldosterone secretion is inappropriately high either of the following tests need to be performed; oral sodium loading, saline infusion, fludrocortisone suppression, or captopril challenge test.

Imaging

CT scan may pick up single discriminatory lesion; however it has limitation in differentiating aldosterone producing adenoma (APA) from hyperplasia and lateralizing the disease. CT scan is particularly useful in ruling out adrenal carcinoma, that may be responsible for mineralocorticoid excess state, which is usually more than 4 cm in size. Occasionally they may be smaller where CT characteristics of malignancy help to identify them. In patients where surgical treatment is desired by the family the distinction between unilateral and bilateral disease is achieved by adrenal venous sampling.

Figure 384.14 shows an approach to suspected patient of PA.

Differential Diagnosis

Primary aldosteronism should be distinguished from familial forms of PA; Familial Hyperaldosteronism (FH) type I, [glucocorticoid-remediable hyperaldosteronism (GRA)], which is specifically treated with glucocorticoids and FH type II. An autosomal dominant pattern of inheritance should raise suspicion for the familial forms of PA. GRA is usually associated with bilateral adrenal hyperplasia accounting for <1% of cases of primary aldosteronism. The mutation in patients with GRA is fusion of the promoter region of the gene for CYP11B1 and the coding sequences of CYP11B2, resulting in ACTH-dependent activation of the aldosterone synthase effect on cortisol, corticosterone, and cortisol precursors. Unlike FH-I, FH-II, does not suppress with dexamethasone, and GRA mutation testing is negative. The molecular basis for FH-II is unclear, although several linkage analyses have shown an association with chromosomal region 7p22.

Glucocorticoid-remediable hyperaldosteronism is diagnosed by specific genetic testing rather than measurements of urinary levels of 18-hydroxycortisol, 18-oxocortisol or

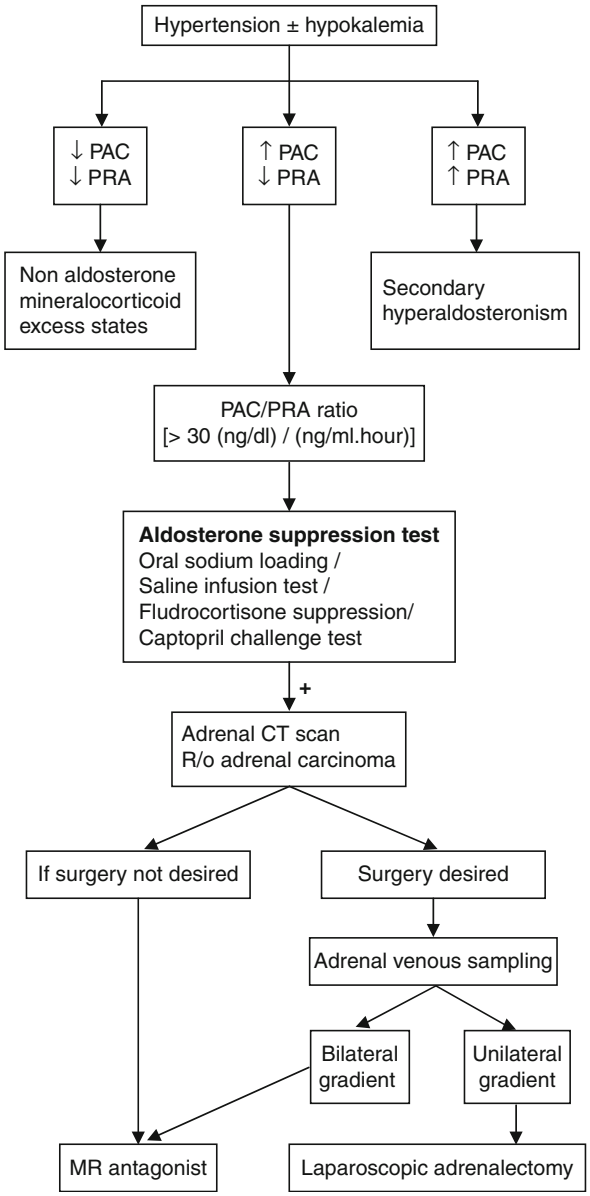

Figure 384.14
Approach to a child with hypertension and/or hypokalemia suspected to have mineralocorticoid excess state

performance of dexamethasone suppression test which may be misleading. Genetic testing to rule out GRA is indicated in patients with confirmed PA and family history of PA, strokes at young age, or onset of HT below 20 years of age. More generally, primary aldosteronism should be distinguished from other forms of hypertension by means of the testing previously discussed.

Treatment

Treatment aims beyond normalization of the serum potassium, blood pressure, and is targeted towards reversal of the effects of hyperaldosteronism on the heart.

For unilateral aldosterone hyper secretion (e.g., adrenal adenoma or unilateral adrenal hyperplasia), laparoscopic adrenalectomy is the treatment of choice. Patients with bilateral adrenal hyperplasia or confirmed unilateral adrenal aldosterone hyper secretion, not desiring surgery, mineralocorticoid receptor antagonist are first line drug treatment as they additionally act on the mineralocorticoid receptors on the heart. Spironolactone is the preferred drug, and can be replaced by eplerenone if side effects particularly anti androgenic effects are limiting factor.

Adrenocortical Carcinoma

Epidemiology

Adrenocortical carcinomas (ACC) are rare malignancy; with overall incidence of 1–2/million population per year and 0.3/million children/year. Children in Southern Brazil have the highest reported annual incidence of ACC (3.4–4.2/million). Girls are more often affected than boys. The age distribution is bimodal with a first peak before the age of five and a second higher peak in the 4th and 5th decade.

Molecular Basis of ACC

Although most cases of ACC appear to be sporadic with mutation in p53 tumor suppressor gene, some have been described as a component of several hereditary cancer syndromes: Li-Fraumeni syndrome, Beckwith-Wiedemann syndrome, and Multiple Endocrine Neoplasia type 1. Two hit theory with evolution of adrenal adenoma to carcinoma is unclear at present. Mutation at 11p15 locus with IGF-II acting via IGF-I receptor leading to adrenal cancer cell proliferation has been shown in vitro.

Clinical Manifestations

In children ACCs are usually hormone-secreting (90%). They may present with virilization alone (50–80%), or a mixed Cushing and virilization syndrome (20–40%),

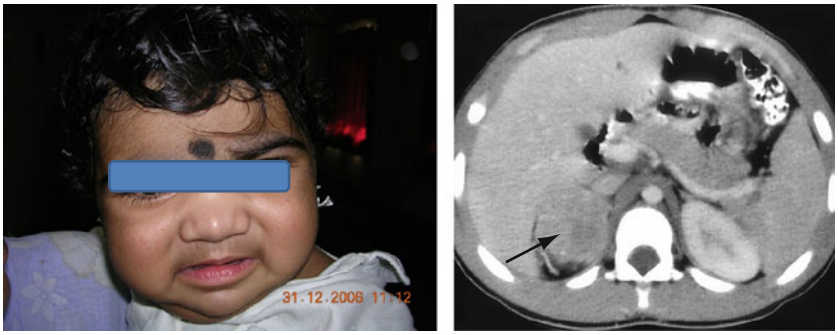

Figure 384.15
Clinical picture of a child with adreno cortical carcinoma and CT scan showing right adrenal mass. This 3 years 4 months old child presented with rapid weight gain and onset of pubic hair development. Examination revealed facial mooning, plethora, and acne with mild hirsuitism observed on the upper lip. She had pubic hair (stage 3) and clitoromegaly. CT scan showed a large lesion on right side suggestive of right adrenal carcinoma

while isolated glucocorticoid excess (Cushing syndrome) is much less common (<5%). Rapidly progressing Cushing syndrome (CS) with or without virilization is a frequent presentation. Androgen secretion in girls can present as virilization with acne, clitoromegaly, growth spurt and premature adrenarche. *Figure 384.15* shows typical facial appearance and CT scan of young child with ACC. In boys virilization presents with acne, muscle development, premature development of pubic, axillary and facial hair. Hypertension (HT) with marked hypokalemia is present in aldosterone secreting ACC. However HT with hypokalemia more often occurs due to cortisol excess state with apparent mineralocorticoid excess state leading to overwhelming of 11 β-hydroxysteroid dehydrogenase type 2 activity. Occasionally patient can present with fever, vomiting, anorexia, weight loss as presentation with very few symptoms/signs of hormone excess state. Feminizing adrenocortical tumors presenting as gynecomastia in males or premature thelarche in girls are reported due to high levels of aromatase activity found in these tumors.

Laboratory Findings and Imaging

Hormonal work up to prove hypercortisolism, increase in sex steroids or its precursors and mineralocorticoid excess state are required. Urinary 17-ketosteroids and serum dehydroepiandrosterone (DHEA), DHEA sulfate, androstenedione and testosterone are usually elevated. Additionally 17 β estradiol (boys), tests for hypercortisolism and hyperaldosteronism are required. Hormonal secretory pattern may point to malignant potential of the tumour. High concentration of DHEAS, estradiol in boys and sex steroid precursors are suggestive of malignant potential and would help to select laprotomy against minimal access surgery. Biochemical exclusion of pheochromocytoma is advisable because imaging modalities cannot reliably differentiate between ACC and pheochromocytoma. ACC are usually more than 4 cm in diameter when discovered. CT scan with delayed contrast wash out studies and MRI with chemical shift technique are equally effective in distinguishing malignant from benign lesions. PET scanning with fluorodeoxyglucose is of value for identifying unilateral adrenal tumors with a higher index of suspicion for malignancy.

Treatment

Initial treatment in patients with potentially resectable disease, is complete surgical resection of the tumour. Even after complete resection of the tumour cure may not be achieved, presumably because occult micrometastases are present at the time of initial presentation. Mitotane is an adrenocorticolytic drug that has been used for primary therapy, in the adjuvant setting, and for the treatment of disease recurrence, either alone, or in combination with other cytotoxic agents (etoposide, doxorubicin and cisplatin). Long term prognosis is dismal, but the disease is less aggressive in children as compared to adults. Prognosis depends upon the size, resectibility, and residual and distant metastasis.

ACC has variable clinical presentation and biological behavior. Progress in better understanding of molecular basis of ACC will allow prediction of response to various

therapeutic agents as well as development of newer modalities of treatment.

Adrenal Incidentaloma

An adrenal incidentaloma is a mass lesion >1 cm in diameter, serendipitously discovered by radiologic examination carried out for indications other than evaluation of adrenal disorder. Reported frequency in adults varies from 4–6% as shown in autopsy and imaging data. The differential diagnosis includes adrenal cyst, haematoma, myelolipoma, adrenal adenoma, adrenocortical carcinoma, pheochromocytoma and metastasis from extra adrenal sources. Commonest cause is benign adrenal adenoma. Diagnostic approach consists of defining hormonal secretory status of the tumor and delineation of its imaging characteristics. Imaging phenotype of the mass may help determine whether the tumor is benign or malignant. Adrenocortical carcinomas are significantly associated with mass size, with 90% being more than 4 cm in diameter when discovered. In the report from the National Italian Study Group, a 4-cm cutoff had a 93% sensitivity of detecting adrenocortical carcinoma; even though specificity was limited (76% of masses larger than 4 cm in diameter were benign). All patients with adrenal incidentalomas should be evaluated for the possibility of subclinical hormonal hyperfunction and cancer. A thorough history and physical examination are important in the initial assessment. Endocrine assessment should be performed to document glucocorticoid, mineralocorticoid, androgen or catecholamine excess state. A homogeneous adrenal mass <4 cm in diameter, with a smooth border, and an attenuation value <10 HU on unenhanced CT, and rapid contrast medium washout (e.g., >50% at 10 min) is very likely to be a benign cortical adenoma. The imaging characteristics that suggest adrenal carcinoma or metastases include: irregular shape, inhomogeneous density, high unenhanced CT attenuation values (>20 HU), delayed contrast medium washout (e.g., <50% at 10 min), diameter >4 cm, and tumor calcification. Fine needle aspiration may be useful to rule out inflammatory or metastatic lesion. Excess catecholamine secretory state must be ruled out before undertaking FNAC as hypertensive crisis is reported in unsuspected cases of pheochromocytoma. Hormonally active tumors, tumors with characteristics of malignancy and lesions > 4 cm in size are recommended to be excised surgically. Smaller lesions which are hormonally inactive are recommended to be followed up at periodic interval for any emerging characteristics like increase in size or manifestations of hormonal secretion where appropriate investigations may be carried out followed by suitable therapeutic intervention.

Pheochromocytoma

Pheochromocytoma is a tumor that arises from the catecholamine producing chromaffin cells in the adrenal medulla. It is defined as an intra-adrenal paraganglioma by World Health Organization in 2004. Closely related tumors that arise from extra-adrenal sympathetic and parasympathetic ganglia are classified as extra-adrenal paragangliomas. Intra-adrenal and extra-adrenal sympathetic paragangliomas commonly secrete catecholamine, whereas parasympathetic paragangliomas are usually nonfunctional. Sympathetic paragangliomas are most commonly found in the abdomen (para-aortic and peri-adrenal), pelvis and rarely in thorax, whereas parasympathetic paragangliomas are most commonly found in head and neck.

With advances in molecular genetics, germ line mutations have been identified in up to 59% and 70% of apparently sporadic pheochromocytomas presenting before 18 and 10 years of age respectively. Pheochromocytomas in children are malignant in 1/4th, bilateral in 1/3rd, familial in 1/5th and extra-adrenal in 1/5th of cases.

Pheochromocytomas account for approximately 1% of hypertensive cases in children. Although pheochromocytoma is rare, it is the most common pediatric endocrine tumor. Estimated incidence of benign pheochromocytoma in children is 0.11 per million children, whereas it is 0.02 per million children for malignant pheochromocytomas.

Etiology

None of the etiologic factors that are implicated in the development of pheochromocytoma are known, except the genetic ones. However, the exact mechanisms leading to the initiation of pheochromocytoma development in patients with genetic mutations are still not fully elucidated. Most genetic mutations associated with pheochromocytoma are inherited as autosomal dominant traits. VHL gene, located on chromosome 3p25-26 is the most commonly mutated gene in children presenting with a pheochromocytoma. Other commonly mutated genes include the RET proto-oncogene located on chromosome 10q11.2 predisposing to multiple endocrine neoplasia type 2 (MEN2) or the NF1 gene located on 17q11.2

predisposing to neurofibromatosis 1 and genes coding the subunits B and D of succinate dehydrogenase (SDHD and SDHB) located on chromosome 11q23 and 1p35-36.1, predisposing to hereditary paraganglioma syndromes 1 and 2 respectively. Pheochromocytomas are very rarely associated with succinate dehydrogenase C (SDHC) mutations, tuberous sclerosis, Sturge-Weber syndrome and ataxia telangiectasia. SDHB mutation is associated with increased risk of malignancy where as extra-adrenal location is common in SDHD, SDHB and VHL mutations.

Histopathology

Histopathological pattern is quite variable. Tumors are composed of polygonal to spindle shaped chromaffin cells or chief cells, clustered with sustentacular cells into small nest or alveoli (Zellballen). Immunohistochemical staining for chromogranin A and synaptophysin may be used to confirm the diagnosis of pheochromocytoma. None of the histological features can differentiate malignant tumors from the benign ones. However, a combination of factors including presence of necrosis, mitotic index, tumor cellularity and growth pattern may be used to predict the likelihood of malignant nature. Presence of metastasis is the only definitive evidence of malignancy. Histopathlogy may also vary with the associated syndromic disease, which may help to direct the genetic screening. Intra-adrenal and extra-adrenal paragangliomas can have identical histological appearances; hence, extra adrenal tumors in the periadrenal location need histopathologic differentiation from intra-adrenal tumors due to their association with higher rates of malignancy.

Clinical Presentation

The average age at presentation of pheochromocytoma in children is 11 years (6–14 years). The clinical manifestations of pheochromocytomas are mainly due to excessive catecholamine secretion, although local tumor related complaints may be the presenting features in few cases. Presentation of childhood pheochromocytoma is highly variable, from incidentally detected adrenal masses to hypertensive crises. Common symptoms are palpitations, headache, excessive sweating, pallor, nausea and vomiting. Less frequent symptoms include weight loss, polyuria, visual disturbances, constipation, flushing and fever. Paroxysms may be triggered by direct stimulation of the tumor (e.g., bladder pheochromocytoma), physical activity and certain drugs. Hypertensive encephalopathy or acute left ventricular failure leading to pulmonary edema may occur in severe cases. Circulatory shock may be the presenting manifestation in rare cases, especially in case of epinephrine producing tumors. Hypertension is the most consistent sign and unlike adults it is more often sustained than paroxysmal. Orthostatic hypotension may be a characteristic feature. Fundus examination may reveal changes of hypertensive retinopathy including papilledema in severe cases.

Diagnosis

Biochemical diagnosis should be the first step in the evaluation of patients with suspected pheochromocytoma. Measurement of catecholamines or their metabolites like metanephrines in plasma or 24-h urine and vanillylmandelic acid (VMA) in 24-h urine are the commonly used tests for biochemical diagnosis. Metanephrines are produced continuously and independently of intracellular catecholamine release. Therefore, quantification of plasma free metanephrine and normetanephrine or 24-h urinary fractionated metanephrines serve as the most accurate biochemical tests for pheochromocytoma in all age groups including children and are characterized by a sensitivity of 100% and a specificity of 94–95% in pediatric age group. Catecholamines levels are usually measured by radioimmunoassay or high performance liquid chromatography. The rate of urinary excretion of catecholamines and metanephrines in young children especially can be less than a third of those in adults and requires age-appropriate reference intervals. Blood samples should essentially be obtained in supine position and care should be taken to avoid drugs like tricyclic antidepressants, beta blockers, calcium channel blockers and acetaminophen and dietary factors like caffeine and vanilla containing fruits and foods that can alter the estimation of catecholamines and their metabolites.

Localization can be achieved either with computerized tomography or magnetic resonance imaging, both of which have very high sensitivity (90–100%) but low specificity. *Figures 384.16* and *384.17* show imaging findings in patients with unilateral and bilateral Pheochromocytoma respectively. MRI may be preferred over CT because radiation exposure associated with the latter. MIBG is very specific (98–100%) but has low sensitivity (78%) and can be used to confirm the catecholamine secreting nature of the tumor. It also helps to localize extra adrenal tumors. Functional [18 F] fluoro-2-deoxyglucose or

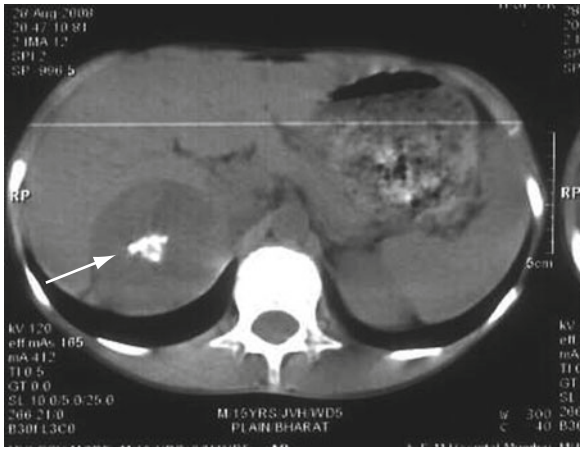

Figure 384.16
CT Scan showing right sided pheochromocytoma. 15-years-old boy presented with pain in abdomen. CT scan was ordered which showed right sided adrenal mass lesion with calcification. Blood pressure was noted at this stage to be 150/105. 24 h urinary VMA was elevated at 26.8 mg/day. Laparoscopic adrenalectomy was performed and patient made uneventful recovery. Post op blood pressure normalized

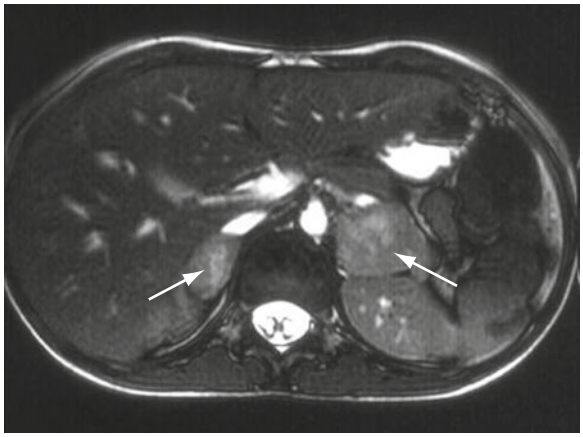

Figure 384.17
MRI scan showing bilateral pheochromocytoma. 12-years-old boy presented with hypertensive encephalopathy. His younger sister was diagnosed to have left sided pheochromocytoma at the age of 8 years. MRI of the patient showed bilateral adrenal masses (*Right*:1.9 × 1.5 × 2.7 cm and *Left*: 3.8 × 3.2 × 2.7 cm). 24 h urinary VMA was 50.1 mg. After adequate alpha and beta blockade, he underwent laparoscopic bilateral cortical sparing adrenalectomy. Patient became normotensive after surgery

[18 F] fluorodopamine positron emission tomography are new modalities for diagnosis of pheochromocytomas especially in those tumors that are difficult to localize.

Differential Diagnosis

Pheochromocytoma has to be differentiated from other causes of young hypertension including renal or renovascular causes, congenital adrenal hyperplasia, coarctation of aorta, Cushing syndrome, primary hyperaldosteronism and essential hypertension. However, neuroblastoma is the most difficult to differentiate since it simulates pheochromocytoma both in terms of biochemical diagnosis and localization. Catecholamine secretion may be excess in both but hypertension is rare with neuroblastoma. Dopamine and homovanillic acid are more elevated in neuroblastoma while other catecholamines are predominantly elevated in pheochromocytoma.

Genetic Screening

Children and their families should be evaluated and detailed assessment including a three-generation family history, clinical examination for neurofibromatosis 1 and genetic counseling should be done before molecular analysis for genetic mutations. In situation where mutation analysis is not readily available, further investigation of the index case and first-degree relatives may be required to direct further screening. Since the genetic testing is not currently cost-effective for every gene in every patient, consideration of tumor location, presence of multiple tumors or metastases, and type of catecholamine produced could be useful in deciding which genes to test.

Follow-up After Molecular Confirmation

Patients or family members with germ line mutations in RET, VHL, SDHB and SDHD genes, should undergo annual screening with blood pressure recording, adrenal ultrasound and plasma free metanephrines (after 5 years of age). Children with VHL mutation need additional screening with annual ophthalmologic review and renal ultrasound after 5 years of age. Triennial MRI of abdomen (after 5 years of age) and triennial MRI of brain and spinal cord (after 10 years of age) are recommended. Additional screening with 6 monthly serum calcitonin, annual calcium and parathyroid hormone is recommended for children with RET mutations. Prophylactic thyroidectomy is

recommended during infancy in MEN-2B and between 2 and 5 years in MEN-2A. In patients with SDHB mutation triennial MRI abdomen and thorax (after 7 years of age) and triennial MRI neck (after 20 years of age) are recommended. Biennial abdominal MRI and 5 yearly thoracic MRI after 7 years of age and biennial MRI neck after 20 years of age are recommended for children with SDHD mutation.

Treatment

Surgery is the definitive treatment but is associated with significant intra-operative risk. It can be minimized by adequate preoperative α blockade which can be achieved with phenoxybenzamine, doxazosin or prazosin. Phenoxybenzamine, a noncompetitive α-blocker may be preferred over competitive blockers such as doxazosin or prazosin. Recommended dose of phenoxybenzamine is 0.5–1 mg/kg twice daily, adjusted according to response. A β-adrenoceptor blocker is added to oppose the reflex tachycardia often associated with a blockade. Adequate α-blockade should be ensured by use of α-blockers for a minimum of 10–14 days before starting beta blockers to avoid worsening of hypertension due to unopposed vasoconstriction. Selective beta blockers like metoprolol and atenolol (1–2 mg/kg PO qd) may be preferred over nonselective blockers like propranolol (1 mg/kg PO qd). Calcium-channel blockers could be useful when α-blockade alone is not sufficient to control blood pressure. Liberal salt and water intake should be encouraged during α-blockade to facilitate volume expansion. Preoperative volume expansion by saline infusion is recommended to reduce postoperative hypotension but due care should be taken to prevent pulmonary edema which is more common in children. Invasive monitoring of BP should be started before or immediately after induction of anesthesia. Acute episodes of hypertension during surgery can be controlled with sodium nitroprusside infusion. Hypotension may occur in immediate postoperative period after resection of the tumor and infusions of dobutamine and/or norepinephrine may be required to maintain normotension for a variable period after surgery. Currently laparoscopic adrenalectomy is the preferred mode of surgery and cortical-sparing adrenalectomies must be considered in children with or at risk of bilateral disease. Tumor embolization, systemic therapy with 131MIBG, or chemotherapy (mostly a combination of cyclophosphamide, vincristine, and dacarbazine) can provide short-lived tumor regression and symptom relief in malignant pheochromocytomas.

385 Disorders of the Posterior Pituitary

Mohamad Maghnie · Andrea Secco · Natascia Di Iorgi

Definition/Classification

Diabetes insipidus is a disease in which large volumes of dilute urine (polyuria) are excreted due to vasopressin (AVP) deficiency (central diabetes insipidus), vasopressin resistance (nephrogenic diabetes insipidus), or excessive water intake (primary polydipsia). Polyuria is characterized by urine volume in excess of 2 L/m^2/24 h or approximately 150 ml/kg/24 h at birth, 100–110 ml/kg/24 h until 2 years, and 40–50 ml/kg/24 h in the older child and adult.

Etiology

In many patients, central diabetes insipidus (CDI) is caused by the destruction or degeneration of neurons originating in the supraoptic and paraventricular nuclei of the hypothalamus. The known causes of these lesions include local inflammatory or autoimmune diseases, vascular diseases, Langerhans cell histiocytosis (LCH), sarcoidosis, germinoma or craniopharyngioma, trauma resulting from surgery or an accident, metastases, and midline cerebral and cranial malformations. In rare cases, genetic defects in AVP synthesis, inherited as autosomal dominant, autosomal recessive, or X-linked recessive traits are the underlying cause. X-linked (Xq28) nephrogenic diabetes insipidus (NDI) is secondary to *AVPR2* mutations, which results in a loss of function or dysregulation of the renal AVP receptor-2 (V_2 receptor). Abnormalities of *AQP2* (aquaporin 2) the water channel gene, located on chromosome 12 at 12q13 explain familial autosomal recessive and dominant forms of nephrogenic diabetes insipidus (*Table 385.1*).

Epidemiology

Diabetes insipidus is a rare disease with a non-univocal reported prevalence of 1:25,000. Less than 10% of diabetes insipidus can be attributed to hereditary forms. In particular, X-linked nephrogenic diabetes insipidus (OMIM 304800) represents 90% of cases of congenital NDI and occurs with a frequency of 4–8 per 1 million male live births; autosomal NDI (OMIM 125800) accounts for approximately 10% of the remaining cases. No gender difference was reported for the other forms.

While the prevalence of Wolfram diseases has been reported as 1–9/1,000,000 (www.orpha.net), the precise frequency of autosomal dominant central diabetes insipidus is currently unknown.

Pathogenesis and Pathology

Anatomy

The posterior pituitary consists of magnocellular neurons that produce the peptide hormones, vasopressin and/or oxytocin. The cell bodies of magnocellular neurons are located in the paraventricular nuclei (PVN) and in the supraoptic nuclei (SON) in the hypothalamus, and axons project to the neurohypophysis, where the hormones are secreted into the blood stream. These axons store quantities of vasopressin large enough to sustain basal release for 30–50 days or to allow maximum antidiuresis for 5–10 days.

While the blood supply for the anterior pituitary is via the hypothalamic-pituitary portal system from the suprahypophyseal arteries, the vascularization of the posterior pituitary is direct from the inferior hypophyseal arteries, which are branches of the posterior communicating and internal carotid arteries. The drainage is into the cavernous sinus and internal jugular vein (*Fig. 385.1*). The adult neurohypophysis weighs on average 120 mg, with weight increasing slightly with age.

Posterior Pituitary Organogenesis

During embryogenesis, neuroepithelial cells of the lining of the third ventricle migrate to the walls of the third ventricle where they mature into paraventricular nuclei (PVN). Some cells continue to migrate laterally to and above the optic chiasm to form the supraoptic nuclei (SON). Their unmyelinated axons traverse the basal hypothalamus, form the neural stalk, and terminate at the floor of the third

Table 385.1
Etiologies of diabetes insipidus

Central diabetes insipidus	Familial
	• Autosomal dominant/recessive (OMIM 125700), AVP mutation (OMIM 192340)
	• X-linked (OMIM 304900)
	• Congenital hypopituitarism with central diabetes insipidus (OMIM 241540)
	• Wolfram (DIDMOAD) syndrome (OMIM 222300), wolframin (WFS1) mutation (OMIM 606201)
	• Unknown genes (?)
	Acquired
	• Idiopathic
	• Intracranial tumors – germinoma, craniopharyngioma, glioma
	• Autoimmune: lymphocytic hypophysitis/ lymphocytic infundibulo-neurohypophysitis/lymphocytic infundibulo-hypophysitis
	• Autoimmune (antibodies against vasopressin-producing cells, T-cells damage)
	• Granulomatosis (tuberculosis[a], sarcoidosis[a], Langerhans cell histiocytosis, [a]Wegener)
	• Infections/post-viral (varicella; congenital CMV and toxoplasmosis; encephalitis, meningitis)
	• Traumatic brain injury
	• Vascular impairment/Hypoxic-ischemic
	• Metastases[a]
	Cerebral malformations
	• Midline brain developmental defects (septo-optic dysplasia, holoprosencephaly, etc.)
	• Associated with ectopic posterior pituitary, anterior pituitary hypoplasia, and congenital hypopituitarism
Nephrogenic diabetes insipidus	Familial
	• X-linked (OMIM 304800), AVPR2 mutation (OMIM 300538) (90%)
	• Autosomal recessive/dominant (OMIM 125800), AQP2 mutation (OMIM 107777) (10%)
	• Nephrogenic diabetes insipidus with mental retardation and intracerebral calcification (OMIM 221995)
	Acquired
	• Hypokalemia, hypercalciuria, alkalosis
	• Polycystic renal disease, others
	• Pyelonephritis, postobstructive
Primary polydipsia	• Psychogenic
	• Dipsogenic

[a]Rare in children

ventricle and in the median eminence. It should be noted that the SON ultimately contain *only* oxytocin and vasopressin-containing neurons, whereas the PVN have distinct cell populations, such as those containing corticotrophin-releasing hormone, TSH-releasing hormone (TRH), and synthesizing somatostatin. Others contain neurotransmitters destined to control the autonomic nervous system.

The early differentiation of these cell lineages has recently become much more comprehensible through the elucidation of the role of transcription factors in hypothalamic development. The SIm1, ARNt2, OTP and BRN2 genes appear to be involved in the cascade of transcription factors implicated in the development of the neuroendocrine hypothalamus leading to the completion of posterior pituitary development by the end of the first trimester, when vasopressin and oxytocin can be detected in neurohypophyseal tissue.

The posterior pituitary gland is formed by the evagination of neural tissue from the floor of the third ventricle. It consists of the distal axons of the hypothalamic magnocellular neurons that shape the neurohypophysis. After its downward migration, it is encapsulated together with the ascending ectodermal cells of Rathke's pouch, which form the anterior pituitary. In a recent study, a *Hes1*-null pituitary gland was revealed to be reduced in size but was otherwise morphologically normal compared with the control. Indeed, in *Hes1-Hes5* double-mutant mice, the evagination of the infundibulum was affected and the neurohypophysis was lost compared to both the wild type and *Hes1*-null mice, suggesting that both *Hes* genes are essential for the formation of the neurohypophysis. A number of transcription factors have been implicated in the development of the hypothalamo-neurophypophyseal system (HNS) and null mutations for these factors caused severe defects in proliferation, migration, and survival during early embryogenesis. Recently, large numbers of genes were identified in a study as being expressed in rat HNS

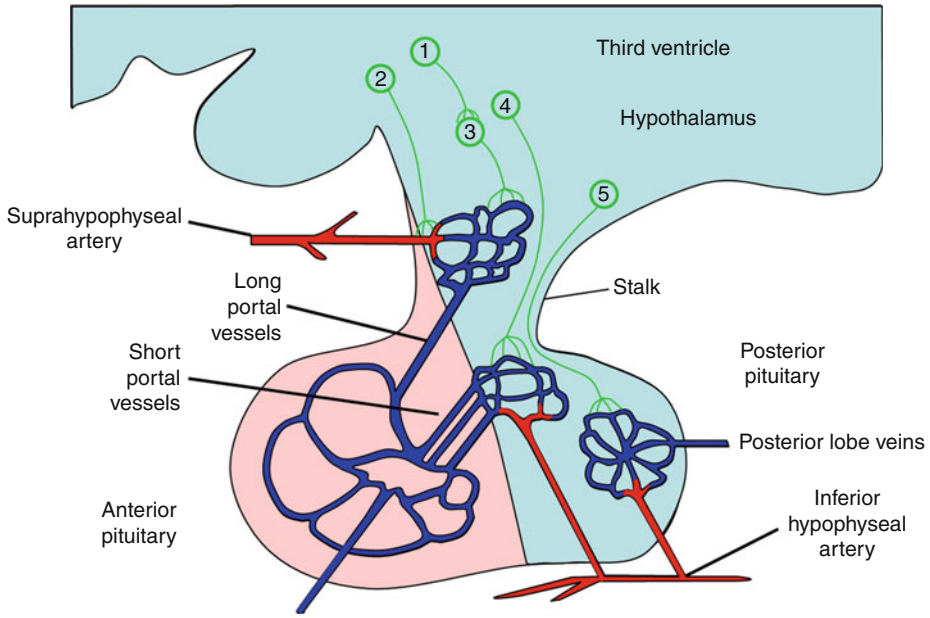

Figure 385.1

Anatomy and vascularization of the posterior pituitary. 1,2,3,4,5 represents the paraventricular and supra-optic nuclei from where vasopressin and oxytocin migrate along the axons projecting to the neurohypophysis where the hormones are secreted into the blood stream

neuronal tissues after dehydration. The pattern of HNS transcripts with marked differences in gene expression indicates that these genes are candidate regulators and effectors of HNS activity and remodeling.

Vasopressin Biosynthesis

The AVP-neurophysin II gene (*AVP-NPII*) is located distally at the short arm of chromosome 20 (20p13). It covers 2.5 kb and comprises three exons. Exon 1 encodes the signal peptide of 19 amino acid residues, the nonapeptide AVP, and the N-terminal region of NPII (9 amino acid residues); exon 2 encodes the central highly conserved region of the NPII peptide (67 amino acid residues); and exon 3 encodes the C-terminal region of NPII (17 amino acid residues) and a 39 amino acid glycopeptide known as copeptin (*Fig. 385.2*).

The *AVP-NPII* gene product, the AVP preprohormone is co-translationally targeted to the endoplasmic reticulum (ER), where the signal is cleaved off by signal peptidase and the copeptide is core glycosylated. Vasopressin and NPII associate after cleavage and then form the tetramer, which increases the binding affinity of vasopressin for NPII. After formation of seven disulphide bonds within NPII and one within AVP and after glycosylation of the copeptide, the proprecursor is packaged into neurosecretory granules and then cleaved into the product peptides during axonal transport to the posterior pituitary. Neurophysin serves to stabilize the hormone during its transport and storage, while recent data suggest the important role of copeptin in the correct structural formation of the AVP precursor as a prerequisite for its efficient proteolytic maturation. Vasopressin and its protein carrier NPII are released from the posterior pituitary by calcium-dependent exocytosis when the axon is depolarized by osmoreceptor or baroreceptor stimuli.

Physiology of Water Homeostasis

The maintenance of water balance in healthy humans is achieved principally by three interrelated determinants: thirst, vasopressin, and kidney function.

Recently, apelin – a bioactive peptide – has been isolated from bovine stomach extracts (like ghrelin, another stomach-hypothalamus association). It is expressed in the supraoptic and the paraventricular nuclei and exerts its action on specific receptors situated on the vasopressinergic neurons. Apelin acts as a potent diuretic neuropeptide which

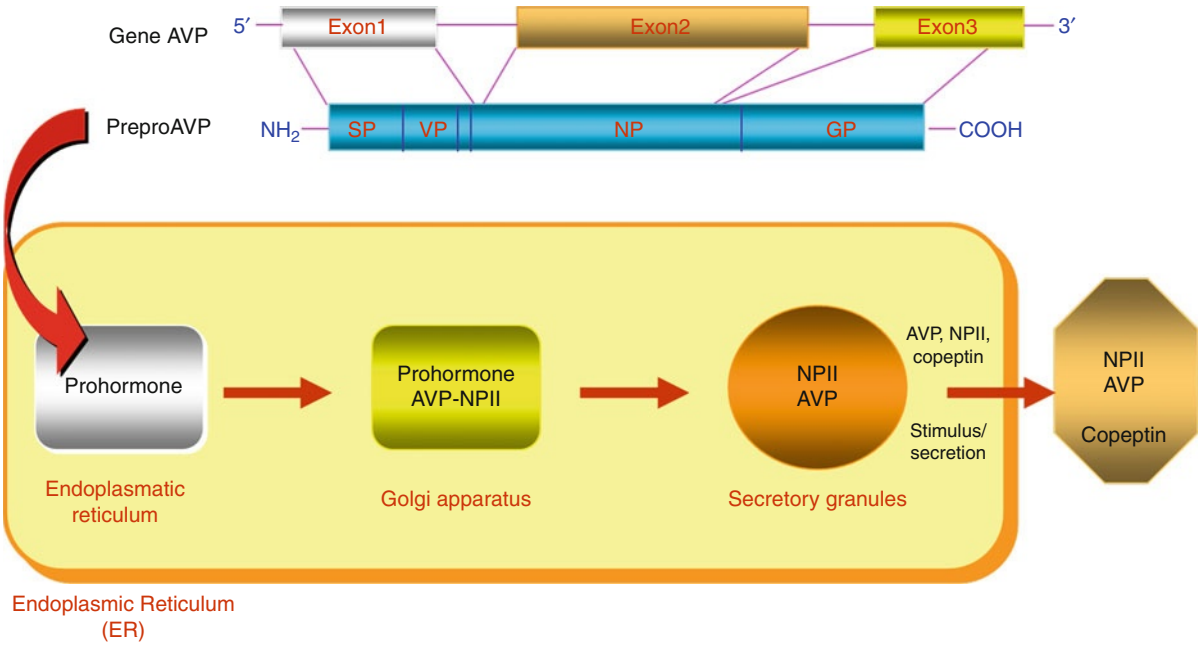

Figure 385.2

counteracts vasopressin actions through inhibition of AVP neuron activity and AVP release. The coexistence of apelin and AVP in magnocellular neurons, and their opposite biological effects and regulation, are likely to play a key role in maintaining body fluids.

As early as the middle of the nineteenth century, the question was asked: how does water get through the lipid bilayer of the cell membrane? The answer used to be "*. . .membranes have pores*." It was not until 1988 that Peter Agre isolated a membrane protein that he realized must be the long-sought-after water channel. He called it aquaporin. This discovery opened the door to a whole series of biochemical, physiological, and genetic studies of water channels in bacteria, plants, and mammals. Today, researchers can follow a water molecule in detail on its way through the cell membrane and understand why only water and not other small molecules or ions can pass through the membrane. In 2000, Agre reported the first high-resolution images of the three-dimensional structure of aquaporin. Now, it is possible to construct a detailed map of water channel functions. Currently, ten mammalian aquaporins (AQP0-AQP10) have been identified.

Vasopressin acts on its major target organ, the kidney, where it increases urine osmolality (*Fig. 385.3*). The hormone binds to the V2-receptors in the basolateral membrane of the renal collecting tubular and activates the Gs – adenyl cyclase system, increasing intracellular levels of cyclic 3′,5′-adenosine monophosphate (cAMP). The latter activates protein kinase A, which in turn phosphorylates preformed acquaporin-2 (AQP2) water channels localized in intracellular vesicles. Phosphorylation promotes trafficking to the apical membrane, followed by exocytic insertion of AQP2 vesicles into the cell membrane. The insertion of AQP2 renders the collecting-duct water permeable, allowing free movement of water from the lumen of the nephron into the cells of the collecting duct along an osmotic gradient, thus concentrating the urine. The synthesis of AQP2 channels, as well as their movement, is regulated by AVP stimulation, while acquaporin-3 and acquaporin-4, responsible for the subsequent passage of water from within the cell into the renal interstitium, are constitutively present in the basolateral membrane.

Regulation of Vasopressin Secretion

Vasopressin release is under the control of osmoreceptors (osmotic), baroreceptors (hemodynamic), and other regulatory mechanisms (*Table 385.2*). The maintenance of

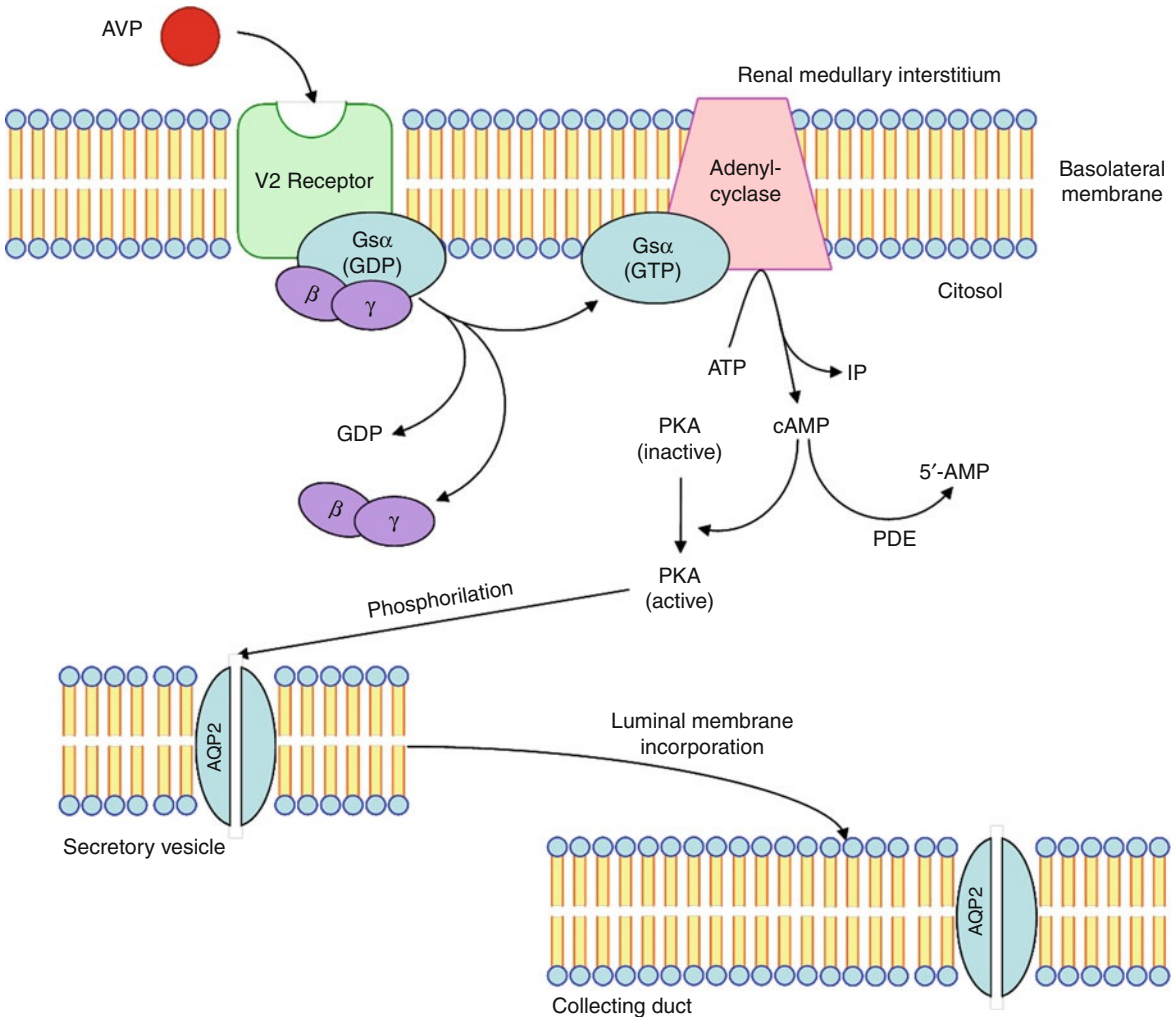

Figure 385.3

V_2 vasopressin receptor signaling cascade. In principal cells of the renal collecting duct, AVP binding to V_2 receptor (V_2R) on the basolateral membrane stimulates adenyl cyclase through the activated $G_s\alpha$-subunit, which leads to an increased formation of the second messenger cAMP. The cAMP-dependent protein kinase phosphorylates aquaporin 2 (AQP2). AQP2 phosphorylation leads to both activation of AQP2 and translocation of AQP-containing vesicles to the luminal surface of the cell. The translocation and vesicle fusion processes lead to the insertion of AQP2 into the apical membrane and thus enhances its water permeability Abbreviations: *AVP* arginine-vasopressin, *ATP* adenosine triphosphate, *cAMP* cyclic adenosine monophosphate, *IP* inorganic phosphate, *5′-AMP* 5′-adenosine monophosphate, *PDE* phosphodiesterase, *PKA* protein kinase A, *AQP2* aquaporine 2, *GTP* guanosine triphosphate, *GDP* guanosine diphosphate

water balance starts with the sensing of plasma osmolality, predominantly represented by the plasma sodium concentration. This sensing mechanism is controlled by specialized neural osmoreceptors in the anterolateral hypothalamus responsible for AVP production and secretion. The osmoreceptors are quiescent below a plasma threshold osmolality of about 280 mOsm/kg H_2O. When plasma osmolality rises above this threshold value, osmoreceptor cells are progressively stimulated to cause AVP release.

Small changes in plasma osmolality regulate AVP release from the posterior pituitary. When water is lost and plasma osmolality increases by as little as 1%, an increased secretion of AVP stimulates water retention by

Table 385.2
Regulation of vasopressin secretion

Mechanism	Receptor	Causes
Osmotic	• Hypothalamic osmoreceptors	• Plasma osmolality
		• Hyperglycemia
		• Hypertonic/ hypotonic solution infusion
		• Water balance change
Hemodynamic	• High pressure arterial baroreceptor (carotid sinus, aortic arch)	• Blood volume/ hypovolemia/ hemorrhage
	• Low pressure volume receptors (atria and pulmonary venous system)	• Blood pressure
		• Vasovagal reaction
		• Congestive heart failure
		• Cirrhosis
		• Nephrosis
		• Pregnancy

the kidneys. There is a sensitive, linear relationship between increased osmolality and increased AVP secretion; there is, similarly, a linear relationship between increased plasma AVP and increased urine osmolality. Osmolality is tightly regulated around each individual's normal value which falls between 280 and 295 mOsm/kg H_2O in the general population. Maximum antidiuresis is attained with plasma AVP concentrations of about 2–5 pmol/l.

In circumstances where individuals lose large amounts of body water, plasma osmolality may rise above 300 mOsm/kg H_2O, but increased AVP secretion of more than 5 pmol/l cannot concentrate urine any further (1,000–1,200 mOsm/kg H_2O). Urine volume does not change markedly over wide variations of urine osmolality until urine osmolality approaches maximum dilution and plasma AVP is completely suppressed. There is then a remarkable exponential increase in urine volume to approximately 18 l/day in adults. The glomerular filtrate is largely reabsorbed in the descending loops of Henley in the kidneys and only approximately 18 l of dilute fluid enter the collecting duct.

Pathogenesis

Increasing polyuria occurs when more than 80% of the AVP-secreting neurons are damaged. Extensive destruction can be caused by a variety of pathologic processes including genetic causes. Autopsy studies after traumatic section of the pituitary stalk have revealed a loss of the large neurosecretory cells in the hypothalamic nuclei. This occurs within 4–6 weeks, with higher damage for lesions that occur at the level of the infundibulum or above it. Autopsy studies of patients with a familial form of diabetes insipidus show a selective loss of magnocellular neurons in the paraventricular nuclei associated with moderate gliosis and relative preservation of small neurosecretory cells, suggesting that the disorder is due to degeneration of these hypothalamic neurons.

Genetic Forms of Central Diabetes Insipidus

At present, more than 50 different mutations resulting in a defective prohormone and a deficiency of vasopressin have been identified in familial neurohypophyseal DI; all except a few show an autosomal dominant pattern of inheritance. One unique homozygous missense mutation in the region encoding the AVP domain shows an autosomal recessive pattern of inheritance which does not seem to affect intracellular trafficking, but rather the final processing of the prohormone into neurophysin II and AVP hormone. Despite some clinical similarities with the dominant form, the symptoms appear to be secondary to the reduced biological activity of the mutant vasopressin peptide. This hypothesis is supported by the high circulating level of mutant hormone, the absence of normal AVP hormone in the homozygous state, and the absence of clinical or subclinical abnormalities in heterozygous carriers.

Indeed, no mutations in the coding region, the intronic region, or the 1.5-kb upstream region from the initial transcription site of the AVP-NPII gene were found in

a Chinese family showing an autosomal dominant inheritance pattern of overt central diabetes insipidus. Linkage analysis indicated that the corresponding gene(s) responsible for the autosomal dominant form in this family was located in a 7-cm interval defined by two short tandem repeat markers on chromosome 20. This suggests the presence of locus heterogeneity of autosomal dominant central diabetes insipidus and implies a genetic diversity in the cause of CDI.

The autosomal dominant inheritance of this disease can occur through many mechanisms including dominant negative activity by interactions of mutant and wild type (WT) precursor, accumulation of mutant precursor in the ER leading to stress protein response and autophagy, and cellular toxicity by pathways that are still not completely defined. The study of the trafficking and processing of the mutant vasopressin prohormone in vitro has demonstrated that the mutation abolishes ER exit and processing of the vasopressin prohormone, resulting in an aberrant endoplasmic morphology and possible cell dysfunction and death. The presence of cytosolic autophagy suggests non-apoptotic cell death; however, programmed cell death cannot be excluded.

Mutations involving the signal peptide decrease its ability to initiate the proper processing of the prepro-AVP-NPII; mutant precursors also impair intracellular trafficking of the WT precursor by forming heterodimers, thus reducing the bioavailability of active AVP by means of a "nontoxic mechanism," i.e., a dominant negative effect.

Recently, the demonstration of two pathways of degradation (via the ER lumen and directly from the cytosol), involving both the WT and the mutant prohormone, suggests that the cytotoxic effect may result from processes that are quantitatively but not fundamentally different from those occurring in cells expressing the WT protein.

Acquired Forms of Central Diabetes Insipidus

Idiopathic CDI

Although 20–50% of cases CDI are considered idiopathic, the identification of antibodies against vasopressin-secreting cells on the one hand, and recent advances in imaging techniques on the other, have shed new light on pathophysiological aspects of CDI, making the idiopathic form a much less common condition.

Various clinical observations suggest an important role for autoimmunity in the pathogenesis of CDI. Indeed, autoimmune polyendocrinopathy and CDI associated with an MRI picture of thickened pituitary stalk suggest that patients with CDI and thickened pituitary stalk may share a common etiology. Indeed, circulating vasopressin-cell autoantibodies (AVPc-Abs) were found in 75% of children and young adults with idiopathic CDI, suggesting that hypothalamic-neurohypophyseal autoimmune involvement is more common in children and young adults with idiopathic CDI than has generally been thought; the higher frequency of AVPc-Abs in pediatric patients, compared to the one third found in adult patients with identical disease duration, underlines the fact that an autoimmune cause in idiopathic CDI is quite frequent. In addition, AVPc-Abs were found in approximately 77% of subjects with combined posterior and anterior pituitary dysfunction, a finding that goes well beyond the reported association of anterior pituitary hormone defects in as many as 23% of subjects with isolated vasopressin deficiency. This indicates that anterior pituitary (AP) involvement in the course of idiopathic CDI is highly suggestive of an autoimmune neurohypophyseal basis and fits well with the bioptic demonstration of the lymphocytic infiltration of the pituitary stalk. In about one fourth of patients with idiopathic CDI, there is a temporal relationship between a viral infection (trigger) and the onset of CDI. This hypothesis is strengthened by the fact that the pituitary gland is susceptible to CD8 T-cell-mediated autoimmunity, triggered by a cell-specific model autoantigen, as well as to the development of autoimmune hypophysitis by immunizing female SJL/J mice with mouse pituitary extracts. The identification of AVPc-Abs in subjects who could have either idiopathic CDI or LCH or germinoma, however, indicates that this finding cannot be considered a completely reliable marker of autoimmune CDI. Thus, to ensure a definitive etiological diagnosis, close clinical and MRI follow-up are needed since AVPc-Abs may mask germinoma or LCH.

The underlying process of pituitary stalk thickening in "idiopathic" CDI is not completely understood. Recent reports of a thickened pituitary stalk in association with autoimmune or inflammatory disease, termed "lymphocytic hypophysitis," "necrotizing infundibulo-hypophysitis," or "lymphocytic infundibulo-neurohypophysitis" focus on adults with histological features of lymphocyte and plasma cell infiltration, fibrosis, and necrosis. Hence, lymphocytic hypophysitis is a rare chronic inflammatory process that variably affects the pituitary gland. It is noteworthy that clear-cut criteria for the diagnosis of lymphocytic hypophysitis in children and adolescents are still lacking and that CDI is manifest in only about 20–25% of cases.

The term "lymphocytic infundibulo-hypophysitis" has been coined to distinguish children and adolescents with CDI, anterior pituitary hormone deficiency,

reduction of AP size, and transient or persistent pituitary stalk (PS) thickening from adult patients with similar posterior pituitary (PP) and PS findings at MRI, but normal AP size and function according to recent diagnostic criteria, and GHD defined in adult patients as GH response after pharmacological stimulation tests higher than 10 μg/l. In adult cases such as those described, the term "lymphocytic infundibulo-neurohypophysitis" is more appropriate.

Vascular CDI

CDI may be caused by vascular brain damage, but the pathophysiology of such a mechanism has never been precisely understood. In a group of patients with idiopathic CDI and normal anterior pituitary function, standard MRI showed normal PS and AP gland size. Indeed, dynamic MRI studies after contrast medium injection demonstrated the absence of posterior pituitary lobe enhancement whereas normal enhancement of the AP was present. The lack of contrast enhancement of the posterior lobe suggests that a selective vascular injury to the inferior hypophyseal arteries could be causally linked to CDI. The mechanism affecting posterior pituitary blood supply remains largely undefined, but the possibility that a congenital lack/poor development of the posterior pituitary vascular system (without any evidence of macroscopic morphological abnormality of the pituitary gland at MRI or secondary changes of vascular supply due to a local inflammatory process) (vasculitis?) cannot be ruled out.

Langerhans Cell Histiocytosis (LCH)

Central diabetes insipidus is the most frequent CNS manifestation of LCH, occurring in 10–50% of all patients. A retrospective multicenter analysis of LCH patients shows that the risk of developing CDI, after diagnosis and specific therapy, was 16% at 5 years and 20% at 15 years, respectively, and strongly correlates with the presence of a multisystem disease followed by lesions in the craniofacial area. Some patients with CDI and endocrinopathies seem to be at risk for neurodegenerative CNS disease. Growth hormone deficiency (GHD) is the most frequent additional deficit accounting for 42% of cases with CDI and LCH. The 10-year cumulative incidence of GHD in the French nationwide LCH survey was approximately 54% among patients with CDI. The identification of circulating AVPc-Abs in LCH patients and their tendency toward spontaneous clearance suggest that these autoantibodies might be an LCH-related immune epiphenomenon.

Pituitary stalk thickening (PST) can be found in approximately 50–70% of patients with LCH at presentation or at follow-up and may even be present before CDI onset. With PST, anterior pituitary size has been found to be normal, reduced or, rarely, enlarged. The search for extracranial lesions (dermatological and bone survey; chest x-ray; ear, nose, and throat examination) suggestive of LCH in patients with PST is recommended and could reduce the need for intracranial biopsies.

Sarcoidosis

Sarcoidosis is a multisystemic disease of unknown etiology; the involvement of the central nervous system occurs in approximately 5–15% of patients and precedes additional symptoms in 25–30% of cases. Autopsy studies have demonstrated that sarcoid granulomas have a predilection for the hypothalamus and less commonly involve the PS or the pituitary gland. Thus, patients with neuroendocrine sarcoidosis commonly have hypothalamic dysfunction and often exhibit hypothalamic disturbances and AP hormone deficiency. Endocrinopathy is relatively rare, polyuria-polydipsia being the most common symptom, reported in 25–33% of adult patients affected by neurosarcoidosis. In pediatric patients, hypophyseal dysfunction was documented in 21% of cases, 66% of whom shows CDI. Children with neurosarcoid behave differently than adults and are more likely to have seizures and less likely to have cranial nerve palsies; eye diseases such as uveitis may occur in younger children.

Brain MRI studies showed heterogeneous features, including periventricular white matter foci, leptomeningeal enhancement, hydrocephalus and enlargement of the PS; the latter entity has been described in four of the five patients reported by Bullmann et al. To our knowledge, only a few pediatric cases of CDI secondary to neurosarcoidosis have been described.

Tumors

Germinomas: Intracranial germ tumors comprise 7.8% of primary pediatric brain tumors. MRI findings suggest that suprasellar and neurohypophyseal germinomas primarily arise from the posterior pituitary to the infundibulum. Partial or complete stalk thickening is detectable in 78–100% of cases at presentation and may be the only finding at presentation in small germinomas; its presence increases the risk of malignancy to about 15–17%, while the risk decreases to 3% in patients with a normally sized stalk.

Serial contrast-enhanced brain MRI in patients affected by CDI with PST (every 3–6 months for the first 2 years) may reduce the amount of time for diagnosis of germinoma by 1 year. However, a thickened stalk has been reported up to 5 years after the onset of CDI and preceded

by lymphocytic tissue infiltration as a host reaction to the presence of a germinoma that could mask diagnosis. Exceptionally, germinoma can mimic multisystemic LCH, with vertebral compression, recurrent ear infections, thickened PS, enlarged pineal gland, serum and negative cerebrospinal fluid for germ cell tumor markers, as demonstrated in a 9-year-old female.

The role of hCG and other tumor markers in the early diagnosis of germinoma is not very well understood. A negative finding for hCG in cerebrospinal fluid does not exclude a diagnosis of germinoma. The presence of circulating AVPc-Abs in these patients prior to treatment could also mask the diagnosis of germinoma and calls for further confirmation. Pituitary stalk biopsy is mandatory in the presence of a progressive thickening of the lesion up to more than 6.5–7 mm and/or anterior pituitary enlargement. Growth arrest and multiple pituitary hormone deficiency are common and early findings in pituitary germinomas (almost 100% of cases at follow-up), but hormone deficiency is not predictive of their presence.

Craniopharyngioma and post-surgical CDI: Craniopharyngioma is a benign tumor arising from squamous cell nests in the primitive Rathke's pouch. It constitutes approximately 6–9% of all intracranial tumors in children and is the most frequent suprasellar neoplasm in the pediatric population, i.e., 54% of cases. Classical presentation includes visual impairment due to chiasmal compression and bilateral optic atrophy; systemic symptoms related to raised intracranial pressure account for 60–75% of cases at presentation. In diverse large pediatric series, signs and symptoms of AP dysfunction were detected in about 20–70% of cases. Central diabetes insipidus and multiple pituitary hormone deficiency are common complications of childhood craniopharyngioma. The frequency of pre-surgery CDI varies from 16% to 55%, while post-surgical and permanent CDI accounts for up to 80% of cases; transient CDI is reported in 13% of affected cases.

Impairment of hypothalamic-posterior pituitary function after complete section of the PS is a common, predictable outcome characterized by the classic triphasic response of urine volume. The initial phase of CDI (1–4 days) is followed by a second phase of oliguria which may reflect degeneration and death of neurosecretory neurons, with release of stored AVP into the circulation (4–7 days), and by a third and final phase of permanent CDI. The diagnosis of CDI after surgery is often made within a few hours, although abnormalities of AVP secretion and fluid balance often begin during the intra-operative period. The trans-sphenoidal approach is now widely used for intrapituitary and some suprasellar tumors, and is associated with a lower incidence of post-operative CDI. CDI after trans-frontal approach has been reported in association with high plasma vasopressin (AVP)-immunoreactivity, but the plasma showed no antidiuretic bioactivity; moreover, antidiuretic response to standard AVP was greatly attenuated, suggesting the presence of a circulating vasopressin antagonist affecting the renal action of endogenous and exogenous AVP.

Metastasis: Metastasis to the posterior pituitary is a well-known event in systemic cancer due to the direct arterious vascularization of the posterior pituitary lobe. The incidence of pituitary metastases varies from 0.14% to 28.1% of all brain metastases and is higher in adult autopsy series. Pituitary metastases most frequently originate from lung carcinoma, breast cancer, gastrointestinal carcinomas, and leukemia/lymphoma with symptoms seen particularly in terminal stages. About 20% of these metastases to the pituitary-hypothalamic axis are diagnosed clinically and CDI is the main presenting symptom. A review of the literature showed that CDI has been reported in association with leukemia in 39 of 5,778 children (0.6%), 4 of whom were under 10 years of age.

In cases of metastasis, a destructive and inhomogeneously enhancing intrasellar and suprasellar lesion and involvement of adjacent structures can be observed at MRI; the pituitary stalk can be involved and appears entirely or partially thickened. Progressive thickening of the PS has been the presenting symptom in various pediatric cases of primary lymphoma of the central nervous system or of myeloid leukemia. CDI and multiple AP hormone deficiencies can precede by one or more years the diagnosis of malignancy.

Other Entities

CDI has been reported in Wegener granulomatosis, a disease characterized by necrotizing vasculitis and granulomatous inflammation of the upper and lower respiratory tract, together with glomerulonephritis; MRI showed an isointense suprasellar mass and enlargement of the infundibulum. Two months after corticosteroid treatment, MRI showed nearly complete resolution of pituitary lesions and dramatic clinical improvement.

Transient CDI associated to CNS tuberculosis is a well-known entity. Tuberculosis of the CNS is the most serious complication in children, accounting for about 3–4% of untreated tuberculosis infections in developed countries. It usually arises from a "metastatic" caseous lesion in the cerebral cortex or meninges that develops during the lymphohematogenous dissemination of the primary infection. A few pediatric reports refer to tuberculous meningitis followed by acute onset of CDI, variably

associated with seizure and/or communicating hydrocephalus; in these cases, MRI showed pituitary stalk thickening.

Acute post-traumatic CDI has been reported in 22 of 85 patients who suffered a moderate to severe traumatic brain injury (TBI); 5 of these patients had persistent abnormal water deprivation test at a median time of 17 months from TBI and expression of permanent partial CDI; the remaining patients had complete recovery of PP function. In the study, permanent CDI correlated with lower Glasgow coma scale but not with age, gender, basal skull fracture, or operative mass evacuation.

Post-traumatic DI may result from inflammatory edema around the hypothalamus or the posterior pituitary, with resolution as the swelling resolves. It can also result from direct damage to the paraventricular and supraoptic hypothalamic neurons, to the pituitary stalk, or to axon terminals in the posterior pituitary.

Clinical Manifestations: Symptoms, Signs

Clinical examination may provide important clues to possible underlying diagnoses. The age at which symptoms develop, together with the pattern of fluid intake, may influence subsequent investigation of diabetes insipidus (*Fig. 385.4*). Leading symptoms are represented with persistent poliuria and polydipsia, and young children may have severe dehydration, vomiting, constipation, fever, irritability, sleep disturbance, failure to thrive, and growth retardation. Nocturia in children often presents as enuresis. Severe dehydration of early onset in males is highly suggestive of nephrogenic diabetes insipidus; some mental retardation has been reported, probably caused by repeated and unrecognized dehydration before the diagnosis has been established.

In a large cohort of patients with CDI of different etiologies, 40% of the patients had symptoms other than polyuria and polydipsia at presentation; while headache was not discriminatory, visual defect was associated with intracranial tumor. Growth retardation was not significantly more common in patients with CNS tumors, in contrast with previous reports indicating that such delays strongly suggest an intracranial tumor as the cause of central diabetes insipidus.

In autosomal dominant CDI, the clinical disease onset typically ranges from the first to sixth year of age, but various cases of early or delayed onset are also reported.

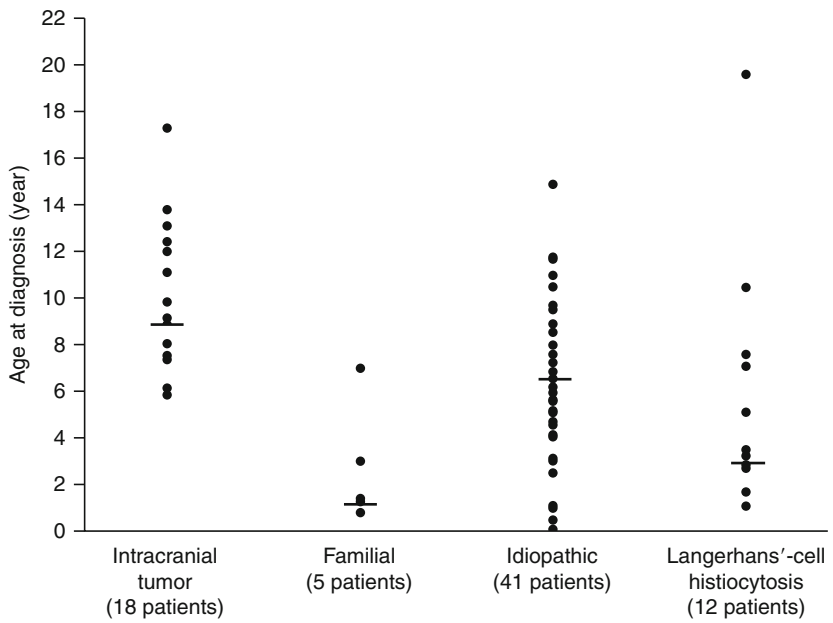

Figure 385.4

Age at diagnosis according to the cause of central diabetes insipidus. The patients who did not have an intracranial tumor were significantly younger at diagnosis than those who did ($P < 0.001$ for all comparisons). The horizontal lines indicate the medians (Reproduced with permission from The Publishing Division of the Massachusetts Medical Society – Publishers of The New England Journal of Medicine)

Usually symptoms worsen with age in patients with early onset of mild polyuria and polydipsia, especially before 10 years of age, but it is also possible that complete CDI is expressed from the neonatal period. The wide variability in the age of onset and the severity of the AVP deficiency among patients with the same mutation may be attributed to individual differences among such patients, such as the rate of production of the mutant precursor, the intensity of neurohypophyseal stimulation, individual susceptibility to the toxic effect of the mutant precursor, the capacity to degrade mutant precursors, and variations in secretory reserve capacity or the development of the gland itself. Further studies on the contribution of any of the mechanisms involved in cell dysfunction and/or impaired AVP secretion, together with MRI follow-up, would help to better understand the disease. The majority of the mutations currently described affect NPII moiety; only a few mutations have been identified within the signal peptide sequence. No substantial temporal relationship between the type of mutation, the time of disease onset, and the degree of severity was found among patients affected by the same missense mutation.

In Wolfram syndrome (WS), diabetes mellitus has been reported to be the usual first symptom to present at a median age of 6 years, followed by onset of optic atrophy at a median age of 11 years. The phenotype–genotype correlations in a series of nine WS families show an average age at onset of diabetes mellitus of 8.4 years in agreement with other studies. The development of polyuria and/or enuresis can indicate diabetes insipidus, and the time of onset varies considerably and does not generally appear until the second or third decade; CDI may initially be partial. The frequency of CDI varies between reports ranging from 48% to 78%.

A wide spectrum of abnormalities affect the endocrine glands and the central nervous system and include anosmia, ataxia, seizures, nystagmus, gaze palsies, dysarthria, dysphagia, psychiatric abnormalities, cognitive deficits, hypo- or areflexia and neurogenic bladder, central sleep apnea, neurogenic upper airway collapse, myoclonus, Parinaud's syndrome, hypothyroidism, hypogonadism, and ACTH deficiency. Treatment with DDAVP can be very successful.

Diagnosis

Measurement of Osmolality

Osmolality measured in vitro by means of freezing point depression usually correlates well with the ton that is the effective osmotic pressure. However, while tonicity and osmolality of sodium and other electrolytes are identical, urea and glucose show large differences between the osmotic pressure ascertained by freezing point depression and the effective osmolality in vivo. The accuracy of the measurement of plasma osmolality by routine hospital laboratories and by freezing point depression is usually not high enough to fulfill the quality criteria required (coefficient of variation of 1% or less at 290 mOsm/kg H_2O), especially when osmolality is determined in serum or frozen plasma.

As a matter of fact, extracellular and plasma osmolality can be reasonably considered to represent sodium salts. Thus, plasma osmolality can be estimated quite well by 2 × plasma sodium concentration. However, the contributions of two other solutes, glucose and urea, should be included to more closely approximate plasma osmolality: Posm = 2 $[Na^+]$ + [blood glucose] + [urea].

The molecular weight of glucose is 180, and that of the two nitrogens in urea is 28. The plasma contents of both are usually expressed as mg/dl (instead of mg/l), so molecular weights must be divided by 10. Thus, glucose can be estimated by the plasma glucose content (in mg/dl)/18 and urea can be estimated by the blood urea nitrogen (BUN, in mg/dl)/2.8. Finally, a good estimation of plasma osmolality, usually accurate to within 1–3% (i.e., within 9 mOsm/kg H_2O) of what is determined directly by osmometry, can be obtained with the formula:

$$P = 2[Na^+] + \frac{\text{glucose}}{18} + \frac{\text{BUN}}{2.8} \qquad (1)$$

Diagnosis of Diabetes Insipidus

For accurate diagnosis, it is essential that 24-h urine volume is completed and polyuria confirmed. A range of baseline investigations including plasma electrolytes, random plasma osmolality and urine osmolality, as well as an assessment of kidney function, may assist in a correct diagnosis. In the absence of an immediate diagnosis, the child's fluid intake and output should be studied in greater detail. The ability of the central nervous system to produce and of the kidney to respond to vasopressin should be established by means of a formal water deprivation test and DDAVP trial.

A 7-h (or less) deprivation test is usually sufficient for diagnosis, except in cases of primary polydipsia, where a longer dehydration period is sometimes required. The test must be discontinued if weight loss exceeds 5% of starting weight and/or plasma Na^+ is found higher than

143 mEq/l and/or plasma osmolality higher than 295 mOsm/kg H_2O and/or urine osmolality increases to normal (Table 385.3, Fig. 385.5).

Diagnosis of CDI is based on the demonstration of plasma hyper-osmolality (>300 mOsm/l) associated with urine hypo-osmolality (<300 mOsm/l or urine/plasma osmolality ratio <1) and polyuria (urinary volume > 4–5 ml/kg/h for two consecutive hours post-surgery). Adrenocorticotropin deficiency may mask signs of partial CDI, and polyuria may become manifest after corticosteroid replacement therapy.

The administration of desmopressin will help to make a differential diagnosis between central and nephrogenic diabetes insipidus. Recently, copeptin and aquaporin-2 have also been used in the differential diagnosis of central versus nephrogenic diabetes insipidus. Aquaporin is both synthesized in the kidney and excreted in urine in response to vasopressin. Patients with CDI show no increase in aquaporin-2 with dehydration, but their excretion increases in response to desmopressin, suggesting that aquaporin-2 expression persists in patients with CDI. Thus, the main value of aquaporin-2 in the differential diagnosis of diabetes insipidus would be to specify a diagnosis of nephrogenic diabetes insipidus when there is no increase in aquaporin excretion following desmopressin administration.

Once the diagnosis of CDI has been established, other investigations are mandatory, including tumor markers, skeletal survey (in LCH, the skull is involved in as many as 85% of cases), and especially brain neuroimaging (Fig. 385.6). On an MRI, the posterior pituitary can be seen as a hyperintense signal on sagittal T1-weighted imaging under basal conditions. A lack of posterior pituitary hyperintensity (although not specific) is a hallmark of hypothalamic-posterior pituitary disorders and may represent the early stage of occult local tumors. In autosomal dominant CDI, the identification of posterior pituitary hyperintensity does not necessarily indicate that the functional integrity of the hypothalamic-neurohypophyseal axis is preserved. When present, the signal disappears on a regular basis at follow-up.

Thickening of the pituitary stalk or infundibulum, defined as exceeding 3 mm, although not specific, is observed in approximately one third of children with CDI. Pituitary stalk size at presentation is variable and can change over time. In two large pediatric series of idiopathic CDI patients, pituitary stalk thickening was found in approximately 50–60% of subjects. Spontaneous evolution of thick pituitary stalk was similar in both reports from unchanged (30%), to reduction (30–50%) or further enlargement (10–20%) of stalk size. Among patients with idiopathic CDI and thick pituitary stalk, 90–94% developed anterior pituitary hormone deficits with isolated GHD accounting for 60% of cases. Multiple pituitary hormone deficits were present in 30–50% of patients with widened pituitary stalk while only 10% of the 19 patients with normal pituitary stalk had an additional hormonal deficit.

Clinical, radiological and endocrine studies are necessary during follow-up. In particular, MRI follow-up is recommended for all patients with widened pituitary stalk (every 3–6 months); enlargement of the pituitary stalk lesion (>6.5 mm) or of the AP gland (AP size is age-dependent) or third ventricle involvement are all indications for pituitary stalk biopsy (Table 385.4, Fig. 385.7). Dynamic MRI may help to identify cases of CDI and normal PS size associated with abnormal blood supply to the posterior pituitary.

CDI central diabetes insipidus, *NDI* nephrogenic diabetes insipidus, *PP* primary polydipsia

Differential Diagnosis

Nephrogenic Diabetes Insipidus

Nephrogenic diabetes insipidus may reflect an intrinsic renal defect or it may be an acquired disorder that is secondary to metabolic disease, including hypercalcemia and hypokalemia, that impairs the action of vasopressin on the distal nephron. There are now a few recognized forms of hereditary NDI: X-linked NDI, which is due to abnormalities of the gene for the vasopressin V2-receptor *(AVPR2)* in the kidney with resistance of renal tubules to the action of vasopressin, and autosomal recessive or autosomal dominant NDI, due to abnormalities of the acquaporin-2 (*AQP2*) water channel. Molecular studies have identified a number of genetic mutations or deletions

of the gene that encodes for the vasopressin V2-receptor located on Xq28. The V2-receptor is a seven-domain transmembrane protein, and genetic abnormalities have been located in the transmembrane domain as well as in the external and internal segments of the receptor. At present, more than 180 different mutations in *AVPR2* have been described. These mutations all cause congenital nephrogenic diabetes insipidus and, consistently, are inactivating mutations, resulting in receptor malfunction at different levels, such as reduced receptor expression at the cell surface or disturbances in hormone binding and G protein coupling. The autosomal recessive form accounts for 10% of patients with familial NDI.

Primary Polydipsia

Primary polydipsia is characterized by excessive water drinking that suppresses vasopressin secretion. The ingested water causes an increase in body fluids and

a modest dilution of serum osmolality. The causes of primary polydipsia include psychogenic and dipsogenic primary polydipsia, whereas frank psychiatric compulsive drinking is an uncommon cause in children. The polyuria and polydipsia are temporary and reversible and strictly correlated to the improvement of the underlying cause. Patients usually remain normonatremic despite large fluid intake, although plasma sodium and osmolality may be low-normal or slightly reduced (*Table 385.3*).

Central Diabetes Insipidus and Thirst Abnormalities

Adipsic disorders are characterized by inappropriate lack of thirst, with consequent failure to drink to correct hyperosmolality. The incidence of postoperative CDI and thirst abnormalities have recently been reported to be about one third of patients with craniopharyngiomas. Adipsic CDI is characterized by abnormally low thirst scores and no thirst response to marked plasma hypertonicity during hypertonic saline infusion.

Patients with craniopharyngioma who develop an adipsic syndrome and postoperative CDI fail to increase serum AVP in response to drug-induced hypotension; moreover, they do not express thirst sensation after either a fall in blood pressure or hypertonic saline infusion, indicating that both osmotic and non-osmotic pathways are involved. A failure to secrete AVP in response to hypotension or hypovolemia may increase the risk of dehydratation and life-threatening hypernatremia. In adipsic patients, a fixed daily fluid intake appropriate for a weight at which the patient is known to be eunatremic and euvolemic should be established. Desmopressin is then administered at a dose and frequency capable of establishing an appropriate urine output and neutral fluid balance, allowing for insensible losses; regular weighing and checking of serum sodium levels are mandatory.

The Syndrome of Inappropriate Antidiuretic Hormone Secretion

Causes of hyponatremia in children include the syndrome of appropriate antidiuretic hormone secretion (SAADH) and the syndrome of inappropriate antidiuretic hormone secretion (SIADH). Although often less discussed and considered than SIADH, SAADH is by far the most common cause of hyponatremia in the pediatric population. Cerebral salt wasting syndrome (CSWS) as a cause of hyponatremia may exist, but is often diagnosed and reported without substantiation. It has been suggested that brain injury results in the direct secretion of natriuretic factors that result in renal salt losses, volume concentration, and AVP secretion, though available evidence shows that the heart is the major source of most circulating natriuretic peptides. The clinical status, assessment of extracellular fluid space volume status, measurement of urinary electrolytes, and responses to infusion of saline solutions can distinguish these conditions. Classical SIADH has basically been defined as an exclusion diagnosis when other causes for hyponatremia can be excluded: (1) in the absence of hypovolemia, (2) no evidence of diseases accompanied by edema, (3) non-endocrine dysfunction, including adrenal insufficiency and hypothyroidism, (4) no renal failure, and (5) no administration of drugs that can influence water homeostasis.

A novel disorder of water balance, with a SIADH-like clinical picture, which has been termed "nephrogenic syndrome of inappropriate antidiuresis" has been reported. Feldman and coauthors describe two unrelated male infants with euvolemic hyponatremia and serum hypo-osmolality, along with inappropriately elevated urine osmolality and urine sodium concentrations. At first glance, the disorder in these boys resembles the syndrome of inappropriate antidiuretic hormone secretion, a relatively common disorder characterized by insufficient suppression of AVP secretion in relation to the degree of hypo-osmolality, which leads to inappropriate urine concentration. Since serum AVP levels were undetectably low in both boys, Feldman et al. ruled out SIADH and hypothesized that a hyperactive V2 receptor could be the underlying cause of the disorder. Sequencing of *AVPR2* in the two patients revealed a hemizygous point mutation in each. In an in vitro functional assay, both mutations were shown to lead to the production of a constitutively active V2 receptor. The consequence was AVP-independent and, therefore, inappropriate, activation of V2 receptor–mediated renal urine concentration. Remarkably, and for reasons that remain unexplained, neither patient showed any clinical or biochemical sign of constitutive activation of extrarenal V2 receptors, which are known to mediate increases in circulating coagulation and fibrinolytic factors and a decrease in diastolic blood pressure after AVP stimulation.

Treatment

Treatment of CDI

The drug of choice for the treatment of diabetes insipidus is desmopressin (DDAVP), a synthetic analog of the endogenous hormone arginine vasopressin, but with a

2,000–3,000-fold lower vasopressor effect. Desmopressin may be administered orally, intranasally, or parenterally. Given intranasally or orally, maximum plasma concentrations are reached in 40–55 min. The drug's half-life is 3.5 h. Generally, urine output will decrease 1 or 2 h after administration, and the duration of action will range from 6 to 18 h. There is broad individual variation in the dosage required to control diuresis. Daily dosages for oral preparations vary from 100 to 1,200 μg in three divided doses, for the intranasal preparation approximately 2–40 μg, and for the parenteral, 0.1–1 μg. A low dose should be used initially and increased as necessary. Oral desmopressin has been shown to be particularly helpful in childhood. Its positive characteristics include better absorption, fewer complications and, due to the easy route of administration, good compliance among children and adolescents. Symptomatic dilutional hyponatremia is the only potential hazard if desmopressin is administered in excess over a prolonged time period. Symptoms of hyponatremia include headache, nausea, vomiting, and seizure. Untreated, these symptoms can lead to coma and death. However, asymptomatic hyponatremia can also occur. Particular attention is required in cases of multidrug therapy because of the risk of extrapontine myelinolysis.

Rare side effects with intranasal delivery of DDAVP include eye irritation, headache, dizziness, rhinitis or epistaxis, cough, flushing, nausea, vomiting, abdominal pain, chest pain, palpitations, and tachycardia. Evidence to date indicates that the use of DDAVP during pregnancy is safe and is not related to adverse effects on the mother or fetus/child.

In the presence of adipsia or hypodipsia, diabetes insipidus presents a difficult challenge and initially is best managed by adjusting the DDAVP dosage and fluid intake in a hospital setting. Daily weight can be used as an index of fluid balance, but regular monitoring of electrolytes will be required as well.

In early infancy, intranasal preparations can be administered by either rhinal tube (dose range 1–10 μg) or by a metered dose spray (5–10 μg). When infants are treated with DDAVP, dilute preparations of the rhinal tube solutions are often used. Because DDAVP stability is reduced by dilution, these preparations should not be used for more than 1 week.

Treatment of Nephrogenic Diabetes Insipidus

To date, no specific treatment that is aimed at restoring the function of the mutant V2 receptor is available to treat patients with X-linked NDI. Volume contraction and thiazide diuretics, amiloride, and indomethacin act only indirectly by decreasing the amount of tubular fluid presented to the distal tubule. Successful treatment has been reported with a combination of amiloride (20 mg/1.73 mq2 per day or 0.3 mg/kg per day orally three times a day) and/or hydrochlorotiazide (1–3 mg/kg/day two to three times per day orally) and/or indomethacin (1–3 mg/kg/day two to three times per day orally).

Treatment of SIADH

The key to effective management of hyponatremia is establishing the type and its cause, so that the cause can be removed, if possible, and management will be appropriate. It is paramount to clarify whether the hyponatremia has developed quickly (over a few days) and is acute, or whether it has developed over days to weeks and is chronic. The speed at which the serum sodium concentration is corrected should be closely linked to the suspected time over which the hyponatremia has developed. If the patient has only mild hyponatremia symptoms (headache, lethargy, dizziness), or is asymptomatic, and the hyponatremia is not severe, with sodium level >125 mmol/l, a conservative approach is recommended. Discontinuation of all possible offending drugs is important. In SIADH or the edema-producing states, a trial of water restriction to less than 1–1.25 l/day (depending on the degree of hyponatremia and the age of the patient) can be attempted; the serum sodium level should be measured at regular intervals to measure improvement. If the serum sodium level continues to fall, the patient may require an intravenous trial of normal saline to clarify the diagnosis: if the patient has ECF volume contraction as in CSWS (which may not be clinically apparent), a trial of saline will always improve serum sodium levels, whereas in cases of SIADH, the hyponatremia will worsen. The trial should be done with caution, following the "rules" for sodium correction by using 3–5% saline infusion at 0.1 ml/kg of body weight/min (up to 1–2 ml/kg of body weight/h) (*Table 385.5*).

Rapid correction can result in osmotic demyelination syndrome, with resultant severe brain injury and, potentially, death. Oral urea for the treatment of chronic syndrome of inappropriate antidiuresis in children has been reported to be successful; 30% oral urea solution at a starting dose of 0.1 g/kg/day divided into four doses and increased gradually to 2 g/kg/day.

Table 385.5
"Rules" for sodium correction

• In general, correct serum sodium concentration at an hourly rate of no more than 0.5 mmol/l
• If symptoms are severe, more rapid correction is necessary in the first 2–3 h, since the patient is at risk of cerebral edema
• Choose an intravenous solution according to the symptoms. Isotonic saline should, as a rule, raise serum sodium concentration by 1–2 mmol/l of infused saline. Reserve hypertonic saline (5 mmol/10 ml) for patients with severe symptoms
• Three to five percent hypertonic saline 0.1 ml/kg body weight/min (up to 1–2 ml/kg body weight/h) for 2 h; this solution should correct serum sodium concentration by about 10 mmol/l over the first day
• In extracellular fluid (ECF) volume contraction, isotonic saline should be the first choice for therapy, as it will expand the ECF volume, which will lead to decreased AVP release and help correct serum sodium concentration

Future Developments

Chaperones in NDI

The indirect forms of treatment of NDI are most effective in patients who have mild to moderate forms of X-linked NDI and bear incomplete loss-of-function mutations. These patients with mild to moderate disease are rare as most patients are completely unresponsive to AVP or DDAVP. The proposed pharmacologic chaperone-based therapy could represent a potential general treatment of severe forms of NDI.

Hyponatremia and Vasopressin Antagonists in Clinical Development

Currently, there are four nonpeptide agents in various stages of clinical trials. Conivaptan is a combined V1aR and V2R antagonist, whereas the others are selective V2R antagonists. In December 2005, conivaptan was approved by the FDA for the treatment of euvolemic hyponatremia, and in February 2007 this indication was extended by the FDA to include hypervolemic hyponatremia. All agents of this class are inhibitors of the cytochrome P450 3A4 (CYP3A4) system, but conivaptan appears to be the most potent in this regard. Although the drug is orally active, to minimize the possibility of drug interactions, the FDA has restricted its distribution to a parenteral form for short-term (4-day) in-hospital use only. The remaining V2R antagonists appear to have more limited CYP3A4 interactions and are currently being developed for long-term oral use.

386 Growth Disorders

Ting-Wen An Lee · Radhika Muzumdar · Paul Saenger

Definition/Classification

Short stature is defined as height that is 2.5 SD or greater below the mean for age. However, suboptimal growth that may be present without absolute short stature should also warrant attention. Suboptimal growth is defined as height velocity less than the 3rd percentile for age. It is important to keep in mind that the most commonly available growth charts may not be applicable to all ethnic groups since they have been derived from primarily white populations.

The differential diagnosis for short stature and abnormal growth is extensive and includes both endocrine and non-endocrine causes. Growth disorders can be broadly categorized into three groups: (1) primary growth abnormalities in which there are intrinsic defects of the growth plate; (2) secondary growth abnormalities in which growth failure is due to chronic disease or endocrine disorders; and (3) genetic short stature. Examples of primary growth abnormalities include intrauterine growth retardation and chromosomal abnormalities. Examples of secondary growth abnormalities include malnutrition, hypothyroidism, and growth hormone deficiency. Given the broad range of causes of short stature, one must consider the pathogenesis/pathology in terms of the specific etiology of short stature. However, regardless of the etiology of short stature, it is important to understand normal growth and the factors that regulate normal growth. The next section will review normal growth. Later clinical manifestation and pathogenesis/pathology will be discussed in the differential diagnoses as they pertain to specific etiologies of short stature.

Etiology

Normal Growth

One of the most important roles of physicians taking care of children is the careful assessment of their growth. Though many factors contribute to growth, children normally grow in a fairly predictable manner. Growth rates vary at different stages in life. Prenatal growth averages 1.2–1.5 cm/week. During the first 2 years of life, growth velocity averages 15 cm/year and slows during mid-childhood to 6 cm/year. The pubertal growth spurt begins earlier in girls than in boys. Total pubertal growth is about 17% of adult height in boys and about 15% in girls. In general, girls grow an additional 5 cm after menarche. Though the timing of the pubertal growth spurt varies in normal children, the final height is not normally affected by the time of onset of the pubertal growth spurt. Growth is complete when chondrocyte proliferation in the growth plate slows and epiphyses fuse, forming the adult skeleton.

Endocrine Regulation of Growth

The pituitary gland is extremely important in understanding the regulation of growth. The pituitary gland is formed from two distinct sources – The adenohypophysis (anterior, intermediate, and infundibular pituitary) is derived from Rathke's pouch and the neurohypophysis (posterior pituitary) is derived from the neural ectoderm of the floor of the forebrain. The adenohypophysis is normally 80% of the pituitary, of which the anterior pituitary is the largest part and contains the most hormone producing cells. Growth hormone (GH)–producing cells can be detected in the adenohypophysis by 9 weeks gestation.

The pituitary is normally found in the sella turcica so that the volume of the sella turcica is a good indicator of pituitary size. The pituitary is also in close proximity to the optic chiasm so that any child with optic chiasm hypoplasia, congenital blindness, or nystagmus should be evaluated for hypothalamic/pituitary dysfunction. This anatomic proximity also explains why pituitary tumors may initially present with visual complaints or decreased peripheral vision.

Growth Hormone

Human GH is a single chain, 191 amino acid, 22-kDa protein. The pulsatile secretion of GH secretion is regulated by the interaction between two hypothalamic peptides, growth hormone–releasing hormone (GHRH),

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_386,

and somatostatin (somatotropin release-inhibiting factor [SRIF]). GHRH regulates GH production mainly at the transcription level. The GHRH receptor is a member of the G-protein-coupled receptors. Abnormalities in the connection between the hypothalamus and the anterior pituitary that prevent GHRH binding to somatotropes are thought to be the most important causes of clinical GH deficiency in children. Somatostatin is believed to be involved in the timing and amplitude of pulsatile GH secretion. Other factors that stimulate GH secretion are: fasting, deep sleep, hypoglycemia, stress, sex steroids, and ghrelin. Factors known to suppress GH secretion are: obesity, glucocorticoids, hyperglycemia, hypothyroidism, and insulin-like growth factor 1 (IGF-1). IGF-1 regulates the synthesis and secretion of GH through feedback regulation.

The pulsatile secretion of GH is characterized by intermittent bursts in serum GH levels separated by periods of low serum GH levels. During these periods of decreased GH secretion, GH levels are normally low, making random serum sampling of GH useless. GH levels peak during deep sleep. The biologic effect of pulsatile GH secretion on growth is not completely understood; however, studies show that larger swings in GH output in an irregular sequence is associated with better growth.

Prenatally, fetal GH can be detected in the serum by the end of the first trimester with peak levels in midgestation. During the neonatal period, GH levels drop and continue to drop through childhood and early puberty. During adolescence, GH secretion peaks again, resulting in high serum IGF-1 levels associated with puberty. GH and IGF levels start to decline from late adolescence into adulthood.

GH exerts its biologic actions both through IGF-dependent and IGF-independent mechanisms. Though GH may have some effect on skeletal growth independent of IGF activity, most of its effect is likely through its ability to stimulate the IGF axis. In addition to its effects on growth, GH has important metabolic effects. In muscle, it increases lean tissue mass by increasing amino acid transport and nitrogen retention. In adipocytes, it causes insulin resistance by decreasing glucose transport and increasing lipolysis.

Growth Hormone Receptor and Binding Protein

The human GH-receptor (GHR) gene is located on chromosome 5p13.1-p12. Upon binding to its receptor, GH stimulates phosphorylation of Janus kinase 2 (JAK2), a tyrosine kinase protein associated with the receptor. Activation of JAK2 leads to phosphorylation of intracellular tyrosines of the GHR, which provide docking sites for important intermediary proteins such as signal transducers and activators of transcription (STATs). In particular, STAT5b plays a crucial intermediary role in GH regulation of *IGF-1* gene transcription and growth.

Growth hormone binding protein (GHBP) is the extracellular domain of the GH receptor and modulates GH binding to its receptor. It is thought that GHBP increases the half-life of GH by impairing its glomerular filtration. GH-receptor levels and activity are directly related to GHBP levels such that GH insensitivity is associated with low levels of GHBP. Various physiologic factors affect levels of GHBP. Low levels are associated with malnutrition, chronic diseases such as diabetes mellitus, hypothyroidism, liver disease, and various inherited abnormalities of the GH receptor; whereas high levels are associated with obesity, refeeding, early pregnancy, and estrogen treatment. GHBP levels are low in infancy, rise through childhood, and stabilize during puberty and adult life.

Insulin-Like Growth Factors

Insulin-like growth factors (somatomedins) are a family of peptides that mediate many of GH actions. IGFs are characterized by having their serum concentrations dependent on GH, having insulin-like activity in extraskeletal tissues, promoting the incorporation of sulfate into cartilage, and stimulating DNA synthesis and cell multiplication. Two types of IGFs are IGF-1 and IGF-2. Both are structurally similar to insulin giving them the ability to bind to the insulin receptor. However, structural differences between the IGFs and insulin prevent insulin from binding with high affinity to the IGF-binding proteins.

GH is apparently the primary regulator of IGF-1 gene transcription via STAT5b. Regulation of IGF-2 gene expression is less clear. IGF-2 gene expression is high in fetal life, but declines postnatally. The IGF system is important for both intrauterine and postnatal growth.

Currently, the most practical method to accurately assess IGF levels with minimal IGFBP interference is done with either ELISA or IRMA. It is important for individual laboratories to develop their own population-specific reference ranges and to take into account ethnic, nutritional, and environmental variations that may impact "normal" IGF-1 values.

IGF-1 levels are relatively low during fetal life. Serum levels rise during childhood and reach adult levels at the

onset of puberty. During adolescence, levels correlate more closely with Tanner stage or bone age than with chronological age. IGF-1 levels peak to about two to three times adult levels during puberty. Levels gradually decline after adolescence to adult levels.

IGF-1 levels are more GH-dependent than IGF-2 levels. However, IGF-1 levels are also affected by age, pubertal status, and nutritional status. In normal children less than 5 years of age, IGF-1 levels are low. There is also overlap between normal values and values in GH-deficient children. IGF-2 levels are less age-dependent, but are less GH-dependent than IGF-1.

Numerous studies have been done to examine the relationship between GH status and IGF-1 levels. Rosenfeld and colleagues found that in 68 GH-deficient children, 197 children with normal stature, and 44 normal children with short stature, 18% of the GH-deficient children had normal IGF-1 levels for age and 32% of normal short children had low IGF-1 levels for age. Fifty-two percent of the GH-deficient children and 35% of normal short children had low IGF-2 levels. However, they found that when IGF-1 and IGF-2 assays were combined, only 4% of GH-deficient children had normal levels of both IGFs and only 0.5% of normal children and 11% of normal short children had low serum levels of both IGFs. The inconsistent correlation between GH status and IGF-1 levels demonstrated in this study may partially be explained by the arbitrary definition of GH-deficiency based on GH stimulation tests and variations in GH assays.

IGF-Binding Protein

IGF-binding proteins (IGFBPs) are a family of proteins that complex with IGFs and extend their serum half-lives, transport them to target cells, and modulate their interaction with surface membrane receptors. Six different human IGFBPs (IGFBP-1 to 6) have been described.

In general, IGFBPs appear to inhibit IGF action by competing with IGF receptors for binding IGF peptides. However, in some situations, IGFBPs may also promote IGF action by helping to deliver IGF to target receptors.

The majority of IGF peptides are carried in a ternary complex made up of one IGF molecule, one IGFBP-3 molecule, and one acid-labile subunit (ALS) molecule. It is the large size of this ternary complex that extends the half-life of IGF from 10 min for IGF alone, to 1–2 h for IGF-IGFBP-3 binary complex, to 12–15 h for the ternary complex. Both IGFBP-3 and ALS levels are GH-dependent. Due to this GH regulation of the IGF axis, patients with GH deficiency or insensitivity have little IGF in the ternary complex with most being in the binary complex with IGFBP-3 or bound by other IGFBPs.

Levels of IGFBP-3 may be most valuable clinically given its GH dependence. In fact, IGFBP-3 measurements may be superior to IGF-1 measurements in the evaluation of GH deficiency since IGF-1 levels are low in childhood and often overlap in normal and GH-deficient children; whereas IGFBP-3 levels reflect both IGF-1 and IGF-2 levels, and are therefore less age-dependent.

Diagnosis

Assessment of Growth

Anthropometric

Deviation in normal growth is often an early sign of an underlying disease, either endocrine or non-endocrine. It is therefore important to review the proper techniques in accurately measuring growth and using growth charts.

Children less than 2 years of age should have their supine length measured. The infant's legs should be fully extended and its head in the Frankfurt plane. Older children who are able to stand should have their height measured using a wall-mounted "Harpenden" stadiometer with a rigid headboard. The child should be fully erect with the head in the Frankfurt plane and the back of the head, thoracic spine, buttocks, and heels touching the vertical axis of the stadiometer. Since diurnal variation in standing height has been observed, serial measurements should ideally be done at the same time of day.

Additionally, it is ideal to have the same individual perform serial measurements of length or height. The average of triplicate measurements should be recorded, with no more than 0.3 cm variation among the values. A minimum of 3–6 months, with 6–12 months being ideal, between measurements is necessary for accurate determination of growth velocity.

When assessing abnormal growth, it is also important to assess disproportionate growth by measuring and comparing the following to published age standards: head circumference, lower body segment (distance from the superior pubic symphysis to the floor), upper body segment (sitting height), and arm span.

After careful assessment of height, the child's height should be evaluated in the context of normal standards, which are typically cross-sectional. The most recent growth charts using cross-sectional data were published in 2000 by the National Center for Health Statistics (NCHS) (www.cdc.gov/growthcharts). These charts allow assessment of

a child's height and growth relative to the 5th, 10th, 25th, 50th, 75th, 90th, and 95th percentiles of normal American children. However, these charts have two major limitations. First, the growth rates of children below the 5th or above the 95th percentiles are not provided. Second, cross-sectional data are more valuable during infancy and childhood than in adolescence when growth rates can vary due to variations in the onset and progression of puberty. A Dutch web-based growth analyzer is also available at www.growthanalyser.org. Tanner and colleagues have developed longitudinal growth charts that account for timing of puberty. Height velocity standards have also been developed using cross-sectional and longitudinal data. Additionally, disease-related growth charts are available for conditions associated with growth failure such as Turner syndrome, achondroplasia, and Down's syndrome.

Since children normally grow in a remarkably predictable manner between the age of 2 years and the onset of puberty, any "crossing" of height percentiles or abnormal height velocities during this time period merit further evaluation.

Radiologic

Genetic factors and hormones such as growth hormone (GH), thyroxine, and gonadal steroids, particularly estrogen, are involved in controlling the appearance and maturation of ossification centers in normal children. The "bone or skeletal age" can be used to estimate the growth potential in tubular bones by evaluating the progression of ossification in the epiphyses compared to normal age-related standards. The bone age is commonly obtained using a radiograph of the left hand and wrist and compared to the published male and female standards of Greulich and Pyle. It is important to keep in mind that the determination of bone age requires experience in order to minimize variability between observers. Additionally, normal skeletal maturation rates depend not only on gender, but also on ethnicity; the standards of Greulich and Pyle were developed between 1931 and 1942 in normal American white children, and are still widely used worldwide. Finally, given the standards were determined using normal children, extrapolation to children with endocrine abnormalities or skeletal dysplasias may be limited.

Height Prediction. A child's adult height can be predicted based on the degree of skeletal maturation observed on the bone age. The more delayed the bone age relative to the chronological age, the more time there is before epiphyses fusion and growth cessation. The more advanced the bone age, the more accurate the predicated adult height since the patient is closer to the final height. The most commonly used height prediction method was developed by Bayley and Pinneau, and utilizes the bone age, height, and a semiquantitative allowance for chronologic age.

Midparental Target Height and Parent-Adjusted Growth Curves

It is helpful to assess the child's growth relative to that of the parents and siblings given the importance of genetic factors in the determination of a child's growth and height potential. Additionally, the child's predicted adult height can be compared to the midparental target height. When there is a discrepancy between these comparisons, one should consider the possibility of a pathologic process. The midparental target height is equal to the mean of the parental heights with the addition of 6.5 cm for boys and subtraction of 6.5 cm in girls. Two standard deviations for the calculated height is ±10 cm.

Biochemical

Upon initial assessment, the following serum values should generally be obtained: complete blood count, chemistry profile, liver function tests, thyroid function tests, sedimentation rate, IGF-1, IGFBP-3, and celiac screening panel. A karyotype should be done on all short, slow-growing females to rule out Turner's syndrome.

Figure 386.1 provides an algorithm for evaluating growth failure.

Diagnosing IGF Deficiency/GH Deficiency

Documentation of serial heights and height velocity provides the foundation for the diagnosis of GH/IGF deficiency. Evaluation of pituitary GH production is difficult given the pulsatile secretion of GH. Additionally, spontaneous GH secretion varies with gender, age, pubertal stage, and nutritional status. GH levels are usually undetectable with conventional assays in between normal pulses of GH secretion, making random GH measurements virtually useless, except in cases of GHI and GH excess. Therefore, GH stimulation tests have been used to measure GH reserve. GH stimulation testing is notoriously difficult to perform and its results often inconsistent. Additionally sex steroid priming in prepubertal children is not physiologic. While some have interpreted these difficulties in measuring GH as a reason to stop performing GH

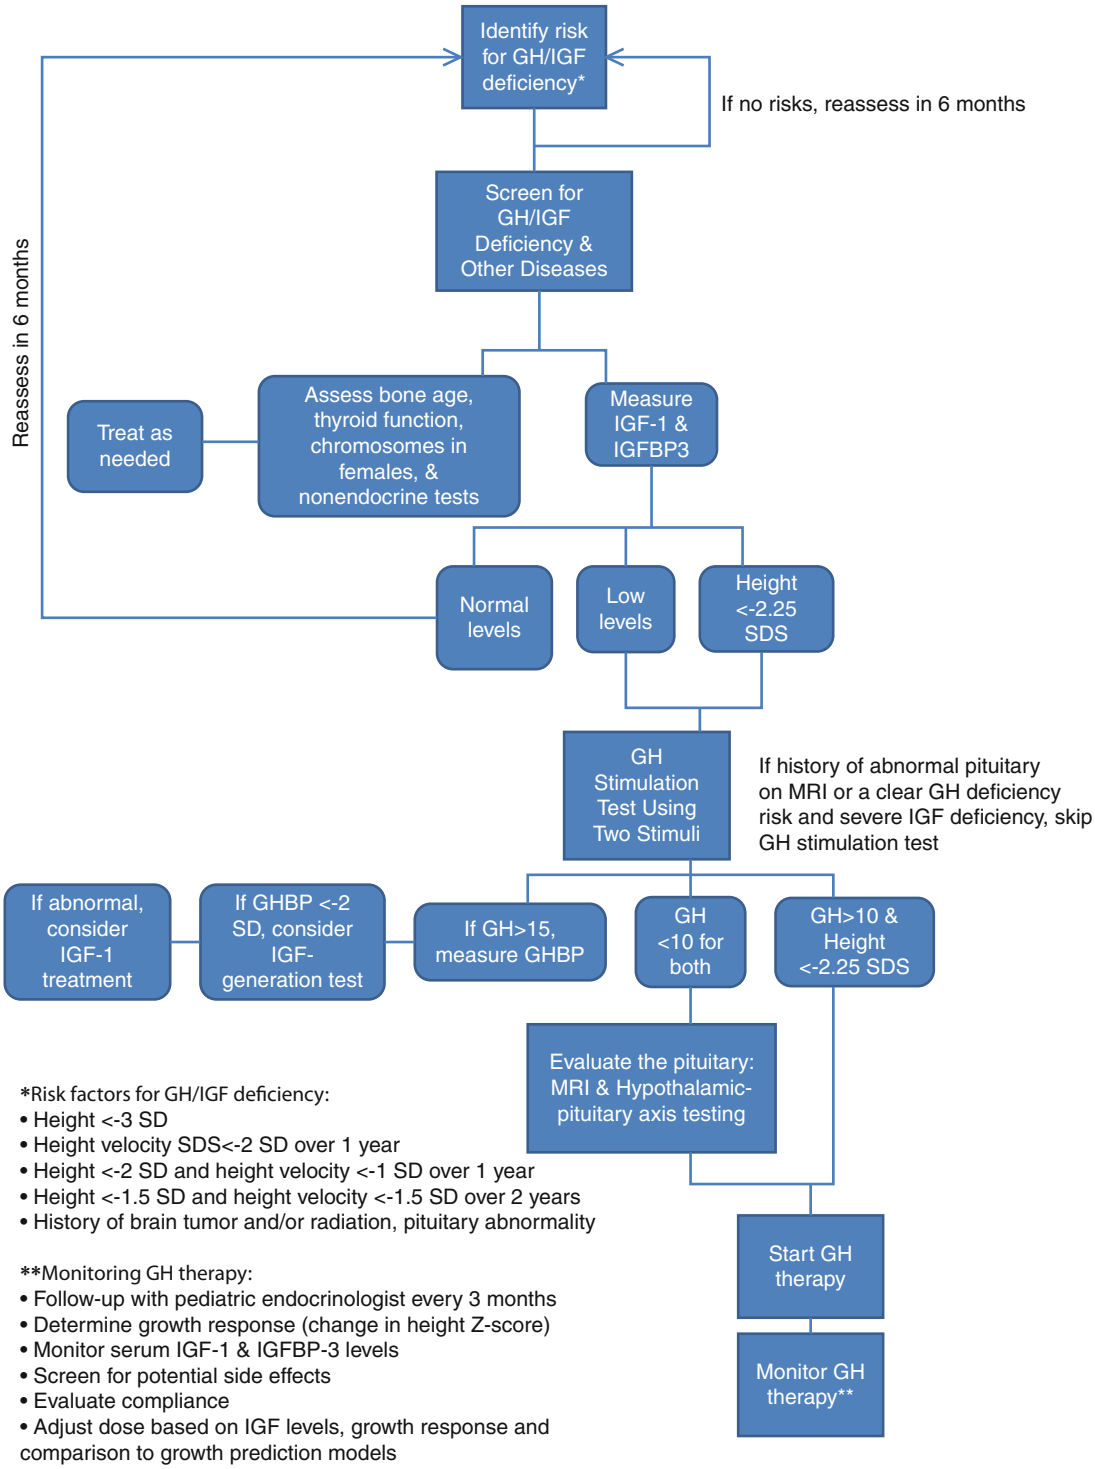

Figure 386.1
Algorithm for evaluating growth failure

Table 386.1
Growth hormone stimulation tests[a]

Stimulus	Dosage	Samples (min)	Comments/side effects
Levodopa (PO)	<15 kg: 125 mg	0, 60, 90	Nausea, emesis, headache
	15–30 kg: 250 mg		
	>30 kg: 500 mg		
Clonidine (PO)	0.15 mg/m^2	0. 30, 60, 90	Fatigue, postural hypotension
Arginine HCl (IV)	0.5 g/kg (max 30 g)	0, 15, 30, 45, 60	Late hypoglycemia
	10% arginine HCl in 0.9% NaCl over 30 min		
Insulin (IV)	0.05–0.1 IU/kg	0, 15, 30, 45, 60, 75, 90, 120	Hypoglycemia, requires supervision[b]
Glucagon (IM)	0.03 mg/kg (max 1 mg)	0, 30, 60, 90, 120, 150, 180	Nausea, late hypoglycemia

[a]Tests should be performed after an overnight fast. Patients should be euthyroid at time of testing
[b]Insulin-induced hypoglycemia is a potential risk of this procedure, which is designed to lower the blood glucose by at least 50%. D50W solution and glucagon should be available. Not recommended in newborn or small children

stimulation testing, it is still strongly recommended. It is critical to differentiate GH deficiency from idiopathic short stature (ISS) and secondary IGF deficiency from primary IGF deficiency. GH stimulation testing is still a cornerstone in the evaluation of short stature though GH measurements must be complemented with IGF-1 and IGFBP-3 measurements.

Physiologic stimuli of GH include fasting, sleep, and exercise. Pharmacologic stimuli include levodopa, clonidine, glucagon, propranolol, arginine, and insulin. *Table 386.1* includes information on pharmacologic GH stimulation testing. Stimuli that are easily administered, have low toxicity and risk, and of low specificity are used for screening and include exercise, fasting, levodopa, and clonidine. Stimuli that are used for definitive testing include arginine, insulin, and glucagon. Many centers will use fasting and a screening stimulus followed by fasting and a definitive stimulus. A child is generally considered to have GHD if there is failure to respond, defined as a peak GH level less than 10 ng/mL, to two separate stimuli.

Differential Diagnosis

Endocrine (Secondary) Causes of Short Stature

GH/IGF-1 Deficiency

Given the integral role of IGF-1 in both prenatal and postnatal growth and the complexity of the GH-IGF-1 axis, the category of GH/IGF-1 deficiency encompasses a wide range of disorders that ultimately result in IGF-1 deficiency (IGFD). IGFD is divided into two main categories – primary and secondary IGFD. Primary IGFD includes disorders characterized by decreased IGF-1 production along with normal or elevated GH secretion, such as in states of GH insensitivity. Secondary IGFD includes disorders in which defects of the hypothalamus or pituitary cause decreased GH and subsequent IGF-1 production. Examples include tumors, infection, trauma, radiation, inflammation to the hypothalamus and/or pituitary, and molecular defects in pituitary development.

Clinical Features of GH/IGF Deficiency

The clinical features of GH/IGFD are dependent on the onset of IGF-1 deficiency. Though IGF-1 is critical to both prenatal and postnatal growth, its production in utero is mostly GH-independent, whereas its production postnatally is largely GH-dependent. Therefore, patients with secondary IGFD or with primary IGFD due to defect of GH action usually have near-normal birth size with growth failure becoming more obvious at several months of age. In contrast, patients with primary IGFD due to defects of the IGF-1 gene resulting in IGF-1 deficiency early in gestation have significant fetal growth retardation. Neonates can present with hypoglycemia, prolonged jaundice with direct hyperbilirubinemia due to cholestasis, microphallus, cryptorchidism, and scrotal hypoplasia. In severe GH/IGFD, growth failure can be evident in the first month of life with lengths 3–4 SD below the mean by 6–12 months. Bone age may be delayed relative to the chronological age, but similar to the height age. However, bone age and chronological age could be matched in acquired GHD, such as with a CNS tumor. Other clinical features include: "infantile" fat distribution, increased

weight/height ratios, poor musculature causing gross motor developmental delay, delayed fontanel closure with normal growth of the skull leading to an appearance of hydrocephalus, facial bone growth retardation causing an underdeveloped nasal bridge and frontal bossing, infantile voice due to hypoplasia of the larynx, sparse and thin hair growth, slow nail growth, small penis, and often delayed puberty. *Table 386.2* lists key history and physical exam findings that may indicate GHD.

Causes of GH/IGF-1 Deficiency

Hypothalamic. Some of the hypothalamic factors that regulate GH synthesis and secretion are GHRH and GH-releasing peptides such as ghrelin and somatostatin. Some cases of IGF deficiency may be explained by mutations in the genes encoding these and other hypothalamic proteins.

A common cause of hypopituitarism is hypothalamic dysfunction from congenital malformations of the brain or hypothalamus. However, somatotropes still differentiate and proliferate despite the absence of hypothalamic regulation, resulting in reduced serum levels of GH and IGF-1 starting in the intrauterine period. GH deficiency is increased in cases of simple clefts of the lip and/or palate alone.

Septo-optic dysplasia (SOD) is a rare syndrome consisting of hypoplasia or absence of the optic chiasm and/or optic nerves, agenesis or hypoplasia of the septum pellucidum and/or corpus collosum, and hypothalamic insufficiency. Pituitary hormone deficiencies can range from isolated GH deficiency or in combination with TSH, ACTH, and/or gonadotropins deficiencies. Structural abnormalities of the pituitary stalk and ectopic posterior pituitary can be identified on MRI in some cases. Familial forms of SOD are associated with mutations of HESX1, which is expressed in early pituitary and forebrain development.

In "idiopathic" hypopituitarism or GHD, the hormone deficiencies are thought to be secondary to abnormalities of synthesis or secretion of hypothalamic hypophysiotropic factors. Idiopathic GHD has also been shown to be associated with abnormal pituitary structure on MRI, with more severe GHD associated with more significant structural abnormalities.

Brain tumors, especially midline tumors, such as optic nerve gliomas, germinomas, meningiomas, and ependymomas, are a major cause of hypothalamic insufficiency. Metastases from extracranial carcinomas, local extension of craniopharyngeal carcinomas, and Hodgkin's disease of the nasopharynx can also cause hypothalamic insufficiency.

Radiation of the brain can cause both hypothalamic and pituitary dysfunction. Damage to the hypothalamus occurs more often as it is more radiosensitive than the pituitary. The degree of dysfunction is relative to the dose of radiation administered with low doses associated more with isolated GHD and higher doses with multiple hormone deficiencies. The length of time after radiation also contributes to the number of deficiencies, which can develop over time. Chemotherapy can also impair adult height due to GH insensitivity, though to a lesser degree than radiation. GH stimulation testing may be normal in such cases due to radiation therapy; however, spontaneous GH secretion may be blunted due to a decrease in pulse amplitude. Radiation can also cause decreased spinal growth potential, and early puberty with premature epiphyseal closure. The use of exogenous GH therapy in children with GHD and growth failure has not been associated with increased relapse of the primary neoplasm, though the response to therapy is variable.

Psychosocial dwarfism is an extreme form of growth failure resulting from a poor home environment and parenting. Fortunately, catch-up growth is possible once the child is removed from the dysfunctional environment.

Table 386.2
The Growth Hormone Research Society 2000 Criteria that may indicate growth hormone deficiency

• Neonatal hypoglycemia, prolonged jaundice, micropenis, or traumatic delivery
• Cranial irradiation
• Head trauma or central nervous system infection
• Consanguinity and/or and affected family member
• Craniofacial midline abnormalities
• Severe short stature – height more than 3 SD below the mean
• Height more than 1.5 SD below the midparental target height
• Height more than 2 SD below the mean and a height velocity over 1 year more than 1 SD below the mean for chronological age, or a decrease in height SD more than 0.5 over 1 year in children over 2 years of age
• In the absence of short stature, a height velocity more than 2 SD below the mean over 1 year or more than 1.5 SD sustained over 2 years; this may occur in GHD, presenting in infancy, or in organic-acquired GHD
• Signs indicative of an intracranial lesion
• Signs of multiple pituitary hormone deficiency
• Neonatal symptoms and signs of growth hormone deficiency

Additionally, abnormal GH secretion during GH stimulation testing associated with psychosocial dwarfism normalizes after removal from the dysfunctional environment. The diagnosis of psychosocial dwarfism is confirmed by normalization of GH secretion and subsequent catch-up growth. The neuroendocrinological mechanism of psychosocial dwarfism is not clear. Although GH secretion is low, exogenous GH therapy is typically not effective until removal from the dysfunctional environment.

Other hypothalamic causes of GHD include myelomeningocele, shunted hydrocephalus, head trauma, inflammation of the brain/hypothalamus due to infections and sarcoidosis, and neurofibromatosis.

Pituitary GH Deficiency. There are a number of abnormalities that specifically affect pituitary somatotrope development and function. Multiple genetic causes of GHD have been described affecting GH production, secretion, and bioactivity. GHD can also result from multiple pituitary hormone deficiency (MPHD) due to mutations of specific genes such as PROP1, POU1F1, SOX3, LHX3, and LHX4.

Primary tumors of the pituitary such as craniopharyngiomas can cause GHD. Growth failure exists at presentation in most children with craniopharyngiomas. The most common associated pituitary hormone deficiencies are GH and gonadotropins, though TSH, ACTH, and/or diabetes insipidus can also occur. Other pituitary tumors that can cause GHD include pituitary adenomas, though rare in childhood and adolescents. The incidence of hypopituitarism is higher with macroadenomas compared to microadenomas.

Langerhans cell histiocytosis is a disorder that is classically associated with diabetes insipidus, though studies have shown 50–75% of patients to have growth failure and GHD at presentation.

GH-Receptor Abnormalities. Primary GH insensitivity (GHI) was initially reported by Laron and colleagues. Approximately 250 worldwide cases have been identified, mostly from the Mediterranean region or Ecuador. Patients with GHI do not respond to exogenous GH with increases in serum IGF-1 and IGFBP-3 levels, growth, and metabolic changes. To date, more than 60 mutations of the GHR gene causing GHI have been reported. Most of the mutations are in the extracellular (GH-binding) domain of the GHR, which impairs GH from binding to its receptor leading to decreased circulating GHBP. Other GHR receptor mutations include those affecting the transmembrane or intracellular domains of the GHR. Levels of GHBP can be elevated in such individuals as the mutant receptor protein becomes detached from the cell receptor surface. As with congenital GHD, the range of clinical phenotypes of GHI due to GHR abnormalities is wide. Some features associated with growth failure due to GHR abnormalities include elevated serum GH levels in children (though may be normal in adults), decreased serum GHBP levels (though may be elevated as mentioned above), and profoundly decreased serum IGF-1, IGF-2, and IGFBP-3 levels.

GHR Signaling Defects. Seven cases of severe growth failure with markedly low serum levels of IGF-1, IGFBP-3, and ALS despite normal levels of GHBP and normal GHR gene sequence have been found to have GHR signaling defects due to mutations of the STAT5b gene. STAT5b is involved in a critical step in the pathway of STAT activation of IGF-1 gene transcription. It is also involved in the signaling pathway for multiple cytokines, which may be related to the immune dysfunction and recurrent pulmonary infections noted in the above cases.

ALS Mutations. Twenty cases with markedly reduced serum levels of IGF-1 and IGFBP-3 have been found to have mutations of the ALS gene. However, their growth relative to patients with mutations of GHR or STAT5b was only modestly affected, with some cases attaining normal adult height.

IGF-1 Gene Deletions. One case of a partial deletion of the IGF-1 gene resulting in a truncated IGF-1 molecule has been identified. IGF-1 levels were low, but IGFBP-3 and GHBP levels were normal. This individual had severe prenatal and postnatal growth failure, sensoneural deafness, mental retardation, and microcephaly, suggesting a role for prenatal IGF-1 in CNS development. Additionally GH overproduction was thought to cause the hyperinsulinism and insulin resistance noted in this patient. The patient was unresponsive to GH therapy, but responded well to IGF-1 therapy.

One case of an inactivating mutation of the IGF-1 gene has also been reported. The patient had similar phenotypical features as the individual with the IGF-1 gene deletion, but IGF-1 levels were markedly elevated.

Other causes of primary IGF-1 deficiency include genetic insensitivity to IGF action, primary defects in IGF transport, and clearance and primary defects in IGF-1 receptor production or responsivity.

Hypothyroidism

Thyroxine is essential for linear growth during the first year of life making early detection of congenital hypothyroidism with newborn screening critical. With proper replacement therapy, patients with congenital hypothyroidism can have normal growth and bone

mineral density, as well as normal pubertal growth and final adult height. In acquired hypothyroidism, growth failure is often the most prominent manifestation, though it can take years to become clinically evident. Children tend to be overweight for their height as linear growth is more affected. Bone age can be very delayed and body proportion is immature with an increased upper to lower body segment ratio. Hypothyroidism is associated with both delayed and precocious puberty, though the former is more common. In acquired hypothyroidism, replacement therapy causes rapid catch-up growth; however, full growth potential may not be attained because skeletal maturation during the first 18 months of treatment is rapid. Deficits in adult stature correlate with the duration of hypothyroidism before starting replacement therapy. Initiating replacement therapy near puberty may compromise catch-up growth even more so that lower replacement doses or pharmacologic delay of puberty may be considered.

Cushing's Syndrome

Both excessive endogenous and exogenous glucocorticoids can cause growth failure by impairing normal bone metabolism through inhibition of osteoblastic activity and enhanced bone resorption. GH secretion and IGF and IGFBP levels are typically normal. The effects of glucocorticoids on the epiphyses may persist even after correction of chronic excessive glucocorticoid exposure so that patients may fail to reach target heights. The degree of catch-up growth is directly related to the duration and level of glucocorticoid excess. Growth arrest may be the presenting sign of Cushing's syndrome in children; however, this may be masked in cases of adrenal tumors that secrete both excess glucocorticoids and androgens.

Pseudohypoparathyroidism

Growth failure is a common feature of pseudohypoparathyroidism along with characteristic dysmorphic features – short metacarpals, truncal obesity, subcutaneous calcifications, round facies, mental retardation, and hypocalcemia and hyperphosphatemia due to end-organ resistance to parathyroid hormone.

Rickets

Prior to the supplementation of vitamin D in breastfed and formula-fed babies, hypovitaminosis D was a major cause of short stature. Vitamin D is important for normal growth as evidenced by the association of the vitamin D receptor gene polymorphism with birth length, growth rate, adult stature, and bone mineral density.

In hypophosphatemic rickets, treatment with oral phosphate replacement and calcitriol improves rickets, but may not correct growth failure; however, earlier initiation of treatment in infancy may result in greater childhood and adult heights. GH therapy has been shown to improve skeletal growth and bone mineral density in some trials.

Idiopathic Short Stature

Idiopathic short stature is a very broad category in which the cause of short stature is unknown/idiopathic and encompasses groups of patients with constitutional delay of growth and maturation (CDGM) and genetic/familial short stature. The cause of such delay in growth and puberty is not well established. ISS is a condition in which an individual's height is more than 2 SD below the mean height for a given age, sex, and population group without systemic, nutritional, chromosomal, or endocrine abnormalities. Individuals with ISS have normal birth weights. Many children classified as having idiopathic short stature may have heights less than the 3rd percentile, slowed linear growth velocity, delayed bone age, and impaired or attenuated pubertal growth spurt. They typically have normal GH secretion, though GH stimulation test results may be blunted, especially in cases of delayed puberty. GH-dependent peptides can be lower based on chronological, but not necessarily, bone age. Children with ISS are often considered variants of normal growth and will naturally grow to final adult heights that are acceptable based on midparental target heights. However, some of these children are as short as those with GHD. Linear growth in children with ISS is often enhanced by treatment with GH.

ISS should be subdivided into those children with a familial history of short stature, whose heights fall within the expected range for parental target height, and those who are short relative to their parents. Children with no family history of short stature tend to have lower adult height compared to target height. ISS should also be subdivided into those with and without delayed bone age as an indicator for the possibility of delayed growth and puberty.

The following screening tests should be performed in the evaluation of ISS: complete blood count, ESR,

liver function tests, chemistry panel, TSH and free T4, IGF-1 levels, celiac screening panel, karyotype for all girls and for boys with genital anomalies, and a bone age X-ray. In order to make the diagnosis of ISS, growth hormone deficiency must be excluded based on clinical and biochemical evaluations. Children with history and physical exams consistent with GHD, low growth velocities, or low IGF-1 levels should be evaluated with growth hormone stimulation testing. However, most experts agree that children with normal growth velocities, no bone age delays, and IGF-1 levels above the mean for age do not require growth hormone stimulation testing. Hypothalamic-pituitary MRI is not indicated if a diagnosis of ISS is made.

Constitutional Delay of Growth and Maturation

Children with constitutional delay of growth and maturation are considered normal variants with respect to rate of maturation. They have short stature, relatively normal growth velocities during childhood, delayed puberty and growth spurt, and achieve normal adult height. Deviation from the normal growth curve occurs early in life around the 5th percentile by the age of 2 years, and may decrease more through the mid-childhood years without impacting final adult height. Final height is often at the lower end of the midparental target height range and is typically less than the predicted height based on bone age, though it is difficult to predict. Delayed growth may adversely affect bone mineralization and lead to the development of osteopenia.

Lower levels of gonadal steroids during delayed puberty may be associated with decreased GH secretion along with a transient partial GH deficiency. Given the lower levels of gonadal steroids, these children have delayed bone ages, normal or slightly low IGF-1 levels, normal IGFBP-3 levels for skeletal age, and normal GH stimulation tests if pretreated with gonadal steroids. Any child that does not fit these parameters should be evaluated for an underlying pathology causing short stature. Predicted adult heights should be normal (greater than 163 cm in males and 150 cm in females) in children with pure CDGM given sufficiently delayed bone ages. Children with both CDGM and familial short stature may have both delayed pubertal growth spurt and short final height.

Table 386.3 lists criteria for presumptive diagnosis of constitutional delay of growth and maturation.

Table 386.3
Clinical criteria that may indicate constitutional delay of growth and maturation

• Delayed puberty: – Males – failure to achieve Tanner G2 by age 13.8 years or P2 by 15.6 years – Females – failure to achieve Tanner B2 by age 13.3 years
• Delayed bone age (more than 1 year delayed)
• Family history of delayed puberty and growth
• No history of systemic illness and/or medications
• Normal nutrition
• Normal physical examination without evidence of skeletal dysplasias
• Normal laboratory findings: thyroid function tests, renal function tests, complete blood cell count, erythrocyte sedimentation rate, electrolytes
• Height between −2.5 and −1.5 SDS
• Height velocity >−1 SDS
• Normal predicted adult height: – Males > 165 cm (65 in.) – Females > 152 cm (60 in.)

Familial Short Stature

Given the polygenic nature of growth, it is important to evaluate a child's growth pattern in the context of familial growth and stature. Thus, a child whose growth rate is inconsistent with that of the family should be further evaluated. Additionally, many disorders, such as mutations of the GH-receptor gene, GH gene deletions, mutations of the PROP-1 or POUF-1 genes, and numerous other endocrine and non-endocrine diseases, causing growth retardation are inherited. Therefore, identifying a short child in the context of a short family requires an evaluation for the possibility of an underlying cause of short stature within the family.

Familial short stature (FSS) represents a constellation of clinical findings that is considered a normal variant. Height is at or below the 5th percentile, but the growth velocity is normal. FSS differs from constitutional delay of growth and maturation in that onset and progression of puberty is normal, resulting in a bone age that is commensurate with the chronological age. Both parents are short, often below the 10th percentile, and with histories of having normal puberty. Final height is short in FSS, but normal for the family. Though the GH-IGF system is normal in FSS, treatment with GH during childhood may improve growth velocity and final height.

Primary Growth Disorders

In primary growth disorders, the abnormalities seem to be intrinsic to the growth plate.

Small for Gestational Age

Babies born small for gestational age (SGA) have weights and lengths more than 2 SD below the mean for their gestational age (2.3 percentile). There are three subtypes of SGA: SGA with low birth weight, SGA with low birth length, and SGA with low birth weight and length. The classification is important for prognosis and response to GH therapy. It has been estimated that 2.3–10% of all infants are born SGA. Though most infants born SGA attain appropriate catch-up growth within the first 2 years of life, about 15% do not and continue to have poor growth throughout childhood. Premature infants born SGA may take longer to catch up. In addition to poor growth and short stature, individuals born SGA are at risk for metabolic disorders. Infants born SGA who have short parents tend to have catch-up growth to the lower familial range based on their parents' heights.

Though the endocrine mechanisms contributing to catch-up growth is not clear, it has been suggested that the mechanisms reside within the growth plate and are based on a delay in normal growth plate senescence. The stature of individuals born SGA seem to be highly dependent on the growth response of infants in the first months of life as most catch-up growth occurs during this time. It has been suggested that SGA neonates are GH insensitive as they have high levels of GH, but low levels of IGF-I. However, the GH-IGF axis normalizes in early postnatal life and most children born SGA have a normal response to GH stimulation testing and have normal levels of IGF-I and IGFBP-3. Children born SGA who do not achieve catch-up growth often require higher doses of GH therapy due to GH resistance. Additionally, children born SGA who do not demonstrate catch-up growth have much higher fasting levels of plasma cortisol than those that achieve catch-up growth. Cortisol may limit IGFBP-3 proteolysis in the perinatal period, leading to decreased availability of circulating IGFs and early growth retardation.

Down's Syndrome

The most common chromosomal disorder associated with growth retardation is probably trisomy 21/Down's syndrome, which affects approximately 1 in 600 live births. Average birth weights are about 500 g below normal and average birth lengths about 2–3 cm shorter than normal. Postnatal growth retardation continues and is usually associated with delayed skeletal maturation and delayed pubertal growth spurt, leading to adult heights of 135–170 cm in males and 127–158 cm in females. There is no known reason for growth retardation in Down's syndrome. One possible explanation is a generalized biochemical abnormality of the epiphyseal growth plate. Though some children with Down's syndrome have been found to have low serum levels of GH and IGF-1 and exogenous GH has been found to increase growth velocity, such treatment should be reserved for study protocols given the risk of leukemia in individuals with Down's syndrome. Thyroid function tests should be evaluated as Hashimoto's thyroiditis is common in Down's.

Turner's Syndrome

Short stature is the most common feature in girls with Turner's syndrome (gonadal dysgenesis), occurring in 95–100% of girls with 45X karyotype. The following abnormal growth features are associated with Turner's syndrome: (1) mild intrauterine growth retardation with average birth weights of 2,800 g and average birth lengths of 48.3 cm, (2) slow growth during early infancy falling to −3 SD by 3 years of age, (3) decline in height velocity from 3 years until about 14 years of age, and (4) prolonged adolescent growth phase with a partial return toward normal height and delayed epiphyseal fusion. Genetic and ethnic factors play an important role in final adult height in girls with Turner's syndrome, with the average adult height in the United States and Europe ranging from 142 to 146.8 cm.

The etiology of growth retardation in Turner's syndrome is unclear. Girls with Turner syndrome are haploinsufficient for the SHOX gene (short stature homeobox-containing gene) located on the short arm of the X chromosome. Two thirds of the height deficit in Turner's syndrome may be due to this defect. It may also account for the skeletal dysplasias, such as Madelung's deformity, often seen in girls with Turner's syndrome. Most girls with Turner's syndrome have normal GH and IGF levels during childhood. The lower levels seen in adolescence may be secondary to low levels of gonadal steroids. Despite the normal levels of GH and IGF, GH therapy is effective in increasing short-term growth and adult height in girls with Turner's syndrome. Turner's syndrome should be considered in any girl presenting with

unexplained growth retardation, especially if she is short relative to her family, but growing between the 5th and 10th percentiles during childhood.

Noonan's Syndrome

Noonan's syndrome affects males and females and is inherited in an autosomal dominant fashion, though 50% of cases are sporadic. Individuals with Noonan's syndrome have normal sex chromosomes. Common physical characteristics include webbing of the neck, malformed ears, a low posterior hairline, cubitus valgus, ptosis, microphallus and cryptorchidism in boys, and cardiac anomalies. Patients may have delayed or incomplete puberty. Mental retardation is present in about 25–50% of patients. Birth weight is usually normal, but mean growth in length and weight throughout most of childhood is below the 3rd percentile in about 50% of Noonan syndrome patients. In contrast to Turner syndrome patients, many Noonan syndrome patients are not short. Though endogenous GH secretion may be slightly reduced, it is not the cause of short stature in Noonan's syndrome. Instead, a gain of function mutation in these individuals may decrease GH-induced IGF production.

Prader–Willi Syndrome

Prader–Willi Syndrome (PWS) occurs in 1 of 10,000–25,000 live births and is due to a functional deletion of the paternal allele within chromosome 15q11–13. Clinical findings include profound neonatal hypotonia, cryptorchidism, microphallus, and hypogonadotropic hypogonadism. Growth failure may be present at birth, but becomes more pronounced postnatally with mean adult heights more than −2 SD below the mean and midparental target height. Hyperphagia and obesity become more obvious with increasing age. Short stature is probably due to GH deficiency secondary to an unidentified hypothalamic defect. The physical characteristics typical of GHD patients, such as small hands and feet, increased fat mass, and low muscle mass and bone mineral density, are similar to those found in patients with PWS. Patients with PWS demonstrate low GH responses after GH stimulation testing and also have low GH-dependent peptides, as opposed to patients with exogenous obesity who have normal levels of GH-dependent peptides despite low GH production. PWS is therefore an IGF-deficient condition due to a deficiency in GH production. Ghrelin levels are low. PWS is now a Food and Drug Administration (FDA)-approved indication for GH treatment, which results in improved growth velocity and final height potential, increased muscle mass, and decreased fat mass. PWS patients receiving GH treatment must be monitored for insulin resistance, diabetes mellitus, and sleep apnea. PWS patients who are very obese and have tonsillar hypertrophy should be treated with extreme caution, if at all.

Russel–Silver Syndrome

The common features of Russel–Silver syndrome (RSS) include IUGR, postnatal growth failure, congenital hemihypertrophy, and small triangular facies. Other less specific findings include clinodactyly, precocious puberty, delayed closure of the fontanels, and delayed bone age. Final adult heights are typically −4 SD below the mean. GH secretion is similar to other short children born IUGR. RSS is likely due to a heterogeneous group of disorders and so far no genetic or biochemical basis has been identified.

18q Deletion

The prevalence of deletion of the long arm of chromosome 18 is approximately 1 in 40,000 live births and has been found to be associated with short stature. Children with 18q deletion have also been found to have low IGF-1 and IGFBPs levels and reduced GH responses to GH stimulation testing. Children with 18q deletion treated with GH have been shown to not only have net height increases +2 SD compared to untreated children, but also improvement in cognitive measures.

Osteochondrodysplasias

Osteochondrodysplasias include a heterogeneous group of disorders that are characterized by abnormalities intrinsic to cartilage and/or bone. At least 100 osteochondrodysplasias have been identified. Short stature is usually disproportionate.

The frequency of achondroplasia is 1:26,000, making it the most common type of osteochondrodysplasia. Its transmission is autosomal dominant, though 80–90% of cases are de novo mutations. Infants with homozygous mutations have small thoraces and typically die in infancy due to respiratory failure. Though short stature may not be obvious until after the first 2 years of life, growth

retardation begins in infancy, leading to mean adult heights of 130 cm in males and 120 cm in females. Growth curves for achondroplasia should be used to follow these patients. GH secretion is normal.

Hypochondroplasia is also an autosomal dominant disorder caused by a mutation in the FGFR3 gene. Short stature in hypochondroplasia is milder than in achondroplasia. Growth retardation may not occur until after the first 2 years of life, but progressive deviation from normal growth after this age leads to adult heights between 120 and 150 cm. Disproportionate growth may not be evident until adulthood often making the diagnosis difficult in childhood. These children can be erroneously considered to have ISS.

Other Secondary Causes of Short Stature

Malnutrition

The most common cause of growth failure worldwide is inadequate caloric and/or protein intake. Marasmus is due to inadequate caloric and protein intake and presents with minimal subcutaneous fat and marked muscle wasting. Kwashiorkor is due to inadequate protein intake. Multiple vitamin and mineral deficiencies are evident in both conditions, and the two conditions often overlap. During the neonatal period, failure to gain weight precedes failure of linear growth by a short period of time, whereas at older ages it may be several years. The GH-IGF system is affected by both acute and chronic malnutrition. Though impaired growth may be associated with low, normal, or elevated GH levels, serum IGF-1 levels are low so that malnutrition may be considered a form of GH insensitivity. GHBP and IGFBP levels are also low. GH insensitivity may be an adaptive response to spare protein from the lipolytic and anti-insulin actions of GH.

Prior to epiphyseal fusion, anorexia nervosa and bulimia can be associated with impaired growth and decreased adult height. Bone mineralization during adolescence is impaired leading to osteopenia in adulthood. Malnutrition can also cause delayed puberty/menarche. The GH-IGF profiles are similar to those seen in other cases of malnutrition mentioned above, and levels return to normal once refeeding is established.

Malabsorption

Growth failure may be the presenting sign of malabsorption and/or chronic inflammatory bowel diseases such as Crohn's disease and celiac disease, which impair absorption of calories and proteins. IGF-1 levels are often reduced due to malnutrition. Malabsorption must be documented by various measures of gut function and fecal analyses in order to differentiate between malnutrition, GHD, and other causes of IGF-1 deficiency.

In Crohn's disease, growth retardation is likely multifactorial resulting from malnutrition, chronic inflammation, trace mineral deficiencies, and treatment with glucocorticoids. The degree of growth failure correlates with disease severity and IGF-1 levels are low. Screening can be done with an elevated erythrocyte sedimentation rate, anemia, and low serum albumin; however, diagnosis is based on colonic biopsy and imaging studies. GH therapy should be considered given poor growth and reduced final height occurs in 30% of patients and about 20% of patients have adult heights more than 8 cm below midparental target heights.

Celiac disease is an autoimmune disorder that often presents with impaired linear growth due to damage of intestinal mucosa by dietary gluten. Celiac disease is associated with Turner's syndrome, Down's syndrome, type 1 diabetes mellitus, and William's syndrome. Patients with celiac disease may have delayed onset and progression of puberty and delayed menarche. Screening for celiac disease is done by measurement of IgA tissue transglutaminase antibody though false negative results can occur in patients with IgA deficiency. Diagnostic testing is confirmed by small intestinal biopsy to demonstrate characteristic mucosal flattening. Changes in clinical status are reflected in changes in serologic profiles. The mainstay of treatment is gluten withdrawal, which typically results in rapid catch-up growth, decreased clinical symptoms during the first 6–12 months of treatment, normalization of IGF-1 and IGFBP-3 levels, and normal final adult height.

Diabetes Mellitus

Most children with insulin-dependent diabetes mellitus (IDDM) grow normally during prepuberty, though growth velocity may decrease during puberty. However, those with longstanding poor glycemic control can experience growth failure. One rare, but extreme condition is the Mauriac syndrome which is characterized by poor glycemic control, severe growth failure, and hepatosplenomegaly due to increased glycogen deposition. Mechanisms for growth impairment in IDDM include chronic intermittent acidosis, hypothyroidism, malnutrition, increased glucocorticoid production, and decreased

sensitivity to GH or IGF. In addition to acquired GH insensitivity, GHBP levels are decreased, supporting the concept of impaired GH-receptor number or function and IGFBP-1 levels are increased due to hypoinsulinism, which may inhibit IGF action.

Renal Disease

Growth can be impaired in any form of renal impairment. Some of the causes of poor growth include decreased caloric intake, osteopenia due to inadequate formation of 1,25-dihydroxycholecalciferol, metabolic acidosis, loss of electrolytes needed for normal growth, protein wasting, chronic anemia, and impaired GH and IGF production and action. Levels of GH vary from normal to elevated depending on the degree of renal failure. The half-life of GH is prolonged up to twofold in children with end-stage renal disease on dialysis and preterminal chronic renal failure. Serum IGF-1 and IGF-2 levels are usually normal, but increases in IGFBPs may interfere with their actions. However, serum IGF-1 and IGFBP-3 levels are low in nephrotic syndrome due to urinary loss of IGF-IGFBP complexes. Treatment with chronic glucocorticoid therapy also interferes with growth by decreasing GH release and interfering with IGF-1 action at growth plates. Chronic renal disease with elevated GH and low IGF-1 levels is considered a state of relative resistance to GH and also IGF-1 in some cases. Growth does not necessarily normalize after successful renal transplant. Final adult height after transplantation is associated with height at the time of transplantation, cumulative doses of steroids, and duration of reduced GFR. Therefore it is important to improve growth velocity and absolute height prior to transplantation. GH treatment is FDA approved in chronic renal diseases and may act by increasing the molar ratio of IGF peptides to IGFBPs and thus overcome the inhibitory actions of IGFBPs.

Liver Disease

Short stature in children with chronic liver disease is due to a combination of malnutrition, malabsorption, and an abnormal GH-IGF system consistent with an acquired GH insensitivity syndrome that persists even with adequate caloric intake. There is a close correlation between GH-dependent peptides and liver function. Improvement in growth is variable after liver transplantation, and is often limited due to treatment with glucocorticoids. Additionally, growth is directly correlated with the degree of growth impairment prior to transplantation. Treatment with exogenous GH has been shown to improve growth in some patients.

Hematologic Disorders

Growth failure can be seen in chronic anemias. Often growth failure is more evident during the adolescent years as puberty and menarche and the subsequent adolescent growth spurt can be delayed. Final adult height may be normal. The mechanism for growth failure in chronic anemias is probably based less on the GH-IGF system and more on impaired oxygen delivery to tissues, increased hematopoiesis, increased cardiovascular workload, and impaired nutrition. However, in disorders requiring chronic transfusions, such as thalassemia, growth failure may also be due to impaired IGF-1 synthesis, hypothyroidism, gonadal failure, and hypogonadotropic hypogonadism, especially in male patients.

Cardiovascular Disease

Growth failure can occur in children with congenital heart disease with cyanosis or chronic congestive heart failure. The most common cause of growth failure in these children is inadequate caloric intake. Additionally chronic congestive heart failure is associated with malabsorption and a greater basal metabolic rate due to increased cardiac and respiratory work.

Pulmonary Disease

Growth impairment can occur in children with asthma depending on the severity of pulmonary disease. Poor linear growth is not necessarily associated with abnormalities of the GH-IGF system, but rather is associated with impaired nutrition, increased energy requirements, chronic stress, and increased endogenous glucocorticoid production. Growth is further impaired in those patients receiving glucocorticoid therapy, especially in the form of prednisone or dexamethasone. The use of alternate-day or inhaled glucocorticoids may decrease the adverse effect on growth.

Early growth failure is also seen in patients with bronchopulmonary dysplasia, and is due to treatment with dexamethasone, chronic pulmonary infections, poor nutrition, long-term hypoxemia, and reactive airway disease. In patients with cystic fibrosis, growth failure is

due to chronic pulmonary infections and exocrine and endocrine pancreatic insufficiency. The degree of growth failure is more closely related to the severity of pulmonary disease than to pancreatic dysfunction. There may also be evidence of acquired GH insensitivity.

Chronic Inflammation/Infection

Growth failure is a common feature of chronic inflammatory diseases. One possible mechanism may be an IL-6-mediated decrease in IGF-1 production. Growth failure is also a feature of childhood acquired immunodeficiency syndrome (AIDS). In developing countries, growth impairment is seen with chronic infections with parasites such as schistosomiasis, hookworm, and roundworm.

Treatment and Prognosis

Growth Hormone Deficiency

Subcutaneous recombinant growth hormone (GH) is used to treat children with growth hormone deficiency. The recommended starting dose is 0.18–0.35 mg/kg/week divided into seven daily doses. The mean American dose is 0.3 mg/kg/week. Response to exogenous GH varies depending on frequency of administration, dosage, age, and weight. Typically a child with GHD goes from a pretreatment growth rate of 3–4 cm/year to 10–12 cm/year in year 1 of therapy and to 7–9 cm/year in years 2 and 3. GH efficacy wanes over time. The current cost of GH therapy in the United States for a 20-kg child at a dose of 0.3 mg/kg/week is from $12,000 to $15,000 per year.

Long-term studies have shown that factors that correlate with enhanced adult height were baseline height, younger age at onset of treatment, longer treatment duration especially during prepubertal years, and a greater growth velocity during the first year of treatment.

Endogenous GH normally increases two- to fourfold during the pubertal growth spurt along with a dramatic increase in IGF-1. Increased pubertal GH doses result in increased near-final height without a more rapid acceleration of skeletal maturation. Combination therapy with a GnRH agonist or aromatase inhibitor to delay puberty may be used when normal or precocious puberty limits the response to GH.

According to a recent consensus guideline, patients with definite GHD due to organic causes can be transitioned to adult protocols directly. However, in idiopathic GHD, GH therapy should be discontinued, and patients should be retested according to adult protocols to determine the need for continued therapy using adult GHD dosing.

IGF-1 Deficiency

Various studies evaluating the use of exogenous IGF-1 therapy in the treatment of growth hormone insensitivity have shown promising results in increasing growth velocities though not as successful as GH. However, the total number of children treated in such studies is still only several hundred, and few have been treated long term. Therefore, little is known about long-term side effects of IGF-1 and ideal dosing and frequency of administration. Studies suggest that the waning effect of IGF-1 may be more than that of GH. Additionally, IGFPB-3 levels do not increase with the administration of IGF-1. Phase II studies are now under way combing IGF-1 and GH in the treatment of ISS. Early results suggest a possible synergism between the two drugs. Side effects in studies include hypoglycemia, headache, convulsions, urolithiasis, and papilledema.

Idiopathic Short Stature

There are several parameters to consider while initiating growth hormone treatment of ISS. Height criteria vary based on geographical and clinical parameters. In the United States and seven other countries, regulatory authorities have approved GH treatment for children shorter than −2.25 SDS (1.2 percentile). Children whose heights are below −2.0 SDS and who are more than 2.0 SD below their MPTH and/or have a predicted height below −2.0 SDS should also be considered for treatment. Age should also be considered with the optimal age for initiating treatment between 5 years to early puberty. Currently there are no biochemical criteria for initiating GH treatment in ISS. Psychological factors such as whether a child himself or herself is concerned about being short should also be considered.

There are several alternatives to GH treatment for ISS. In males with CDGP and mild to moderate short stature, anabolic steroids such as oxandrolone and low dose testosterone may cause short-term acceleration of linear growth without much impact on final adult height. In ISS children who do not respond to GH treatment, IGF-1 treatment is an option, though data regarding efficacy and safety in this population is lacking. The use of GnRH analogues as monotherapy is generally not

recommended. However, combination therapy of GnRH analogues and GH may have potential benefits if height prediction is below −2 SDS at the time of pubertal onset in either sex and if the GnRH analogue is used for at least 3 years. Aromatase inhibitors have been found to increase predicted adult height in males with ISS, but adult height data are not available. The long-term efficacy and safety of aromatase inhibitors has not been well established. Aromatase inhibitors are not treatment options for females with ISS. Psychological counseling should be considered either instead of or as an adjunct to hormone treatment.

In children with ISS who are treated with GH for an average of 4–7 years, the mean increase in adult height is 3.5–7.5 cm compared to initial predicted adult height, though responses are highly variable and dose dependent. Various factors are thought to affect growth response though many are unknown. The first year response is negatively affected by age at start of treatment. It is positively affected by GH dose, weight at start of treatment, and difference from target height. Adult height outcome is negatively affected by age at start of treatment, and positively affected by midparental target height, height at start of treatment, bone age delay, and the first year response to GH. Two-year studies suggest that short-term height gain correlates with rise in IGF-1 levels.

The upper GH dose limit used in ISS is approximately 0.49 mg/kg/day, though the long-term safety of doses greater than 0.35 mg/kg/day in children with ISS is not certain. The duration of GH treatment in ISS can be based on two outcomes. One is to stop treatment when near adult height is achieved (height velocity <2 cm/year and/or bone age >16 years in boys and >14 years in girls). The other is to stop treatment when height is in the "normal" adult range (above −2 SD).

Constitutional Delay

Most children with constitutional delay of growth and maturation can be closely observed once evaluation to rule out other causes of delayed growth and puberty is performed. The bone age can be used to explain the potential for normal growth to patients and parents. However, for patients who are psychologically disabled by the social stigmata of short stature and delayed puberty, use of short-term gonadal steroids can be considered. Androgen treatment targets two aspects of constitutional delay. The first is short stature, especially in boys ages 10–14; the second is delayed puberty after age 14. Oral oxandrolone (0.1 mg/kg/day) has been used extensively to treat the younger age group with studies showing increased linear growth velocity without negatively impacting predicted or actual final height. Intramuscular testosterone enanthate (50–200 mg every 3–4 weeks for four to six injections) has been used successfully in older boys for delayed puberty. Criteria for treatment include minimal age of 14 years, height below the 3rd percentile, prepubertal or early Tanner stage G2 with an early morning serum testosterone less than 3.5 nmol/L (<1 ng/mL), and a poor self-image despite reassurance alone. Early secondary sex characteristics are usually visible by the fourth injection with an average of 10 cm growth in the ensuing year. Testosterone enhances growth velocity through a direct effect as well as by increasing GH. Short courses of testosterone do not cause rapid skeletal maturation, compromise adult height, or suppress pubertal maturation. It is important to emphasize to the patient that he is normal and that therapy allows puberty to progress earlier than it would on its own and that final adult height will not necessarily increase. Other forms of testosterone such as the gel and patch, which are approved for treating adult hypogonadism, can also be used though dosing has not been well established in children. The use of aromatase inhibitors in combination with testosterone therapy can also be considered.

Short-term estrogen therapy for girls with constitutional delay can be used; however, the doses required for enhanced growth velocity and sexual maturation poses a higher risk of bone age advancement.

Current Food and Drug Administration Indications for GH Treatment

The United States FDA has approved GH for use in the following pediatric conditions: growth hormone deficiency, Turner syndrome, chronic renal insufficiency, small for gestational age or intrauterine growth retardation, Prader–Willi syndrome, idiopathic short stature, SHOX gene haploinsufficiency, and Noonan syndrome.

Monitoring GH Treatment

Children receiving GH should be monitored every 3–6 months for height, weight, pubertal development, and adverse effects. A successful first year response to therapy includes an improvement in height SD score of at least 0.3–0.5, an increase in height velocity great than 3 cm/year, or a height velocity SD score of great than 1. Annual bone age assessments can be obtained to reassess height prediction and to consider potential intervention to modify

pubertal progression. Biochemical assessment of efficacy, safety, and compliance can be made with serial IGF-1 measurements during GH therapy, though the significance of abnormally elevated levels remains unknown. IGF-1 levels can help guide GH dose adjustments. Thyroid function tests should be monitored annually.

The maximal recommended doses for GHD are 0.25–0.35 mg/kg/week before puberty and 0.7 mg/kg/week during puberty. Doses may be higher in indications such as Turner's syndrome, SGA, and ISS. If after 2 years of treatment, the growth rate is inadequate despite maximal recommended dosing, GH therapy should be discontinued and alternative treatments considered.

GH Side Effects

Though the safety profile of GH has been encouraging over the past 20 years, there are numerous potential complications that require continued assessment. GH manufacturers have played a large part in this assessment through extensive databases. The most common side effects include edema, joint pain, and bruising at the injection site. Rare complications include recurrence of central nervous system tumors, pseudotumor cerebri, slipped capital femoral epiphysis, and type 2 diabetes mellitus. Other potential side effects include prepubertal gynecomastia, pancreatitis, growth of nevi, behavioral changes, scoliosis and kyphosis, worsening of neurofibromatosis, tonsillar and adenoidal hypertrophy, and sleep apnea. The management of such side effects may include a dose decrease or temporary interruption of treatment.

Studies suggest that GH therapy is not associated with future development of neoplasms in the absence of other risk factors; however, long-terms studies are still needed. The Drug and Therapeutics Committees of Lawson Wilkins Pediatric Endocrine Society and European Society of Pediatric Endocrinology have recommended the monitoring of IGF-1 and IGFBP-3 and dose adjustments accordingly in order to avoid IGF-1 levels at the upper end of normal.

387 Diabetes Mellitus

Joseph I. Wolfsdorf · Mark A. Sperling

Introduction

Diabetes mellitus is a syndrome characterized by disturbed metabolism of carbohydrate, fat, and protein with persistent fasting or postprandial hyperglycemia resulting from defects in insulin secretion or insulin action. Diabetes mellitus occurs when the glucose disposition index, the product of insulin secretion and insulin sensitivity (*Fig. 387.1*), is inadequate to prevent hyperglycemia and its clinical consequences of polyuria, polydipsia, and weight loss.

Diabetes mellitus may be the result of absolute insulin deficiency or absolute insulin resistance or, more commonly, a combination of milder defects in insulin secretion and action. The chronic metabolic derangements affect small and large blood vessels causing long-term complications that result in retinopathy, nephropathy, neuropathy, ischemic heart disease, and cerebral and peripheral vascular disease.

Definition and Diagnosis of Diabetes in Children

Diabetes mellitus is diagnosed in one of four ways: (1) classic symptoms plus a plasma glucose (PG) $\geq$ 11.1 mmol/L (200 mg/dL), (2) fasting (for at least 8 h) PG $\geq$ 7.0 mmol/L (126 mg/dL), (3) 2 h post load PG $\geq$ 11.1 mmol/L (200 mg/dL) during an oral glucose tolerance test (OGTT), or hemoglobin A1c $\geq$ 6.5%. *Table 387.1* shows the biochemical criteria for diabetes mellitus and lesser degrees of impaired glucose tolerance. In the absence of acute metabolic decompensation with unequivocal hyperglycemia, these criteria should be confirmed by repeat testing on a different day. The OGTT is not recommended for routine clinical use. When indicated, it should be performed after at least 3 days of adequate carbohydrate consumption ($\geq$150 g/1.73 m^2) using 1.75 g/kg anhydrous glucose dissolved in water for individuals $\leq$43 kg and 75 g for weight >43 kg.

When the renal threshold of ~180 mg/dL is exceeded, osmotic diuresis from glucose lost in urine causes polyuria, dehydration leads to polydipsia, loss of calories causes weight loss and sometimes polyphagia; blurred vision results from lens swelling caused by the osmotic effects of hyperglycemia. Chronic hyperglycemia in infants and toddlers of both genders and in girls commonly leads to perineal candidiasis. The diagnosis of type 1 diabetes mellitus (T1D) is usually obvious because most children present with classic symptoms for several days to a few weeks accompanied by marked hyperglycemia or with diabetic ketoacidosis (DKA) (see below).

The quoted definitions are based on venous PG levels. Portable glucose meters are useful for screening purposes in clinics and physicians' offices, but the diagnosis of diabetes mellitus must be confirmed by measurement of venous PG on an analytic instrument in a clinical chemistry laboratory. Blood samples should be processed and promptly delivered to the laboratory to prevent glucose utilization by erythrocytes, which would spuriously lower PG concentration (*Table 387.1*).

Classification

Diabetes mellitus is a heterogeneous group of disorders that lead to abnormal glucose tolerance. *Table 387.2* shows an etiologic classification of diabetes mellitus in children modified from the "Report of the Expert Committee on the Diagnosis and Classification of Diabetes Mellitus" published by the American Diabetes Association. Among the insulin-dependent forms, severe insulinopenia resulting from autoimmune destruction of ß-cells, referred to as type 1a diabetes, accounts for most cases of childhood diabetes mellitus. Genetic defects in insulin secretion cause the monogenic forms of diabetes (formerly referred to as maturity onset diabetes of youth [MODY]) and neonatal diabetes mellitus, and contribute to the spectrum of type 2 diabetes (T2D) (*Table 387.2*).

Severe insulin-dependent diabetes, clinically indistinguishable from the autoimmune form, may have no evidence of autoimmunity and can result from mitochondrial or other gene defects that interfere with the generation of intraislet energy required for insulin

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_387,

secretion or, rarely, from pancreatic agenesis. The more severe monogenic forms of diabetes may also require insulin. Clinically similar forms of diabetes may occur secondary to cystic fibrosis, from exposure to drugs such as cyclosporine and tacrolimus, with the hemolytic uremic syndrome, or after pancreatectomy for congenital hyperinsulinism.

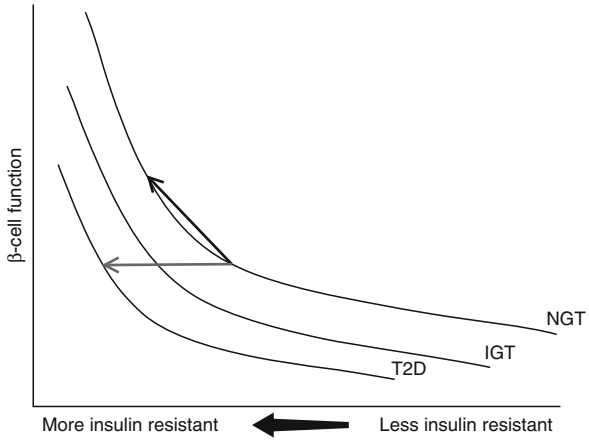

Figure 387.1

The hyperbolic relationship of insulin resistance and ß-cell function. In a subject with normal ß-cell reserve, an increase in insulin resistance results in increased insulin release and normal glucose tolerance (*black arrow*). In an individual in whom the capacity to increase insulin release is compromised, increased insulin resistance with no ß-cell compensation results in progression from normal glucose tolerance to impaired glucose tolerance to diabetes (*gray arrow*). The product of insulin sensitivity (the reciprocal of insulin resistance) and acute insulin response (a measurement ß-cell function) has been called "disposition index." This index remains constant in an individual with normal ß-cell compensation in response to changes in insulin resistance. IGT, impaired glucose tolerance; NGT, normal glucose tolerance; T2D, type 2 diabetes

Type 1 Diabetes Mellitus

Etiology, Genetics, and Family Risk of Type 1a Diabetes

Type 1a diabetes mellitus (T1aD) occurs in genetically susceptible individuals as a consequence of chronic T-cell-mediated destruction of insulin-secreting ß-cells of the islets of Langerhans. Markers of immune-mediated destruction of ß-cells include circulating autoantibodies to cytoplasmic and cell surface components of islet cells, including antibodies to insulin (IAA), glutamic acid decarboxylase (GAD_{65}), the tyrosine phosphatases IA-2 and IA-2ß, and the zinc transporter ZnT8 (Slc 30A8). At least one autoantibody is present in 85–98% of newly diagnosed children. Insulitis characterized by lymphocytic infiltration of the islets of Langerhans was observed in children who died soon after the onset of type 1 diabetes (T1D). There is strong linkage to the major histocompatibility complex (MHC) locus. Variation in the MHC locus accounts for about half of the genetic risk for T1aD. Increased susceptibility to T1aD is conferred by certain MHC alleles such as HLA-DR4-DQ8, and HLA-DR3-DQ2, whereas decreased susceptibility is conferred by several MHC alleles including HLA-DR2-DQ6. Numerous non-MHC genetic loci weakly contribute to the risk of T1aDM.

Approximately 90% of new cases of T1aDM occur in persons *without* an affected first-degree relative. It is estimated that a sibling sharing both HLA D haplotypes with an index case has a risk for T1D of 12–20%; for a sibling sharing only one haplotype, the risk is 5–7%; and with no haplotypes in common, the risk is 1–2%. HLA typing is not recommended for routine practice. For purposes of genetic counseling, in whites the overall risk of occurrence in siblings is approximately 6% if the proband was younger than 10 years of age and 3% if older at the time of diagnosis. The risk to the child of a parent with T1aD is 1.3–4% or 6–9%, respectively, depending on whether the mother or the father has diabetes. The cumulative incidence of T1aD is 65% in monozygotic twins who were

Table 387.1

Biochemical criteria for diabetes mellitus and lesser degrees of impaired glucose regulation

Test	Normal	Impaired fasting glucose (IFG)	Impaired glucose tolerance (IGT)	Diabetes mellitus
FPG mmol/L (mg/dL)	<5.6 (<100)	5.6–6.9 (100–125)		≥7.0 (126)
2 h PG mmol/L (mg/dL)	<7.8 (<140)		7.8–11.0 (140–199)	≥11.1 (200)
Casual PG mmol/L (mg/dL)	<11.1 (200)			≥11.1 (200)
Hemoglobin A1c %	4–6			≥6.5

Table 387.2
Etiologic classification of diabetes mellitus

1. *Type 1 Diabetes (ß-cell destruction usually leading to absolute insulin deficiency)*
A. Immune mediated
B. Idiopathic
II. *Type 2 Diabetes (variable combinations of insulin resistance and insulin deficiency)*
A. Typical
B. Atypical
III. *Genetic defects of ß-cell function*
A. MODY syndromes
1. MODY 1 chromosome 20, HNF-4α
2. MODY 2 chromosome 7, glucokinase
3. MODY 3 chromosome 12, HNF-1α, TCF-1
4. MODY 4 chromosome 13, IPF-1
5. MODY 5 chromosome 17, HNF-1ß, TCF-2
6. MODY 6 chromosome 2q32, neuroD1
7. MODY X-several candidate genes identified in the 5%–10% of patients with clinical characteristics of MODY who do not have the gene defects of 1–6
B. Mitochondrial DNA mutations (includes one form of Wolfram syndrome; Pearson syndrome; Kearns-Sayre, diabetes mellitus, deafness)
C. Wolfram syndrome – DIDMOAD (diabetes insipidus, diabetes mellitus, optic atrophy, deafness); WFS-Wolframin – chromosome 4p
1. Wolfram locus 2–chromosome 4q22–24
2. Wolfram mitochondrial
D. Thiamine responsive
IV. *Drug or chemical induced*
A. Anti-rejection–cyclosporine
B. Glucocorticoids (with impaired insulin secretion; e.g., cystic fibrosis)
C. L-Asparaginase
D. ß-Adrenergic blockers
E. Vacor (rodenticide)
F. Phenytoin (dilantin)
G. α-Interferon
I. Diazoxide
H. Nicotinic acid
V. *Diseases of exocrine pancreas*
A. Cystic fibrosis
B. Trauma – pancreatectomy
C. Pancreatic – ionizing radiation

Table 387.2 (Continued)

VI. *Infections*
A. Congenital rubella
B. Cytomegalovirus
C. Hemolytic-uremic syndrome
VII. *Variants of type 2 diabetes*
A. Genetic defects of insulin action
1. Rabson–Mendenhall syndrome
2. Leprechaunism
3. Lipoatrophic diabetes syndromes
4. Type A insulin resistance – acanthosis
B. Acquired defects of insulin action
1. Endocrine tumors – rare in childhood
A. Pheochromocytoma
B. Cushing syndrome
2. Anti-insulin receptor antibodies
VIII. *Genetic syndromes with diabetes and insulin resistance/ insulin deficiency*
A. Prader–Willi syndrome, chromosome 15
B. Down syndrome, chromosome 21
C. Turner syndrome
D. Klinefelter syndrome
E. Other syndromes
1. Bardet-Biedel
2. Alstrom
3. Werner
IX. *Gestational diabetes*
X. *Neonatal diabetes*
A. Transient – chromosome 6q24, KCNJ11, ABCC8
B. Permanent – agenesis of pancreas, homozygous glucokinase deficiency, KCNJ11, ABCC8

initially discordant for diabetes, whereas the incidence in dizygotic twins is similar to that of siblings. Over 40 genes have now been identified as contributing to T1DM, the majority of which relate to immune regulation.

Factors other than inheritance must be involved in the pathogenesis of T1aD, because not all monozygotic twins become concordant, DR3 or DR4 occurs in approximately 50% of the general population and other DQ markers occur in approximately 20% of white non-diabetics in the United States, yet the risk for T1aD in these individuals is one-tenth that of the HLA-identical sibling of an index case with T1aD. Also, approximately 10% of patients with T1aD have neither HLA-DR3 nor -DR4. These data suggest that environmental triggers or

post-zygotic processes such as the selection of certain autoreactive T-cell clones that bear receptors recognizing "self" must be involved.

The environmental factors that contribute to the pathogenesis of the disease are unknown and, as yet, there are no proven environmental interventions that reduce the risk of T1aD. Overweight in a child at risk may hasten the onset of clinical presentation. Possible environmental trigger factors currently under investigation include viral infections, dietary factors, hygiene, and toxins.

Chronic progressive destruction of the ß-cells of the pancreas eventually leads to severe insulinopenia and dependence on exogenous insulin to prevent ketosis and preserve life. Basal plasma insulin concentrations may be normal in newly diagnosed patients; however, insulin production in response to a variety of secretagogues is blunted and progressively decreases over months to years usually disappearing completely by 5 years from the date of diagnosis. The rate of ß-cell destruction is variable, being rapid in some individuals, especially in infants and young children, and slower in adolescents and adults, some of whom may retain the ability to secrete insulin for years.

Type 1 diabetes with no known etiology, referred to as type 1b diabetes, accounts for a minority of cases in which there is neither an HLA-association nor evidence of ß-cell autoimmunity.

Epidemiology

Diabetes mellitus is one of the most common chronic diseases of childhood. The incidence of T1D varies enormously among geographic regions, with age-standardized rates as high as 64.2/100,000 per year in Finland in 2005 and as low as 0.1/100,000 per year in areas of China and Venezuela. The incidence in children $\leq$14 years of age is similar in the United Kingdom and the United States, 15–26 and 15–18 per 100,000 per year, respectively. Secular increases in the incidence of pediatric T1D during the mid-late twentieth century have been documented in North America and Western Europe at rates higher than can be explained by genetic shifts. The incidence of childhood diabetes is rising worldwide at a rate of approximately 2.8% per year, with increases documented in six continents. There has also been an alarming trend toward a younger age of onset and diabetes is no longer uncommon in toddlers and preschool aged children in whom the onset is frequently more abrupt than in older children.

T1aD predominantly affects Europoid Caucasians, is less frequent in African Americans, and is much less common in Asians and Native North Americans. Males and females are almost equally affected. There is no apparent correlation with socioeconomic status. Peaks of presentation occur in two age groups: at 5–7 years, corresponding to a time of increased exposure to infectious agents with the beginning of school, and during puberty, which is characterized by physiologic insulin resistance.

Seasonal variations, most apparent in the adolescent years, and long-term cyclical variations have been observed in the incidence of T1D. New cases are more common in the autumn and winter. There is no consistent pattern linking long-term cyclicity with the incidence of viral or other infections.

Type 2 Diabetes Mellitus

T2D is a heterogeneous disorder characterized by deficiency of insulin as well as resistance to its actions in various tissues. It has long been known that obese individuals with diabetes secrete less insulin than equally obese individuals or those with comparable degrees of insulin resistance but without diabetes. Thus, the degree of insulin deficiency is relative. In absolute terms, the amounts of insulin secreted in response to any stimulus in patients with T2D may be greater than that of lean healthy individuals without diabetes. Implicit is the concept that there must be genetic defects in insulin secretion and this would be consistent with the strong familial aggregation of T2D and its greater prevalence among certain populations such as the Native American Indian, African American, Hispanic, Pacific Islanders, and Southeast Asian populations. Recent studies have identified more than 20 genes responsible for deficient insulin secretion among patients with T2D. Generally, these defects are sufficiently mild to permit glucose tolerance to be normal when the patient is young, lean, and insulin sensitive (Fig. 387.1). However, when the patient develops resistance to insulin, as occurs during puberty (because of increased GH secretion) or with obesity, or in both as with the obese adolescent, and has limited ability to compensate for insulin resistance by increasing insulin secretion, then diabetes develops (Fig. 387.1). Although numerous genes that contribute to obesity have now been uncovered, the modern epidemic of obesity is a reflection of our changing lifestyle and not our gene pool, which could not possibly have changed in the past 50 years. The "epidemic of obesity" has unmasked the prevalence of defects in insulin secretion and brought with it an "epidemic" of T2D. The prevalence of T2D is increasing and in some geographic areas accounts for up to 30–50% of all new childhood cases of diabetes. The "metabolic syndrome" characterized by dyslipidemia, hypertension, acanthosis nigricans,

features of polycystic ovary syndrome, and increased levels of inflammatory markers such as soluble C-reactive protein also is strongly linked with obesity and insulin resistance.

Atypical Diabetes Mellitus

Atypical forms of diabetes mellitus referred to as Flatbush diabetes, idiopathic type 1 diabetes, ketosis-prone diabetes, and type 1.5 diabetes have been described in various populations. There is no consensus definition, but the hallmark characteristic is a propensity to hyperglycemia with ketosis or ketoacidosis without key features of T1aD such as evidence of autoimmunity or sustained insulin dependence. These forms of diabetes have been described primarily in individuals of African or Asian ancestry and there is often a strong family history; however, the genetic defects remain to be determined in the majority of cases. Treatment of atypical diabetes is based on the clinical characteristics particular to each case. Characteristics that are helpful in distinguishing among the more common forms of diabetes in children and adolescents are shown in ❯ *Table 387.3*.

Genetic Defects of Insulin Secretion

Maturity Onset Diabetes of the Young (MODY)

MODY was originally described as a form of non-insulin-dependent or "maturity-onset"-type diabetes with onset before age 25 and inherited in an autosomal dominant pattern. MODY, which may account for 1–5% of all cases of diabetes in industrialized countries, is now known to be a heterogeneous group of disorders caused by a variety of monogenic mutations (❯ *Table 387.2*). Mild to moderate hyperglycemia resulting from varying degrees of insulin deficiency, with minimal or no defect in insulin action, typically begins during puberty or as a young adult. Other features common to each MODY type include a family history of diabetes in successive generations, absent pancreatic autoantibodies, no propensity to ketosis, and no predisposition to obesity beyond that of the general population (❯ *Table 387.3*). Confirmation of the diagnosis and identification of the specific type of MODY requires molecular genetic testing.

Table 387.3
Characteristics of prevalent forms of primary diabetes mellitus in children and adolescents

	Type 1a	Type 2	MODY	Atypical DM[a]
Prevalence	Common	Increasing	≤5% in Caucasians	≥10% in African American
Age at onset	Throughout childhood	Pubertal	Pubertal	Pubertal
Onset	Acute severe	Insidious to severe	Gradual	Acute severe
Ketosis at onset	Common	~1/3	Rare	Common
Affected relative	5–10%	60–90%	90%	>75%
Female:male	1:1	1:1–1.7:1	1:1	Variable
Inheritance	Polygenic	Polygenic	Autosomal dominant	Autosomal dominant
HLA-DR3/4	Association	No association	No association	No association
Ethnicity	All, Caucasian highest risk	All	Caucasian	African-American/Asian
Insulin secretion	Decreased/absent	Variable	Decreased	Variably decreased
Insulin sensitivity	Normal when controlled	Decreased	Normal	Normal
Insulin dependence	Permanent	Variable	Variable	Episodic
Obesity	No[b]	>90%	Uncommon	Varies with population
Acanthosis nigricans	No	Common	No[b]	No[b]
Pancreatic Autoabs	Yes[c]	No	No	No

[a]Atypical diabetes mellitus (ADM), also referred to as Flatbush diabetes, type 1.5 diabetes, ketosis-prone diabetes, and idiopathic type 1 diabetes mellitus In North America, type 2 diabetes predominates in African-American, Mexican-American, Native American, Canadian First Nation children and adolescents and is also more common in Asian and South Asian than in Caucasians
[b]Mirrors rate in general population
[c]Autoantibodies to insulin (IAA), islet cell cytoplasm (ICA), glutamic acid decarboxylase (GAD), or tyrosine phosphatase (insulinoma associated) antibody (IA-2 and IA-2ß) at diagnosis in 85–98%

The specific MODY variant predicts the therapeutic response; certain MODY variants respond to sulfonylureas. Exercise and medical nutrition therapy (MNT) to maintain normal weight and insulin sensitivity should be emphasized. Pharmacologic treatment, when necessary, is tailored to the patient's specific MODY type and level of hyperglycemia. Regardless of mode of therapy, patients require careful monitoring to insure good glycemic control.

Mitochondrial Diabetes

Diabetes may be the presenting manifestation of syndromes caused by mutations in mitochondrial DNA. *Maternally inherited diabetes and deafness syndrome* (MIDD, MIM#520000) may present in childhood or adulthood. The most common mutation occurs at position 3243 in the tRNA leucine gene, leading to an A-to-G transition. This and other mutations in related tRNA mitochondrial genes can be associated with multiple other features including myopathy, encephalopathy, lactic acidosis, and myoclonic epilepsy. *Kearns–Sayre syndrome* (MIM #530000) is also caused by various mitochondrial gene mutations. It is characterized by ophthalmoplegia, retinal pigment degeneration, cardiomyopathy, and may include several hormone deficiencies including diabetes in approximately 13% of cases. Initially, diabetes can be treated with diet and sulfonylureas but may require insulin. Patients with impaired mitochondrial function are inherently prone to develop lactic acidosis; therefore, metformin should not be used.

Neonatal Diabetes Mellitus

A monogenic defect can be determined in the majority of cases of diabetes with onset within the first 6 months of life and, occasionally, when the onset is between 6 and 12 months of life. Many of the monogenic etiologies are associated with various congenital defects, conditions, or syndromes. Approximately half the cases are transient, resolving within months; however, in a substantial proportion mild non-insulin-dependent diabetes recurs in adolescence or early adulthood. Imprinting defects in chromosome region 6q24 are the most common cause of transient neonatal diabetes. Activating mutations in the Kir6.2 inwardly rectifying ATP-sensitive potassium channel (KCNJ11) or the sulfonylurea receptor (ABCC8) genes as well as autosomal dominant or recessive mutations in the insulin gene itself account for a majority of the remaining cases; they are associated with later onset and less microsomia than 6q24 defects and often can be successfully treated with sulfonylureas. Sulfonylurea treatment may also improve some of the peripheral nerve abnormalities that can accompany neonatal diabetes mellitus caused by KCNJ11 mutations, but sulfonylureas cannot be used in the insulin gene mutations causing neonatal DM.

Insulin is initially used to control hyperglycemia in neonatal diabetes and catch-up growth is usually rapid. A trial of therapy with a high dose (0.5–1.0 mg/kg/day) of glibenclamide (glyburide) should be attempted in patients with mutations of KCNJ11 or ABCC8.

Secondary Causes of Diabetes

Cystic Fibrosis–Related Diabetes (CFRD)

The life expectancy of patients with cystic fibrosis has increased dramatically over the past few decades and CRFD has become more common (*Table 387.2*). Insulinopenia is caused by pancreatic destruction and amyloid deposition in the islets; first-phase insulin release is particularly affected. Insulin resistance is prominent during exacerbations of pulmonary disease and whenever glucocorticoids are used, causing deterioration in glucose tolerance. DKA is rare. CFRD can present in the first decade, but usually is seen in the second and third decades. The development of CFRD is associated with progressive clinical deterioration and increased mortality. Screening for glucose intolerance should begin at the age of 14 years and hyperglycemia should be treated aggressively. Insulin is the only recommended treatment for CFRD. It prevents protein catabolism, promotes weight gain, and improves pulmonary function. The ideal treatment is a flexible basal-bolus regimen using a long-acting insulin and rapid-acting insulin with meals (see "Insulin Therapy" below). Diet should not be restricted in CFRD. Patients should be taught how to count carbohydrates and to use rapid-acting insulin with meals. Destruction of the pancreatic alpha cells results in glucagon deficiency and chronic use of glucocorticoids can cause adrenocortical insufficiency. Patients with CFRD are at increased risk for severe hypoglycemia owing to malabsorption and impaired counterregulatory responses.

Presentation of Type 1 Diabetes Mellitus

Most children with newly diagnosed T1D present with classic symptoms (polyuria, polydipsia, weight loss) for a few days to several weeks. Other presentations include

recent onset of enuresis in a previously toilet-trained child, failure to gain weight appropriately in a growing child, vulvovaginal candidiasis, candidal balanitis in uncircumcised boys, recurrent pyogenic skin infections, irritability, and deteriorating school performance. Some children have an insidious onset characterized by lethargy, weakness, and weight loss. Diabetes should be suspected in a child with unexplained weight loss and confirmed or ruled out by measurement of the postprandial PG concentration and/or hemoglobin A1c concentration. In the child with polyuria, the urine should be tested for glucose.

The frequency of DKA at diabetes onset varies widely by geographic location, ranging from 15% to 67% in Europe and North America and is even more common in developing countries. There is an inverse correlation between the frequency of DKA and the background incidence of T1D in different populations. DKA at initial presentation is more frequent in infants, toddlers, and preschool-age children (in whom the history of polyuria and polydipsia may be not be elicited), in children who do not have a first degree relative with T1D, and in children whose families are of a lower socioeconomic status. The early manifestations of DKA may be relatively mild consisting of nausea, vomiting, polyuria, and dehydration. In more prolonged and severe cases, Kussmaul respiration, which may be confused with bronchiolitis or asthma, is present and there is an odor of acetone on the breath. Abdominal pain may be present and mimic an acute abdominal emergency such as appendicitis or pancreatitis. The abdominal manifestations usually disappear after several hours of fluid and insulin treatment. Cerebral obtundation and, ultimately, coma are related to the severity of acidosis and hyperosmolality. Laboratory findings include glucosuria, ketonuria, hyerglycemia, hyperketonemia, and metabolic acidosis. Leukocytosis and nonspecific hyperamylasemia are common; serum lipase levels are usually not elevated. Management of DKA is discussed below.

The progression of T1D tends to follow a characteristic course including an abrupt onset of classical symptoms that rapidly disappear after starting insulin replacement therapy. This is often followed by a temporary remission ("honeymoon phase") with partial recovery of endogenous insulin secretion, demonstrable by plasma C-peptide levels and characterized by stable near-to-normal blood glucose levels and decreasing insulin requirements. Severe DKA and young age at presentation reduce the likelihood of a remission phase. Recurrence or persistence of the autoimmune attack leads to further ß-cell destruction and progressive decline in insulin production until, eventually, it ceases completely.

Presentation of Type 2 Diabetes Mellitus

At onset, the characteristics of pediatric type 2 diabetes (T2D) include frequent family history of T2D, female preponderance, average age in mid-puberty, acanthosis nigricans, and obesity (*Table 387.3*). The presentation can range from insidious to severe and DKA is not uncommon, which contrasts with adult onset T2D in which ketoacidosis is rare. Many youth with T2D present with classic symptoms, including weight loss. Diagnosis in asymptomatic individuals is also common, either as a consequence of the incidental finding of glucosuria or hyperglycemia or as a result of screening individuals at risk. It is likely that many individuals with youth onset T2D experience a prolonged period of mild hyperglycemia with minimal or no symptoms.

Distinguishing Between Type 1 and Type 2 Diabetes in Children

The phenotype of T1D used to be that of a thin child with a classic history. The current high prevalence of overweight and obesity in children and adolescents and an increasing incidence of T2D in youth have presented clinicians with a diagnostic challenge when evaluating a child or adolescent with new-onset diabetes mellitus. As many as 25% of newly diagnosed T1D patients are obese. Because there may be considerable overlap in presentation, distinguishing between T1D and T2D may be difficult (*Table 387.3*). Insulin requirements typically decrease after several weeks of treatment of T2D, which may resemble the remission or "honeymoon" period of T1D. Measuring pancreatic autoantibodies and markers of insulin secretion (fasting C-peptide levels) at the time of diagnosis helps to distinguish between T1 and T2D in obese patients. A fasting plasma C-peptide level >0.85 ng/mL suggests T2D; however, initially, C-peptide may be temporarily low in T2D owing to glucotoxicity and lipotoxicity, and rechecking the level after several weeks or even months of therapy will sometimes demonstrate hyperinsulinemia indicating insulin resistance and help to confirm a diagnosis of T2D. The fasting insulin-like growth factor binding protein-1 (IGFBP-1) level, whose secretion is acutely inhibited by insulin, is a marker of insulinization, and may be another useful biochemical parameter. An IGFBP-1 concentration ≤3.6 ng/mL is

highly suggestive of T2D. The subgroup of children with clinical features of T2D and autoantibody positivity has been referred to as latent autoimmune diabetes in youth (LADY). A binary classification is not always possible at the time of diagnosis; there are patients who have clinical and biochemical features of both insulin deficiency and insulin resistance (*Fig. 387.1*). Regardless of the type of diabetes, the choice of initial therapy must be based on a clinical assessment of the metabolic state. Subsequent therapy is modified, if necessary, guided by the individual patient's response to treatment.

Differential Diagnosis

Other Causes of Glucosuria

Diabetes mellitus occasionally is diagnosed in an asymptomatic individual because glucosuria is discovered incidentally. The diagnosis must always be confirmed by at least two independent measurements of PG concentration. Glucosuria can occur *without* hyperglycemia as a result of renal tubular dysfunction, e.g., Fanconi–Bickel syndrome (GLUT2 deficiency), or Fanconi syndrome from causes such as heavy-metal intoxication; an isolated reduction of the renal tubular threshold for glucose reabsorption (benign renal glucosuria) is diagnosed by performing an OGTT with simultaneous measurements of PG and urine glucose concentrations. Glucosuria will be evident, whereas PG concentrations are in the normal range. Hepatic glycogen synthase deficiency (glycogen storage disease type 0) is a rare cause of intermittent postprandial hyperglycemia and glucosuria in children. Intermittent postprandial hyperglycemia (frequently followed by hypoglycemia) is common after bolus feeds in patients who have a gastrostomy and Nissen fundoplication.

Transient Hyperglycemia

The incidence of transient hyperglycemia is approximately 1 per 8,000 pediatric office visits and 1 per 200 emergency department or hospital visits and is common in patients with asthma treated with sympathomimetics and glucocorticoids. A minority of children with transient hyperglycemia will develop diabetes mellitus. When transient hyperglycemia is detected in a child with a minor illness, the risk of developing diabetes is much higher than if a severe illness is present. The presence of pancreatic autoantibodies strongly predicts progression to diabetes.

Management of Diabetes Mellitus

Initial Management of Newly Diagnosed Type 1 Diabetes Mellitus

The goals of initial management depend on the clinical presentation and are: to restore fluid and electrolyte balance, to stabilize the metabolic state with insulin, and to provide basic diabetes education and self-care training for the child (if age and developmentally appropriate) and other caregivers. The diagnosis of diabetes in a child is a crisis for the family. Shocked, grieving, and overwhelmed parents typically require at least 2–3 days to learn basic "survival" skills while they cope with the emotional upheaval that typically follows the diagnosis of diabetes in a child. Even without severe metabolic decompensation, children with newly diagnosed T1D usually are admitted to hospital for metabolic stabilization, diabetes education, and self-management training. Outpatient or home-based management is preferred at some centers that have the appropriate resources.

Psychosocial Issues

Parents should receive sympathetic support and not be overwhelmed by unrealistic expectations from the diabetes treatment team. A medical social worker should perform an initial psychosocial assessment of all newly diagnosed patients to identify families at high risk who need additional services. Thereafter, the mental health specialist should be consulted when emotional, social, environmental, or financial concerns are suspected or identified that interfere with the ability to maintain acceptable diabetes control.

The treatment of pediatric diabetes is complicated by multiple factors inherent to childhood. Because childhood is characterized by cognitive and emotional immaturity, the involvement of responsible adults is essential for optimal treatment of pediatric diabetes. Treatment-related conflicts are not uncommon, arising in part due to natural discord in goals between caretakers and the child. Each phase of childhood has intrinsic characteristics that complicate treatment, e.g., the unpredictable eating of toddlers and the spontaneous intense physical play of school age children that can hinge on unpredictable factors such as the weather. Adolescence is characterized by multiple

physiologic and psychosocial factors that make maintenance of glycemic control more difficult. Diabetes treatment goals and regimens should be tailored to each child and family based on factors such as age, family resources, cognitive faculties, the schedule and activities of the child and family, and their goals and desires.

Mental health should be given equivalence to screening for other diabetes-related complications. Routine screening for behavioral disturbance should begin in children at the time of diabetes diagnosis, with further assessment of parental mental health and family functioning for those children identified as being "at risk." Interventions can then be targeted based on the specific needs of individual children and families.

Outpatient Diabetes Care

The Diabetes Team

Because the care of children with T1D is complex and time consuming, children should be managed by a multidisciplinary diabetes team that provides diabetes education and care in collaboration with the child's primary care physician. The team consists of a pediatric endocrinologist or pediatrician with training in diabetes, a pediatric diabetes nurse educator, a dietitian, and a mental health professional, either a clinical psychologist or social worker. A physician or nurse should always be available by telephone to respond to metabolic crises that require immediate intervention and to provide guidance and support to patients.

Initial Diabetes Education

Parents and children with newly diagnosed diabetes are typically overwhelmed and cannot assimilate a large amount of abstract information. Therefore, the education program should be staged: initial educational goals should be limited to essential "survival" skills so that the child can be safely cared for at home and as soon as possible return to his or her daily routine. At this stage, diabetes education and self-management training should include: understanding what causes diabetes, how it is treated, how to administer insulin, basic meal planning, self-monitoring of blood glucose and ketones, recognition and treatment of hypoglycemia, and how and when to contact the diabetes team. When the child is medically stable and parents and other care providers have mastered "survival" skills, the child is discharged from the hospital or ambulatory treatment center.

Continuing Diabetes Education and Long-Term Supervision of Diabetes Care

In the first few weeks after diagnosis, frequent telephone contact provides emotional support, helps parents to interpret the results of blood glucose monitoring and, if necessary, insulin doses are adjusted. Within a few weeks of diagnosis, many children enter a partial remission, evidenced by normal or near-to-normal blood glucose levels on a low dose ($\leq$0.5 units/kg/day) of insulin. Most patients and parents are less anxious, have mastered basic diabetes management skills, and are now ready to learn the intricate details of intensive diabetes management. The diabetes team should provide patients and parents with the more advanced knowledge and skills needed to maintain optimal glycemic control while coping with the normal challenges of a child's life. In addition to teaching facts and practical skills, the education program should promote desirable health beliefs and attitudes in the young person with a chronic incurable disease. For some children, this is best accomplished in a nontraditional educational setting such as a summer camp for children with diabetes. Parents, grandparents, older siblings, school nurse, and other important people in the child's life are encouraged to participate in the diabetes education program so they can share the burden of care and help the child to participate fully in school and extracurricular activities.

In the first month after diagnosis, the patient is seen frequently to review the diabetes education and consolidate the practical skills acquired in the first few days and to extend the scope of diabetes self-care training. Thereafter, follow-up visits should occur at least every 3 months and, as cognitive development progresses the child should become more involved in diabetes management and assume increasing age-appropriate responsibility for daily self-care.

Goals of Therapy

The Diabetes Control and Complications Trial (DCCT) and the long-term follow-up observations of the DCCT cohort (Epidemiology of Diabetes Interventions and Complications, EDIC), the Stockholm Diabetes Intervention Study, and the UK Prospective Diabetes Study (UKPDS) in adults with T2D all unequivocally demonstrated the importance of lowering glycated hemoglobin (HbA1c) values to reduce the risk of development and progression of retinopathy, nephropathy, neuropathy, and macrovascular disease. Treatment that reduces average HbA1c to ~7% (about 1% above the upper limit of normal) is associated with fewer long-term micro- and

macrovascular complications. Moreover, a sustained period of improved glycemic control also is associated with a decreased rate of development of diabetic complications (see chronic complication of type 1 diabetes below).

The aim of diabetes management is to achieve recommended glycemic targets known to reduce the risk of long-term complications. There is no consensus on appropriate targets for children of different ages. Management of young children with diabetes, especially those younger than 5 years, must balance opposing risks of hypoglycemia and future complications. The relative contribution of the prepubertal years to the development of microvascular complications is uncertain. Recent evidence indicates that longer prepubertal duration of diabetes increases the risk of retinopathy and, possibly, microalbuminuria in adolescence and young adulthood albeit at a slower rate than the postpubertal years.

Biochemical treatment goals for children and adolescents recently published by the International Society for Pediatric and Adolescent Diabetes (ISPAD) are: ideal HbA1c <6.5%, optimal <7.5%, suboptimal 7.5–9.0%, and action is required when the value exceeds 9.0%. The ISPAD guidelines are accompanied by the statement: "... each child should have their targets individually determined with the goal of achieving a value as close to normal as possible while avoiding severe hypoglycemia as well as frequent mild to moderate hypoglycemia."

The risk for microalbuminuria increases steeply with HbA1c >8%. Based on these considerations, an HbA1c of ≤8.0% is a reasonable general goal for children with diabetes; however, biochemical goals should be individualized taking into account both medical and psychosocial considerations. Less stringent treatment goals are appropriate for preschool age, children with developmental handicaps, psychosocial challenges, or lack of family support, children who have experienced severe hypoglycemia, and those with hypoglycemia unawareness.

Insulin Therapy

Plasma insulin levels in nondiabetic individuals are characterized by basal levels on which are superimposed meal-related spikes in insulin concentrations. The ideal insulin regimen should attempt to mimic physiologic insulin patterns by employing a basal-bolus approach to insulin replacement. Insulin pump therapy and multiple daily insulin injections most closely mimic insulin secretion (*Fig. 387.2*). Truly physiologic replacement of insulin, however, remains an elusive goal because insulin is injected or infused subcutaneously rather than directly into the portal vein, rates of absorption are variable, and doses are determined empirically, lacking the precision of endogenously secreted insulin. Also, other islet hormones such as glucagon and amylin are not present when a patient receives exogenous insulin.

Practical considerations, including socioeconomic circumstances, age, supervision of care, ability and willingness to self-administer insulin several times each day, and

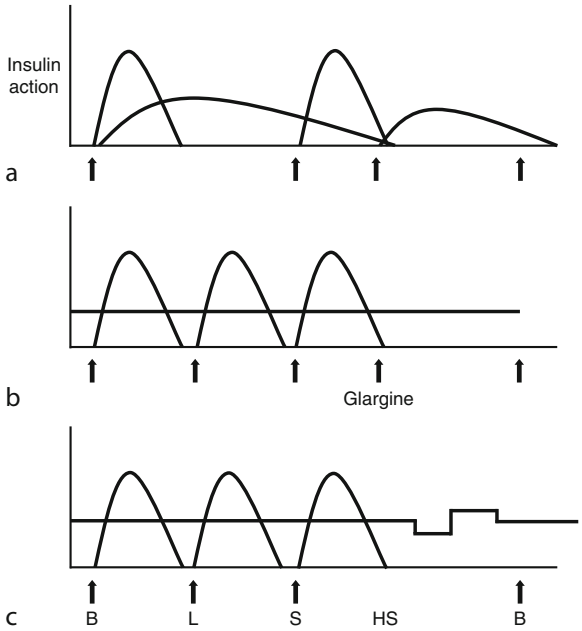

Figure 387.2
Commonly used insulin regimens. (a) Schematic representation of idealized insulin action provided by a regimen consisting of a mixture of rapid-acting insulin analog (lispro, aspart, or glulisine) with intermediate-acting insulin (NPH, isophane) before breakfast, rapid-acting insulin before supper, and a smaller dose of NPH at bedtime. (b) Schematic representation of idealized insulin action provided by an insulin regimen consisting of four daily injections: rapid-acting insulin before each meal (B, L, S) and a separate injection of insulin glargine or detemir, either at bedtime (as shown here) or at dinner or breakfast. (c) Schematic representation of idealized insulin effect provided by continuous subcutaneous insulin infusion via an insulin pump delivering rapid-acting insulin. In this figure, alternative basal rates are illustrated; insulin delivery is shown to decrease from midnight to 3 a.m. and to increase before breakfast to combat the dawn phenomenon. B, breakfast; L, lunch; S, supper; HS, bedtime. Arrows indicate times of insulin injection or boluses before meals

difficulty maintaining long-term adherence, make physiologic replacement of insulin challenging. No single insulin regimen can be used for all children with T1D. The diabetes team has to design an insulin regimen that best meets the needs of the individual patient and is acceptable to the patient and/or family member(s) responsible for administering insulin to the child or supervising its administration. Whenever possible, subcutaneous (SC) insulin treatment in the newly diagnosed child should start with at least three injections per day (*Fig. 387.2*, panel A) or a basal-bolus regimen (*Fig. 387.2*, panel B). All insulin regimens have the same general goal: to provide basal insulin throughout the day and night and additional insulin for meals and snacks.

In addition to severity of metabolic decompensation, the child's age, weight, and pubertal status guide selection of the initial insulin dose. When diabetes has been diagnosed early, before significant metabolic decompensation, 0.25–0.5 unit/kg/day usually is an adequate starting dose. When metabolic decompensation is more severe (e.g., ketosis without acidosis or dehydration) the initial dose typically is at least 0.5 unit/kg/day. After recovery from DKA (an insulin-resistant state), prepubertal children usually require at least 0.75 unit/kg/day, whereas adolescents require at least 1 unit/kg/day. In the first few days of insulin therapy, while the focus of care is on diabetes education and emotional support, it is reasonable to aim for premeal blood glucose levels in the range 4.5–10 mmol/L (80–180 mg/dL) and to supplement at 3–4 h intervals, if necessary, with 0.05–0.1 unit/kg of rapid- or short-acting insulin SC.

Three major categories of insulin preparations are available, classified according to their time course of action (*Table 387.4*). Various insulin replacement regimens consisting of a mixture of short- or rapid-acting insulin and an intermediate- or long-acting insulin are used in children and adolescents, typically given two to

Table 387.4
Insulin preparations classified according to their pharmacodynamic profiles

	Onset of action (h)	Peak action (h)	Effective duration of action (h)
Rapid-acting			
Insulin lispro[a]	0.25–0.5	0.5–2.5	≤5
Insulin aspart[a]	<0.25	1–3	3–5
Insulin glulisine	<0.25	1–1.5	3–5
Short-acting			
Regular (soluble)	0.5–1	2–3	5–8
Intermediate-acting			
NPH (isophane)	1–2	4–10	10–16
Long-acting			
Insulin glargine[a]	2–4	Relatively peakless	20–24
Insulin detemir[a]	0.8–2	Relatively peakless	12–24[b]
Premixed combinations			
50% NPH, 50% regular	0.5–1	dual	10–16
50% NPL, 50% lispro	<0.25	dual	10–16
70% NPH, 30% regular	0.5–1	dual	10–16
70% PA, 30% aspart[a]	<0.25	dual	15–18
75% NPL, 25% lispro[a]	<0.25	dual	10–16

[a]Insulin analog developed by modifying the amino acid sequence and/or chemical adducts of the human insulin molecule
[b]Dose dependent; 12 h for 0.2 U/kg; 20–24 h for ≥ 0.4 U/kg
Pharmacodynamic effects of lispro insulin and insulin aspart appear to be equivalent
PA, protamine-crystallized insulin aspart suspension; NPL, neutral protamine lispro suspension. Both PA + soluble aspart and NPL + lispro are stable premixed combinations of intermediate- and rapid-acting insulins
The human insulins and insulin analogs are available in vials, prefilled disposable pen injectors, and cartridges for non-disposable pen injectors
These data are for human insulins and are approximations from studies in adult test subjects. Time action profiles are estimates only. The kinetics of NPH insulin may be more rapid in children
The times of onset, peak, and effective duration of action vary within and between patients and are affected by numerous factors, including size of dose, site and depth of injection, dilution, exercise, temperature, regional blood flow, and local tissue reactions

four (or more) times daily. Clear superiority of any one regimen in children and adolescents in terms of metabolic outcomes has not been demonstrated.

NPH-Based Conventional Treatment Regimens

For many years the "split-mixed" regimen, which typically consisted of two daily doses of Neutral Protamine Hagedorn (NPH, isophane) and short-acting (regular) insulin (*Table 387.4*) mixed together in the same syringe, was a standard approach to insulin replacement. A practical advantage of this regimen is that the child does not receive an injection before lunch. More recently, the regular insulin component usually is replaced by a rapid-acting insulin analog. The total daily dose typically is divided so that about two-thirds is given before breakfast and one-third is given in the evening. With a three-dose regimen, short- or rapid-acting insulin is given before supper and the second dose of NPH insulin is given at bedtime rather than before the evening meal (*Fig. 387.2*, panel A). The initial ratio of rapid- to intermediate-acting insulin at both times is approximately 1:2. Individual components of the regimen are subsequently adjusted based on results of blood glucose monitoring. The optimal ratio of rapid- or short-acting to intermediate-acting insulin for each patient is determined empirically guided by the results of frequent blood glucose measurements. At least five daily measurements are initially required to determine the effects of each component of the insulin regimen. The blood glucose concentration is measured before each meal, before the bedtime snack, and once between midnight and 4 a.m. Parents are taught to identify patterns of hyperglycemia or hypoglycemia that indicate the need for a dose adjustment. Adjustments are made to individual components of the insulin regimen, usually in 5–10% increments or decrements, in response to patterns of consistently elevated (above the target range for several consecutive days) or unexplained low blood glucose levels, respectively. This is referred to as pattern adjustment. The insulin dose is adjusted until satisfactory blood glucose control is achieved with >50% of blood glucose values in the child's target range.

Within several days to a few weeks, many children enter a period of partial remission ("honeymoon") during which normal or nearly normal glycemic control is relatively easily achieved with a low dose of insulin. The doses of rapid-acting insulin may be reduced or discontinued due to low prelunch and bedtime values. As further destruction of ß-cells occurs, the insulin dose increases ("intensification phase") eventually reaching a full replacement dose. The average daily insulin dose in normal weight prepubertal children with long-standing diabetes is approximately 0.8 unit/kg/day and in adolescents about 1–1.5 unit/kg/day. Beyond the remission period, it is usually not possible to achieve near-normal glycemia with two injections per day without causing hypoglycemia during the overnight period. A major limitation of a two-dose "split-mixed" regimen is that the peak effect of the predinner intermediate-acting insulin occurs at the time of lowest insulin requirement (midnight to 4 a.m.), increasing the risk of nocturnal hypoglycemia. Thereafter, insulin action declines from 4 to 8 a.m., when the basal insulin requirement normally increases. Consequently, the tendency for blood glucose levels to rise before breakfast (dawn phenomenon) may be aggravated by waning insulin effect before breakfast and/or by counterregulatory hormones secreted in response to a fall in blood glucose levels during sleep.

A three-dose insulin regimen with mixed short- or rapid- and intermediate-acting insulin before breakfast, short- or rapid-acting insulin before dinner, and NPH insulin at bedtime (*Fig. 387.2*, panel A) may reduce these problems. An alternative regimen substitutes glargine or detemir, injected at dinnertime, for the bedtime dose of NPH. Intensive insulin regimens that employ intermediate-acting insulin demand consistency in the daily meal schedule, amounts of food consumed at each meal, and the timing of insulin injections.

Basal-Bolus Regimens and Continuous Subcutaneous Insulin Infusion

A basal-bolus insulin regimen or continuous subcutaneous insulin infusion (CSII) using an insulin pump can more closely simulate normal diurnal insulin profiles and permit flexibility with respect to timing and content of meals. A peakless long-acting insulin, glargine or detemir (*Table 387.4*), is used to provide basal insulin (typically 40–60% of the total daily dose) and is used together with short- or rapid-acting insulin injected before each meal (*Fig. 387.2*, panel B). Insulin glargine is injected once daily (in the morning, evening, or at bedtime), has a 20–24 h duration of action and little peak activity. Insulin detemir is an alternative long-acting, peakless basal insulin with effects similar to those of glargine during the first 12 h after administration. Thereafter, its effect wanes; accordingly, it usually has to be administered twice daily in patients with severe insulin deficiency. Doses of rapid-acting insulin are selected based on preprandial

glucose values, anticipated carbohydrate intake, and physical activity after the meal.

There has been a marked increase in the number of children and adolescents using CSII (pump) therapy. Pumps are battery powered, about the size of a beeper, and contain a reservoir (a modified syringe) to hold insulin, and deliver insulin via an infusion set consisting of fine plastic tubing with a tiny cannula at the end, which is inserted into the subcutaneous tissue. The infusion set is replaced every 2–3 days. Small amounts of rapid-acting insulin (down to 0.025–0.05 unit/h) are infused at a basal rate and bolus doses are given before each meal or snack. The basal rate can be programmed to change over the course of the day to meet an anticipated increase or decrease in need (*Fig. 387.2*, panel C). This feature can be advantageous in combating the dawn phenomenon or preventing hypoglycemia during or after exercise.

Increased lifestyle flexibility, reduced blood glucose variability, improved glycemic control and a reduced frequency of severe hypoglycemia are all documented advantages of CSII. Success requires a high degree of motivation to achieve normal or near-normal blood glucose levels, frequent blood glucose monitoring, record keeping, accurate carbohydrate counting, and frequent contact with the diabetes team. Only short- or rapid-acting insulin is used with CSII; therefore, any interruption in the delivery of insulin rapidly leads to metabolic decompensation. To reduce this risk, meticulous care must be devoted to the infusion system and blood glucose levels must be measured frequently.

Medical Nutrition Therapy (MNT)

Nutrition recommendations and interventions for diabetes are described in a detailed position statement from the American Diabetes Association and are supplemented by commentary and evidence-based nutrition practice guidelines from the American Dietetic Association. Evidence-based recommendations are available for adults with T2D, but not yet for children and adolescents. The guidelines are targeted at three levels. First, primary prevention to prevent T2D; MNT is used in conjunction with public health interventions in obese individuals and those with pre-diabetes. Secondary prevention is used for metabolic control of diabetes. Tertiary intervention aims to delay and manage complications of diabetes. Primary prevention is addressed below as part of lifestyle interventions for obesity with or without T2D.

Here we focus on the principles of MNT for metabolic control of diabetes. Key points emphasize caloric needs; proportions of carbohydrate, protein, and fat; the use of sucrose-, fructose-, and calorie-dense fruit juices and soft drinks; the use of carbohydrate counting and/or exchange lists to facilitate insulin dose adjustments; the composition of the fat components of MNT; recommended fiber intake; and formulation of a meal plan.

Calories

Two convenient formulas often are used to determine total calories. Some recommend using the formula 100 kcal/kg/day for the first 10 kg of body weight; 1,000 kcal plus 50 kcal/kg/day for weight between 10.1 and 20 kg; 1,500 kcal plus 20 kcal/kg/day up to 75 kg of *ideal* body weight. An alternative approach is 4 kcal/kg/h in year 1 of life; 2 kcal/kg/h from 1 to 6 years of life; 1 kcal/kg/h thereafter. In practice, these guidelines are virtually identical since 4 kcal/kg/h is equal to 96 kcal/kg/day, in line with the recommended 100 kcal/kg/day in the first year of life when an infant attains a weight of approximately 10 kg. To lose weight, a 20% reduction in daily calories for ideal body weight is recommended. During the pubertal growth spurt, calorie needs are generally at least 20% greater. In addition, the total caloric intake is influenced by the degree of physical activity; less for sedentary lifestyles and significantly more for those who are active, particularly in adolescents who participate in structured sports.

Proportions of Macronutrients

Of the total caloric needs, approximately 50% should derive from carbohydrate (1 g = 4 kcal). The American Diabetes Association guidelines emphasize that the composition of the diet should include carbohydrates from a variety of sources: fruits, vegetables, whole grains, legumes, and low-fat milk. Carbohydrate intake should be monitored by either carbohydrate counting or use of exchanges. Some people use experience-based estimation. All methods are valuable in achieving good glycemic control. Sucrose-containing foods can be substituted for other carbohydrates providing that they are covered with the appropriate amount of insulin and care is taken to avoid excess energy intake. Likewise, consumption of moderate amounts of fructose is beneficial rather than harmful; however, care should be taken to avoid high-fructose-, high-calorie-containing soft drinks and fruit juices. Patients should be encouraged to consume a variety of fiber-containing foods; the recommendation is for 14 g of fiber per 1,000 kcal consumed per day. Non-nutritive

sweeteners are safe when consumed within the daily intake levels recommended by the Food and Drug Administration.

Protein

Protein should constitute 15–20% of daily energy intake (1 g = 4 kcal). Protein intake >20% of calories is not practical and not recommended; moreover, the long-term effect on diabetes complications is unknown. The recommended daily allowance of protein is approximately 0.8 g of good-quality protein per kilogram body weight per day. This amounts to approximately 10% of daily calories and may be doubled in growing children to achieve 15–20% of total daily energy intake. Examples of good-quality proteins are meat, poultry, fish, eggs, milk, cheese, and soy. Cereals, grains, nuts, and vegetables are not considered to be sources of good-quality protein.

Dietary Fat and Cholesterol

Fat should constitute 30–35% of daily calories. Saturated fat should be limited to <7% of total daily calories and intake of *trans* fat should be minimal. Cholesterol should be limited to <200 mg/day. Finally, two or more servings of fish (but not commercially fried fish filets) provide n-3 polyunsaturated fatty acids and are recommended. The optimal mix of macronutrients, micronutrients, and antioxidants is addressed in the ADA position statement.

The distribution of total daily caloric intake is formulated to provide 20–30% at breakfast, 20% at lunch, and 30% at dinner, leaving 20–30%, which can be distributed as a mid-morning, mid-afternoon, and bedtime snack. Consultation with and counseling by a certified dietician trained in the management of diabetes is invaluable. Planning meals according to lifestyle is crucial. For example, adolescents frequently omit breakfast, whereas vigorous structured exercise will require more calories to match expenditure. The bedtime snack is important to reduce the risk of nocturnal hypoglycemia; a mid-morning snack often is omitted if hypoglycemia does not occur at that time.

Adherence to a structured meal plan and particularly to its carbohydrate content by using carbohydrate counting or exchange lists is critical for the optimal management of diabetes and to inform decisions to adjust daily insulin doses for either T1 or T2D. Sample meal plans are published by the United States Department of Agriculture: www.health.gov/dietaryguidelines.

Exercise

Children with diabetes should be encouraged to participate in sports and include regular physical exercise in their lives because this normalizes the child's life, enhances self-esteem, improves physical fitness, helps to control weight, and may improve glycemic control. Regular exercise increases insulin sensitivity, cardiovascular fitness, and lean body mass, improves blood lipid profiles, and lowers blood pressure.

Although physical exercise is complicated for the child with T1D, especially by the need to prevent hypoglycemia, with proper guidance and planning, exercise can be a safe and enjoyable experience. Blood glucose responses to prolonged moderate-intensity exercise are repeatable when pre-exercise meal, exercise, and insulin regimens are kept constant. Exercise acutely lowers the blood glucose concentration by increasing utilization of glucose to a variable degree that depends on the intensity and duration of physical activity and the concurrent level of insulin in the blood. In T1D, acute strenuous anaerobic exercise increases levels of epinephrine and glucagon and may cause transient hyperglycemia for 30–60 min.

Hypoglycemia can usually be prevented by anticipatory reduction in the pre-exercise insulin dose or a temporary interruption or reduction of basal insulin infusion (with CSII) and supplemental snacks before, during, and after physical activity, depending on its duration and intensity. Nearly all forms of activity lasting more than 30 min require some adjustment to food and/or insulin. Continuous moderate-intensity exercise tends to cause a lesser decline in blood glucose levels than intermittent high-intensity exercise of short duration. The optimal strategy depends on timing of the exercise relative to the child's meal plan and the insulin regimen. Factors to be considered when selecting the content and size of the snack are the current blood glucose level, the action of insulin most active during and after the period of anticipated exercise, the interval since the last meal, and the duration and intensity of physical activity. The appropriate amount is learned by trial and error; a useful guide is to provide up to 1 g of carbohydrate per kilogram of body mass per hour of strenuous exercise. Prolonged and strenuous exercise in the afternoon or evening should be followed by a 10–30% reduction in the presupper or bedtime dose of intermediate- or long-acting insulin or

an equivalent reduction in overnight basal insulin delivery in patients using CSII. To reduce the risk of nocturnal or early-morning hypoglycemia caused by the lag effect of exercise, the bedtime snack should be larger than usual and contain carbohydrate, protein, and fat. Parents should be encouraged to monitor the blood glucose concentration in the middle of the night until they are experienced modifying the evening dose of insulin after exercise.

Blood glucose monitoring is essential for the active child with diabetes because it allows identification of trends in glycemic responses. Records should include blood glucose levels, timing, duration, and intensity of exercise as well as the strategies used to maintain glucose concentrations in the target range.

If possible, the insulin injection preceding exercise should be given in a site least likely to be affected by exercise (usually the abdomen). Because physical training increases tissue sensitivity to insulin, children who participate in organized sports are advised to reduce the dose of the insulin preparation most active during the period of sustained physical activity. The dose reduction is best determined by measuring blood glucose levels before and after exercise, but is generally reduced by 10–30% or more of the usual dose.

In the child with poorly controlled diabetes, vigorous exercise can aggravate hyperglycemia and ketoacid production; accordingly, a child with uncontrolled diabetes and ketonuria should not exercise until satisfactory biochemical control has been restored.

Management of Type 2 Diabetes Mellitus

The management of T2D in children and adolescents is targeted at its two major interacting causes – insulin resistance and insulin deficiency. To reduce insulin resistance and enhance insulin sensitivity, lifestyle interventions aimed at weight loss and physical fitness coupled with an oral insulin sensitizer, principally metformin, are used. Also important, if applicable, is the reduction or elimination of drugs that antagonize insulin action such as glucocorticoids and certain atypical antipsychotic medications. To correct insulin deficiency, exogenous insulin injections or secretagogues of endogenous insulin are used. The decision to initiate insulin injections is determined by the severity of metabolic decompensation at the time of presentation. For patients with T2D presenting with DKA or non-ketotic hypersosmolar coma (NKH), fasting glucose >200 mg/dL or HbA1c $\geq 8.5\%$, exogenous insulin is recommended as the primary therapy in order to rapidly correct hyperglycemia and, possibly, allow for recovery of endogenous insulin secretion. Insulin secretion may be depressed as a consequence of the deleterious effects of glucotoxicity and lipotoxicity, which refers to the negative effects of chronic hyperglycemia and elevated FFA levels on insulin secretion.

Lifestyle Interventions

Lifestyle interventions are obligatory in obese or overweight patients. The goals of lifestyle intervention are to achieve and maintain a 5–10% reduction in body weight through a healthy, low-calorie, low-fat diet. The general principles are those recommended for adults in whom such an intervention, coupled with exercise to increase calorie expenditure, have been highly effective in preventing progression from impaired glucose tolerance to T2D. Practice guidelines for the treatment and prevention of pediatric obesity have recently been published. In children and adolescents, total recommended calories and dietary composition must be developmentally appropriate, nutritionally balanced, and include recommended fiber intake, minerals, and vitamins. The participation of a trained dietician with experience in managing nondiabetic children with obesity and non-obese children with diabetes is invaluable. Published recommendations are from consensus and expert committees, but evidence-based recommendations await the results of the TODAY (Treatment Options for Diabetes in Adolescents and Youth) study currently in progress.

Closely linked to nutritional modifications are guidelines for increased physical activity to increase energy expenditure. Here, evidence-based guidelines for school-age youth are available. These recommend *daily* moderate to vigorous physical activity for a total of 60 min or more. The physical activity need not be completed in a single session, may involve a variety of activities, and should be developmentally appropriate and "enjoyable." Incorporating these activities as part of the daily school curriculum or through other structured programs is under investigation.

Insulin Therapy

As described above, insulin therapy is used in the more severe presentations of T2D. Before starting exogenous insulin, we recommend testing patients with clinically suspected T2D for the presence of pancreatic autoantibodies (ICA, GAD65, IA-2, IAA). A positive result

suggests the coexistence of autoimmunity, which implies that the patient has both T1D and T2D. This has prognostic value as patients with autoantibodies may have ongoing autoimmune destruction of ß-cells that may preclude them from being weaned off insulin and they predict that the patient will require insulin in the future. After correcting DKA or NKH, we recommend a basal-bolus regimen using a long-acting insulin (glargine or detemir) at bedtime plus a rapid-acting insulin before meals. The total daily dose (TDD) must be empirically determined, being of the order of 0.5–1.0 unit/kg, of which approximately 50% is basal and the remaining 50% bolus insulin divided among the three main meals according to the patient's blood glucose responses. This requires extensive education of the patient and family in all aspects of diabetes mellitus management (as described above for T1D), including blood glucose testing, types, use and mixing of insulins, recognition of hypoglycemia and its treatment, as well as principles of MNT. This is best accomplished as an inpatient. We recommend insulin treatment for 3 months to allow recovery of endogenous insulin secretion (reversal of glucotoxicity and lipotoxicity) before attempting to wean the patient off insulin. In some patients with T2D, a single injection of a long-acting insulin is sufficient to achieve acceptable glycemic control. In patients with poor compliance a premixed insulin preparation (e.g., 70% NPH/30% rapid-acting insulin; *Table 387.4*) is given twice daily, before breakfast and dinner, and may suffice to maintain reasonable metabolic control. Some physicians recommend measuring fasting C-peptide levels to gauge residual insulin secretory capacity before weaning patients off exogenous insulin.

If the patient now has, or originally presented with, mild to moderate hyperglycemia, defined as a fasting PG 126–199 mg/dL (7–11 mmol/L) and/or a hemoglobin A1c of <8.5%, the lifestyle modification program in combination with metformin is a safe and effective regimen in pediatric patients. Metformin is a biguanide that acts as an insulin sensitizer by decreasing hepatic glucose production and increasing insulin-mediated glucose uptake in peripheral tissues, principally muscle. Metformin is approved for use in pediatric patients with T2D. The starting dose is 850 mg once daily or 500 mg twice daily with increments of 500 mg every 2–4 weeks to a maximum of 2 g/day. The limiting factor is its gastrointestinal side effects such as nausea, vomiting, and abdominal discomfort, which generally subside if the patient perseveres in taking the medication. Lactic acidosis is rare in children with normal renal function. Renal and liver function tests should be performed before starting metformin; contraindications to its use include renal impairment, markedly abnormal liver enzymes, and cardiopulmonary insufficiency. Metformin should be discontinued before undergoing a radiographic procedure involving use of contrast agents that are known to predispose to lactic acidosis. If glucose control is not satisfactory after 3–6 months of lifestyle modification and metformin, consideration should be given to using insulin secretagogues or exogenous insulin.

Insulin Secretagogues

Insulin secretagogues such as the sulfonylureas (glyburide, glipizide and glimepiride) and the meglitinides such as repaglinide increase insulin secretion in response to eating. Their side effects include hypoglycemia, increased appetite, and weight gain, which is undesirable in T2D. These agents are not commonly used in children. Thiazolidinediones are not approved for use in children, although rosiglitazone is under investigation in children with T2D. Other agents are rarely used.

Experimental Therapies for Type 2 Diabetes in Children

These approaches are not presently standard therapy in children but are used extensively in adults with T2D. Surgically induced weight loss by means of gastric banding or bypass procedures in adults has been successful in reversing T2D. A small cohort of adolescents who underwent gastric bypass for morbid obesity experienced remission of T2D and a significant improvement in fasting PG and insulin concentrations, hemoglobin A1c and insulin sensitivity. In addition, markers of cardiovascular risk such as blood pressure and serum lipid levels improved. Although it is not generally recommended, in selected cases gastric bypass may be an option for morbidly obese adolescents with T2D.

In adults, analogs of glucagon-like peptide I (GLP-1) and drugs that prevent its inactivation, dipeptidyl peptidase-IV inhibitors (gliptins), have found increasing acceptance. GLP-1 increases insulin secretion, reduces glucagon secretion, and delays gastric emptying without increasing hypoglycemia. Exenatide, an agent that binds to the GLP-I receptor, and gliptins are widely used by adults with T2D. The long-term actions and safety of these drugs are unknown and their use in childhood has been extremely limited.

Pramlintide, a synthetic amylin analog, also has been used in adults with both T1D and T2D. It decreases

glucagon secretion and delays gastric emptying thereby facilitating weight loss without causing hypoglycemia. Its major drawback is that it must be given by injection with each meal. As more experience is gained, these drugs are likely to become part of the armamentarium used to treat adolescents with T2D.

Biochemical Outcomes in Type 2 Diabetes Mellitus

Glucose and HbA_1c

Ideal treatment outcomes for T2D in adolescents are fasting PG of 80–125 mg/dL (4.4–6.9 mmol/L) and 2 h postprandial values of <140 mg/dL (7.8 mmol/L). Two hour postprandial PG values up to 160 mg/dL (8.9 mmol/L) would maintain an HbA_1c of 7% or less, which is the recommendation of the ADA. Some investigators recommend that an HbA_1c of <6.5% should be the goal to avoid micro- and macrovascular complications.

Lipids

Dyslipidemia is common in T2D and targets for its management in children and adolescents with T2D have been promulgated by the ADA. Somewhat different targets have been recommended by the American Heart Association (AHA). Target goals for lipids are: total cholesterol <170 mg/dL, low-density lipoprotein (LDL) <130 mg/dL, triglycerides (TG) <150 mg/dL, and high-density lipoprotein (HDL) > 40 mg/dL.

If lifestyle modifications alone do not reduce hyperlipidemia to normal levels after 6 months, then HMG-CoA reductase inhibitors (e.g., atorvastatin, lovastatin, pravastatin) are recommended. Statins are especially recommended for boys older than 10 years and for postmenarcheal girls with hyperlipidemia and a family history of familial hypercholesterolemia and coronary artery disease or early myocardial infarction in first-degree relatives.

Monitoring Diabetes Control

Self-monitoring of Blood Glucose (SMBG)

SMBG is the cornerstone of modern diabetes care. Glucose meters are accurate to within 5–10% of laboratory measurements. Patients/parents must be taught how to use the data to assess the efficacy of therapy and to adjust the components of their treatment regimen to achieve individual blood glucose goals. Most glucose meters have an electronic memory; however, it is valuable for patients/parents to keep written records of their results and to analyze the data for patterns and trends and to make adjustments when necessary. Patients with T1D should routinely measure blood glucose levels at least four times daily: before each meal and at bedtime. To minimize the risk of nocturnal hypoglycemia, blood glucose should be measured between midnight and 4 a.m. once each week or every other week and whenever the evening dose of insulin is adjusted. If HbA1c targets are not being met, patients should be encouraged to measure glucose levels more frequently, including 90–120 min after meals. Frequency of glucose monitoring is a predictor of glycemic control in children with T1D. Children who are able to independently perform SMBG must be properly supervised because it is not unusual for children to fabricate data with disastrous consequences.

Continuous Glucose Monitoring (CGM)

The technology of continuous glucose monitoring (CGM) has evolved rapidly over the past several years. Current CGM devices measure glucose in the interstitial fluid by means of a short, thin glucose oxidase–based electrochemical probe inserted into the subcutaneous tissue, which can be used for 3–7 days. The accuracy of CGM devices has improved, but is not yet considered sufficient to substitute for SMBG by glucose meters, and treatment decisions are based on glucose results from a meter. Furthermore, each newly placed CGM probe must be calibrated during a period of stable glycemia over several hours by performing simultaneous capillary blood glucose measurements. Importantly, there is a lag of several minutes between actual PG and interstitial glucose concentrations; thus, current CGM devices cannot substitute for SMBG.

Real-time CGM (RT-CGM) devices report the estimated PG values in real time every 1–5 min via a user interface. Several such RT-CGM devices are commercially available and approved for use in the United States and Europe. Information from RT-CGM allows the user to detect the early phases of a hyperglycemic or hypoglycemic episode, thereby enabling corrective action to be taken after confirmatory SMBG. A short-term (6 month) controlled trial RT-CGM has demonstrated significantly improved HbA1c concentrations in intensively treated T1D in adults and more modest benefits in children. The long-range goal is to develop a closed-loop system whereby the CGM

regulates the rates of insulin infusion anticipating both the rise and fall of PG and appropriately adjusting the rates of insulin delivery to prevent hypo- and hyperglycemia.

Urine Ketone Testing

Urine should routinely be tested for ketones during acute illness or stress, when blood glucose levels are persistently elevated (e.g., two consecutive values >300 mg/dL [16.7 mmol/L]), or when the patient feels unwell, especially with abdominal pain, nausea or vomiting. False-negative readings may occur when the strips have been exposed to air (improperly stored) or when urine is highly acidic (e.g., after consumption of large doses of ascorbic acid). Urine ketone tests using nitroprusside-containing reagents can give false-positive results in patients who take valproic acid or any sulfhydryl-containing drug, including captopril.

Blood Ketone Testing

Meters that measure blood ß-hydroxybutyric acid (ßOHB) levels are available for home use; however, strips are expensive. Quantification of blood ßOHB, the predominant ketone body, is preferred over urine ketone testing for diagnosing and monitoring metabolic decompensation during intercurrent illness, with pump failure, and in DKA. Blood BOHB determination is helpful in managing patients via the telephone and avoiding emergency room visits and offers the advantage of accurately assessing improvement after starting treatment.

Glycated Hemoglobin, Hemoglobin A1c (HbA1c)

HbA1c is a minor fraction of adult hemoglobin, which is formed slowly and nonenzymatically from hemoglobin and glucose. Because erythrocytes are freely permeable to glucose, HbA1c is formed throughout the lifespan of the erythrocyte; its rate of formation is directly proportional to the ambient glucose concentration. The concentration of HbA1c, therefore, provides a "glycemic history" of the previous approximately 120 days, the average lifespan of erythrocytes. Although HbA1c reflects glycemia over the preceding 6–12 weeks, it is weighted toward the most recent 4 weeks. HbA1c measurement is a fundamental component of the management of patients with diabetes and is used to monitor long-term glycemic control and as a measure of the risk for the development of diabetes complications.

More than 30 different methods are used to measure hemoglobin A1c, which has led to different nondiabetic reference ranges because different glycated hemoglobin fractions are measured. The International Federation of Clinical Chemistry has developed a new reference method that precisely measures the concentration of glycated hemoglobin (betaN1-deoxyfructosyl-hemoglobin), and a recent study has accurately determined the relationship between mean blood glucose over many weeks and the glycated hemoglobin concentration: Average Glucose (mg/dL) = 28.7 × A1c − 46.7. It is anticipated that the new assay will be reported as "estimated average blood glucose" or "A1c-derived average glucose," and the units will be mmol/L or mg/dL.

HbA1c should be measured approximately every 3 months to determine whether a patient's metabolic control has reached or has been maintained within a target range. Average glucose levels are underestimated by HbA1c in conditions that shorten the average circulating red blood cell lifespan, such as hemolysis, sickle cell disease, transfusion, and iron deficiency anemia. When accurate HbA1c measurement is not possible, as in the above conditions, alternative measures of chronic glycemia such as fructosamine or glycated serum albumin should be used. These measure the glycation of serum proteins rather than hemoglobin, and reflect glycemia over the preceding 2–4 weeks.

Acute Complications of Diabetes

Diabetic Ketoacidosis (DKA)

DKA is a potentially life-threatening medical emergency that reflects metabolic decompensation in a patient with diabetes mellitus. The biochemical criteria for the diagnosis of DKA include hyperglycemia (blood glucose >11 mmol/L) (~200 mg/dL) with acidosis (venous blood pH <7.3 and/or serum bicarbonate ≤ 15 mmol/L), ketonemia with total serum ketones (ß-hydroxybutyrate and acetoacetate) >3 mmol/L, and ketonuria. The risk of DKA in patients with established type 1 diabetes is 1–10% per patient per year, and is increased in children with poor metabolic control or previous episodes of DKA; peripubertal and adolescent girls; children with psychiatric disorders, including those with eating disorders; and those with difficult family circumstances, including lower socioeconomic status and lack of health insurance. In the era of insulin pump therapy, interruption of insulin delivery is an

important cause of DKA. Children seldom have DKA when insulin administration is closely supervised or performed by a responsible adult.

Pathophysiology

DKA is the result of absolute or relative deficiency of circulating insulin and the combined effects of increased levels of the counterregulatory hormones, catecholamines, glucagon, cortisol, and growth hormone. Absolute insulin deficiency occurs in previously undiagnosed type 1 diabetes and when patients on treatment deliberately or inadvertently do not take insulin. Relative insulin deficiency occurs when the concentrations of counterregulatory hormones increase with stress (e.g., sepsis, trauma, or gastrointestinal illness with diarrhea and vomiting). Low serum levels of insulin and high concentrations of the counterregulatory hormones lead to an accelerated catabolic state whose effects are: increased glucose production by the liver and kidney (via glycogenolysis and gluconeogenesis), impaired peripheral glucose utilization resulting in hyperglycemia and hyperosmolality, and increased lipolysis and ketogenesis, causing ketonemia and metabolic acidosis (*Fig. 387.3*). Hyperglycemia and hyperketonemia cause osmotic diuresis, dehydration, and obligatory loss of electrolytes, which often is aggravated by vomiting. Ketoacidosis is aggravated by lactic acidosis from poor tissue perfusion and/or sepsis.

DKA is characterized by severe depletion of water and electrolytes. Despite dehydration, patients continue to have considerable urine output unless they are extremely

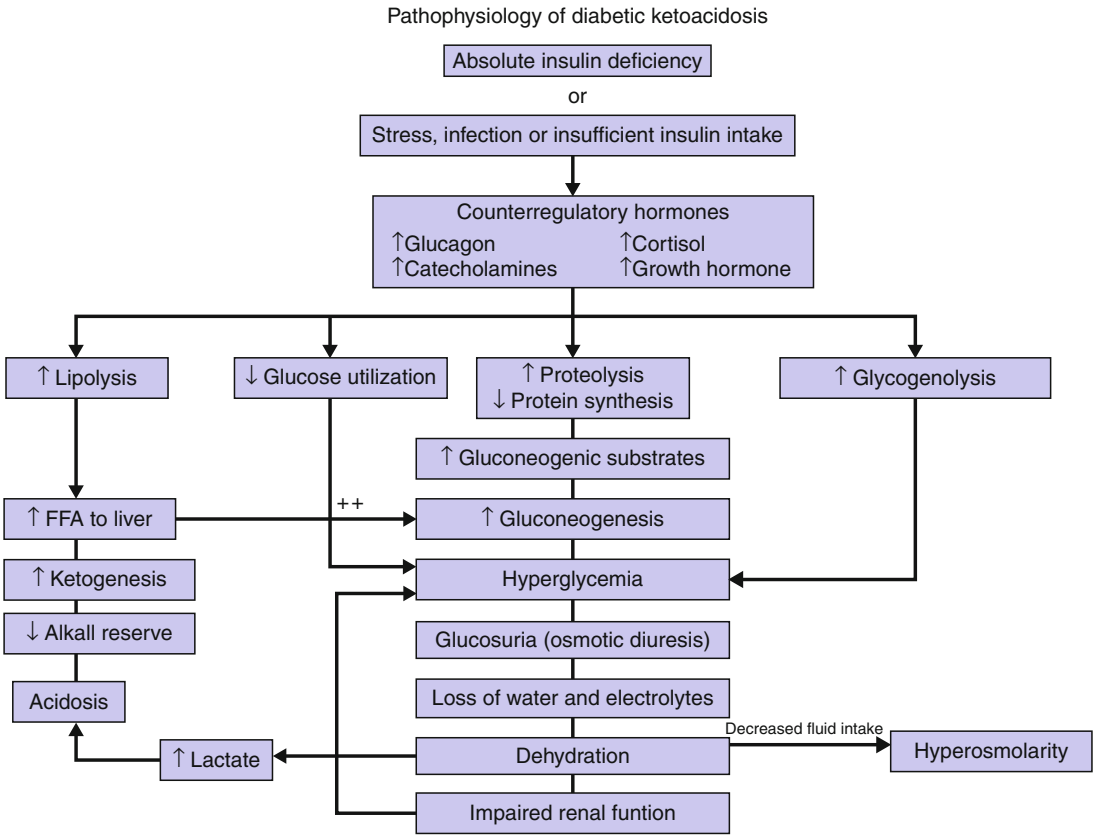

Figure 387.3

The pathophysiology of diabetic ketoacidosis is illustrated as a function of absolute insulin deficiency or insufficient insulin administration in the presence of stress, which leads to increased levels of the counterregulatory hormones. These changes increase glucose production via glycogenolysis and gluconeogenesis resulting in hyperglycemia, osmotic diuresis, and dehydration. Simultaneously, increased lipolysis leads to ketone body production and acidosis, which is augmented by lactic acidosis from dehydration

volume depleted. The magnitude of specific deficits in an individual patient at the time of presentation varies depending upon the duration of illness, the extent to which the patient was able to maintain intake of fluid and electrolytes, as well as the content of food and fluids consumed before presentation.

DKA should be distinguished from hyperosmolar nonketotic coma (HNK), a metabolic state characterized by severe hyperglycemia (blood glucose $\geq$ 600 mg/dL), absence of or only mild ketosis, nonketotic acidosis, severe dehydration, depressed sensorium or frank coma, and various neurologic signs that may include grand mal seizures, hyperthermia, hemiparesis, and positive Babinski signs. Although infrequent in children, HNK occurs in children with neurologic damage and in obese youth presenting with T2D.

Treatment of HNK is similar to that of DKA (described below), and is directed, initially, at repletion of the volume deficit with isotonic saline until the condition is stable, and then gradual correction of the hyperosmolar state over ~48 h. Insulin may be infused as for DKA, or at 0.05 unit/kg/h, half the amount typically used for DKA.

Management of DKA

The immediate aims of therapy are expansion of intravascular volume; correction of deficits in fluid, electrolyte, and acid–base status; initiation of insulin therapy to correct intermediary metabolism; and the exclusion of a treatable precipitating event such as infection. Treatment should commence as soon as the diagnosis is confirmed.

Initial Evaluation

- Perform a clinical evaluation to establish the diagnosis and determine its cause (especially any evidence of infection). Weigh the patient and measure height or length. Determine body surface area. Assess the patient's degree of dehydration.
- Determine the blood glucose concentration with a glucose meter and the blood or urine ketone concentration.
- Obtain a blood sample for laboratory measurement of glucose, electrolytes, and total carbon dioxide (TCO2), blood urea nitrogen, creatinine, serum osmolality, venous (or arterial in critically ill patient) pH, pCO2, hemoglobin, hematocrit, total and differential white blood cell count, and calcium, phosphorus, and magnesium concentrations.
- Perform a urinalysis and obtain appropriate specimens for culture (blood, urine, throat).
- Perform an electrocardiogram for baseline evaluation of potassium status.

Supportive Measures

- Secure the airway and empty the stomach by continuous nasogastric suction to prevent pulmonary aspiration in the unconscious or severely obtunded patient.
- Antibiotics should be given to febrile patients after obtaining appropriate cultures of body fluids.
- Oxygen should be given to patients with severe circulatory impairment or shock.
- If the child is unconscious or unable to void on demand (e.g., infants and very ill young children), the bladder should be catheterized.
- A flowchart is essential to record the patient's clinical and laboratory data, including vital signs (heart rate, respiratory rate, blood pressure, level of consciousness [Glasgow coma scale]), details of fluid and electrolyte therapy, amount of administered insulin, and urine output. A key to successful management of diabetic ketoacidosis is meticulous monitoring of the patient's clinical and biochemical response to treatment so that timely adjustments in therapy can be made when indicated by the patient's clinical or laboratory data. Frequent reexamination of laboratory parameters is required to prevent serious electrolyte imbalance and administration of either insufficient or excessive fluid.
- A heparin-locked intravenous catheter should be placed for convenient and painless repetitive blood sampling.
- A cardiac monitor should be used for continuous electrocardiographic monitoring.

Fluid and Electrolyte Therapy

All patients with DKA are dehydrated and suffer total body depletion of sodium, potassium, chloride, and phosphate, of the order of 5–13, 3–6, 3–9, and 0.5–2.5 mmol/kg, respectively. The high effective osmolality of the extracellular fluid (ECF) compartment results in a shift of water from the intracellular fluid compartment (ICF) to the ECF and decreases the serum sodium concentration ~1.6 mmol/L per 5.6 mmol/L (100 mg/dL) of blood glucose above normal. The serum sodium concentration, therefore, may give a misleading

estimate of the degree of sodium deficit. The effective osmolality at the time of presentation is frequently in the range 300–350 mOsm/L. Increased serum urea nitrogen and hematocrit are useful markers of severe ECF contraction. At the time of presentation, patients have a contracted ECF, and clinical estimates of the deficit in patients with severe DKA are usually in the range of 7–10%. In mild to moderately severe DKA, fluid deficits are more modest, in the range 30–50 mL/kg. Shock with hemodynamic compromise is uncommon in childhood.

The onset of dehydration is associated with a reduced glomerular filtration rate (GFR), which results in decreased glucose and ketone clearance. Intravenous fluid administration expands the intravascular volume and increases glomerular filtration, which increases renal excretion of glucose and ketones, and results in a prompt decrease in blood glucose concentration. The goals of fluid and electrolyte replacement therapy in DKA are: restoration of circulating volume, replacement of sodium and water deficits, and restoration of GFR with enhanced clearance of glucose and ketones from the blood, and avoidance of cerebral edema. Although there is no compelling evidence showing the superiority of any fluid regimen over another, there are data that suggest that rapid fluid replacement with hypotonic fluid in the first several hours of treatment is associated with an increased risk of cerebral edema and slower fluid deficit correction with isotonic or near-isotonic solutions results in earlier reversal of acidosis. Large amounts of 0.9% saline have also been associated with the development of hyperchloremic metabolic acidosis.

Initial intravenous fluid administration and, when necessary, volume expansion, should begin immediately with 0.9% saline. The volume and rate of administration depends on the patient's circulatory status. When volume expansion is clinically indicated, 10–20 mL/kg is given over 1–2 h and may be repeated if necessary. Continue to use 0.9% saline for at least 4–6 h. Thereafter, use a solution with a tonicity $\geq$0.45% saline with added potassium. The rate of intravenous fluid administration should be calculated to rehydrate the patient at an even rate over 48 h. The daily volume of fluid should usually not exceed 1.5–2 times the usual daily requirement based on age, weight, or body surface area (*Table 387.5*). Urinary losses should not be added to the calculation of replacement fluids. The development of hyponatremia or failure to observe a progressive rise in serum sodium concentration with a concomitant decrease of blood glucose concentration during treatment is a risk factor for cerebral edema. Monitor the effective serum osmolality and allow it to decrease gradually. If the effective osmolality starts low or does not increase appropriately as the plasma glucose concentration falls, increase the infused sodium concentration.

When the blood glucose concentration reaches ~17 mmol/L (300 mg/dL), 5% dextrose is added to the infusion fluid; the concentration is adjusted to avoid hypoglycemia. Because hyperglycemia corrects more quickly than ketoacidemia, it may be necessary to use $\geq$10% dextrose while continuing with insulin infusion to correct ketoacidosis. Administration of intravenous fluids and insulin should be continued until acidosis is corrected (venous pH $\geq$7.30 and anion gap is near to normal) and the patient can tolerate fluids and food. Inadequate fluid administration should be evident from examination of the cumulative fluid balance and persistent tachycardia in the absence of a fever.

Table 387.5

Replacement procedure for a child (30 kg, 1 m^2) with diabetic ketoacidosis estimated to be 10% dehydrated. Normal saline 10 mL/kg is given over 1 h for initial volume expansion; thereafter, the child is rehydrated over 48 h at an even rate at two times the maintenance rate of fluid requirement

Approximate duration and rate	Fluid composition and volume	Sodium mEq	Potassium mEq	Chloridem Eq	Phosphate mmol
Hour 1 (300 mL/h)	300 mL 0.9% NaCl (normal saline)	46	–	46	–
Hour 2–4 (125 mL/h) Start regular insulin at 0.1 unit/kg/h	375 mL (normal saline) + 20 mEq K acetate/L + 20 mEq K phosphate/L	58	15	58	5.1
Hours 5–48 (125 mL/h) Continue regular insulin 0.1 unit/kg/h until pH $\geq$ 7.3 or $HCO_3 \geq$ 18 mEq/L	5,500 mL (1/2 normal saline + dextrose) +20 mEq K acetate/L + 20 mEq K phosphate/L	424	220	424	75
Total in 48 h	6,175 mL fluid	528	235	528	80

Potassium phosphate 4.4 mEq potassium and 3 mmol phosphate (1 mEq potassium and 0.68 mmol phosphate)

Insulin

Whereas hydration per se decreases the plasma glucose concentration, insulin is essential to restore blood glucose to normal and suppress lipolysis and ketogenesis, and to reverse ketoacidosis. Low-dose intravenous insulin administration is the standard of care. At a dose of 0.1 unit/kg/h, intravenous regular (soluble) insulin suppresses glucose production, significantly increases peripheral glucose uptake, and inhibits lipolysis and ketogenesis. The dose of insulin should typically remain at 0.1 unit/kg/h until resolution of ketoacidosis. In insulin-sensitive patients (especially young children and patients with mild to moderate DKA), the dose may be reduced to 0.05 unit/kg/h; however, even if the blood glucose concentration is near to normal, intravenous insulin must not be discontinued until ketoacidosis has resolved. Continuous intravenous insulin should be administered via an infusion pump. Regular insulin is diluted in normal saline (50 units regular insulin in 50 mL saline) and is given at a rate of 0.1 unit/kg/h. The insulin infusion should commence *after* initial volume expansion (1–2 h after starting fluid therapy). An intravenous priming dose is unnecessary and may increase the risk of cerebral edema.

Rare patients with severe insulin resistance do not satisfactorily respond to low-dose insulin infusion and require two or three times the usual dose. It is essential to monitor the blood glucose, venous (or arterial) pH, and anion gap response to insulin therapy. Also, one should consider other possible explanations for failure to respond to insulin (sepsis or an error in insulin preparation). When intravenous insulin is not possible, the intramuscular or subcutaneous route of administration may be used and hourly or 2-hourly rapid-acting insulin (lispro or aspart) may be preferable to regular insulin in these circumstances. Poor tissue perfusion in a severely dehydrated patient impairs SC absorption of insulin and, initially, insulin should be given intramuscularly.

When ketoacidosis has resolved and the change to SC insulin is planned, the first SC injection should be given at an appropriate interval before stopping the infusion to allow sufficient time for the injected insulin to begin to be absorbed.

Potassium

Acidosis causes intracellular potassium to enter the extracellular compartment from which it is lost in urine and vomitus. Upon presentation, serum potassium concentrations may be normal, increased or, infrequently, decreased. Hypokalemia at presentation is related to prolonged duration of disease and persistent vomiting, whereas hyperkalemia primarily results from impaired renal function. Total body potassium deficits are of the order of 3–6 mmol/kg. Insulin promotes uptake of glucose and potassium by cells, and correction of acidosis promotes the return of potassium to the intracellular compartment. The serum potassium concentration may decrease abruptly, predisposing to cardiac arrhythmias. In the unusual patient who presents with hypokalemia, potassium replacement should be started immediately and insulin administration should be deferred. Otherwise, it should be started *after* initial volume expansion and concurrent with insulin administration. If the patient presents with hyperkalemia, potassium administration should be delayed until urine output has been documented and the potassium concentration has decreased to the upper limit of the normal range. The amount of potassium administered should be sufficient to maintain serum potassium levels in the normal range. The usual starting potassium concentration is 40 mmol/L and the maximum rate of intravenous potassium administration is 0.5 mmol/kg/h. Potassium administration should continue throughout the period of intravenous fluid therapy. Careful monitoring of the serum level and provision of adequate potassium is essential to prevent hypokalemia. The plasma potassium concentration should be rechecked every hour if the plasma concentration is outside the normal range. Potassium may be given as the chloride, acetate, or phosphate salt. Use of potassium acetate and potassium phosphate reduces the total amount of chloride administered and partially corrects the phosphate deficit.

Phosphate

Depletion of intracellular phosphate occurs in DKA and phosphate is lost as a result of osmotic diuresis. After starting therapy, plasma phosphate levels rapidly decrease as a result of urinary excretion and because insulin causes phosphate to reenter cells. Low serum phosphate levels have been associated with a variety of metabolic disturbances; however, the effects of hypophosphatemia on 2,3-diphosphoglycerate concentrations and on tissue oxygenation are especially relevant to DKA management. Although phosphate depletion persists for several days after resolution of DKA, prospective studies have not shown any significant clinical benefit from phosphate replacement. Nevertheless, serum phosphate should be monitored and severe hypophosphatemia treated with

potassium phosphate while serum calcium is carefully monitored to avoid phosphate-induced hypocalcemia.

Acidosis and Bicarbonate

Even severe acidosis is reversible by fluid and insulin replacement. Insulin stops synthesis of ketoacids and promotes ketone utilization. The metabolism of ketones results in the regeneration of bicarbonate and correction of acidemia. Treatment of hypovolemia improves tissue perfusion and restores renal function, thus increasing the excretion of organic acids and reverses any lactic acidosis.

In DKA, the anion gap is increased primarily because of a marked increase in the concentrations of the major ketone bodies, ß-OHB and acetoacetate (AcAc). Acetone is formed by spontaneous decarboxylation of AcAc. AcAc and acetone, but not ß-OHB, are measured by the commonly used clinical reagent strip or tablet methods based on the sodium nitroprusside reaction. At initial presentation with DKA, the concentration of ß-OHB is four- to tenfold higher than that of AcAc. With insulin therapy and correction of the acidosis, ß-OHB is reoxidized to AcAc, which is eventually metabolized. Blood ketone meters only measure ß-OHB.

Controlled trials of sodium bicarbonate in children and adults have not shown clinical benefit or any important difference in the rate of rise in the plasma bicarbonate concentration. There are physiologic reasons not to use bicarbonate. Its use may cause paradoxical CNS acidosis. Bicarbonate combines with H^+ and then dissociates to CO2 and H2O. The HCO3− diffuses poorly across the blood–brain barrier, whereas CO2 freely diffuses into the cerebrospinal fluid. Hence, the use of bicarbonate may worsen acidosis within the central nervous system while serum acidosis improves. Rapid correction of acidosis causes hypokalemia, may aggravate sodium load, and contributes to serum hypertonicity. It may, also, impair tissue oxygenation by increasing the affinity of hemoglobin for oxygen (i.e., shift the hemoglobin–oxygen dissociation curve to the left). Alkali therapy may increase hepatic ketone production and thus slow the rate of recovery from ketosis. The use of bicarbonate in children with DKA is associated with an increased risk for cerebral edema.

There may be selected patients, however, who may benefit from cautious alkali therapy, including patients with severe acidemia (arterial pH <6.9) in whom decreased cardiac contractility and peripheral vasodilatation can further impair tissue perfusion, and patients with life-threatening hyperkalemia. Administration of bicarbonate is indicated when acidosis is severe (arterial pH $\leq$ 6.9), and when hypotension, shock, or an arrhythmia is present: 1 to 2 mmol/kg sodium bicarbonate is infused over 2 h and the plasma bicarbonate level is rechecked. Bicarbonate should not be given as a bolus because this may precipitate an acute cardiac arrhythmia.

Clinical and Biochemical Monitoring

Initially, plasma glucose should be measured hourly. Thereafter, plasma glucose, serum electrolytes (and corrected sodium), pH, pCO2, TCO2, anion gap, calcium, and phosphorus should be measured every 2 h for the first 8 h, and then every 4 h until they are normal. The data must be carefully recorded on a flow sheet.

Investigating the Cause of Ketoacidosis

The management of DKA is incomplete until its cause has been identified and treated. An intercurrent infection is not usually the cause when the patient/family is properly educated in diabetes management, is receiving regular follow-up care, and has telephone access to a diabetes team. In established patients, omission of insulin is the most common cause. In patients who use an insulin pump, failure to take extra insulin with a pen or syringe when unrecognized failure of insulin delivery occurs (hyperglycemia with hyperketonemia or ketonuria) is a common cause of DKA. There is often an important psychosocial reason for insulin omission: an attempt to lose weight in an adolescent girl with an eating disorder, a means of escaping an intolerable or abusive home situation, clinical depression or other reason for the inability of the patient to manage his or her own diabetes unassisted. A psychiatric social worker or clinical psychologist should be consulted to help to identify the psychosocial reason(s) underlying the development of DKA.

Morbidity and Mortality from DKA in Children

DKA is the leading cause of acute morbidity and mortality in children with T1D. Reported mortality rates are in the range of 0.15–0.31%. In areas with sparse medical facilities the risk of dying from DKA is greater, and children may die before receiving treatment. Cerebral edema accounts for 57–87% of all deaths from DKA. The incidence of cerebral edema is approximately 0.5–1% and mortality rates are 21–25%. Significant morbidity occurs in

10–26% of survivors. Other causes of DKA-related morbidity and mortality include hypokalemia, hyperkalemia, hypoglycemia, sepsis, and other CNS complications such as thrombosis.

Cerebral edema typically occurs 4–12 h after commencement of treatment, but can occur before treatment has begun or at any time during treatment. Symptoms and signs are variable and include onset of headache, change in neurological status (restlessness, irritability, drowsiness, deterioration in level of consciousness), inappropriate slowing of the heart rate, and an increase in blood pressure. Cerebral edema is more common in children with severe DKA, new onset T1D, younger age, and longer duration of symptoms. The cause of cerebral edema remains poorly understood.

Treatment of Cerebral Edema

Treatment should be initiated as soon as the condition is suspected, and maintaining a high index of suspicion is the best safeguard for early intervention. Give intravenous mannitol (0.5–1 g/kg) and repeat if there is no response in 30 min. Hypertonic saline (3%), 5–10 mL/kg over 30 min, has been used as an alternative to mannitol and is recommended if there is no response to mannitol. Intubation may be necessary for the patient with impending respiratory failure, but aggressive hyperventilation (to a pCO_2 <22 mmHg [2.9 kPa]) has been associated with poor outcome and is not recommended. *After* treatment for cerebral edema has been started, a cranial CT scan should be obtained to rule out other possible intracerebral causes of neurologic deterioration (10% of cases), especially thrombosis or hemorrhage, which may benefit from specific therapy.

Side Effects of Treatment

Weight Gain

Intensively treated subjects in the DCCT had a considerably increased risk of becoming overweight and weight gain was greatest in individuals with higher baseline HbA1c levels. Weight gain is attributable to reduced glucosuria, to a reduction in daily energy expenditure, frequent symptomatic hypoglycemia necessitating consumption of carbohydrate to restore normoglycemia and, possibly, lack of amylin to regulate appetite.

Children and adolescents who adopt basal-bolus insulin therapy may be tempted to eat more liberally and increase their calorie consumption as they are no longer obliged to follow a regimented meal plan. Anticipatory counseling should candidly address this issue. The highly motivated patient can take advantage of the flexibility of a basal-bolus regimen to carefully balance insulin replacement with calorie intake to avoid obesity or even lose weight.

Local Effects of Insulin

Lipohypertrophy refers to the accumulation of excess adipose tissue at the sites of SC insulin injection. It is the most common cutaneous side effect of insulin administration, occurring in 25–50% of individuals with T1D. Rotation of injection sites usually prevents lipohypertrophy. Apart from its undesirable cosmetic appearance, lipohypertrophy causes erratic absorption of insulin.

Lipoatrophy and insulin allergy are much less common with use of human insulin preparations. Insulin allergy may result in local or systemic effects, with acute (redness, itching, burning, hives) or chronic reactions. Since the exclusive use of synthetic human insulins, severe reactions such as generalized urticaria and anaphylaxis are rare. Some patients are allergic to the diluent or excipients used in insulin preparations. In rare instances, insulin desensitization may be necessary and should be done in a supervised setting after preliminary skin testing.

Cellulitis or abscess may occur at the injection site, but is rare when patients use sterile disposable syringes and needles and employ basic principles of hygiene. Insulin pump therapy is associated with increased rates of cellulitis, abscess, and local scarring at the sites of subcutaneous cannula insertion. It is essential to replace the infusion set every 2–3 days and immediately remove a cannula if the site becomes red or painful.

Hypoglycemia

Hypoglycemia is the most common acute complication of the treatment of diabetes mellitus in children and adolescents and is the principal barrier to the pursuit and maintenance of near-normal glycemic control. Patients, parents, and the diabetes team have to continuously balance the risks of hypoglycemia against those of long-term hyperglycemia. Concern about nocturnal hypoglycemia causes more anxiety for some parents than any other aspect of diabetes, including the fear of long-term complications.

Biochemical hypoglycemia (with or without symptoms) is defined by the American Diabetes Association

as any PG $\leq$70 mg/dL (3.9 mmol/L), the level at which counterregulatory hormone responses engage and at which awareness of symptoms normally occurs in nondiabetic adults. In healthy 8–16-year-olds and in children and adolescents with T1D who have poor glycemic control, such responses may be triggered at higher PG levels. In nondiabetic children, the initial response to falling PG levels is suppression of insulin secretion and an abrupt increase in the circulating concentrations of glucagon and epinephrine, which acutely counteract the effects of insulin. Cortisol and growth hormone levels also rise; however, these hormones are less important in acutely counteracting the effects of insulin because their effects on glucose metabolism are delayed. Exogenously supplied insulin levels do not decrease and the glucagon response to hypoglycemia is lost early in the course of the disease. Consequently, patients with T1D depend on sympathoadrenal responses to prevent or correct hypoglycemia. Repeated mild hypoglycemia itself reduces epinephrine responses and symptomatic awareness of subsequent episodes of hypoglycemia. The repeated episodes of mild hypoglycemia that frequently occur in intensively treated patients blunt catecholamine responses to and symptom awareness of subsequent hypoglycemia. This phenomenon, referred to as hypoglycemia-associated autonomic failure (HAAF), significantly increases the risk of hypoglycemia. Catecholamine responses to hypoglycemia are impaired during sleep, another important reason most severe hypoglycemia episodes occur during the night.

Patients with T1D are susceptible to hypoglycemia because of errors related to insulin dosage, erratic eating behaviors, decreased food intake, unplanned exercise, and other factors. Long after strenuous exercise has ended, there is a sustained increase in insulin action on muscle and liver and blunting of the counterregulatory response to hypoglycemia. Exercise in the afternoon, therefore, increases the risk of hypoglycemia during the night. Collectively, these factors account for 50–85% of episodes of hypoglycemia in children and adolescents. After years of living with diabetes, some patients and/or their parents conduct their routine diabetes self-care practices without carefully considering the intricate interplay among insulin, food, and exercise.

Symptoms and Signs of Hypoglycemia

Symptoms and signs of hypoglycemia are caused by neuronal deprivation of glucose and are either autonomic (sweating, trembling, pallor, palpitations, tachycardia, apprehension) or neuroglycopenic (hunger, confusion, drowsiness, unusual behavior, speech difficulty, incoordination, seizures, and coma). Mood and behavioral changes are often the primary manifestation of hypoglycemia in young children. This has important implications for parent education on hypoglycemia.

Hypoglycemia is classified in terms of its severity as mild, moderate, or severe. Most episodes are mild. Cognitive impairment usually does not accompany mild hypoglycemia and older children are able to treat themselves. Mild symptoms abate within 15 min of treatment with rapidly absorbed carbohydrate. Moderate hypoglycemia has both neuroglycopenic as well as adrenergic symptoms, causes more protracted symptoms and may require a second treatment with oral carbohydrate. Young children typically require assistance with treatment because they are often confused and have impaired judgment; also, weakness and poor coordination may make self-treatment difficult. Severe hypoglycemia is characterized by unresponsiveness, unconsciousness, or convulsions and requires emergency treatment with parenteral glucagon or intravenous glucose.

Improved methods of replacing insulin (CSII and multiple dose regimens with insulin analogs) combined with education specifically informing subjects about hypoglycemia, behavioral educational approaches such as blood glucose awareness training, and intermittent CGM, may enable patients to achieve improved glycemic control with less risk of severe hypoglycemia than was previously possible. Insulin pump therapy is associated with fewer hypoglycemic events despite improved glycemic control. Rapid-acting insulin analogs decrease the frequency of hypoglycemia, and when compared to NPH combined with regular insulin, insulin glargine together with premeal insulin lispro decreases the incidence of nocturnal hypoglycemia in adolescents.

Treatment of Hypoglycemia

Except in preschool-age children, most episodes of symptomatic hypoglycemia are self-treated with rapidly absorbed carbohydrate, e.g., glucose tablets, glucose gel, fruit juice, soft drinks, candy, crackers, or milk. Glucose tablets raise blood glucose levels more rapidly than orange juice or milk, and the dosage is easily calibrated and is the treatment of choice for children old enough to chew and safely swallow large tablets. The recommended dose is 5–15 g of oral fast-acting carbohydrate or 0.3 g glucose per kilogram body weight. Blood glucose should be remeasured 15 min after treatment, and treatment should

be repeated if the blood glucose level does not exceed 3.9–4.4 mmol/L (70–80 mg/dL). The glycemic response to oral glucose usually lasts less than 2 h. Therefore, after treatment with oral glucose, unless a scheduled meal or snack is due within an hour, the patient should be given either a snack or a meal containing carbohydrate and protein.

Severe reactions (unresponsiveness, unconsciousness, or convulsions) require emergency treatment with parenteral glucagon (IM or SC). The usual recommended dose is 0.5 mg if less than 5 years and 1 mg if older than 5 years. Glucagon raises blood glucose levels within 5–15 min and usually relieves symptoms of hypoglycemia. The increase in blood glucose concentration after glucagon administration is sustained for at least 30 min. Because the glycemic response is transient after bolus administration of glucose, intravenous glucose infusion should be continued until the patient is able to swallow safely. Parents and school nurses need to be instructed on when and how to perform an injection of glucagon.

If severe hypoglycemia was prolonged and the patient had a seizure (hypoglycemic encephalopathy), complete recovery of mental and neurologic function may take many hours despite restoration of blood glucose levels to normal. Permanent hemiparesis or other neurologic sequelae are rare; however, the post-ictal period may be complicated by headache, lethargy, nausea, vomiting, and muscle ache.

Driving a Motor Vehicle

Driving is impaired at PG concentrations $\leq$3.3 mmol/L (60 mg/dL). The adolescent with diabetes who is learning to drive should be counseled to always measure his blood glucose level before driving and not to drive unless it is $>$4 mmol/L (70 mg/dL). The glove compartment should be stocked with a source of rapidly absorbed carbohydrate and nonperishable snacks. When symptoms of hypoglycemia are perceived, the diabetic driver should stop the car as soon as it is safe to do so.

Dead in Bed Syndrome

Sudden unexplained deaths during sleep are a rare occurrence in adolescents and young adults with T1D. Lethal cardiac arrhythmias triggered by hypoglycemia may be responsible for some cases; severe hypoglycemia related to recreational drug abuse may account for others.

Other Autoimmune Diseases Commonly Associated with Type 1a Diabetes

Autoimmune diseases affecting thyroid, upper small intestine, and adrenal are more common in patients with T1aD. Antithyroid autoantibodies can be detected in up to 20% of children and adolescents with T1aD, but only a minority of patients with thyroid autoimmunity develop hypothyroidism, whose earliest manifestation is an elevated TSH level. Annual measurement of TSH is recommended for patients with T1aD. Likewise, celiac disease occurs in up to 5–7% of patients with T1aD; weight loss or failure to gain weight, erratic blood glucose control, and unexpected hypoglycemic episodes should alert the clinician to perform a tissue transglutaminase determination, along with measurement of serum IgA, to screen for celiac disease. Definitive diagnosis requires endoscopy and a duodenal biopsy before initiating treatment with a gluten-free diet. Adrenal failure is the least common associated autoimmune disease and may be heralded by increasing frequency of unexplained hypoglycemia, reduction in insulin requirement, weight loss, asthenia, and pigmentation of skin and buccal mucosa. The combination of T1aD and either thyroid or adrenal autoimmunity or both is known as Schmidt syndrome.

Chronic Complications of Diabetes Mellitus

Management of diabetes mellitus in children requires eternal vigilance by the patient and family in monitoring blood glucose, delivery of insulin by manual or automated devices, and integration of food intake, with or without exercise, in an overall plan to achieve near-normal glycemia while avoiding hypoglycemia and DKA. Microvascular complications include retinopathy, nephropathy, and neuropathy that greatly contribute to increased morbidity and increased mortality of patients with diabetes. Macrovascular complications, primarily cardiovascular disease (CVD), are due to atherosclerotic obstruction of large blood vessels with their resultant cerebral, cardiac, and lower limb ischemia and infarction. These complications contribute markedly to the reduction in life expectancy among patients with both T1D and T2D. Estimates from the United States indicate that children diagnosed with diabetes mellitus at the age of 10 years will lose approximately 19 years of life expectancy when compared to nondiabetic controls. In Norway, the overall standardized mortality ratio (SMR) was fourfold higher in both

men and women with diabetes mellitus and the SMR was 20-fold higher for ischemic heart disease in those over 30 years of age. Acute metabolic complications such as DKA and hypoglycemia, dead in bed syndrome and violent deaths, were the most likely causes of death in those <30 years of age.

The DCCT conclusively demonstrated that glycemic control reduces the rate of microvascular complications; these beneficial effects persisted during follow-up of the original cohort in the EDIC study. Intensive treatment also reduced macrovascular disease in this cohort followed for up to 17 years. Compared with the conventional treatment group, those who received intensive treatment reduced their risk of retinopathy, neuropathy, or nephropathy by 50–60%, benefits which persisted for several years even when metabolic control as judged by HbA_1c had reverted to the level of the conventional treatment group. Thus, in the 17 year follow-up period of the EDIC study, the formerly intensive treatment group had 50–85% less retinopathy, nephropathy, and neuropathy and had less macrovascular disease. Also, improved metabolic control over the past 25 years has had a significant impact, reducing the rates of proliferative retinopathy and renal complications in a nationwide cohort. An impact on macrovascular disease and mortality is less apparent.

In addition to metabolic control, other factors significantly contribute to the risk of developing microvascular complications. A positive family history of microvascular complications increases risk for retinopathy and nephropathy reflecting that genetic factors contribute to risk. Puberty and duration of diabetes post puberty contribute to the risk; younger prepubertal children are somewhat protected. Poorly controlled diabetes causes an inflammatory stress response with deleterious effects on vascular endothelium. Hypertension, dyslipidemia, higher BMI, sedentary lifestyle, and smoking all contribute to increased risk of micro- and macrovascular complications. Cessation of smoking is of paramount importance and risk factors must be appropriately treated.

To identify and manage these vascular complications early so as to delay or prevent their progression, ISPAD has published screening guidelines. Screening for retinopathy and microalbuminuria should start at age 11 years in children who have had T1D for 2 years and from age 9 years in those who have had T1D for 5 years. Annual retinopathy screening examinations performed by a trained observer by means of dilated pupil ophthalmoscopy generally suffice. The presence of background retinopathy, defined as microaneurysms and dot-blot hemorrhages, requires at least biannual monitoring and more detailed evaluation to determine the extent of involvement by fundus photography, and/or fluorescein angiography. Depending on the extent of involvement, consideration may be given to using retinal laser therapy to reduce the likelihood of visual loss.

Annual screening for microalbuminuria is done by several methods described in the ISPAD guidelines. Because menstruation and exercise may confound results, screening should not be performed in a female who has recently menstruated or after vigorous exercise. Normal values for albumin excretion rate (AER) are <21 mcg/min corresponding to <30 mg/24 h. AER in the range 30–300 mg/24 h constitutes microalbuminuria; if present in two consecutive samples, the patient should be carefully monitored with repeated AER measurements at 6 monthly intervals to determine if microalbuminuria has regressed or is progressing. In the early stages, albuminuria may be transient, may appear in adolescence, and may regress thereafter without being progressive. Persistent or progressive microalbuminuria or albuminuria >300 mg/24 h (macroalbumuria) require expert care by a diabetologist and nephrologist working in tandem.

Fasting lipid screening should be performed in children with diabetes mellitus after the age of 12 or as early as 2 years of age if there is a family history of hyperlipidemia and/or early onset CVD in first-degree relatives. Persistent hypercholesterolemia above the 95th percentile for age, despite attempts to correct it by dietary means and optimizing metabolic control, requires referral for specialist care and consideration of the use of a statin.

Nonvascular Complications of Diabetes Mellitus

Infections

Patients with diabetes mellitus are generally not more prone to infectious disease when metabolic control is adequate, e.g., $HbA_1c \leq 8\%$. Two exceptions are mucocutaneous candidiasis and rhinocerebral mucormycosis. Candidiasis occurs primarily in the vulovaginal area and under the prepuce because candida thrives in high glucose concentrations. Rhinocerebral mucormycosis, a rare but life-threatening fungal infection, is more frequent in patients with diabetes especially during DKA. Presentation is with facial or ocular pain, nasal stuffiness, proptosis, chemosis, and necrosis of the nasal mucosa. Alertness to this occurrence and early intervention by surgical debridement and antifungal agents are the keys to a successful outcome.

Eating Disorders

Eating disorders are reported in 5–10% of women with T1D, a much higher prevalence than in control female populations, and may be a means to control weight gain. Omission of insulin is another method adolescent females with diabetes commonly use to control their weight. These disorders are associated with poor metabolic control and an early onset and high incidence of microvascular complications.

Connective Tissue and Joint Diseases

The glycation of various connective tissues such as joints, skin, and periarticular areas leads to stiffness and deformity, limited joint mobility, and stiff hand syndrome, features seen in poorly controlled diabetes mellitus. With improved metabolic control over the past 25 years, these connective tissue abnormalities are now seldom seen.

Psychiatric Disorders

Depression, suicidal ideation, and psychosis occur in patients with diabetes. It is not clear, however, if they do so at an increased rate as compared with the general population. These disorders may contribute to the increased mortality during the first 10 years of diabetes, as reported in a survey from Sweden where social and mental dysfunction and careless use of alcohol or drugs contributed to the increased mortality. By contrast, in a well-developed health care system, no clear excess death rate was caused by suicide or traffic accidents among young diabetic subjects in whom the chief causes of early death were DKA and hypoglycemia.

Concluding Remarks

Diabetes mellitus is a manifestation of failing insulin secretion compounded by resistance to its actions in various tissues. The remarkable increase in our understanding of the various forms of diabetes, the development of new insulin formulations and increasingly sophisticated devices to deliver them, and improved methods to monitor patients have made it possible to achieve better metabolic control and has markedly improved the prognosis for children with diabetes. The quickening pace of discovery suggests that many unanswered questions will be solved for the benefit of children affected by this complex disease.

388 Thyroid Disorders

Senthil Senniappan · Khalid Hussain

Introduction

Thyroid hormones play a critical role in prenatal and postnatal brain development, growth, and metabolism. These effects on growth, development, and metabolism are achieved by regulating protein synthesis, cell growth, and affecting metabolic pathways. Thyroid disorders are common in pediatric practice. Congenital hypothyroidism is the most common disorder of the thyroid gland in the childhood period and is a preventable cause of mental retardation. A goiter is also a common clinical presentation in the childhood period, and worldwide, the most common cause for goiter is iodine deficiency. Graves' disease and Hashimoto's thyroiditis make up the autoimmune thyroid diseases and important causes of hyperthyroidism and hypothyroidism, respectively. Transient hypothyroxinemia is the most common thyroid dysfunction in preterm infants and is defined by temporary low levels of T4, T3, and normal or low TSH. This chapter provides a clinical overview of the common thyroid disorders.

Thyroid Anatomy and Embryology

The thyroid gland is located in the neck and consists of two lobes (left and right) which are connected by the isthmus. It lies against and around the larynx and trachea, reaching posteriorly the esophagus and carotid sheath. Microscopically, the thyroid is composed of spherical follicles, each composed of a single layer of follicular cells surrounding a lumen filled with colloid (mostly thyroglobulin). Embryologically, the thyroid gland develops from the fusion of a medial outpouching from the floor of the primitive pharynx (which will give rise to the precursor of the thyroxine (T4)-producing follicular cells) and bilateral evaginations of the fourth pharyngeal pouch (which will form the parafollicular or calcitonin (C)-secreting cells).

A number of key transcription factors (such as *NKX2.1*, *FOXE1*, *and PAX8*) are involved in regulating the development and growth of the thyroid gland. As the developing thyroid gland moves caudally, the pharyngeal portion of the gland contracts to form a narrow stalk (thyroglossal duct). A thyroglossal cyst can develop anywhere along a thyroglossal duct, and it is usually located as a midline neck lump (in the region of the hyoid bone) that is typically painless, smooth, and cystic.

In humans, the development of the thyroid gland is complete by 10–12 weeks of gestation. At this gestational age, follicle precursors can be seen, iodine binding can be identified, and thyroglobulin detected in follicular spaces. T4 and triiodothyronine (T3) are measurable in fetal serum by 11–12 weeks of gestational age. As gestational age advances, there is a progressive increase in T4 and T3 as well as serum thyroxine-binding globulin (TBG). Whereas the TBG and total T4 levels rise throughout gestation, the concentrations of free T4, and TSH rise until 31–34 weeks, declining thereafter to term. The progressive increase of the free T4 concentration allows maturation of the hypothalamic-pituitary-thyroid axis.

The Hypothalamic-Pituitary-Thyroid Axis

Thyroid gland function is dependent on the proper development and maturation of the hypothalamus and pituitary gland. Levels of thyroid hormones in serum are tightly regulated by the hypothalamic-pituitary-thyroid axis. Hypothalamic thyrotropin-releasing hormone (TRH) is secreted mainly from the paraventricular nucleus in the hypothalamus and reaches the median eminence through axonal transport. TRH is then carried via the hypothalamic portal vein to thyrotrophs, which produce thyroid-stimulating hormone (TSH), where it binds to TRH receptors and stimulates the genes that express the TSH β subunits. Apart from these thyrotropic effects, TRH also regulates the conjugation of the TSH α and β chains and glycosylation of the TSH molecule to control its biological activity.

Mature TSH is secreted from the pituitary gland and reaches the thyroid gland, where it stimulates thyroid hormone production and release. TRH and TSH start being secreted from the fetal hypothalamus and pituitary respectively at 18–20 weeks of gestation. Fetal production of T_4 reaches a clinically significant level at 18–20 weeks whereas fetal T_3 remains low (less than 15 ng/dL) until

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_388,

30 weeks of gestation, and increases to 50 ng/dL at term. The negative feedback control of thyroid hormone synthesis and secretion is established at about 20 weeks of gestation.

Physiology of Thyroid Hormones

The thyroid gland uses tyrosine and iodine to manufacture T4 and T3. The iodine comes from the diet as iodide and gets converted in the gut to iodide which is then rapidly absorbed. Iodide is taken into the thyroid follicular cells by an active transport system (against a concentration gradient) and then oxidized to iodine by thyroid peroxidase.

The incorporation of iodine into thyroglobulin for the production of thyroid hormone (organification) occurs when iodine is attached to tyrosine molecules located on thyroglobulin, forming monoiodotyrosine (MIT) and diiodotyrosine (DIT). The coupling of two molecules of DIT forms tetraiodothyronine (T4). The coupling of one molecule of MIT and one molecule of DIT forms T3.

Both T4 and T3 are composed of a phenyl ring attached via an ether linkage to a tyrosine molecule. Both have two iodine atoms on their tyrosine (inner) ring. They differ in that T4 has two iodine atoms on its phenyl (outer) ring, whereas T3 has only one. The compound formed if an iodine atom is removed from the inner ring of T4 is 3, 3′, 5′-triiodothyronine (reverse T3, rT3), which has no biological activity. Thyroglobulin, with T4 and T3 attached, is stored in the follicular lumen. TSH activates the enzymes needed to cleave T4 and T3 from thyroglobulin. In most situations, T4 is the primary hormone produced by and released from the thyroid gland. *Figure 388.1* outlines the physiology of thyroid hormones.

Approximately 20–30% of T3 is released by the thyroid gland, the remainder being produced by monodeiodination (removal of the iodine from carbon atom number five) of T4 in peripheral tissues. T3 is the primary mediator of the biologic effects of thyroid hormone and does so by interacting with a specific nuclear receptor. T3 has a half-life of 2.5 days whereas T4 has a half-life of 6 days.

Serum concentrations of T4 and T3 are maintained by a negative feedback loop involving T3-inhibition of hypothalamic thyrotropin-releasing hormone (TRH) and pituitary thyroid-stimulating hormone (TSH) secretion. TSH stimulates the secretion of T4 and T3 by stimulating multiple steps involved in the production of thyroid hormone biosynthesis. Thyroid hormone receptors bind to enhancer elements in the promoters of target genes, and can regulate both positive and negative transcription. Cellular actions of thyroid hormone may be initiated within the cell nucleus, at the plasma membrane, and in the cytoplasm.

Fetal and Neonatal Thyroid Function

The fetal hypothalamic-pituitary-thyroid axis develops independently of the maternal axis, but it is dependent on the maternal-placental system for adequate supply of iodide substrate. This iodide is supplied by direct transfer

of maternal plasma iodide and by placental deiodination of T4. In addition, although placental transport of iodothyronines is limited, significant maternal-fetal transfer of T4 occurs, accounting for approximately 30% of the average 10 μg/dL serum-T4 concentration in fetal-cord blood at term. Current information suggests that this maternal contribution to the fetal-T4 levels is important for normal fetal maturation, particularly of the central nervous system. In fetuses with hypothyroidism, maternal T4 provides (possibly by alterations in iodothyronine metabolism) sufficient T3 to prevent irreversible brain damage in most cases. Combined maternal-fetal hypothyroxinemia can lead to irreversible fetal central nervous system damage. At the time of birth, cord blood T4 and free T4 are higher than the respective maternal T4 levels. There is a surge of TSH about 90 min after birth possibly related to the exposure to the extrauterine environment. However by day 3, normal T4 levels are reached.

Hypothyroidism

Introduction

The most common cause of hypothyroidism in children is congenital hypothyroidism. Transient hypothyroxinemia

is the most common thyroid dysfunction observed in preterm infants. Hashimoto's thyroiditis accounts for most of the acquired juvenile hypothyroidism cases and is a common cause of nontoxic goiter. Secondary hypothyroidism occurs when the hypothalamus produces insufficient TRH or the pituitary produces insufficient TSH. *Table 388.1* summarizes the causes of hypothyroidism.

Congenital Hypothyroidism

Congenital hypothyroidism (CH) is the most common endocrine disorder observed in newborn infants. The incidence figures vary between 1 in 2,500 and 1 in 3,500. The typical biochemical finding is an elevated TSH level with low T4 levels except in patients with abnormalities in the hypothalamic-pituitary axis. The causes of CH can be classified into two major subgroups. Approximately 85% of the cases are due to disturbances in the gland's organogenesis, which result in a thyroid gland that is absent (thyroid agenesis or athyreosis), hypoplastic (thyroid hypoplasia), or located in an unusual position (ectopic thyroid). All these entities are grouped under the term "thyroid dysgenesis" (TD). The remaining 15% of cases are due to abnormalities in the enzymatic pathways involved in thyroid hormone synthesis (dyshormonogenesis).

Most cases of TD are sporadic where the underlying cause is not known and there is a clear female preponderance. In some rare cases, defects in several transcription factors have been identified. For example, mutations in the transcription factor *NKX*2.1 are associated with CH and neonatal respiratory distress, ataxia, and developmental delay. Similarly, mutations in *FOXE*1 (*TTF*2) have been found in siblings with CH and combination of thyroid agenesis, cleft palate, spiky hair, and choanal atresia. Finally, mutations in *PAX*8 have been reported in some patients with sporadic thyroid dysgenesis.

A number of enzymatic defects lead to CH. These inborn errors of thyroid hormonogenesis are commonly associated with an autosomal recessive form of inheritance, consistent with a single gene abnormality. These include defects in the genes for the TSH receptor (*TSHR*), the sodium–iodide symporter (*NIS*), thyroid peroxidase (*TPO*), dual oxidase (DUOX) 2, thyroglobulin (*Tg*), and iodotyrosine deiodinase (*DEHAL1*). Pendred syndrome is now known to be caused by mutations in the pendrin gene (*PDS*, now called *SLC26A*4), which encodes a sulfate transporter of iodide on the apical surface of the thyroid follicular cell as well as the cochlea. Mutations in this gene have also been found to be an important genetic cause of isolated sensorineural deafness. All of the inborn errors of thyroid hormonogenesis except decreased TSH responsiveness are associated with a normally placed ("eutopic") thyroid gland that may be increased in size at birth.

Screening for Congenital Hypothyroidism

The introduction of neonatal screening programs for congenital hypothyroidism in the 1970s is now regarded as a highly cost-effective strategy to detect the commonest congenital metabolic disorder seen in the newborn. There is no doubt that early diagnosis and treatment of the condition has led to the disappearance of mental retardation, which was the most dramatic long-term sequel of congenital hypothyroidism. Screening for CH involves measurement of T4 and/or TSH from a blood sample collected on filter paper on day 1–4 of life. In parts of the USA and Holland, T4 is measured initially and then TSH is checked on the same blood spot in those specimens in which the T4 concentration is low. Using T4 as a screening method, primary hypothyroidism, secondary or tertiary hypothyroidism, babies with a low serum T4 level but delayed rise in the TSH concentration, TBG deficiency, and hyperthyroxinemia can be identified. However, this method can miss subclinical hypothyroidism.

In many parts of Europe, the screening approach involves measuring TSH as a first step. The T4 concentration is measured in the initial blood spot in all babies in whom the screening TSH is high. Using a TSH screening approach, overt and subclinical hypothyroidism will be identified, but secondary or tertiary hypothyroidism, a delayed TSH rise, TBG deficiency, and hyperthyroxinemia can be missed.

Clinical Presentation of CH

Screening for congenital hypothyroidism was introduced in the early 1970s and now is routine in most of the industrialized world. Neonatal thyroid screening is highly successful in the early diagnosis and the improvement of developmental prognosis in the hypothyroid neonate. Careful management of detected infants is essential, and it is important to remember that some infants (possibly up to 10% of the total) may escape detection in screening programs. A high index of suspicion is therefore necessary to assure early clinical detection and treatment of these infants. As cases can be missed, so it is important to be aware of the early symptoms and signs of hypothyroidism.

Infants born with congenital hypothyroidism may show no symptoms, or may display mild effects that often go unrecognized as a problem. The typical symptoms include hypothermia, constipation, jaundice, poor feeding, hoarse cry, lethargy, somnolence, macroglossia, and hypoactivity.

On examination, there may be presence of umbilical hernia, edema of genitals and extremities, cardiomegaly, bradycardia, goiter, and asymptomatic pericardial effusion. Both anterior and posterior fontanelles tend to be wide-open with coarse facies as well as hypertelorism, depressed nasal bridge, puffiness of eyes, open mouth, and a short neck. The skin may appear yellow due to carotenemia and the hairline reaches far down on forehead. The infant's voice will be hoarse and child might have hypotonia. As the child grows, infantile proportions are maintained and child may have disproportionate short stature. *Table 388.2* summarizes the symptoms and signs of hypothyroidism.

Those infants identified to have abnormal thyroid function tests on the screening program must have repeated laboratory serum measurements of T4/TSH as soon as possible (preferably within 24 h). The diagnosis of neonatal hypothyroidism is confirmed by the demonstration of a decreased concentration of T4 (<6.5 μg/dL; 3.7 nmol/L) and an elevated TSH level (>20 mU/L after 1 day of life) in serum.

The next stage of investigation will involve arranging a radionuclide scan. Technetium^{99m} (^{99m}Tc) Pertechnetate and Iodine^{123} are both used and both have advantages and disadvantages. ^{99m}Tc is more easily available and is cheaper. Iodine^{123}, if available, is usually preferred because of the greater sensitivity and because Iodine^{123}, unlike pertechnetate, is organified. These radionuclide scans provide information about the location, size, and trapping ability of the thyroid gland; ectopic thyroid glands, frequently sublingual, may be located anywhere along the pathway of thyroid descent from the foramen cecum to the anterior mediastinum. Thyroid scintigraphy may provide insights into clinical and genetic correlates in CH.

The use of ultrasound in CH has become an increasingly popular alternative to thyroid scintigraphy to provide information about the size and location of the thyroid gland. Ultrasound appears to be somewhat less sensitive than a radionuclide scan in detecting ectopic thyroid tissue and does not provide information about function.

Table 388.2
Clinical manifestations of hypothyroidism

Neonate	
Symptoms	*Signs*
Poor feeding	Lethargy
Prolonged neonatal jaundice	Jaundice
Weak and hoarse cry	Macroglossia
Sleepiness	Coarse facies
Constipation	Goiter
Failure to thrive	Mottled skin
	Umbilical hernia
	Distended abdomen
	Hypothermia
	Edema of the extremities
Children and adolescents	
Symptoms	*Signs*
Poor growth	Goiter
Excessive weight gain	Short stature
Constipation	Widely patent fontanelle
Cold intolerance	Myxedematous facies
Menstrual irregularity	Obesity
Poor school performance	Dry skin
	Pallor
Delayed puberty (rarely precocious puberty)	Delayed dentition
	Delayed relaxation phase of deep tendon reflexes
Mental retardation	Pseudohypertrophy of muscles

Treatment of CH

The importance of thyroid hormone to brain growth and development is demonstrated by comparing treated and untreated children with congenital hypothyroidism. Thyroid hormone is necessary for normal brain growth and myelination and for normal neuronal connections. The most critical period for the effect of thyroid hormone on brain development is the first few months of life.

The overall goals of treatment are to assure normal growth and by restoring the serum T4 concentration rapidly to the normal range followed by continued clinical and biochemical euthyroidism. Therefore, once the diagnosis of CH is confirmed, treatment with L-thyroxine should be commenced as soon as possible. Parents will need to be counseled with regard to the diagnosis and the importance of compliance. The prognosis will be good in most babies if therapy is started early and is adequate. Oral T4 is the treatment of choice. Although T3 is the more biologically active hormone, the majority of brain T3 is derived from local deiodination of T4; thus, it is not necessary to use T3. The aim of replacement therapy is to normalize the serum T4 level as quickly as possible and an initial dosage of 10–15 μg/kg is generally recommended. Initial T4 dose and faster time to normalization of thyroid function are important for optimal neurodevelopmental

outcome. In severe CH, it is important to choose an initial dose at the higher end of the recommended range to achieve these goals. Hence, some studies have suggested using an even higher initial dose (12–17 μg/kg).

Thyroid hormone tablets should be crushed and administered with juice or formula, but care should be taken that all of the medicine has been swallowed. Thyroid hormone should not be given with substances that interfere with its absorption, such as iron, soy, or fiber. Recently an oral thyroid hormone solution has become available (Evotrox). Evotrox Oral Solution contains the active ingredient levothyroxine sodium and is indicated for hypothyroidism (congenital or acquired) and also for diffuse, nontoxic goiter or Hashimoto's thyroiditis and thyroid carcinoma.

Transient Hypothyroxinemia in Premature Infants

Transient hypothyroxinemia is the most common thyroid dysfunction in preterm infants and is defined by temporary low levels of T4, T3, and normal or low TSH. Low T4 levels in preterm infants are associated with persistent neurodevelopmental deficits in cognitive and motor function. The etiology of transient hypothyroxinemia is complex. There are significant contributions from the withdrawal of maternal-placental thyroxine transfer, hypothalamic-pituitary-thyroid immaturity, developmental constraints on the synthesis, and peripheral metabolism of iodothyronines and iodine deficiency. Observational studies have shown an association between transient hypothyroxinemia and abnormal neurodevelopmental outcome, suggesting that thyroid hormone therapy might prevent this morbidity. However, several large Cochrane reviews do not support the routine use of thyroid hormones in preterm infants to reduce neonatal mortality, improve neurodevelopmental outcome, or to reduce the severity of respiratory distress syndrome.

Primary Hypothyroidism in Infants and Adolescents

Autoimmune thyroid diseases are characterized by the presence of antibodies directed toward different components of the thyroid gland. Graves' disease and Hashimoto's thyroiditis make up the autoimmune thyroid diseases. Autoimmune thyroid diseases arise due to complex interactions between environmental and genetic factors. Three gene regions consistently associated with autoimmune diseases include the Human Leucocyte Antigen (HLA) region, CTLA4, and PTPN22, which represent general autoimmune risk loci and encode molecules vital for correct immune system function.

Hashimoto's thyroiditis accounts for most of the acquired juvenile hypothyroidism cases and is a common cause of nontoxic goiter. Thyroglobulin or microsomal antibodies are present in serum of virtually all individuals. Asymptomatic goiter is the most common presentation though subclinical hypothyroidism and growth failure are frequently seen. Thyroid function is variable depending on the degree of thyroid destruction.

Children typically present with a goiter and possibly growth failure. In the early stages of the disease, patients may be hyperthyroid but will eventually develop hypothyroidism. Once hypothyroid, they may have symptoms of cold intolerance, constipation, dry skin, poor memory, and bradycardia. Hypothyroid children have delayed puberty, but in severe long-standing hypothyroidism, sexual precocity can also occur, and in some cases, galactorrhea has been reported. In boys, testicular enlargement may be found with normal gonadotropin levels. The extremely elevated TSH in the serum can cross-react with the follicle-stimulating hormone (FSH) receptor, leading to the syndrome of "pseudopuberty" in hypothyroid patients. Serum prolactin levels are also elevated due to the elevated TRH which stimulates prolactin as well as TSH release.

If the hypothyroidism is severe and long standing, immature facies with an underdeveloped nasal bridge and immature body proportions (increased upper-lower body ratio) may be noted. Dental and skeletal maturation are delayed, the latter often significantly.

Radiologically, in children with long-standing severe hypothyroidism, there may be enlargement of the sella turcica due to hyperplasia of the thyrotrophs. Hypothyroid children have an increased incidence of slipped femoral capital epiphyses. The combination of severe hypothyroidism and muscular hypertrophy is known as Kocher–Debre–Semelaigne syndrome, giving the child a "Herculian" appearance.

Laboratory Investigations

Serum T4 and TSH should be measured in patients suspected of primary hypothyroidism. An elevated serum TSH with low or undetectable serum T4 will support the diagnosis. TRH testing has been used in the past to distinguish a hypothalamic versus pituitary origin of the hypothyroidism; in hypothalamic hypothyroidism, there tends to be a delayed peak in TSH secretion (60–90

min versus the normal maximal response at 15–30 min), whereas in hypopituitarism, there usually is little or no TSH response. However, this test is not reliable in the pediatric population.

Treatment

Replacement therapy with thyroxine should be commenced as soon as possible. In those children with long-standing primary hypothyroidism, the lowest dose possible of thyroxine should be commenced and gradually titrated if no side effects develop. If normalization occurs too rapidly, then there may be side effects (deterioration in school performance, short attention span, hyperactivity, insomnia, and behavior difficulties). Pseudotumor cerebri is a rare side effect of replacement therapy.

Secondary Hypothyroidism

Secondary hypothyroidism occurs when the hypothalamus produces insufficient TRH or the pituitary produces insufficient TSH. Sometimes, deficient TSH secretion due to deficient TRH secretion is termed tertiary hypothyroidism. Patients with secondary hypothyroidism typically will present with multiple other pituitary hormone deficiencies. The causes of secondary hypothyroidism include traumatic brain injury, subarachnoid hemorrhage, hypothalamic-pituitary tumors, Sheehan syndrome, and mutations in genes involved in regulating the development (such as TRHR, POU1F1, PROP1, HESX1, SOX3, LHX3, LHX4, and TSHB) of the hypothalamic-pituitary region.

Hyperthyroidism

Introduction

Hyperthyroidism can occur in the neonatal period and is usually due to an autoimmune basis (associated with maternal Graves' disease) or rarely due to mutations in the stimulatory G protein. Graves' disease is an important cause of hyperthyroidism and is caused by TSH receptor antibodies that mimic the action of TSH with stimulation of adenyl cyclase, thyroid hormonogenesis, and growth.

Neonatal Hyperthyroidism

Neonatal hyperthyroidism occurs in two forms. An autoimmune form (transient) is associated with maternal Graves' disease, resulting from transplacental passage of maternal thyroid-stimulating antibodies. A non-autoimmune form occurs due to mutations in the stimulatory G protein (McCune–Albright syndrome) or the thyrotropin receptor (TSHR), causing constitutive activation of intracellular signaling cascades. About 1–2% of infants born to mothers with Graves' disease or Hashimoto's thyroiditis develop neonatal hyperthyroidism.

Fetal hyperthyroidism may be associated with intrauterine growth retardation, nonimmune fetal hydrops, craniosynostosis, and intrauterine death. Features of this condition in the neonate include hyperkinesis, diarrhea, poor weight gain, vomiting, ophthalmopathy, cardiac failure and arrhythmias, systemic and pulmonary hypertension, hepatosplenomegaly, jaundice, hyperviscosity syndrome, thrombocytopenia, and craniosynostosis.

The diagnosis of hyperthyroidism is confirmed by the demonstration of an increased concentration of circulating T4 (and free T4, and T3, if possible) accompanied by a suppressed TSH level in neonatal or fetal blood. Demonstration in the baby or mother of a high titer of TSH receptor antibodies will confirm the etiology of the hyperthyroidism.

The time course of neonatal hyperthyroidism depends on etiology; remission by 20 weeks is most common in neonatal Graves' disease.

Treatment of hyperthyroidism in neonates may require the use of antithyroid drugs, beta-adrenergic receptor blocking agents, iodine, or iodinated contrast agents, and at times, with glucocorticoids and digoxin. Nonremitting causes of neonatal hyperthyroidism may even require ablative treatments such as thyroidectomy.

Graves' Disease

Graves' disease is another type of autoimmune thyroid disease with female to male ratio being 6–8:1. Graves' disease is caused by TSH receptor antibodies that mimic the action of TSH with stimulation of adenyl cyclase and thyroid hormonogenesis and growth. Although it can occur at any age, it is most common in adolescence. Prepubertal children tend to have more severe disease, to require longer medical therapy, and to achieve a lower rate of remission as compared with pubertal children. This appears to be particularly true in children who present at <5 years of age. Patients with Graves' disease have an increased risk of developing other autoimmune diseases such as diabetes mellitus, Addison's disease, vitiligo, systemic lupus erythematosus, rheumatoid arthritis, myasthenia gravis, periodic paralysis, idiopathic

thrombocytopenia purpura, and pernicious anemia. There is an increased risk of Graves' disease in children with Down syndrome (trisomy 21).

Clinical Presentation of Graves' Disease

Patients with Graves' present with some degree of thyroid enlargement, and most have symptoms and signs of excessive thyroid activity (tremors, inability to fall asleep, weight loss despite an increased appetite, proximal muscle weakness, heat intolerance and tachycardia). There may also be a shortened attention span, and emotional lability may lead to behavioral and school difficulties. Some patients complain of polyuria and of nocturia, the result of an increased glomerular filtration rate. Acceleration in linear growth may occur, often accompanied by advancement in skeletal maturation (bone age).

Physical examination reveals a diffusely enlarged, soft or "fleshy" thyroid gland, smooth skin and fine hair texture, excessive activity, and a fine tremor of the tongue and fingers. A thyroid bruit may be audible. In contrast, the finding of a thyroid nodule suggests the possibility of a toxic adenoma. The hands are often warm and moist, and on cardiovascular examination, a tachycardia, a wide pulse pressure, and a hyperactive precordium may be found. Café au lait spots, particularly in association with precocious puberty, on the other hand, suggests a possible diagnosis of McCune–Albright syndrome while if a goiter is absent, thyrotoxicosis factitia should be considered. The ophthalmopathy characteristic of Graves' disease in adults is considerably less common in children, although a stare and mild proptosis are observed frequently.

Thyroid storm, also referred to as thyrotoxic crisis, is an acute, life-threatening, hypermetabolic state induced by excessive release of thyroid hormones in individuals with thyrotoxicosis (Graves' disease). Thyroid storm may lead to life-threatening heart, liver, or kidney failure. Thyroid storm begins suddenly and may be caused by a stressful event. Thyroid storm may be the initial presentation of thyrotoxicosis in undiagnosed children, particularly in neonates. The clinical presentation includes fever, tachycardia, hypertension, and neurological and gastrointestinal abnormalities. Hypertension may be followed by congestive heart failure that is associated with hypotension and shock. Because thyroid storm is almost invariably fatal if left untreated, rapid diagnosis and aggressive treatment are critical.

The clinical diagnosis of hyperthyroidism is confirmed by the finding of increased concentrations of circulating thyroid hormones (T4 and T3). In hyperthyroidism, the circulating T3 concentration frequently is elevated out of proportion to the T4 because, like TSH, TSH receptor antibodies stimulate increased T4-to-T3 conversion. The diagnosis is confirmed by the demonstration of TSH receptor antibodies in serum.

Therapy

There are three possible forms of therapy (medical therapy, radioactive iodine, or surgery). The three therapeutic options should be individualized and discussed with the patient and his/her family. Each approach has its advantages and disadvantages with respect to efficacy, both short- and long-term complications, the time required to control the hyperthyroidism, and the requirement for compliance.

Medical Therapy

The thiouracil compounds propylthiouracil, methimazole, and carbimazole exert their antithyroid effect by inhibiting the organification of iodine and the coupling of iodotyrosine residues on the thyroglobulin molecule to T3 and T4.

Radioactive Iodine

Definitive therapy with either medical (radioactive iodine) or surgical thyroid ablation is usually reserved for patients who have failed drug therapy, developed a toxic drug reaction, or are noncompliant. In recent years, however, radioactive iodine is being favored increasingly, even as the initial approach to therapy. The advantages are the relative ease of administration, the reduced need for medical follow-up, and the lack of demonstrable long-term adverse effects. Radioactive iodine therapy should be used with caution in children <10 years of age and particularly in those <5 years of age because of the increased susceptibility of the thyroid gland in the young to the proliferative effects of ionizing radiation.

Surgery, the third therapeutic modality, is performed less frequently now than in the past. An advantage of this form of therapy is the rapid resolution of the hyperthyroidism. Near-total thyroidectomy is the procedure of choice in order to minimize the risk of recurrence. Surgery usually is reserved for patients who have failed medical management, who have a markedly enlarged thyroid, who refuse radioactive iodine therapy, and for the rare patient with significant ophthalmopathy in whom radioactive iodine therapy is contraindicated. The most common potential complication is transient hypocalcemia which occurs in approximately 10% of patients. Other, less

common potential complications are keloid formation (2.8%), recurrent laryngeal nerve paralysis (2%), and hypoparathyroidism (2%).

The Approach to a Child with Goiter

Introduction

The term "goiter" simply refers to the abnormal enlargement of the thyroid gland. Goiter may extend into the retrosternal space, with or without substantial anterior enlargement. Because of the anatomic relationship of the thyroid gland to the trachea, larynx, superior and inferior laryngeal nerves, and esophagus, abnormal growth may cause a variety of compressive syndromes. The presence of goiter does not necessarily mean that the thyroid gland is malfunctioning. Goiter can be associated with hyperthyroidism, hypothyroidism, or euthyroidism.

Individuals with multinodular goiters have one or more nodules within the gland which cause thyroid enlargement. This is often detected as a nodular feeling gland on physical exam. Patients can present with a single large nodule with smaller nodules in the gland, or may show as multiple nodules when first detected. Multinodular goiter and solitary thyroid nodule are rare in the pediatric age group: Both conditions can reveal a malignant lesion. In this case, a total thyroidectomy should be performed. Long-term outcome is excellent with an exception for medullary carcinoma which can be part of a multiple endocrine neoplasia (MEN type 2 A).

Causes of Goiter

Worldwide, the most common cause for goiter is iodine deficiency. In countries that use iodized salt, Hashimoto's thyroiditis is the most common cause and Graves' disease can also cause goiter. The different etiologic mechanisms that can cause a goiter are shown in *Table 388.3*.

Examination of the goiter is best performed with the patient upright, sitting, or standing. Inspection from the side may better outline the thyroid profile, as shown below. Asking the patient to take a sip of water facilitates inspection. The thyroid gland should move upon swallowing. A retrosternal goiter may not be evident on physical examination. Palpation of the goiter is performed either facing the patient or from behind the patient, with the neck relaxed and not hyperextended.

A firm rubbery thyroid gland suggests Hashimoto thyroiditis, and a hard thyroid gland suggests malignancy or Riedel struma. Multiple nodules may suggest a multinodular goiter or Hashimoto thyroiditis. A solitary hard nodule suggests malignancy, whereas a solitary firm nodule may be a thyroid cyst. Auscultation of a soft bruit over the inferior thyroidal artery may be appreciated in a toxic goiter. Palpation of a toxic goiter may reveal a thrill in the profoundly hyperthyroid patient.

Table 388.3
Causes of goiter

Iodine deficiency
Puberty
Autoimmune thyroiditis – Hashimoto's, postpartum thyroiditis, Graves' disease
Excess iodine
Goitrogens (including drugs such as lithium and amiodarone)
Stimulation of TSH receptors by TSH from pituitary tumors, pituitary thyroid hormone resistance, gonadotropins, and/or thyroid-stimulating immunoglobulins
Inborn errors of metabolism causing defects in biosynthesis of thyroid hormones
Exposure to radiation
Thyroid hormone resistance
Subacute thyroiditis (de Quervain thyroiditis)
Silent thyroiditis
Riedel thyroiditis
Granulomatous disease

A toxic goiter is associated with hyperthyroidism (diffuse toxic goiter as in Graves' disease, toxic multinodular goiter, and toxic adenoma (Plummer disease)). A nontoxic goiter is associated with hypothyroidism or euthyroidism. It may be diffuse or multinodular, but a diffuse goiter often evolves into a nodular goiter. Examination of the thyroid may not reveal small or posterior nodules. Examples of nontoxic goiters include chronic lymphocytic thyroiditis (Hashimoto's disease), goiter identified in early Graves' disease, endemic goiter, sporadic goiter, congenital goiter, and physiologic goiter that occurs during puberty. Autonomously functioning nodules may present with inability to palpate the contralateral lobe. Unilobar agenesis may also present like a single thyroid nodule with hyperplasia of the remaining lobe.

Thyroid Nodules

Thyroid nodules are common in clinical practice. They may be solitary within a "normal" thyroid gland or

dominant within a multinodular goiter. The incidence of thyroid nodules has been on the rise in recent decades, mainly due to the wider use of neck imaging. Therefore, the incidental finding of a thyroid nodule in an asymptomatic patient is not rare. The differential diagnosis of a thyroid nodule is crucial, as malignancy necessitates surgery, while strict patient follow-up is necessary in the case of benignity. Fine-Needle Aspiration biopsy is considered to be the "gold standard" in the selection of patients for surgery. Ultrasonography (US) can be used to determine changes in the size of nodules during follow-up or to detect recurrent lesions in patients suspected for thyroid malignancy, although there are no specific US findings that suggest malignancy. Surgery is mandatory in cytologically malignant nodules or in cases suspicious for malignancy. The definite diagnosis and consequent therapy is based on the histological findings after surgery.

Cancer of the Thyroid Gland

Thyroid malignancy is rare in children. More than 50% of isolated thyroid nodules are cysts or benign adenomas. The most common types of thyroid cancer are papillary and follicular carcinomas. Anaplastic carcinoma, medullary thyroid carcinoma, lymphoma, and metastatic tumors include the rare forms. Genetic factors and irradiation are the major risk factors. Girls are affected twice more than the boys. The clinical manifestations include painless rapidly enlarging thyroid nodule, hoarseness of voice, dysphagia, and lymphadenopathy. The lungs are the most common site of metastases outside the neck, while the other sites include mediastinum, long bones, skull, and axilla. Nearly all patients are clinically euthyroid. Ultrasound is useful in identifying the cystic lesions, which are nearly always benign. Radioisotope scan is indicated for non-cystic lesions to identify cold, warm, or hot nodules.

Fine-needle aspiration biopsy is the most definitive diagnostic test. Surgery includes removal of the affected lobe followed by total thyroidectomy if frozen sections confirm malignancy. Radioactive iodine treatment is used for patients with metastatic disease. Postoperatively, adequate thyroxine therapy is essential to suppress TSH to avoid tumor regrowth. Regular follow-up including periodic measurements of thyroglobulin and ultrasound is useful to detect tumor recurrence. The prognosis in the papillary and follicular carcinomas is very good, while aggressive treatment is necessary for anaplastic carcinoma in view of poor prognosis.

Medullary thyroid carcinoma arises from the parafollicular C cells of the thyroid. It can be isolated or part of multiple endocrine neoplasia syndrome (MEN syndrome). In children with a family history of MEN 2A or 2B syndrome, complete thyroidectomy before the age of 5 years is now recommended if the genetic studies confirm that the child is affected. Calcition is used for the follow-up of patients with medullary thyroid carcinoma.

Rare Thyroid Disorders

Thyroid Hormone Resistance Syndrome

Some patients have resistance to the action of thyroid hormone, which is variable among the tissues. They present with goiter and elevated levels of T3 and T4 and may be misdiagnosed as Grave's disease. However, unlike Grave's disease, TSH levels are inappropriately normal or elevated. Most patients are clinically euthyroid, although subtle clinical features of hypothyroidism may be present. The condition is most often inherited in an autosomal dominant fashion due to mutations in the gene encoding the β thyroid hormone receptor. No treatment is necessary unless growth retardation is present. Rarely, the resistance to thyroid hormone may be selective and affect the pituitary gland while the other tissues remain sensitive. Such patients present with goiter and features of hyperthyroidism and elevated T3 and T4 levels. Treatment includes T3 (aimed at suppressing TSH) and propanalol.

Disorders of Thyroid-Binding Globulin

The major carrier proteins for circulating thyroid hormones are TBG, thyroid-binding prealbumin (TBPA), and albumin. The role of these carrier proteins seems to be a buffer to maintain relatively normal hormone concentrations. Unbound, or free, T4 accounts for only about 0.03% of circulating T4 and is the portion that is metabolically active. TBG levels are influenced by liver disease as well as sex steroids (estrogen and progesterone increase whereas androgens decrease TBG level). Conditions leading to hypothyroidism can cause TBG levels to increase whereas hyperthyroidism leads to a decrease in TBG levels. Infants born with low levels of TBG, as in congenital TBG deficiency, have low total T4 levels but are physiologically normal. Familial congenital TBG deficiency can occur as an X-linked recessive or autosomal recessive condition.

Euthyroid Sick Syndrome

Euthyroid sick syndrome is the abnormal findings of thyroid function tests in the setting of a nonthyroidal illness, without preexisting hypothalamic-pituitary and thyroid gland dysfunction. The most prominent alterations observed in this syndrome are low serum T3 and elevated reverse rT3. TSH and T4 are affected in variable degrees based on the severity and duration of the nonthyroidal illness. As the severity of the illness increases, both serum T3 and T4 levels drop and gradually normalize as the patient recovers.

Subacute Thyroiditis

This is a self-limiting disorder where the pathogenesis is not completely understood. In some cases, there is a history of a viral infection which might be the cause of the inflammation. Patients present with an enlarged painful and tender thyroid gland that tends to come on quite rapidly. Biochemically, there is evidence of hyperthyroidism in some patients which is transient. This occurs due to disruption of the thyroid follicles giving rise to the elevated serum T4 and T3 concentrations. Rarely, there may be transient hypothyroidism.

389 Hypoglycemia

Chela James · Khalid Hussain

Introduction

Hypoglycemia is one of the most common biochemical abnormalities observed in the neonatal, infancy, and childhood periods. Despite the commonality, there is still confusion about the definition and management of hypoglycemia. Hypoglycemia can be due to many causes in the neonatal, infancy, and childhood period. For example, hyperinsulinemic hypoglycemia is the most severe form of hypoglycemia in the neonatal period whereas "ketotic" hypoglycemia presents in the childhood only during an intercurrent illness. Thus, having an understanding of normal glucose physiology will not only help the clinician to understand the biochemical basis of hypoglycemia but will also allow the clinician to organize appropriate investigations and institute the correct management. The early recognition and prompt management of hypoglycemia is the cornerstone in preventing brain injury. The aim of this chapter is to provide a brief background to normal glucose physiology, review the mechanisms that help to maintain normoglycemia, and then from a clinical perspective, to focus on the clinical approach to a patient with hypoglycemia and finally to review the different causes of hypoglycemia in the childhood period.

Definition

The definition of hypoglycemia remains one of the most contentious and confusing areas (especially in the newborn) in glucose physiology. This is because there is poor correlation between plasma glucose concentrations, the onset of clinical symptoms, and the long-term neurological sequelae. It is difficult to define a blood glucose level that will require intervention (especially in neonates) since there is uncertainty over the level and duration of hypoglycemia that can cause neurological damage.

Several different approaches have been used to define hypoglycemia (an approach based on clinical manifestations, the epidemiologic approach based on measured range of glucose values, an approach based on acute changes in metabolic and endocrine responses and on neurologic function, and an approach based on long-term neurologic outcome) but none of these approaches is satisfactory. The approach based on neurophysiological responses to falling blood glucose concentrations has led to the proposal that hypoglycemia should be defined as a concentration less than 2.6 mmol/L as measured with a laboratory research method. However, around 20% of entirely normal full-term infants will demonstrate blood glucose concentrations less than this in the first 48 h after delivery. These infants will show a concurrent hyperketonemia and the assumption (which still needs to be proved) is that the babies will not demonstrate neural dysfunction at this time because of the protective effect of the availability of alternative fuels.

Recently, it has been recommended that operational thresholds are used when assessing an interventional response in a patient with hypoglycemia. An operational threshold is defined as the concentration of plasma or whole blood glucose at which clinicians should consider intervention, based on the evidence currently available in the literature. Significant hypoglycemia is not and can never be defined by a single number that can be applied universally to every individual patient. Rather, it is characterized by a value(s) that is unique to each individual and varies with both their state of physiologic maturity and the influence of pathology. It can be defined as the concentration of glucose in the blood or plasma at which the individual demonstrates a unique response to the abnormal milieu caused by the inadequate delivery of glucose to a target organ (for example, the brain).

Thus, it is not possible to define a blood glucose level that requires intervention in every newborn infant because there is uncertainty over the level and duration of hypoglycemia that cause damage, and little is known of the vulnerability, or lack of it, of the brain of infants at different gestational ages for such damage. It is therefore clear that hypoglycemia is a continuum and the blood glucose concentration should be interpreted in the context of the clinical presentation, counter-regulatory hormonal responses and in relation to the intermediate metabolites.

Normal Glucose Physiology

Metabolic and Endocrine Changes at the Time of Birth

At birth, the healthy term newborn must adapt to an independent existence. The transplacental supply of nutrients including glucose is interrupted and the newborn must now initiate metabolic and endocrine responses to maintain adequate circulating blood glucose concentrations. For extrauterine adaptation there must be adequate glycogen stores, intact and functional glycogenolytic, gluconeogenic and lipogenic mechanisms and appropriate counter-regulatory hormonal responses.

A normal infant at term shows an immediate postnatal fall in blood glucose concentrations during the first 2–4 h from values close to maternal levels to around 2.5 mmol/L. The trigger for the metabolic and endocrine adaptation with reference to glucose control is unclear but surges in catecholamines and glucagon secretion are thought to be important. The raised plasma insulin to glucagon ratio is reversed at birth allowing glucagon to activate adenylate cyclase and increase the activity of cAMP-dependent protein kinase, PKA. This in turn activates phosphorylase kinase, which facilitates glucose release.

The catecholamine surge activates lipolysis and lipid oxidation resulting in increases in the levels of glycerol and free fatty acids. Free fatty acids are then used to generate ketone bodies, which are used as an alternative source of fuel. Healthy term breast-fed babies have significantly lower blood glucose concentrations than those who were bottle-fed, but their ketone body concentrations were elevated in response to breast feeding. Major changes occur in the function of several physiological systems after birth, which enables the neonate to adapt to postnatal nutrition. Successful enteral feeding in healthy term newborns triggers the secretion of gut peptides and plays a key role in triggering a cascade of developmental changes in gut structure and function, and in the relation of pancreatic endocrine secretion to intermediary metabolism. Hence full-term infants are functionally and metabolically programmed to make the transition from their intrauterine-dependent environment to their extrauterine existence without the need for metabolic monitoring or interference with the natural breast-feeding process. This complex metabolic and endocrine adaptation process is incomplete and compromised when the infant is born prematurely or following intrauterine growth retardation.

The Endocrine and Metabolic Changes During Feeding and Fasting

A normal (fasting blood glucose levels 3.5–5.5 mmol/L) circulating blood glucose concentration is vital for brain function. Any defect that leads to hypoglycemia will cause hypoglycemic brain injury. Glucose homeostasis is regulated systemically by hormones such as insulin and glucagon, and at the cellular level by energy status. A complex network of transcription factors, coactivators, and corepressors coordinates changes in blood glucose levels. Despite periods of feeding and fasting, in normal individuals plasma glucose remains in a narrow range. This tight control of glucose concentration is determined by a balance between glucose absorption from the intestine, production by the liver, and uptake in muscle and fat. The liver can produce glucose by breaking down glycogen (glycogenolysis) and by *de novo* synthesis of glucose from non-carbohydrate precursors such as lactate, pyruvate, glycerol, and alanine (gluconeogenesis). Glycogenolysis occurs more rapidly, beginning within 2–3 h after a meal in humans, but gluconeogenesis assumes a much greater importance with prolonged fasting. In liver, glycogen is mainly stored as a glucose reservoir for other tissues. As a consequence, the level of hepatic glycogen changes considerably (between 1 and 100 mg) with the feeding condition. The estimated contribution of hepatic glycogenolysis to the total glucose production during the first day of starvation varies from 40 to 80%, depending on the experimental design and methodology.

In liver, the glycogen-metabolizing enzymes have properties that enable the liver to act as a sensor of blood glucose and to store or mobilize glycogen according to the peripheral needs. The prime effector of hepatic glycogen deposition is glucose, which blocks glycogenolysis and promotes glycogen synthesis in various ways. Other glycogenic stimuli for the liver are insulin, glucocorticoids, parasympathetic (vagus) nerve impulses, and gluconeogenic precursors such as fructose and amino acids. Hepatic gluconeogenesis plays a key role in the maintenance of glucose homeostasis. In addition to the key hormones such as insulin, glucagon, and glucocorticoids, the rate of hepatic gluconeogenesis is also controlled by nutrients, but how the nutrient response is controlled is unclear. The rate of gluconeogenesis is controlled principally by the activities of certain unidirectional enzymes, such as phosphoenolpyruvate carboxykinase (PEPCK), fructose-1,6-bisphosphatase, and glucose-6-phosphatase (G6Pase). The genes encoding these proteins are powerfully controlled at the transcriptional level by key

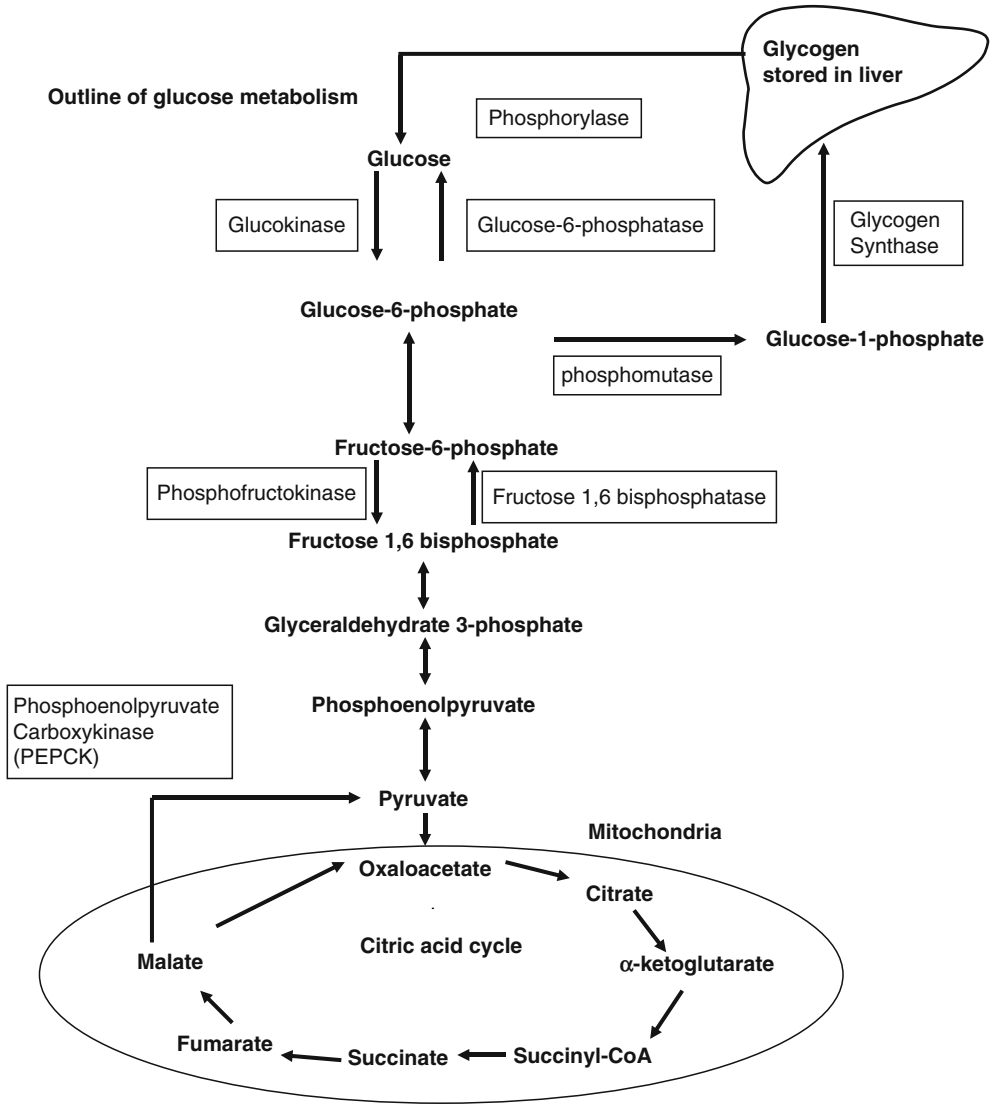

Figure 389.1
Outline of the processes of glycolysis and gluconeogenesis

hormones, particularly insulin, glucagon, and glucocorticoids. In the fasted state, insulin levels drop while glucagon secretion goes up resulting in increased glycogenolysis and gluconeogenesis. In the fed state, insulin suppresses glycogenolysis and hepatic glucose production.

The molecular mechanisms that regulate gluconeogenesis are complex and still not completely understood in humans. Pancreatic glucagon normally triggers the activation of catabolic programs in the liver in part via the cAMP-response element binding protein (CREB). CREB in turn stimulates hepatic gluconeogenesis as well as fatty acid oxidation by inducing expression of the nuclear hormone receptor coactivator PGC-1α (peroxisome proliferation-activated receptor-g coativator-1). The ability of CREB to regulate gluconeogenesis is largely dependent on the transcription factor PGC-1 α. CREB has been identified as a critical transcriptional checkpoint for the induction of hepatic gluconeogenesis in response to cAMP.

Prolonged fasting is characterized by low insulin concentrations and high glucagon, glucocorticoids, and

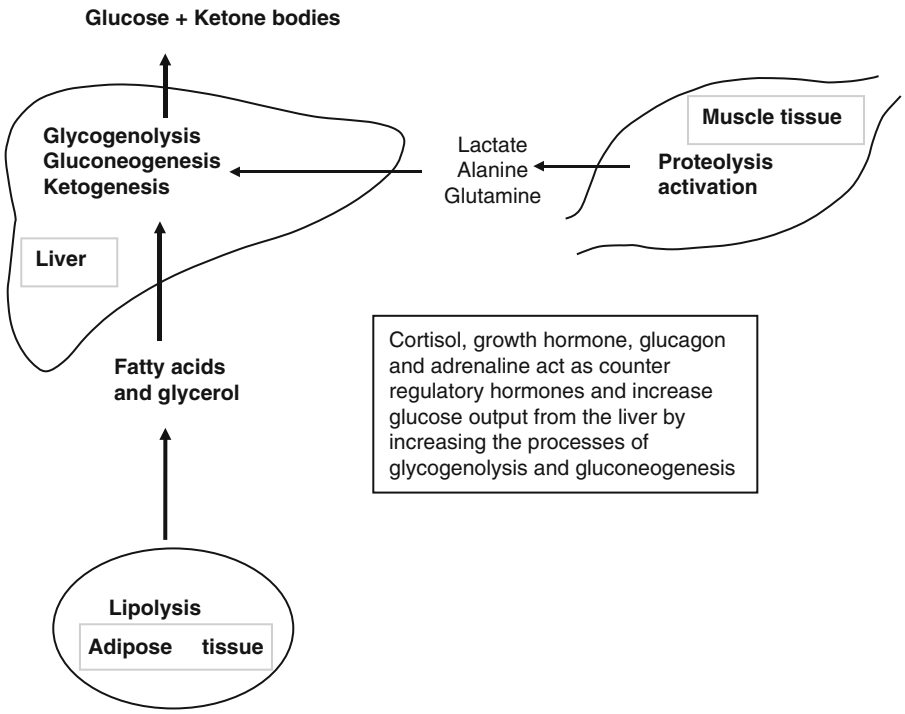

Figure 389.2
Summary of the role of counter-regulatory hormones in glucose physiology

adrenaline (noradrenaline) concentrations in plasma. This hormonal profile promotes the hydrolysis of triacylglycerols in adipose tissue, thereby increasing the concentration of free fatty acids in plasma. The fatty acids are taken up by the liver, where they are either re-esterified to triacylglycerol and secreted as very-low-density lipoprotein (VLDL) or oxidized in the mitochondria via β-oxidation. During late stages of fasting, free fatty acids become the predominant substrate for energy production. The majority of fatty acids are only partially oxidized to acetyl-coenzyme A (acetyl-CoA), which then condenses with itself to form ketone bodies, an important fuel for the brain. The energy released in the process of β-oxidation is used by the liver to carry out gluconeogenesis from substrates such as glycerol, lactate, and amino acids. Thus, efficient hepatic fatty acid oxidation is obligatory to the metabolic response to fasting. *Figure 389.1* outlines the processes of glycolysis and gluconeogenesis.

Counter-regulatory Hormonal Responses

During the post-absorptive phase (4–6 h interval following the ingestion of a meal), plasma glucose concentrations are maintained by interactions between insulin and the various counter-regulatory hormones including glucagon, cortisol, growth hormone, adrenaline, and noradrenaline. Glucagon allows the controlled release of stored glycogen from the liver and insulin restrains the effects of glucagon by preventing accelerated lipolysis and proteolysis. The counter-regulatory hormones including cortisol and growth hormone play permissive roles in setting the sensitivity of the peripheral tissues to glucagon and insulin.

Growth hormone and cortisol play an essential role in the regulation of a normal blood glucose concentration. Both of these hormones counteract the actions of insulin on glucose metabolism. Both hormones reduce the peripheral utilization of glucose as well as increasing the rates of gluconeogenesis. Cortisol as with growth hormone decreases insulin-induced peripheral utilization of glucose, increases hepatic glucose production, and stimulates protein breakdown. This has the effect of providing amino acids for gluconeogenesis.

Cortisol secretion from the adrenal gland is regulated by adrenocorticotropic hormone (ACTH). This is cleaved from a larger precursor protein (pro-opiomelanocortin, POMC). The release of ACTH from the anterior pituitary

is regulated by corticotropin-releasing hormone (CRH), from the hypothalamus. Growth hormone is produced and secreted by specialized cells in the anterior pituitary called the somatotrophs. Both cortisol and GH have numerous effects on glucose metabolism. *Figure 389.2* summarizes the role of counter-regulatory hormones in glucose physiology.

The Diagnostic Approach to a Patient with Hypoglycemia

The careful clinical history, description of symptoms, physical examination, and a systematic step-by-step approach are the cornerstones of diagnosis. Given the complexity of the metabolic and endocrine adaptations that occur at birth, hypoglycemia occurs more commonly during the first days after birth than at any other time of life. Furthermore, it is a transient phenomenon in the majority of the cases. The symptoms of hypoglycemia may be very nonspecific (*Table 389.1*); hence any symptomatic child must have a blood glucose level measured and documented.

In the neonatal period, the clinical history should include details of pregnancy and delivery, birth weight, gestational age of the infant, noting in particular any evidence for fetal distress, birth asphyxia, and smallness for dates. The relationship of a hypoglycemic episode to the most recent meal can be important diagnostically. Hypoglycemia occurring after a short fast (2–3 h) may be suggestive of glycogen storage disease. Hypoglycemia occurring after a long fast (12–14 h) may suggest a disorder of gluconeogenesis. Postprandial hypoglycemia may indicate galactosemia, hereditary fructose intolerance, or the dumping syndrome. A family history of sudden infant deaths may be a clue to an unrecognized, inherited metabolic disorder. Any provocation factors such as an upper respiratory tract infection or an episode of gastroenteritis leading to hypoglycemia should be documented.

From the history and physical examination, certain at-risk groups of infants (*Table 389.2*) can be identified on the basis of obvious conditions that are usually associated with transient hypoglycemia and need monitoring.

The recognition and diagnosis of hypoglycemia in the neonatal period depends on routine monitoring of blood glucose levels at frequent intervals after birth in asymptomatic infants at risk, and in any infant who demonstrates any symptom which might be suggestive of hypoglycemia. Again in this group, it is important to monitor blood glucose in relation to the time of feeds. Thus, a blood glucose concentration that increases after a feed is probably less worrying than one which is

Table 389.1
Summary of the symptoms of hypoglycemia

The symptoms of hypoglycemia may be very nonspecific
Symptoms of hypoglycemia

Perinatal asphyxia
Erythroblastosis fetalis
Beckwith–Wiedemann syndrome
Macrosomia
Any "sick" infant
Polycythemia
Hypothermia
Congenital heart disease
Infections such as malaria
Maternal administration of some drugs such as sulphonylureas/beta-blockers

persistently low. If low concentrations are obtained during routine bedside monitoring in asymptomatic high-risk infants or at the time of symptoms in symptomatic infants, it is necessary to confirm the result in the laboratory, but intervention does not need to wait for the result in infants who are severely symptomatic and in whom reagent strip test results suggest hypoglycemia. Resolution of symptoms after glucose confirms that they were due to hypoglycemia.

Other important points from the history and examination include the presence or absence of maternal diabetes or rhesus incompatibility. Increased birth weight and macrosomia should raise the possibility of neonatal hyperinsulinism. Distinctive physical signs such as transverse ear lobe creases, exomphalos, and macroglossia should raise the possibility of the Beckwith–Wiedemann Syndrome (BWS), while the presence of micropenis and undescended testes might indicate the presence of hypopituitarism. Midline defects, including cleft palate, could also indicate congenital hypopituitarism while the existence of ambiguous genitalia could indicate congenital adrenal hyperplasia.

Hepatomegaly should always be looked for and is associated with abnormal glycogen metabolism, defects in gluconeogenesis, and galactosemia. Moderate hepatomegaly due to glycogen accumulation may, however, also develop in infants with hyperinsulinism who are receiving very high infusion rates of glucose to maintain normoglycemia. In the childhood period, particular attention should be paid to the rate of growth, micropenis, undescended testes, skin pigmentation, blood pressure, and weight loss.

After the clinical history has been taken and the examination completed, a diagnostic cascade of appropriate tests is necessary. These may be guided in the context of the most common causes of hypoglycemia as listed *Table 389.4*.

Blood Sample at Time of Hypoglycemia

By far the most important investigation is the obtaining of a blood sample at the time of hypoglycemia. The blood glucose must be considered in the context of the whole fuel economy and in the light of concurrent hormone concentrations. Essential diagnostic information can be obtained by measuring the metabolites and hormones listed in *Table 389.3*, in the blood sample drawn at the time of hypoglycemia. The next urine sample, which is passed, should also be deep frozen for subsequent assay for abnormal constituents.

Table 389.3

Ammonia	

The Diagnostic Fast

In many conditions, hypoglycemia occurs only in relation to periods of low caloric intake or starvation. Starvation tests are potentially very dangerous, and they must be conducted only under strictly controlled conditions by staff experienced in their administration, with a secure intravenous infusion available for immediate correction of hypoglycemia. The hazards are greatest in defects in fatty acid oxidation, since the induced hyper-fatty acidemia carries a risk of inducing a cardiac arrhythmia. Sequential measurements of intermediary metabolites and glucose are taken throughout the fast, with the crucial blood sample being drawn when hypoglycemia occurs. The urine sample passed then or after restoration of normoglycemia should be deep frozen for measurement of organic acids and other abnormal metabolites.

Other measurements from this specimen obtained at the time of hypoglycemia can also help in diagnosis. Thus, cortisol deficiency will be revealed by showing a low cortisol concentration. Further tests to define the integrity of the hypothalamo–pituitary–adrenal axis are mandatory if a low cortisol level is found at the time of hypoglycemia since cortisol deficiency may be lethal if not corrected by appropriate substitution therapy. Low growth hormone levels at the time of fasting hypoglycemia do not rule out or indicate deficiency. If this deficiency is suspected from abnormal growth, then a validated test such a glucagon provocation test should be performed.

The documentation of abnormal urinary organic acids is particularly helpful when hypoglycemia is due to methylmalonic acidemia, maple syrup urine disease

(MSUD), or mitochondrial beta-oxidation defects. In the latter, clues to the deficient enzymes are provided by the chain length of the dicarboxylic acids in the urine and the presence of hydroxyl groups or unsaturated bonds. The presence of urinary glycine conjugates may also be diagnostic of fatty acid oxidation defects.

Overview of the Different Causes of Hypoglycemia in Childhood

Hypoglycemia in childhood can be due to many causes. These can be broadly summarized into those due to hormonal abnormalities such as hyperinsulinism, cortisol or growth hormone deficiency, defects of hepatic glycogen release/storage, defects in gluconeogenesis, defects in carnitine metabolism, defects in fatty acid oxidation, postprandial, metabolic, and unknown causes such as idiopathic ketotic hypoglycemia. These are summarized in *Table 389.4*.

Hypoglycemia due to Hormonal Abnormalities

Hyperinsulinism of Infancy (HI)

Hyperinsulinism of infancy (HI) is the commonest cause of recurrent and severe hypoglycemia in the neonatal and infancy period. It is characterized by the excessive and inappropriate secretion of insulin in relation to the prevailing blood glucose concentration. HI can be either persistent or transient. In adolescents or older children presenting with HI, insulinoma must be considered as a possibility. Insulinomas may be a part of multiple endocrine neoplasia (MEN1) and hence a family history may provide a diagnostic clue in the familial cases.

Transient Hyperinsulinism

The transient form of HI is associated with maternal diabetes mellitus, intrauterine growth retardation, perinatal asphyxia, erythroblastosis fetalis, the Beckwith–Wiedemann syndrome, after the maternal administration of some drugs such as sulphonylureas, and after intravenous maternal glucose infusions during labor. The mechanism/s causing transient HI in these conditions is not clear. In these cases, the HI tends to resolve spontaneously. However, in some infants with intrauterine growth retardation, the HI may be protracted and require treatment with diazoxide. Iatrogenic hyperinsulinism due to a malpositioned umbilical artery catheter was reported in two infants. Repositioning of the catheter to avoid direct infusion into the arterial blood supply to the pancreas resulted in prompt cessation of hyperinsulinemic hypoglycemia. However, transient HI is seen most commonly in the infant born to a poorly controlled diabetic mother.

Most infants of diabetic mothers (IDM) have transient asymptomatic hypoglycemia before a spontaneous increase in blood glucose levels occurs after the age of 1–4 h. Others have a more prolonged period of severe symptomatic hypoglycemia and a minority develop late hypoglycemia after an initial benign course. However, all regain normal blood glucose control within the first few days after birth.

IDMs have hyperinsulinism at birth due to increased placental transfer of glucose and other nutrients submitting increased insulin secretion. The pancreas shows hyperplasia and hypertrophy in the islets of Langerhans, without any evidence of so-called nesidioblastosis. Some infants fail to develop the normal increase in plasma glucagon at 2–4 h of age although others have demonstrated a substantial counter-regulatory hormone response, which may curtail the period of hypoglycemia.

In relation to management, peripheral blood glucose values should be monitored 3–4 h before feeds for 6–12 h after birth. Transient hypoglycemia may be prevented by giving enteral feeds with milk within 1–2 h after delivery. Sick infants unable to tolerate enteral feeding or those who remain hypoglycemic despite full enteral feeds should receive an intravenous infusion of glucose at a rate of 4–6 mgs/kg/min in the first instance to prevent the development of hypoglycemia. Slow withdrawal of glucose support should then be instituted.

HI may also be associated with syndromes. Beckwith–Wiedemann syndrome (BWS) is a congenital overgrowth syndrome which is clinically and genetically heterogeneous. Phenotypically BWS is associated with pre- and postnatal overgrowth, organomegaly, hemi-hypertrophy, omphalocele, ear lobe anomalies, and renal tract abnormalities with predisposition to embryonic tumors. Genetically BWS is a multigenic disorder caused by dysregulation of imprinted growth regulatory genes within the 11p15 region. At this location, genetic imprinting with loss of maternally expressed tumor and/or growth suppressor genes (p57KIP2 and H19) or duplications and uniparental disomy of paternally expressed growth promoter genes (IGFII) have been implicated in the pathogenesis of BSW (21). About 20% of patients with BWS have paternal uniparental disomy for 11p15.

Table 389.4
Summary of the causes of hypoglycemia

Hyperinsulinemic hypoglycemia
Transient: Infant of diabetic mother/perinatal asphyxia/ Rhesus disease/intrauterine growth retardation/ Beckwith–Weidemann syndrome
Congenital: *ABCC8/KCNJ11/GCK/GDH/HADH/HNF4A/ SLC16A1*
Insulinomas
Hormonal deficiency
ACTH/cortisol/growth hormone/glucagon/adrenaline
Hormone resistance
Laron syndrome
Defects in hepatic glycogen release/storage
Glycogen storage diseases: glucose-6-phosphatase, amylo 1–6 glucosidase deficiency, liver phosphorylase deficiency. GSD type 0.
Defects in gluconeogenesis
Fructose-1, 6-bisphosphatase deficiency, (PEPCK) deficiency
Pyruvate carboxylase deficiency
Carnitine metabolism
Carnitine deficiency (primary and secondary)
Carnitine palmitoyl transferase deficiency (CPT 1 and 2)
Fatty acid oxidation
Medium-chain acyl-CoA dehydrogenase (MCAD) deficiency
Very-long-chain acyl-CoA dehydrogenase (VLCAD) deficiency
Short-chain Acyl-CoA dehydrogenase (SCAD) deficiency
Long-/Short-chain-L-3-hydroxy-acyl CoA (L/SCHAD) deficiency
Defects in ketone body synthesis/utilization
HMG CoA synthase deficiency/HMG CoA lyase deficiency
Succinyl-CoA: 3-oxoacid CoA-transferase (SCOT) deficiency
Metabolic conditions (common ones)
Organic acidemias (propionic/methylmalonic)
Maple syrup urine disease, galactosemia, fructosemia, tyrosinemia
Hereditary fructose intolerance
Glutaric aciduria type 2
Mitochondrial respiratory chain complex deficiencies
Congenital disorders of glycosylation (CGD)
Drug induced
Sulphonylurea/insulin/beta-blocker/salicylates/alcohol
Miscellaneous causes (mechanism/s not clear)
Idiopathic ketotic hypoglycemia (diagnosis of exclusion)
Infections (sepsis, malaria), congenital heart disease

The incidence of hyperinsulinemic hypoglycemia in children with BWS is about 50%. This hypoglycemia can be transient or prolonged which in the majority of infants will be asymptomatic and resolve within the first 3 days of life but about 5% of children will have persistent hyperinsulinemic hypoglycemia beyond the neonatal period requiring either continuous feeding or a partial pancreatectomy. The milder forms respond to treatment with diazoxide and somatostatin analogues. There are only few detailed histological studies of the resected pancreas in patients with BWS and all suggest that the histology may be similar to the diffuse form of hyperinsulinism of infancy. The underlying mechanism/s leading to persistent hyperinsulinemic hypoglycemia in this syndrome is/ are unclear. It is not clear why the HI of this syndrome is usually a transient phenomenon.

Congenital Hyperinsulinism of Infancy (CHI)

Of all of the conditions causing persistent hypoglycemia in infancy and childhood, that caused by organic hyperinsulinism is by far the most difficult to manage clinically. It is associated with a very high incidence of neurological handicap. Up to 20% of infants with this condition may have persistent neurological handicaps. The organic hyperinsulinism causes hypoglycemia primarily as a result of increased utilization of glucose together with a decreased rate of endogenous glucose production. These effects are entirely due to inappropriate secretion of insulin. CHI is the most common cause of severe persistent hypoglycemia in neonates and infants during their first year of life. It has previously masqueraded under a variety of different descriptive names including "idiopathic hypoglycemia of infancy", leucine sensitive hypoglycemia, neonatal insulinoma, microadenomatosis, focal hyperplasia, nesidioblastosis, and persistent hyperinsulinemic hypoglycemia of infancy (PHHI).

Both sporadic and familial variants of congenital hyperinsulinism of infancy are recognized, with sporadic forms being relatively uncommon (incidence 1 per 40,000 live births), and familial forms being common in communities with high rates of consanguinity; in these communities the incidence may be as high as 1 in 2,500 live births.

Clinical Presentation

The condition presents primarily in the newborn period and during the first 2–6 months after birth in term and preterm neonates. Many neonates have a characteristic appearance resembling strikingly that of an infant of

a diabetic mother. It may also be present in infants and even in the childhood period.

Diagnosis

The characteristic metabolic and endocrine profile in a blood sample drawn at the time of hypoglycemia is one of hyperinsulinemic, hypoketotic, hypo-fatty acidemic hypoglycemia with inappropriately raised insulin and accompanied by high concentrations of C-peptide levels. High intravenous infusion rates of glucose may be required to maintain a blood glucose concentration above 3.5 mmol/L. Because of the anabolic effects of insulin, the hypoglycemia occurs despite a liver engorged with glycogen that can be mobilized by administration of glucagon. It is important to emphasize that the level of insulin in the blood may not necessarily be particularly high. However, what is an appropriate insulin concentration for normoglycemia becomes inappropriate in the presence of hypoglycemia. The demonstration of any measurable insulin in a hypoglycemic sample is strong evidence for a failure of basal insulin control.

Management

The immediate imperative is to give sufficient glucose to maintain blood glucose concentrations above 3.5 mmol/L. Infusion rates in excess of 4–6 mg/kg/min may be necessary, rarely; infusion rates $>$ 20 mg/kg/min may be needed. Having stabilized the blood glucose concentration, it is then imperative to determine whether or not the patient will respond to the conventional medical therapy of a combination of diazoxide together with a diuretic. It is important to give both drugs concurrently to overcome the tendency of diazoxide to cause fluid retention and to capitalize on the fact that both drugs have a synergistic effect in increasing blood glucose concentration. A convenient starting dose of diazoxide is 5–10 mg/kg/day in three 8 hourly aliquots, increasing to a maximum of 20 mg/kg/day. The administration of glucagon by continuous infusion (starting dose 1.0ugm/kg/h) concurrently with a continuous infusion of the somatostatin analogue Octreotide (initial dose 10ugm/kg/day) may confer substantial benefit.

Pathophysiology of CHI

The pancreatic ß-cell adenosine triphosphate-sensitive potassium channels (K_{ATP} channels) play a pivotal role in glucose-stimulated insulin secretion. These channels are hetero-octameric complexes comprising of four inwardly rectifying potassium channel (Kir6.2) subunits and four of the sulphonylurea receptor 1 (SUR1) subunits. The channels couple glucose metabolism to membrane electrical activity and insulin release in pancreatic ß-cells. Glucose metabolism leads to an increase in the intracellular ratio of ATP/ADP within the ß-cell causing closure of the channels; this results in cell membrane depolarization, Ca^{2+} influx via voltage-gated calcium channels and insulin exocytosis.

The SUR1 and Kir6.2 proteins are encoded by the *ABCC8* and *KCNJ11* genes, respectively. Therefore, it is not surprising that the most common known cause of congenital hyperinsulinism (CHI) is loss of function mutations in these two genes. These mutations either impair the ability of MgADP to stimulate channel activity, or affect the expression of the K_{ATP} channels at the surface membrane. This results in continuous depolarization of the ß-cell membrane and dysregulated insulin secretion. The majority of K_{ATP} channel mutations have been known to act recessively. However, recent reports of autosomal dominantly inherited mutations in patients with CHI.

Heterozygous activating mutations have been reported in the glucokinase gene (*GCK)* in patients with CHI. Glucokinase is the rate-limiting enzyme for glucose metabolism in the ß-cell and hence is pivotal in regulating glucose-induced insulin secretion. Activating mutations cause an increased affinity of glucokinase for glucose with increased rates of glycolysis at low blood glucose concentrations. This increases insulin secretion independent of blood glucose concentration.

Heterozygous mutations in the *GLUD1* gene, which encodes the enzyme glutamate dehydrogenase (GDH), have been identified in patients with hyperinsulinism and hyperammonemia (HI/HA Syndrome) with plasma ammonium levels being persistently raised to 3–8 times the upper limit of normal. HI/HA syndrome typically causes protein-sensitive hypoglycemia, in addition to the fasting hypoglycemia. The mechanism by which *GLUD1* mutations cause hyperammonemia remains to be determined.

Recently, three further rare genetic etiologies have been described in patients with CHI. Recessively inherited mutations in the *HADH* gene that encodes the enzyme hydroxyacyl-Coenzyme A dehydrogenase (HADH) (previously known as short-chain L-3-hydroxyacyl-CoA dehydrogenase (SCHAD)) have been described in a few patients with CHI. HADH catalyzes the penultimate step in fatty acid ß-oxidation in the mitochondria. Patients typically present with raised plasma hydroxybutyrylcarnitine and urinary 3-hydroxyglutarate levels. The precise mechanism of dysregulated insulin secretion in patients with a HADH deficiency is not understood.

More recently, heterozygous loss-of-function mutations in the hepatocyte nuclear factor 4A (*HNF4A*) gene, resulting in transient or persistent CHI, and heterozygous

gain-of-function mutations in the *SLC16A1* gene, which encodes the monocarboxylate transporter (MCT-1) causing physical exercise-induced hyperinsulinism (EIHI), have been reported.

The Therapeutic Dilemma

The pediatrician is faced with an important challenge when managing a child who proves to be unresponsive to conventional therapy with diazoxide. There are two options, either contemplate the long-term combined continuous subcutaneous infusion of glucagon and somatostatin or consider surgical resection of the pancreas.

Partial pancreatectomy is not without risk and is not a procedure to be undertaken lightly. The operation most commonly performed at present is a 95% pancreatectomy in the first instance. Some children remain hypoglycemic despite this then a further attempt can be made to control the procedure by diazoxide therapy. In a minority of cases, a total pancreatectomy may be necessary to control the severe hyperinsulinism.

Two main histological subtypes have been described in patients with CHI. Focal pancreatic lesions appear as small regions of islet adenomatosis measuring 2–10 mm, which are characterized by ß-cells with enlarged nuclei surrounded by normal tissue. In contrast, diffuse pancreatic disease affects all the ß-cells within the islets of Langerhans. The histological form of CHI can be a guide as to the mode of inheritance. Diffuse disease can be familial or sporadic and can result from recessively inherited or dominantly acting mutations in the genes previously described while focal disease is always sporadic.

Focal disease results from paternal uniparental disomy (UPD) encompassing chromosome11p15.5-11p15.1 within a single pancreatic ß-cell, which unmasks a paternally inherited K_{ATP} channel mutation at 11p15.1. Paternal UPD at 11p15.5 causes altered expression of a number of imprinted genes, including the maternally expressed tumor-suppressor genes *H19* and *CDKN1C*, and the paternally expressed growth factor *IGF2*, which is likely to lead to clonal expansion of the single cell and dysregulated insulin secretion from the resulting focal lesion.

Patients with a paternal mutation in *ABCC8* and *KCNJ11* (or those with no mutations in these genes) potentially have a focal disease and thus will require further imaging studies with ^{18F}DOPA-PET scan for precise preoperative localization of the focal lesion. Patients with genetically confirmed diffuse disease do not require further imaging studies. However it is important to be aware that mutational analysis may not be definitive in some cases. The principle of ^{18F}DOPA-PET scan is based on the fact that pancreatic islets take up L-3, 4- dihydroxyphenylalanine (L-DOPA), and convert it to dopamine by DOPA decarboxylase, present in the islet cells. The uptake of the positron emitting tracer ^{18F}DOPA-PET is increased in ß-cells with a high rate of insulin synthesis and secretion compared to unaffected areas allowing visualization of the focal lesion. The sensitivity for detecting focal lesions varies between 88 and 94% with a specificity of 100%. Patient with diffuse disease will require a near total pancreactectomy or long-term therapy with octreotide in combination with high calorie and volume feeds.

Postprandial Hyperinsulinemic Hypoglycemia (PPHH)

PPHH refers to the development of hypoglycemia within a few hours of meal ingestion. It is associated with inappropriate insulin secretion in response to the meal. The most common cause is due to the "dumping" syndrome in infants who have undergone gastro-esophageal surgery. PPHH occurs in the insulin autoimmune syndrome, which is characterized by the presence of insulin-binding autoantibodies in subjects that have not been previously exposed to exogenous insulin (38). Most other causes of PPHH have been reported in adults.

Hypoglycemia due to Hormone Deficiency

Glucagon and adrenaline are the two hormones that are important in the immediate restoration of the blood glucose concentration, whereas cortisol and growth hormone are thought to have permissive roles in restoring normoglycemia.

Deficiency of any one of these hormones can cause hypoglycemia. Glucagon and adrenaline deficiency is extremely rare and so far no true human genetically proven defect in glucagon and adrenaline deficiency have been described.

Growth hormone and cortisol have numerous effects on glucose metabolism including increasing the rates of gluconeogenesis and glycolysis and antagonizing the effects of insulin. In adults, the glycemic thresholds for the activation of glucose counter-regulatory hormones such as growth hormone and cortisol lies within or just below the physiological blood glucose concentration and slightly higher than the threshold for symptoms. This implies that growth hormone and cortisol start to rise in response to blood glucose concentrations within the normoglycemic range and it is thought that these increases are inversely proportional to the nadir in blood glucose.

Serum growth hormone and cortisol respond differently to spontaneous hypoglycemia and that induced by the insulin tolerance test. This is not related to the pulsatile nature of growth hormone secretion but may be related to the rate of fall of the blood glucose concentration. Hence, a low serum growth hormone value at the time of spontaneous hypoglycemia may not necessarily indicate growth hormone deficiency.

The etiology of the hypoglycemia due to cortisol and growth hormone deficiency is due to a combination of factors including reduced gluconeogenic substrate availability (decreased mobilization of fats and proteins) and increased glucose utilization due to increased insulin sensitivity of tissues in the absence of these two hormones.

Congenital hypopituitarism may present with life-threatening hypoglycemia, abnormal serum sodium concentrations, shock, microphallus in males, and, only later, growth failure. Causes of congenital hypopituitarism include septo-optic dysplasia, other midline syndromes, and mutations of transcription factors involved in pituitary gland development. Children with acquired hypopituitarism typically present with growth failure and may have other complaints depending on the etiology and the extent of missing pituitary hormones. Acquired hypopituitarism may result from tumors (most commonly craniopharyngioma), radiation, infection, hydrocephalus, vascular anomalies, and trauma. The incidence of hypoglycemia due to panhypopituitarism can be as high as 20%, and hypoglycemia associated with hypopituitarism may be a cause of sudden death in the childhood period. Appropriate replacement therapy with hydrocortisone and growth hormone can alleviate the hypoglycemia. ACTH deficiency will also cause hypoglycemia and may be isolated or part of multiple pituitary hormone deficiency.

Laron syndrome is an autosomal recessive disorder caused by defects of growth hormone receptor (GHR) gene. It is characterized by severe postnatal growth retardation and characteristic facial features as well as high circulating levels of growth hormone (GH) and low levels of insulin-like growth factor I (IGF-I) and insulin-like growth factor binding protein-3 (IGFBP-3). Children with Laron syndrome can present with episodes of hypoglycemia.

Hypoglycemia due to Defects in Hepatic Glycogen Release/Storage

Glucose is stored as glycogen mainly in the liver but also in the muscle and in the kidneys. Defects in the storage or release of hepatic glycogen can also cause hypoglycemia. Glucose-6-phosphatase deficiency (glycogen storage disease type I, Von Gierke's disease) is the commonest of the glycogen storage diseases causing hypoglycemia. The deficiency of this enzyme results in the inability to release free glucose from glucose-6-phosphate, with resultant hepatomegaly due to stored glycogen. These children present with recurrent hypoglycemia associated with lactic acidosis, hyperuricemia, and hyperlipidemia. The aim of treatment is to prevent hypoglycemia. Continuous nasogastric tube feeding and cornstarch form the mainstay of therapy.

The two other glycogen storage diseases causing hypoglycemia are due to deficiencies of the enzymes amylo-1,6-glucosidase (glycogen storage disease type III) and liver phosphorylase (glycogen storage disease VI). The clinical and biochemical features of GSDIII subjects are quite heterogeneous. The clinical manifestations of GSDIII are represented by hepatomegaly, hypoglycemia, hyperlipidemia, short stature and, in a number of subjects, cardiomyopathy and myopathy. Glycogen-storage disease type VI (GSDVI) represents a heterogeneous group of hepatic glycogenoses with mild clinical manifestations and benign course. Patients typically exhibit prominent hepatomegaly, growth retardation, and variable but mild episodes of fasting hypoglycemia and hyperketosis during childhood. Hyperlacticacidemia and hyperuricemia characteristically are absent. In addition, patients may demonstrate elevated serum transaminases, hyperlipidemia, hypotonia, and muscle weakness.

The enzyme hepatic glycogen synthase plays an important role in the storage of glycogen in the liver. Hepatic glycogen synthase deficiency is a rare cause of hypoglycemia in childhood. The characteristic features include fasting hypoglycemia, with hyperketonemia but with normal lactate. After a meal, the plasma lactate will increase as glucose is channeled along the glycolytic pathway with hyperglycemia. Mutations in the liver glycogen synthase gene (*GYS2*) localized on chromosome 12p12.2 have been described in some patients.

Hypoglycemia due to Defects in Gluconeogenesis

Gluconeogenesis, or the formation of glucose from mainly lactate/pyruvate, glycerol, glutamine, and alanine, plays an essential role in the maintenance of normoglycemia during fasting. Inborn deficiencies are known in each of the four enzymes of the glycolytic–gluconeogenic pathway that ensure a unidirectional flux from pyruvate to glucose: pyruvate carboxylase, phosphoenolpyruvate

carboxykinase (PEPCK), fructose-1,6-bisphosphatase, and glucose-6-phosphatase. Gluconeogenesis can essentially be viewed as a reversal of glycolysis but with few important differences. Patients with defects in gluconeogenesis present with fasting hypoglycemia and lactic acidosis. Pyruvate carboxylase deficiency may lead to a more widespread clinical presentation with lactic acidosis, severe mental and developmental retardation, and proximal renal tubular acidosis.

Hypoglycemia due to Disorders of Carnitine Metabolism and Defects of Fatty Acid Oxidation

Serious clinical consequences may occur if fatty-acid oxidation (FAO) is impaired, including hypoglycemic seizures, muscle damage, cardiomyopathy, metabolic acidosis, and liver dysfunction. Fatty acids are taken up by hepatocytes and muscle, where they are subsequently activated to their coenzyme A (CoA) esters. FAO disorders are individually rare, but they are collectively common because of the number of different enzymes affected. They are typically inherited in an autosomal recessive pattern. When defects occur in fatty-acid degradation, excess acylcarnitine intermediates accumulate in the tissues, including heart, liver, and skeletal muscle, which can lead to organ dysfunction. The diversion of acyl-CoA intermediates into beta-oxidation results in accumulation of toxic dicarboxylic acids. Acylcarnitines that spill into the blood provide a marker for diagnosis, including early detection on newborn screening. The diagnosis of some FAO disorders may require more invasive specimens to be tested because substrate profiles alone can be normal or only mildly abnormal. Cultured skin fibroblasts are useful for testing enzyme activity or metabolism of labeled fatty-acid substrates.

Primary carnitine deficiency is an autosomal recessive disorder of fatty acid oxidation that can present at different ages with hypoketotic hypoglycemia and cardiomyopathy and/or skeletal myopathy. This disease is suspected based on reduced levels of carnitine in plasma and confirmed by measurement of carnitine transport in the patient's fibroblasts. Carnitine transport is markedly reduced (usually $<5\%$ of normal) in fibroblasts from patients with primary carnitine deficiency.

The "hepatic" CPT1 isoform is expressed in liver, kidney, and fibroblasts and at low levels in the heart, while the other isoform (muscle) occurs in skeletal muscle and is the predominant form in heart. Patients with hepatic isoform of CPT 1 deficiency present with hypoketotic hypoglycemia, hepatomegaly with raised transaminases, renal tubular acidosis, transient hyperlipidemia and, paradoxically, myopathy with elevated creatinine kinase or cardiac involvement and seizures and coma in the neonatal period. The typical biochemical finding in the urine is dicarboxylic acids of chain lengths C6–C10.

CPT2 deficiency has several clinical presentations. The infantile-type CPT2 deficiency presents as severe attacks of hypoketotic hypoglycemia, occasionally associated with cardiac damage commonly responsible for sudden death before 1 year of age. In addition to these symptoms, features of brain and kidney dysorganogenesis are frequently seen in the neonatal-onset CPT2 deficiency, almost always lethal during the first month of life. Treatment is based upon avoidance of fasting and/or exercise, a low-fat diet enriched with medium-chain triglycerides and carnitine.

The commonest disorder of fatty acid β-oxidation is medium-chain acyl-CoA dehydrogenase (MCAD). This is an autosomal recessive condition characterized by intolerance to prolonged fasting, recurrent episodes of hypoglycemic coma with medium-chain dicarboxylicaciduria, impaired ketogenesis, and low plasma and tissue carnitine levels. MCAD deficiency usually presents between infancy and 2 years of age, although onset of symptoms can occur as early as the first days of life to as late as 6 years. Children are typically asymptomatic except during times of fasting and metabolic stress, usually associated with a viral illness. They present with fasting non-ketotic hypoglycemia associated with vomiting, lethargy, apnea, coma, encephalopathy, and sudden death. If undiagnosed, 20–25% of affected patients will die during the first episode. Routine laboratory studies during an acute illness may show hypoketotic hypoglycemia, metabolic acidosis, lactic acidosis, hyperammonemia, increased blood urea nitrogen and transaminases, and elevated uric acid. Serum and urine-free carnitine levels may be normal or low. Elevated suberylglycine and hexanoylglycine (dicarboxylic acid esters of glycine) are typically found in urine. Enzyme deficiency can be shown in fibroblasts. Screening of the *ACADM* gene often identifies a common A985G mutation that accounts for 85% of mutations. Some of the children detected with newborn screening have a genotype that may not be associated with clinical manifestations. The disorder may be severe, and even fatal, in young patients. Other defects of β-oxidation (long-chain acyl-CoA dehydrogenase) may present with hypoketotic hypoglycemia associated with neurological (hypotonia) and cardiovascular complications (cardiomyopathy). The pattern of

dicarboxylicaciduria accumulation is characteristic for each enzymatic defect of the β-oxidation spiral.

As is true for the defects in carbohydrate metabolism leading to hypoglycemia, treatment of the fatty acid oxidation defects involves avoidance of fasting and provision of adequate glucose. Restriction of dietary fat intake and supplemental L-carnitine therapy are recommended.

Hypoglycemia due to Defects in Ketone Body Synthesis/Utilization

Ketone bodies are an alternative form of fuel to glucose especially for the brain. Each ketone body is synthesized from the combination of Acetyl-CoA and Acetoacetyl-CoA to from hydroxymethylglutaryl-CoA (HMG-CoA), which is then split by HMG-CoA lyase to yield acetoacetate. Acetoacetate is then converted to β-hydroxybutyrate. Defects in either the synthesis or the utilization of ketone bodies may lead to hypoglycemia. Hereditary deficiency of mitochondrial HMG-CoA synthase can cause episodes of severe hypoketotic hypoglycemia. Typical biochemical findings include hypoketosis, elevated free fatty acids, normal acylcarnitines, and specific urinary organic acids during acute episodes. A rare cause of hypoglycemia due to the inability to utilize ketone bodies is deficiency of succinyl-CoA: 3-oxoacid CoA-transferase (SCOT). This is characterized by intermittent ketoacidotic crises and persistent ketosis.

Idiopathic Ketotic Hypoglycemia

Idiopathic ketotic hypoglycemia usually presents between the ages of 18 months and 5 years and remits spontaneously by the ages of 9–10 years. The typical history is of a child who may miss a meal and develop hypoglycemia usually following an upper respiratory tract infection. The hypoglycemic episodes seem to be unpredictable, only developing sometimes. Biochemically, the hypoglycemia is associated with raised ketone bodies and free fatty acids with suppressed insulin levels. Ketotic hypoglycemia is characterized by low levels of plasma alanine but the precise mechanism responsible for the hypoglycemia is not understood.

Idiopathic ketotic hypoglycemia is a poorly defined term and may include groups of conditions in which there is no clear cause of the hypoglycemia. Conditions such as hepatic glycogen synthase deficiency and acetoacetyl CoA thiolase deficiency have been reported as presenting with ketotic hypoglycemia. Ketotic hypoglycemia is a diagnosis of exclusion.

Miscellaneous Causes of Hypoglycemia

Metabolic

Hypoglycemia can also occur due to a number of metabolic conditions including galactosemia, fructosemia, tyrosinemia, organic acidemias, maple syrup urine disease, glutaric aciduria type II, and in mitochondrial respiratory chain defects. Hereditary fructose intolerance, caused by catalytic deficiency of aldolase B (Fructose 1,6-phosphate aldolase), is a recessively inherited condition in which affected homozygotes develop hypoglycemic and severe abdominal symptoms after taking foods containing fructose and cognate sugars. Continued ingestion of noxious sugars leads to hepatic and renal injury and growth retardation.

Factitious

Hypoglycemia can also be induced pharmacologically, either intentionally as a diagnostic tool, accidentally as a complication of the treatment of diabetes mellitus, or as a consequence of poisoning either with insulin itself or with drugs such as sulphonylureas, which stimulate insulin release. Whenever severe hypoglycemia occurs with documented hyperinsulinism, the possibility of Munchausen syndrome by proxy should be considered. The possibility of malicious administration of insulin or an oral sulphonylurea should always be suspected in cases of sudden onset of hypoglycemia in a previously healthy child. In the case of insulin administration, the clue in the biochemistry will be a raised insulin level with normal C-peptide.

Summary

Hypoglycemia is one of the most common biochemical abnormalities observed in the childhood period. Any symptomatic child must have his/her blood glucose level measured and documented. Hypoglycemia (especially hyperinsulinemic hypoglycemia) is a major cause of brain injury, hence the urgent need to identify and manage patients appropriately. A thorough medical history followed by a careful clinical examination in combination

with routine biochemical testing should help to elucidate the underlying cause of the hypoglycemia.

Adolescent Medicine

Leslie R. Walker

390 Normal Adolescent Development

Laura Kastner · Elizabeth McCauley

Adolescence represents one of the healthiest periods in the life span with respect to physical illness but is marked by a dramatic increase in problems related to the control of emotions and behavior such as accidents, mental health concerns, and substance use. During this period, adolescents are experiencing the most rapid growth phase outside of infancy, ushering in biopsychosocial changes which intensify teens' own emotional experiences of themselves and those of the adults interacting with them. Structural remodeling takes place in the prefrontal cortex starting in early adolescence. The prefrontal cortex helps make possible the executive functioning skills of planning, reasoning, impulse control, and weighing risks and rewards. Until brain maturation is complete in the early twenties, cognition and decision-making are compromised. Put simply, behavior is often governed more by the emotional region of the brain than the cognitive region especially in high arousal situations.

A 15-year-old adolescent boy named John is accompanied by his mother who complains of his decline in grades at school (from A's and B's, to several C's), sullen attitude, completing chores only with reluctance, withdrawal whenever possible to his room and general emotional reactivity. She read on a web site that these characteristics could be symptoms of depression or substance abuse. She would like to know if these problems exist or if there is a physical reason for his marked behavioral and emotional changes in the last year.

Adolescent health-care practitioners are frequently asked whether there is a clinical diagnosis, or "is it just adolescence?" Epidemiological studies indicate that only about 20% of adolescents have clinical disorders, but most teens do experience increased moodiness, conflicts with parents, and risk-taking behaviors during this period of life. To fully assess the psychosocial *and* health status of teenage patients, their behaviors must be evaluated within the developmental context of their family, school, community, and culture.

Physical Development

Pubertal Development

The physical changes associated with puberty are of central concern to most teens, but the equally important neurodevelopmental changes occurring in adolescence are also triggered by pubertal hormones. Neuroscientists now suggest that the pubertal hormones stimulate the brain systems that regulate arousal and appetite which leads to changes in the intensity of emotions and motivations. This in turn contributes to alterations in the sleep–wake cycle and increases in romantic interests, risk-taking or novelty-seeking behavior, and moodiness observed in many adolescents.

Last year John seemed happy hanging out at home and even spending time with his younger sister playing video games. In middle school, he was a bit smaller than some of the other boys in his class and not very interested in what he wore or how he looked. Over the summer, his mother noticed that his voice began to change and he had more acne, then he grew about 3 in. "overnight." Now he is talking about getting "piercings," likes to stay up late at night, and is always texting to keep up with what his friends are doing.

Understanding the meaning and implications of puberty for an individual adolescent requires consideration of both timing and tempo of pubertal development as well as the youth's gender and cultural/ethnic context. Youths, whose development is "out of synch" from the majority of their peers are at increased risk for behavioral and emotional problems. However, the youths' perceptions that they are developing earlier or later than their peers, may be more important than the actual timing of pubertal changes. Also, youth may be more vulnerable if visible markers, such as breast development, are seen as early or late than if less visible indicators, such as menses, are early or delayed. Early maturing girls, with obvious physical changes, are the most at risk group. A number of well-designed studies have documented increased risk for

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_390,

conduct problems, early drinking, and depression among these girls. For boys, early pubertal development was long considered to have positive effects on self-confidence and social status but more recent research suggests that both early and late maturation confer increased risk for depression and anxiety in boys as well as girls. Coupled with timing, the pace of the developmental process can also shape how well the young person adjusts to pubertal changes. Experiencing rapid physical changes particularly during early adolescence can be very disruptive especially since physical coordination may not keep pace with an accelerated growth rate. So the tall, lanky eighth or ninth grader who gets asked about basketball all the time may be very self-conscious about his/her lack of coordination and avoid even trying out for the team.

Early pubertal development is thought to increase risk because it presents the adolescent with a set of challenges that his/her friends are not yet facing. Evidence suggests that early developing girls seek out peers who are like them physically and in turn find themselves in demanding social and emotional situations without the necessary coping skills. Pubertal development does not hasten all aspects of development, so the early maturing teen does not have the benefit of advanced cognitive, social, or problem-solving skills. Early development is most problematic when friendships with more deviant peers develop in the context of lax parental supervision. Parents can be encouraged to take an active role in helping their child navigate these challenges by working to establish and promote healthy activities, by continuing involvement with positive peers, and by keeping actively involved in their youth's life. Parents sometimes think of supervision as only rulemaking or reminding their children to do chores or homework but it can come in the form of being willing to drive to the movies, having kids "hang out" at their house, or making the effort to attend their adolescent's school and sports activities.

Alterations in Sleep

Changes in sleep are another marker associated with the physical brain development of adolescence. A physiological shift or phase delay occurs with adolescents shifting naturally to later bedtimes. Changes in sleep architecture also occur such that adolescents engage in less deep, slow wave sleep. Homework, social and work demands also take time away from sleep. A recent survey found that 45% of adolescents report not getting enough sleep on school nights and many endorse feeling irritable and sleepy during the day. Insufficient sleep negatively impacts mood and ability to perform in school. Adolescents' night owl patterns frequently upset parents and interfere with getting up for school. Simple adjustments in acceptable bedtimes may be all that is needed, but significant reversals in sleep–wake cycles can occur if youth get "online" or communicates with peers late into the night. Many young people try to make up for the lost sleep by sleeping in on the weekends. Some compensatory sleep may be helpful but it can also perpetuate a pattern of late nights followed by struggles to get up for school. Practitioners need to educate parents and teens about these normative shifts in sleep patterns while stressing the importance of getting adequate sleep and simple strategies for getting to sleep at night such as turning off computers and cell phones, trying to stick to a regular bedtime schedule and routine, and developing relaxation strategies to avoid lying in bed worrying.

Vulnerability to Drugs

Experimentation with alcohol and drugs is one important component of the risk-taking behavior that characterizes adolescent development and is triggered in part by the physical changes in the adolescent's brain. The Monitoring the Future Study, 2008 reports widespread use (e.g., 42% of 12th graders report use of alcohol in the last 30 days) even though these figures support a gradual decline in substance use since peaks in the 1990s. While some experimentation has been associated with more positive psychosocial outcomes than total abstinence, use of drugs in adolescence can be particularly risky. Initiation of drug use during adolescence is associated with an "accelerated dependency course" with, in relation to alcohol and marijuana use, shorter time between first use and dependence. Adolescents drink less frequently than adults, but when they drink, they are more likely to drink to excess or "binge." As substance use becomes more significant, negative consequences are more common, such as falling grades, fighting or doing something that the teen later regrets. Alcohol use, specifically, appears to play an important role in lowering the threshold for self-harm.

There is also evidence to suggest that adolescents have an insensitivity to some of the negative effects of alcohol (feeling or acting intoxicated) that might contribute to increased intake. They are also more likely to become more sensitive to experiencing a reduction in social inhibition, which may reinforce alcohol use. It is common for adolescents to report that they drink because it helps them feel "less shy" and more able to "think of things to say" in social situations. Gonadal hormone increases and rapid

rate of growth might also contribute by altering drug metabolism and excretion rates. It has been hypothesized that the increased dopamine inhibitory input to the prefrontal cortex noted in early adolescence may lead to changes in "excitatory drive" or experience of reward. This in turn may lead some adolescents to seek out more novelty, which could increase risk of drug use, vulnerability to abuse, and other risk-taking behaviors.

Psychosocial Development

Cognitive Development

The cognitive changes that adolescents undergo are dramatic as they become increasingly capable of high-level thinking, which can approximate an adult's reasoning abilities by the age 15 or 16. They begin to think in terms of cause and effect, make elaborate plans for the future, and evaluate alternative outcomes for various actions. As impressive as their thinking capacity may be in some circumstances, like on a trigonometry test or in a conversation about the health impact of smoking, adolescent cognition truly depends on the situation. Students with "A's" in health class who understand statistical risk (and want to avoid) the potential consequences of unprotected sex, drinking and driving, or smoking may engage in any one of these behaviors without knowing quite how to explain themselves later when pondering their regrets.

Although John's mother acknowledged that he mostly obeyed home rules of curfew and staying in touch, he recently lied in order to go to a rock concert on a school night, claiming that he was going to "study group" for a school project that did not exist. He reported that he felt guilty about lying but was resentful that his parents were strict about social restrictions on school nights.

When adults come face to face with what is considered irrational adolescent behavior, they often ask, "What were you thinking?" Or they chide about poor "choices." Clinicians are often tempted to offer health education, even when their adolescent patients may already have sufficient information about management of their sexual health, chronic illness, or substance use. What they are lacking is rational decision-making, motivational clarity, and lucid thinking while under the influence of their strong emotions in social contexts. Not only are adolescents put off by lecturing, but an exclusive reliance on information obscures the complexity of all the neurological, social, and emotional factors in play when a teen is on a lark with friends.

With the expanded ability of adolescents to reason and analyze, they enjoy the process of arguments (especially with parents) and testing out their theories, new ideas, and wild speculations. Life experience and interpersonal relating with both the peer and adult world help alleviate the teen's egocentric and off-base thinking over time, but it is easy to become ensnared in an adversarial encounter with an adolescent who may claim, "AIDS is not the big deal it was in the 1980s" or "school is stupid and does not matter." While exploration of these topics may be important, the adult who can stay respectful, Socratic, and calm will do far better maintaining rapport with the teen than the one who merely criticizes, counters, and corrects.

Cognition lays the foundation for moral reasoning, analyzing the consequences of possible actions, and evaluating values, laws, and ethical codes. Adolescents enjoy reveling in their newfound autonomy, both in thinking and action, but the adult world of parents, teachers, mentors, and others remind them of the importance of responsibilities, competencies, and the ethic of care for others that truly create a civil society.

Emotional Development

Emotional development in the adolescent usually includes self regulation, coping with feelings, coordinating cognition and emotion, and building a sense of identity. Emotional regulation refers to the ability to identify, process, and express feelings appropriately. Moodiness, emotional reactivity, and impulsivity have long been the rocky turf of burgeoning adolescence, but now research has documented a neurophysiological basis for these behaviors with imaging techniques that reflect limbic brain activity. With the immaturity of the prefrontal cortex, the incomplete myelination process, and the proclivity for neurons to fire in the limbic area during arousal, adolescents possess vulnerability for temper outbursts. Indeed, hot emotions like fear, anxiety, and anger register in the amygdala, which is part of lower cortical limbic area of the brain, and cool logic and higher intellectual functions are associated with neuronal activity in the neocortex, which is still under active reorganization during the adolescent years.

Another complaint from John's mother in the initial interview is that John seems be "blowing his top" all the time, whether he is being asked to take out the garbage or reminded of his regular baby-sitting obligation to a neighbor. He snipes at his sister regularly during dinner no matter how kind she is to him. John goes along with the mandated "electronic-free" study hall imposed by his parents to help him bring up his grades, but the focus of his life seems to be music and his friends. Although he still attends church with

the family, John acknowledges that his favorite activity is downloading music, adjusting his playlist, and writing music reviews for his Facebook homepage. He admits to "losing it" when his mother nags and criticizes him for his computer "addiction." He loves to write music reviews – his friends rave about them!

The cognitive control network in the adolescent brain is disrupted by the activation of social and emotional parts of the brain. As described by Steinberg (2008), the adolescent is like a driver who has a big engine, poor driving skills, no map, faulty brakes, and high octane gas in the tank. The development of emotional regulation capabilities is a work in progress for the average adolescent. Poor emotion regulation is a key component of the increase in both risk-taking and mental health problems observed in adolescence. Parents can influence their adolescents' emotional regulation by using warm, firm intervention strategies, selective reinforcement, modeling, and active parental monitoring. Guidance for both parents and pediatric specialists addresses the specific importance of emotional regulation in adolescents and in the families.

Identity Development

Identity is a fuzzy concept but it refers to the establishment of a coherent sense of self in the context of relationships, values, and goals. The "who am I?" question involves notions of one's current self as well as the future and possible self – i.e., who I might become and who I want to become. Identity can include personal characteristics (e.g., short, math geek), roles (e.g., mama's boy, best Hebrew scholar), goals (e.g., ballerina, construction manager), and personal beliefs and philosophies (e.g., Christian fundamentalist, progressive democrat, open source software enthusiast). Although identity development is traditionally cast as the central task of adolescence, it is now considered to continue actively into early adulthood, if not the rest of life to some degree.

Although anxiety is associated with the "who am I?" questioning process and the adolescents who are firmly adherent to parental beliefs can seem quite stable from a behavioral perspective, identity exploration seems to reflect a certain security in investigating the unknown. Since parent support and monitoring are associated with higher identity achievement, practitioners can reassure parents that there is a "method to the madness." With the positive involvement of parents, adolescents as a group develop desirable strengths and qualities as a result of the exploration process, as long as they stay safe within their experimentation.

Social Development

Although adolescents generally shift their focus from their family to their friends as the center of their social world, parent attachment is vital. Research demonstrates the important role of parents in virtually all areas of adolescent health. With parents as the secure base, adolescents can afford to take them for granted while they try out interesting and novel social experiences. Peers serve as a new reference group for trying out innovations, adopting customs of the new tribe, and experimenting with new exciting behaviors, which may include novel ways of dressing, talking, walking, dancing, and relating.

Peer acceptance is important for long-term adjustment, while popularity is not. Although sometimes parents are concerned about the number of friendships their children develop, more important is whether they have friends at all. Social isolation among peer-rejected children and adolescents has been associated with negative outcomes like academic difficulty, delinquency, and psychosocial maladjustment, whereas peer acceptance and the development of social relationships have been linked to positive outcomes.

Younger adolescents yearn for acceptance and the predominant focus is "being cool." It is not until there is some consolidation of the new self by the end of middle adolescence (14–16 years) that the adolescent can feel confident to shed some of the need for conformity. The term "peer pressure" implies overt and extrinsic influence, which can certainly occur amongst adolescents, but it is dwarfed by the intrinsic drive that adolescents have to belong to the new teen culture. The value on individuality, mutuality, and intimacy in friendships develops between middle and later adolescence.

Beyond age, research has demonstrated that there are differences in adolescent social development based on gender, race, class, culture, and temperament. For instance, the social context of development for African-American adolescents is different from mainstream white teens when they experience economic stress, high-risk neighborhoods, and crowded schools. Introverted adolescents will have fewer friends. Novelty-seeking boys will seek out the same so that they can be exhilarated in the presence of their friends. Girls will enjoy spending their time with friends talking, whereas boys will seek out more action-oriented activities. Compared to mainstream whites, family loyalty and respect for elders are more highly valued by Asian-American adolescents and Latinos.

Sexuality Development

Sexual Behavior

Pubertal maturation, and the developmental changes in arousal, motivation, and emotion that come with it, stimulates romantic and sexual interest. Biological development is far more important than chronological age in determining sexual interests. There is also a link between puberty and both sensation seeking and a sensitivity to social status, all of which helps to explain why pubescent adolescents can become preoccupied with fantasy, jealousy, sexual yearning, and outlets for their sexual curiosity.

One of their recent conflicts was when John's mother found pornography on his computer. His father gave him a stern but sympathetic warning and there seemed to be no further violations. In the computer raid, John's mother found huge amounts of "instant messenger" contacts with a particular girl. Subsequently she noted that John's decline in his grades did accompany what his mother called the "the major crush."

Romantic patterns and dating have changed markedly among adolescents in the last generation with Internet use, "cyberdating," and group socializing, and savvy kids know how to throw their parents off their tails by referring to partners as "just friends." Often younger adolescents will refer to "going out" with a particular person, when they have not even shared a single direct conversation. "Hooking up" is a similar term which is vague, in that it can refer to anything from kissing to sexual intercourse. Does "having sex" refer to just sexual intercourse or does it include oral sex? Practitioners are advised to inquire directly to make sure they understand their patients' meanings of terms.

Adolescent relationships usually last for a few months, and as the time in the relationship increases, sexual involvement is more likely to occur. Approximately, 47% of high school students in 2005 reported having had sexual intercourse at least once, ranging from one third of 9th graders and increasing to a majority of 12th graders. Rates are higher among males than females at every age. Racial differences occur, with rates of 12th-grade sexual activity among African-Americans at 68%, Hispanic students at 51%, and white students at 43%.

Despite public impressions about problems associated with teens and sexuality, rates of adolescent sexual activity, pregnancy, and childbirth have actually decreased over the last decade. Still, the United States has the highest rate of adolescent pregnancy in the Western industrialized world, even though the adolescent sexual activity rate is similar to that of Canada and Europe.

Research has shown that adolescents with the most connected relationships with their parents have the most responsible sexual behaviors, including delaying intercourse, having fewer partners, and practicing safer sex. Most health experts agree that teens need and deserve comprehensive sexuality education, which includes information about abstinence, refusal, and negotiation skills and up-to-date information about birth control and sexually transmitted infections.

Sexual Identity

As adolescents explore their sexuality, they may think about or experiment with people of the same sex. Same sex attractions do not necessarily mean that the adolescent is homosexual – they may or may not be. Sexuality can be fraught with anxiety for anyone but particularly so for young people who may be trying to consolidate a minority sexual identity in a society that discriminates against homosexuals. Homosexuality was eliminated from psychiatric diagnostic manuals decades ago, but that has not eliminated the risk factors associated with being a gay, lesbian, or bisexual youth.

Sexuality, Psychosocial Development, and Media Influences

The effect of electronic media on the psychosocial development of the average adolescent is unknown, but studies have linked exposure to many negative outcomes in adolescent health. Violent media exposure has been associated with aggression, hostility, and poor school performance as well as violent behavior in adulthood. Viewing sexually explicit online media has been correlated with casual attitudes about sex. Television advertizing exposure has been associated with parent–child conflict and materialism. The enormous amount of time that adolescents spend interacting with social networking sites, instant messenger, music downloading, gaming, blogging, and various entertainment has been well documented.

While electronic media plays a role in the lives of virtually all adolescents, the tricky question for practitioners is when this role may be destructive. Given the importance of time allotted to physical fitness, sleep, education, direct interaction in social relationships, talent development, family, religion or spirituality, and even spending time in the natural world, one way to evaluate the way media affects the individual adolescent is calculating how much it robs time from other important avenues of healthful child development.

Table 390.1
Stages of normal adolescent development

	Early (10–13 years)	Middle (14–16 years)	(17–19 years)
Physical	Beginning of physical changes in the brain, shifting of sleep/wake cycle and rapid physical development: Girls: breast buds, pubic hair, start of growth spurt, menarche for many Boys: 1–2 years after girls, testicular and penile growth, pubic hair	Ongoing brain maturation and sexual development with most girls moving into Tanner stages VI and V and boys experiencing continuing development of testicles, penis, body and facial hair, and beginning of linear growth spurt	Brain maturation continues into young adulthood with maturation of frontal lobes which facilitates regulatory competence. Most youth reach Tanner Stage V
Cognitive	Gradual shift to hypothetical ("what if") and abstract thinking from concrete operations of childhood; self-centeredness is characterized by egocentricism, self-consciousness, and self-absorption	Cognitive comparisons between real and ideal in parents, friends and selves, mature analytic thinking in "cold logic" contexts (e.g., lab, classroom, and other low-arousal situations) but frequent lapses in "hot" or emotional circumstances	Maturing of accurate perspective taking and self-reflection, increased consideration of future life goals, improved executive functioning skills (planning, reasoning, judgment, and impulse control)
Emotional	Increased moodiness, irrational behavior, emotional reactivity and impulsivity related to puberty and changes in the prefrontal cortex	Increased arousal and novelty seeking, low motivation for what is perceived as boring; increased conflict with parents, emotional dysregulation hyper-aroused amygdala	Growing ability to recognize and manage emotions, demonstrate empathy, resolve conflicts constructively, and work cooperatively with others
Social	Increased desire to be with friends, push for greater independence, less contentment in being exclusively with family, increased identification with peer culture, value on independence and individualism highly influenced by culture and ethnic background	Identity formation and values exploration, strong preference for the company of friends but still connected to parents for support, desire for approval and long-term attachment, peer conformity driven by strong desire for peer acceptance	Integration of values internalized from parents, experience, and generational influences; friendship choices less related to similar interests and more to valued individual characteristics and qualities; intimacy increasingly sought

Summary

With the information reported by John and his mother thus far, there is a lack of clinical evidence for ruling a problem in or out. All of the behaviors of concern to his mother could be considered within normal developmental limits for a teen of his age (see *Table 390.1*). In fact, the initial interview revealed "protective factors" suggestive of resilience and positive development. These include John's compliance (albeit reluctant) with parental expectations regarding curfew, his baby-sitting job, chores, imposed study hall time at home, and church attendance, as well as other family factors associated with adaptive teen development like authoritative parenting, organized family life (e.g., the family dinner), and successful mediation of previous conflicts.

Although further interviewing and a physical exam are needed in order to address the family's questions, it is remarkable how much preliminary developmental data has already been collected. The practitioner's challenge is to ask questions skillfully so that the teenager feels comfortable, respected, and validated for whatever concerns he may present as the evaluation proceeds. The practitioner who is aware of normal adolescent developmental issues will demonstrate a genuine appreciation in John's array of interests, ranging from independence and sexuality to music and friendships as well as his behavioral competencies.

391 Adolescent Nutrition and Weight Control

Alicia Dixon Docter · Cora Collette Breuner

Factors Influencing Nutritional Needs

The onset of puberty and emergence into adolescence presents unique nutritional challenges due to dramatic changes in physical, cognitive, and emotional development. There is increased demand for nutrients due to pronounced change in body composition, linear growth and increases in muscle mass, subcutaneous fat, and bone density. Layered on to this is substantial individual variability for each adolescent dependent on their genetic, environmental, and psychosocial milieu. Reliance on peers, greater independence in food choice, and widely variant increases in physical activity add complexity to helping adolescents meet their nutritional needs. School, community, and societal influences are appropriate to acknowledge when working with this population.

Normal Eating and Adolescent Nutrition

An adolescent's relationship with food has been developing since infancy. In an ideal situation, the teen will gradually emancipate and begin to meet their own nutritional needs during the latter half of adolescence, usually between 18 and 25 years of age.

Common eating patterns emerge include: grazing, skipping breakfast, fast food consumption, drinking excessive sugar-sweetened beverages, restrictive eating to control weight, and non-traditional eating patterns, often to establish identity. One-third of teens use a multivitamin/mineral supplement. Seventy-five percent use caffeine daily in the form of carbonated beverages, energy drinks, and coffee drinks. Fast food intake has increased over time. In a review of project EAT (population-based, longitudinal study in Minnesota), almost a quarter of adolescents ate fast food $\geq$3 times/week, which increases to one third in young adult males. At follow-up in early young adulthood, this eating behavior increased among males (33%, $p < .001$), yet there was no further increase among females (23%; $p = .16$). Baseline snack frequency was positively associated with frequency of fast food intake at follow-up among both genders. Baseline peer support for healthy eating among males and concern about health and self-efficacy for healthy eating among females were inversely related to follow-up fast food intake. Among females, baseline perceptions of time and taste barriers to healthy eating, lunch frequency, television viewing, and unhealthy food availability at home were also positively associated with fast food intake. A small but significant positive association was seen between fast food consumption and overweight status. Within-person comparisons showed that energy intakes were higher on a fast food day than on a non-fast food day. Conclusion: Fast food consumption was associated with a diet high in energy and energy density and low in essential micronutrient density. Frequent fast food consumption may contribute to weight gain.

By late adolescence, a teen should be expected to eat at least three meals a day and a snack after school. Breakfast is an important fulcrum and has been associated with less overeating later in the day and in some cases, with a lower BMI. In one review, it was found that 10–30% of those living in the United States and Europe skipped breakfast. Importantly, children who reported eating breakfast had better nutritional profiles and were less likely to be overweight than their peers who did not eat breakfast. Does eating breakfast improve cognitive function, memory, school performance, and even attendance? In this review there is some evidence that this is true, although more research is necessary. In another paper looking at a school feeding program in Jamaica, children ages 12–13 had improved performance in arithmetic and attendance, but no weight gain.

A teen should be encouraged to manage daily activities and snacking in order to make family meals a priority. Regular family meals have been associated with positive regard for family. Teens should be encouraged to find their own ways with food away from home: what to eat, how

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_391,

much to eat, how to get what he needs. Finally, before teens leave home, meal planning, food preparation, and shopping should be reviewed and practiced.

Nutrition Needs Due to Growth

Clinicians should consider Sexual Maturity Rating (SMR) or Tanner staging when making nutritional recommendations as chronological age is a poor indicator of physiological maturity.

Weight gain should be expected through adolescence due to increases primarily in bone, lean body mass, and adipose tissue. For females, the average increase in height is estimated at 8.24 in. (20.5 cm). During the peak of the growth spurt, females gain roughly 3.5 in. (8–9 cm) per year. Adolescent males experience increases in height of 4–12 in. (10–30 cm) during puberty, with an average of 2.8–4.8 in. (7–12 cm) attained each year. Pubertal weight gain accounts for approximately 50% of an individual's ideal adult body weight. More than 90% of adult bone mass accrues by 18 years of age.

During childhood boys and girls have relatively equal proportions of lean body as skeletal mass and body fat. By the end of puberty, however, men have 1.5 times more lean body mass and skeletal mass than women who have double the fat mass.

While girls experience a slightly less intense growth spurt in height, less marked increase in skeletal muscle, and a more continuous increase in fat mass than boys, this should be normalized so that the girl feels positive about her growth experience. Average weight gain for females are equal to 38.5 lb(17.5 kg). While weight gain slows around menarche, females may gain as much as 14–20 lb(6.36 kg–9.09 kg). during the latter half of adolescence. Adolescent males may gain an average of 20 lb(9.09 kg). per year during the pubertal growth surge. Overall, males gain an average of 52.2 lb. (114.8 kg).

Nutrient Needs in Adolescence

The Dietary Reference Intake (DRI) is the most up-to-date data; however, it is based on chronological age. A clinician needs to consider growth and sexual maturation status. That said, DRIs are general guidelines and are set to meet 97–98% needs (see *Table 391.4*). In Europe, investigators from various countries are working together to standardize diet and nutrition methods for nutrition surveys to overcome uncertainties over the nutritional quality of the diets of European children and adolescents.

Table 391.1
Percentage of body fat during puberty

Stage of puberty	% Body fat
Female	
1	15.7
2	18.9
3	21.6
4	26.7
Male	
1	14.3
2	11.2
* Percentage of body fat remains unchanged in stages 3, 4, and 5 in males	

From Malina R, Bouchard C, Bar-Or O (2004) Growth, maturation, and physical activity, 2nd edn. Human Kinetics, Champaign

In the Healthy Lifestyle in Europe by Nutrition in Adolescence (HELENA) Study, an assessment of food intake in 13–16-year-old European adolescents showed that mean energy intake in boys range from 1,532 to 2,868 kcal per day and from 1,450 to 2,818 kcal per day in girls. Overall, there was a tendency to report a lower energy intake with increasing BMI.

In the 2003 Children's Lifestyle and School-Performance Study, a survey of Canadian fifth graders of height and weight were also asked to respond to the question "I like the way I look." Response choices included "never or almost never," "sometimes," and "often or almost always." Interestingly, 7.3% of girls and 7.8% of boys had "bad body satisfaction."

Researchers also found that rural girls or those with poorly educated parents were likely not to like their bodies. Austin et al. found that links between body satisfaction, weight-related behaviors, and weight gain require that overweight prevention in children can be enhanced through better knowledge of factors underlying body dissatisfaction. Mechanisms should also be studied in families with low parental education and in rural communities.

Nutritional Concerns in Adolescence

Risks associated with undernutrition include delayed puberty, amenorrhea, decreased bone mineralization, iron deficiency, and dehydration.

Situations that include an inadequate intake of nutrients, including energy (calories) in which teens may need some additional guidance, include:

- The adolescent athlete
- Alternative dietary preferences
- Eating disorders
- Obesity and overweight

Nutrition needs related to pregnancy, drug and alcohol use, and chronic illnesses are found elsewhere in this textbook.

The Adolescent Athlete

In the teen athlete, energy needs are very high due to growth and development needs as well as sport energy needs. Specific nutrient recommendations vary based on age, developmental stage and should be tailored by assessment of a nutrition professional with expertise in adolescents and sports. The over-arching approach is to help the teen athlete achieve an adequate baseline intake and tailor eating around individual preferences and tolerance at practice and events. Regular menstrual periods indicate the patient is meeting energy requirements.

Meal or snack skipping due to sport, studies, and busy lifestyle may prevent meeting energy needs. Adolescent athletes need a baseline of three full meals and two to three snacks per day. A meal should include four to five items representing a variety of food groups including grains, protein, fruits, vegetables, fats and oils, and dairy as appropriate. Desserts and snack foods may be considered as a way to ensure that the athlete is consuming adequate caloric daily requirements. Meals should include high quality proteins supported by adequate carbohydrate and fat. Teen athletes should be reminded that energy bars are not acceptable meal replacements in that they do not provide calories equivalent to that in a balanced meal.

During exercise, primary goals are to replace fluid losses and provide carbohydrates (approximately 30–60 g/h) for maintenance of blood glucose levels. Athletes need to immediately replenish energy used (within 30 min and then again every 2 h for up to 4–6 h after exercise) after practice or competition by having small snacks high in carbohydrate (1.0–1.5 g/kg body weight) or a combination of carbohydrate and protein.

Athletes should have unlimited access to fluids *during* exercise to improve hydration and temperature regulation. Athletes must be urged to rehydrate themselves because the thirst mechanism imprecisely guides water needs. After exercise, the athlete should drink adequate fluids to replace sweat losses during exercise, approximately 450–675 mL (16–24 oz) for every 0.5 kg (1 lb.) of body weight lost during exercise.

Athletes should be counseled regarding the appropriate use of ergogenic aids. Such products should only be used after careful evaluation for safety, efficacy, potency, and legality.

An Adolescent with Alternative Dietary Preferences

Teens with alternative dietary preferences require clear, practical nutrition education about functions of foods in order to understand that eliminate of food, requires up for the deficit in calories or a nutrient by substituting in an alternative that supplies those nutrients. For example, vegetarians cannot eliminate protein and expect to meet their needs – they need to utilize foods that will provide high biological value proteins. Additionally, teens need to understand the concept of getting enough energy (calories) to support growth as well as lifestyle. As with all teens, they will need education about food selections and how the body uses food to avoid dichotomous thoughts that may interfere with what they require. With guidance in meal planning, vegetarian diets can be appropriate and healthful choices for adolescents.

Nutrition Assessment

A physical nutrition assessment should include: plotting weight, height, and BMI (kg/m^2) on gender-appropriate CDC growth charts (2–20 years). This data should be compared with weight and height history to determine change in weight and growth velocity. An optimal healthy weight range, often referred to as ideal body weight (IBW), is estimated based upon available growth history and is generally between the 25th and 75th percentile of BMI-for-age. A weight goal is typically 90–110% of IBW. A weight at $\leq$85–90% IBW may increase risk of delayed puberty or amenorrhea. Arm muscle and fat stores measured by the Registered Dietitian can be a helpful assessment and educational tool.

A dietary assessment should include a diet history from infancy to present, preferred and disliked foods, dietary restrictions/food allergies, and any supplements. It should also include a review of a typical day: schedule, activities, foods and beverages consumed with approximate amounts. Family composition, food availability,

location of meals and snacks, rules around food, involvement in school feeding programs, and involvement in extracurricular activities need to be evaluated.

If a medical provider does not have the time to conduct a thorough review yet suspects eating issues, a referral should be made to a nutrition professional who has training with adolescents and is comfortable collaborating with a team. The designation, R. D. (Registered Dietitian), ensures that the professional has rigorous clinical training.

Eating Disorders

Introduction

Eating disorders, including anorexia and bulimia nervosa, originate in late childhood and early adolescence. Prevalence rates for anorexia range from 0.5% to 1.0% in females and 0.1% in males. Bulimia nervosa is not as common in those under 18 years of age; bulimic behaviors occur in 1–3% of females and less than 0.2% of males.

Depression and anxiety are particularly common comorbidities for anorexia nervosa and bulimia nervosa. It has been reported that 50–70% of patients with anorexia and bulimia also have depressive, obsessive-compulsive, or anxiety disorders.

Despite a relatively broad base of knowledge about this disorder, the treatment of eating disorders in children and adolescence is limited to few controlled studies. It is unclear whether all aspects of the illness must be addressed simultaneously or in sequence if treatment is to be successful, or whether by solely addressing the eating habits other concerns will also be effectively managed.

An interdisciplinary team including pediatrics or general medicine, nutrition, and mental health provides the most comprehensive treatment approach when all providers are in regular contact with one another and share a similar philosophy in the understanding and treatment of the disorder.

- Questions to ask: What is your maximum and minimum weight? What is your desired weight?
- Do you eat with your family?
- Are there any "off limit" foods?
- Any friends/family members with abnormal eating behavior?
- How much do you exercise? How do you feel if you cannot exercise?
- Do you ever eat more than what feels comfortable to you? Then what do you do?
- How is your sleep?
- Are you taking any supplements to lose weight? Improve your sleep?

Nutrition Approach to Eating Disorders

In both inpatient and outpatient settings, the clinician needs to identify what teens and families are doing in terms of eating. Then, through education and support, the teen should be encouraged to make small changes to allow for a balanced meal pattern that will support gradual weight restoration (.5–1 lb. (1.1–2.2 kg)) per week. Education regarding the role of nutrients, the need for adequate nutrients and energy, and effects of semi-starvation can be helpful. It is important to work with a collaborative multidisciplinary team that is familiar not only with eating disorders but also with adolescents. Refeeding to stabilize a teen medically in an inpatient setting, may be more aggressive but should still be gradual over a 3–7 day period.

Psychological Approach to Eating Disorders

There are many different types of psychotherapeutic interventions including cognitive behavioral therapy, narrative therapy, body image therapy, and motivational interviewing. The challenge of using any of these options is that in patients with anorexia nervosa they often lack motivation for weight gain and this must be addressed

Table 391.2
Criteria for hospitalization in the adolescent eating disorder patient

• Sinus bradycardia, rate less than 40 beats per minute
• Other arrhythmia, including prolonged corrected QT interval
• Hypothermia (temperature $<97.5^{\circ}$F)
• Orthostatic hypotension by pulse or by blood pressure
• Precipitous weight loss in a short time period
• Severe electrolyte imbalances (potassium <3.0, phosphorus <2.0)
• Unable to eat or drink, acute food refusal
• Intractable vomiting
• Marked depression, with suicidal ideation and intent
• Failure to progress in outpatient treatment, especially when risk of growth delay is present

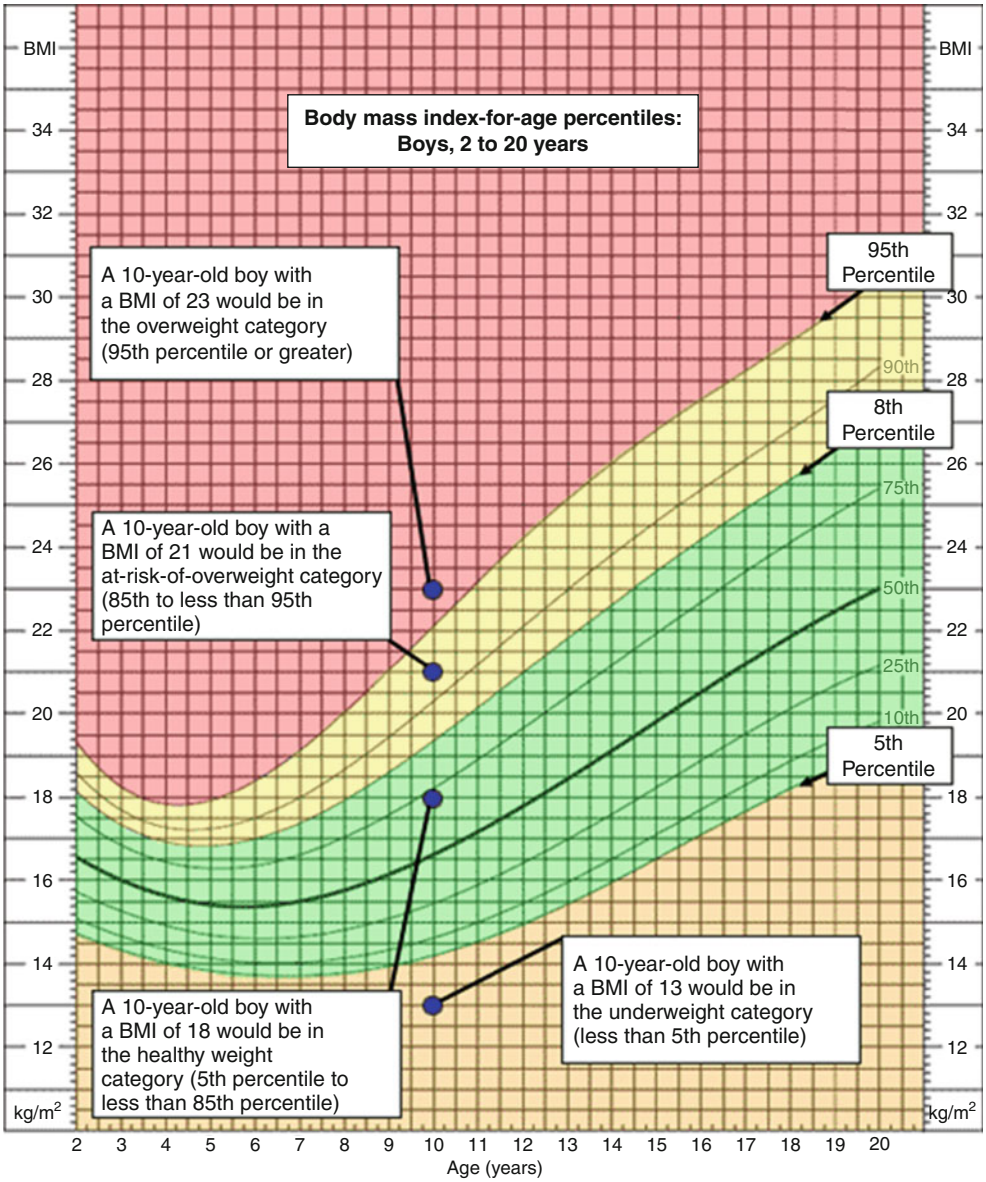

Figure 391.1

What is BMI? Body Mass Index (BMI) is calculated from a child's weight and height. BMI is a reliable indicator of body fat for most children and teens. Your child's pediatrician should assess BMI at each well visit beginning at age 2. For children and adolescents, BMI is age- and sex-specific and is often referred to as BMI-for-age. After BMI is calculated for children and teens, the BMI is plotted on the CDC BMI-for-age growth charts (for girls or boys) to obtain a percentile ranking

first in the initial phase of treatment in order to cultivate and sustain motivation for change. In family-based therapy (FBT), parents are directly involved in the patient's treatment and recovery process. Patients with an eating disorder are often in denial about the seriousness of their disease and generally incapable of making good choices regarding their health and eating habits. In one randomized control trial of 80 patients and their families, participants with less severe eating disorder psychopathology (Eating Disorder Examination global score), receiving FBT, were more likely to meet criteria for partial remission at follow-up.

Medical Approach to Eating Disorders

The medical management of the adolescent with an eating disorder requires knowledge of the physical presentations and quick attention to the medical complications that may occur. Some of the physical symptoms and findings include dry skin, cold intolerance, acrocyanosis, constipation, bloating, lanugo hair, scalp hair loss, delayed gastric emptying, weakness, fatigue, delayed puberty, primary or secondary amenorrhea, breast atrophy, atrophic vaginitis, and pitting edema of extremities. Cognitive changes have been found in some anorexic patients. Mouth sores, pharyngeal trauma, dental caries, heartburn, chest pain, muscle cramps, weakness, bloody diarrhea (in laxative abusers), bleeding or easy bruising, irregular periods or amenorrhea, fainting and swollen parotid glands are noted in those with bulimia nervosa. Recognizing these signs and symptoms as the mortality for those with eating disorders is the highest among psychiatric conditions in adolescents.

Myocardial abnormalities include sinus bradycardia, sinus arrhythmia, low blood pressure, or myocardial abnormalities. In anorexia nervosa, a pulse differential of greater than 30 beats/min, with underlying bradycardia, suggests excess vagal tone counterbalanced by excess sympathetic tone. Prolonged QT interval, fatal ventricular dysrhythmias, and abnormal contractility have been noted in both adults and adolescents. Reversal does occur with restoration of weight.

Electrolyte abnormalities include hypophosphatemia, hypokalemia, noted predominantly in bulimic patients, and hypomagnesaemia and should be treated with oral supplements until they normalize.

It is known that peak bone mass is gained during puberty and also that hypoestrogenemic osteopenia may be seen in as many as 50% of adolescents with eating disorders. The impact that this may have on the developing bone mass in a young woman can have significant deleterious effects in the adult. The treatment of an abnormal DEXA scan in the patient with an eating disorder has been controversial. It is known that weight-recovered patients had improved BMD (bone mineral density). Estrogen replacement has not been shown to be an effective treatment for decreased bone mineral densities in adolescents except in those with exceedingly low weight.

The absence of menses in the adolescent with an eating disorder is commonly observed and may be due to a decrease in leptin levels and thyroid dysfunction.

Hospitalization is imperative when a patient is severely medically impaired but does it improve long-term outcome of those with eating disorders? Only one randomized controlled trial has compared the benefits of admission with no treatment or outpatient psychological therapies. A further study has questioned the medium to long-term benefits of admission for adolescent anorexia nervosa. Unfortunately, there is still no clear data supporting the theory admission of adolescents with an eating disorder is associated with improved medium- to long-term outcome (*Table 391.2*).

Obesity and Overweight

Obesity is an excess percentage of body weight due to fat that puts people at risk for many health problems. In children older than 2 years of age, obesity is assessed by a measure called the Body Mass Index (BMI) (*Fig. 391.1*). Evidence increasingly identifies higher levels of physical inactivity (watching television and computer screen time), lower levels of moderate physical activity (active play), and excessive consumption of sugar-sweetened beverages as critical contributors to the ever higher rates of childhood obesity. In infancy, breast feeding appears to provide some protection against later obesity.

Table 391.3
Problems associated with obesity

• Glucose intolerance and insulin resistance
• Type 2 Diabetes
• High blood pressure
• High cholesterol
• Hepatic steatosis (fatty liver disease (FLD))
• Cholelithiasis (gallstones)
• Sleep apnea
• Asthma
• Skin conditions
• Menstrual abnormalities
• Impaired balance
• Orthopedic problems
• Low self-esteem
• Negative body image
• Depression
• Stigma
• Teasing and bullying
• Negative stereotyping
• Discrimination
• Social marginalization

Adapted from National Alliance for Nutrition and Activity Obesity Fact Sheet, 2009

Children and adolescents with a BMI over the 85% but less than the 95th percentile are considered overweight and those with a BMI greater than the 95th percentile are considered obese.

Overweight or obese children and adolescents are at risk for many health problems. Some of the negative health outcomes that may be more obvious to children and their parents are asthma, sleep apnea, skin infections, and complaints of joint pain (*Table 391.3*). All of these are significant health problems and need attention by a doctor; however, in addition to these there are other serious health risks associated with obesity that may be less obvious to the child or parent, such as high blood pressure (hypertension) and Type 2 Diabetes. These conditions can have serious long-term health effects and may require ongoing medical treatment and management. The bottom line is obesity can cause immediate health problems as well as a number of very serious chronic health conditions.

Research indicates that obese children have lower self-esteem and self-confidence than their thinner peers. Low self-esteem and self-confidence have been linked to poor academic performance, fewer friends, and depression. For all of these reasons it is important to try and prevent childhood obesity and identify overweight and obese children quickly so they can begin treatment and attain and maintain a healthy weight. Over the past 2 decades, the prevalence of children who are obese has doubled, while the number of adolescents who are obese has tripled. According to the National Health and Nutrition Examination Survey (NHANES), 31.9% of children and adolescents were overweight (BMI at or above the 85th percentile) and 16.3% were obese (BMI at or above the 95th percentile).

Although overweight has increased for all children and adolescents over time, NHANES data indicate disparities among racial/ethnic groups. Non-Hispanic black girls and Mexican American girls are more likely to have high BMI-for-age than non-Hispanic white girls. Among boys, Mexican Americans are more likely to have high BMI-for-age than non-Hispanic white boys.

As for treatment of obesity, it has been suggested that a much disciplining team provide care. Additionally, at least 25 hours of contact over 6 months has been found to improved BMI.

Table 391.4
Important nutrients for the adolescent

Nutrient	Function	Approach/food Source
Energy	Growth and development; normal menstruation that supports healthy bone accrual; adequate energy intake allows adolescent to meet nutrient needs	Female: 9–13 years: 2,071 kcal/day; female 14–18 years: 2,368 kcal/day
		Male: 9–13 years: 2,279 kcal/day; male: 14–18 years: 3,152 kcal/day
Protein	Growth and development	20% of total energy, which is generally achieved with eating normal meals and snacks at estimated goal energy level; needs may be higher with athletes
Carbohydrates	Energy	50–65% of energy needs, depending on activity
Fat	Cell structure; energy; satisfaction	25–30% of energy needs
Iron	Iron is required for adequate developmental, growth, and healthy red blood cells	• Bioavailability of iron sources (meats, egg yolk, breads, and cereals) and vitamin C intake (tomatoes, peppers, oranges, melons)
		• Supplement if medically necessary
Calcium	Bone health	Adequate; if amenorrhea – 1,500 mg/day (five servings high calcium foods per day)
Vitamin D	Assists with calcium metabolism: immune function	Sunlight; food sources: fortified milk, fish, liver, egg yolk. Provider to determine deficiency and supplement
Folic acid	Cell health and prevent of birth defects (neural tube defects)	Explore intake and food choices (e.g., fresh oranges and/or fortified cereals)
Zinc	Normal growth and reproductive health; skin health	Meat, cheese, legumes, whole grains

Approaches to Communication with Adolescents in Nutrition Intervention

- It is essential to develop a rapport using Motivational Interviewing (MI) tools such as *open-ended questions*, *reflective listening* and *affirmations*, and *working with resistance*.
- Adolescents are typically well educated with respect to "healthy" food choices or calories, but often have a distorted sense of regular eating frequency, meal and snack patterns, and appetite/satiety awareness.
- Expect experimentation with unhealthy eating behaviors. Help patient identify the pros and cons of less healthy choices.
- Connect education to life goals or to something the patient cares about such as continued height increase, appearance, and muscle mass development.
- Ask patient to identify 1–2 goals he/she is willing to work on over a specified period of time to improve health.
- Avoid making choices or giving ultimatums to teens. Instead, recognize what the teen is doing well and provide education and recommendations to consider when making his/her own wise choices.
- Respect patient's wishes for independence and privacy from parents. Ask teens if there are acceptable ways that parents can help meet goals.

Conclusion

Nutritional care during adolescence is challenging requiring patience, flexibility, and sensitivity to the adolescent wherever they are socially, emotionally, and physically. Food and adequate diet are not panaceas that solve juvenile delinquency and learning problems, improve athletic performance, and allow youth to attain new and exciting cognitive achievements. It is fun. It is hard. It is worth it (*Table 391.4*).

392 Adolescent Gynecology: Approach to the Female Adolescent

Taraneh Shafii · Gale R. Burstein

Adolescent Gynecology: Approach to the Female Adolescent

Broaching the topic of sexuality can be challenging for some healthcare providers and adolescent alike. However, it is an opportunity for healthcare providers to guide young women in understanding their bodies, controlling their reproductive future, and developing healthy sexual relationships.

Healthcare Providers' Personal Views of Adolescent Sexuality

Teenagers having sex can be an emotionally charged subject and may conflict with clinicians' personal beliefs. Regardless of individual ideology, to ensure the health and well-being of their patients, providers must offer adolescents comprehensive and scientifically based reproductive healthcare or else refer them to colleagues who are able and willing to do so.

Starting the Sex Conversation: Do You Talk About Sex with a 13-Year Old the Same Way as with a 17-Year Old?

Adolescents' ability to reason lies somewhere between the continuum of concrete operations of childhood and formal operations of adulthood, so before initiating an interview with an adolescent, it is helpful for providers to be aware of adolescent psychosocial development (psychsoc dev). For example, when asked if she is sexually active, the concrete adolescent may think that the provider is asking if she is "active" during sex instead of whether she has *ever* had sex.

The early adolescents (11–13 years) are unable to think abstractly or develop a plan for the future, which limits their ability to seek hormonal contraception or condoms prior to sex and limits their ability to think of the potential consequences of unprotected sex such as sexually transmitted infections (STIs) and unintended pregnancy. Middle adolescents (14–16 years) develop capabilities for abstract thinking and conceptualization, yet their ability to carry out such behavior may be limited. They may revert back to concrete thinking during times of stress such as triggered by peer pressure or alcohol and drug use. Late adolescents (17–21 years) are able to plan for and effectively use contraception and condoms; however, as the use of hormonal contraception increases in these older adolescents, condom use decreases, thereby providing an opportunity for STI transmission.

How Do You Know If Your Patient Is Having Sex?

In the United States, 62% of high school 12th-grade students have had vaginal intercourse and more than one third of all high school students have had sex in the past 3 months with 14% having had four or more lifetime partners.

The average age of first sex in the United States is 16.5 years. Unfortunately, many adolescents do not seek healthcare until well after first intercourse. Providers must always consider that their patients may already be engaging in oral, anal, or vaginal intercourse and are, therefore, at risk of STIs and pregnancy and should be screened through sexual history and laboratory testing.

How Young Is Too Young to Ask About Sex?

As 6% of US youth report first vaginal intercourse before 13 years of age, it is important to ask even early adolescents (11–13 years) about sexual behavior.

What About Cultural and Religious Differences?

Healthcare providers must be in tune with the varying cultural and religious beliefs of their patient population

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_392,

and demonstrate cultural sensitivity to different practices. For example, youth may be resistant to discussing the topic of sex regardless of their level of sexual experience because sexual activity prior to marriage is shunned by many cultures and religions. Therefore, framing information about sexuality in the context of helping their peers and friends who may be or become sexually active is a nonthreatening and effective method to provide sexual education to all patients.

How Do I Get My Patients to Tell Me What They Are Actually Doing?

Building rapport is the most important skill a provider needs in taking care of adolescents to create an environment where the patient feels safe disclosing confidential sexual behaviors and health concerns. Adolescents are surprisingly candid about sensitive topics when they feel safe, respected, and are promised confidentiality.

Tell Her What You Are Going To Do Today

Since genital exams are a source of great anxiety and embarrassment for youth, if a genital exam will take place, the provider should inform the adolescent patient. If a pelvic exam will be performed, a full explanation is imperative, especially if this is the patient's first exam. Allowing the adolescent to remain dressed during the interview and covered as much as possible during the exam contributes to feelings of safety and a sense of being in control of their bodies and their environment. Showing the adolescent the speculum, and even letting her handle it, usually helps in diminishing rather than escalating the anxiety. Diagrams or plastic genitalia models and mirrors during the exam are useful to educate youth as most young females are unaware of their anatomy and unfamiliar with proper terms. Many young women have never seen their own anatomy.

Ensure Confidentiality from Your Office and the Bill that Is Sent Home

All young people (age minimum varies per state) in the United States may legally give consent for their own sexual healthcare, so confidentiality may be offered to young women with the exception of the three caveats of harm: "What we talk about today is confidential from your family unless I am worried that you are thinking about hurting yourself; hurting someone else; or if someone is hurting you."

Health insurance presents another confidentiality challenge. However, insurance regulations mandate commercial health plans to provide subscribers explanation of benefits listing services received. To avoid disclosure through billing, providers can use as ICD-9 codes *symptoms* (e.g., dysmenorrhea, irregular menses) and general *clinical findings* (i.e., vaginal discharge, pyuria, or urinary complaints) rather than specific STI diagnoses such as trichomonas or chlamydia.

What Kind of Sex and with Whom?

What Kind of Sex?

As adolescents present in varying stages of cognitive development and sexual knowledge and sexual experience, providers need to ask very specific questions to make an accurate assessment of sexual health and risks. "Have you had sex with guys, girls or both? Have you ever had oral sex? Anal sex? Vaginal sex?" If in doubt of a youth's understanding of the definitions of oral, anal, or vaginal sex, the provider should pose the questions to ensure they are discussing the same behavior. "Tell me what 'having sex' means to you." The provider then has the opportunity to provide the definitions, for example, "I want to make sure we are talking about the same thing: so oral sex means your partner puts his/her mouth on your vagina/penis; some people call it 'going down on each other,' have you ever done that?"

With Whom?

Adolescents are in the process of understanding and accepting their sexuality, and survey data suggests that anywhere from 3% to 10% of US adults report being lesbian or gay. Sensitivity and awareness of sexual minorities is important when interviewing and obtaining a sexual history from an adolescent. For example, a provider is interviewing a 15 year-old female about her sexual behavior and asks, "So do you have a boyfriend?" If that young woman is struggling with her sexuality, the provider may have alienated her, when instead, he/she could have offered a safe venue for discussion of sexual feelings. An *alternative* example of initiating a conversation about sex: "You are at the age when you start figuring out if you are interested in or attracted to guys, girls or

both . . . have you thought about that yet? Have you ever had sex with a guy, girl or both?" By acknowledging different sexual orientations, providers are sending the message that same-sex attractions are within the range of human sexuality. For the heterosexual youth, providers are modeling a position of acceptance and tolerance for sexual minorities.

Could the 15-Year Old with Abdominal Pain Really Be Worried that She Is Pregnant? (If You Ask They Will Tell You; If You Don't They Won't)

The *Hidden Agenda* is the phenomenon of adolescents seeking care for a sensitive health issue (e.g., pregnancy symptoms) and assuming that their provider will know what is wrong with them without actually verbalizing the problem. For example, an adolescent female presents with complaints of a belly ache; the provider works up the abdominal pain but does not screen for sexual behaviors and treats the patient for presumed gastritis. The patient leaves the office reassured that she is not pregnant since she believes that the provider is omniscient and would have told her if she were pregnant. An adolescent will not always volunteer her true health concerns but is surprisingly candid when asked directly. Providers must ask the questions to which they want answers and should not rely on adolescents to bring them up themselves.

The Physical Exam

Foremost, the provider should always make the adolescent feel like she is in control. Providers should let the adolescent know what part of the exam is going to be performed next and that the physical examination will stop at any time if she is uncomfortable. Providers should explain that they are doing the exam to best take care of their patients' health and want to make sure that they are indeed healthy. As many options as possible can be offered during the exam to empower the patient and make her feel as safe and comfortable as possible. For example, the adolescent can be asked if she would be more comfortable completely undressing and changing into a gown before the exam or would prefer to undress only the part of the body being examined to remain partially dressed throughout the exam. Younger adolescents may prefer the latter option since they may feel insecure about their bodies. Also, females who require only an external genital exam can be permitted to continue wearing their underwear. For the genital exam, the provider can shift the underwear to one side allowing full visibility of the genitalia.

With new urine-based STI testing and revised Pap testing guidelines (recommending first Pap smear at age 21 years) many asymptomatic adolescent females do not require a pelvic exam. However, females presenting with genital symptoms and/or requiring their first Pap smear do need a pelvic exam performed.

Yolanda Evans

Contraception

Adolescent pregnancy is a worldwide problem with rates that vary by nation. For example, the following are pregnancy rates for 15–19 year olds per 1,000 females: Japan, 4.6; Australia, 18.4; the UK, 30.8; and the USA, 52.1. Overall, rates have been declining since the 1990s, in part due to availability of contraception. Among sexually active high school students in the USA, an estimated 46% of pregnancies occurred from failure to use contraception. Counseling teens on appropriate contraceptive options is an important step in preventing adolescent pregnancy, and should involve assessing risk and contraindications to various methods with an emphasis placed on determining the option that will be most effectively adhered to.

Barrier Methods

Barrier methods of contraception include the male condom, female condom, diaphragm, and cervical cap. They may be used in conjunction with spermicides. The male latex condom is by far the most widely used. It is readily accessible, portable in packaging, and somewhat easy to use. It is also the only method, aside from abstinence, that has been proven effective in preventing the spread of sexually transmitted infections and the human immunodeficiency virus. Diaphragms and cervical caps have never been the most popular barrier methods and must be fitted by a clinician. The female condom is difficult to use and users often complain that it comes out of place. As there is not sufficient awareness or proper training in the use of the female condom, it is not used consistently by adolescent women. Use of all barrier methods must be anticipated and planned; during adolescence, having forethought about actions, especially during sexual encounters is a difficult developmental task.

Combined Oral Contraceptive Pills

The combined oral contraceptive pill (OCP) is the most commonly used method of contraception among adolescents. It is a well accepted and safe method of contraception for teens. All combined pills in the USA contain ethinyl estradiol and a progestin. The mechanism of action is inhibition of ovulation, but there are also effects on cervical mucus and the endometrium that contribute to efficacy. There are a wide range of estrogen doses and various types of progestins available, making the choice of the best pill somewhat of a challenge. Many practitioners chose pill preferences based on comfort and familiarity with a particular formulation. The major disadvantage of the pill is that it must be taken daily and around the same time to have maximum benefit. All combined OCPs have similar side effect profiles and benefits. The benefits include predictable, regular periods that are often associated with lighter menstrual flow and less menstrual cramping. Most also help with acne. The newer progestin, drospirenone, has antimineralcorticoid properties and has been approved to help with symptoms of premenstrual dysphoric disorder (PMDD). Common side effects of OCPs include headache, breakthrough bleeding, breast tenderness, and nausea or bloating. These typically all improve with continued use. Hypertension can also result, so blood pressure should be monitored. Contraindications are based mainly on the estrogen ingredient. They include a history of thromboembolic event or known thrombogenic mutations, migraine headache with aura (significant increased risk of stroke), and liver failure. Patients receiving contraception containing estrogen should be counseled on signs of deep vein thrombosis, including severe acute onset of chest pain, abdominal pain, and lower extremity pain without a history of trauma.

Combined OCP packing typically consists of 21 days of hormone containing pills and 7 days of placebo or spacer pills. During the 7 days of placebo, a menstrual

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_393,

period is expected. Continuous, or extended cycling consisting of taking 84 hormone containing pills, then seven spacer pills is often used and has been shown to have similar efficacy and compliance. If patients desire shorter menstrual periods or have estrogen withdrawal headache, regimens consisting of taking 24 hormone containing pills with four spacer pills can also be used.

Other Combined Hormonal Methods

Other common combined estrogen and progestin containing methods include the transdermal patch and the intravaginal ring. Both methods have the same mechanism of action, contraindications, and side effect profiles as combined OCPs.

The transdermal patch is applied for 1 week for 3 consecutive weeks, followed by a patch-free week during which withdrawal bleeding occurs. It should not be applied to the breasts. Unlike oral contraceptive pills and the ring, it is not recommended for continuous use. Compared to 30 μg estrogen containing OCPs, the patch is associated with a 60% increased estrogen exposure over the course of a month. This may translate to increased side effects, but there is not clear evidence that it increases venous thromboemboli. In women >90 kg, there have been greater incidences of unplanned pregnancy, even with consistent use of the patch when compared to combined oral contraceptive pills, so the patch is not recommended for morbidly obese patients.

The intravaginal ring is flexible and easy to insert. It is used for 3 weeks, and then removed for 1 week of withdrawal bleeding. The majority of women find it easy to use and partners typically do not feel the ring during intercourse. To place the device, patients should be instructed to hold it between the thumb and forefinger, than place it into the vagina as far as possible. If it is uncomfortable, the device may not have been placed far enough. Providers may offer to place the ring in the office for the first insertion. The intravaginal ring does not need to be fitted. It rests around the cervix and is held in place by the pelvic muscles. To remove the device, patients should use the forefinger to hook around the ring and gently remove it. Placement and removal is similar to use of tampons that do not have applicators. Placement and removal of the ring from the vagina may not be acceptable to some adolescents; however, adherence is made easier because it is only changed once per month. Adverse events include foreign body sensation (it may not be placed far enough into the vagina), expulsion, and sensation of the device by the sexual partner. The ring can be used for continuous use in a similar regimen as combined OCPs, usually with four menstrual cycles per year.

Progestin-Only Methods

Progestin-only methods are often options that are used if there is a contraindication to estrogen. The mechanism of action is thinning of the endometrial lining and thickening of cervical mucus. The higher dose used in the intramuscular injection also inhibits ovulation.

The progestin-only pill can have similar efficacy as the combined OCP, but it has a shorter half-life and must be taken daily and at the same time (within 3 hours). Irregular bleeding can occur during the first few months of use. The need for very regular timing of this pill makes it a less optimal choice for teens.

Depot medroxyprogesterone is an intramuscular injection administered every 12 weeks. Non-daily use is a benefit, so compliance is facilitated, but receiving an injection can be a deterrent. Bleeding can be irregular, especially with initiation, but often is lighter than the usual menstrual flow. It is associated with a high rate of amenorrhea (30–50% after 1 year of use) and is often used to control menses. Adverse effects include significant weight gain, decreased bone mineral density (BMD), and a delayed return to fertility. Weight gain is caused because the high dose of progestin stimulates appetite. Patients should be counseled on this side effect and appropriate diet and exercise. The decrease in BMD is related to ongoing use. The rate of loss is progressive for the first 18–24 months, than seems to plateau and levels of BMD are regained after the injections are stopped. Pregnancy rates at 1 year after stopping injections are the same as control populations, but there can be a delay in ovulation of up to 10 months.

The subdermal implant containing etonogestrel is a single rod that is placed along the biceps muscle. It provides contraception for 3 years, but can be associated with unpredictable irregular bleeding for the duration of time it is in place. which may be unacceptable to some patients. It does not cause significant weight gain or decreased BMD.

Emergency Contraception

Emergency contraception is a nonabortifacient hormonal medication that can be used up to 5 days after unprotected

intercourse. It is most effective if used within 72 hour. The most efficient method consists of levonorgestrel 1.5 mg that can be divided into two doses taken 12 hour apart or all at once. Emergency contraception is available in most industrialized countries and widely available throughout Asia and Africa. US. federal law has recently been changed so that people 17 years of age or older can purchase emergency contraception from a pharmacy without a prescription; however, providers can prescribe it to any sexually active individual. Teens should be counseled on the availability of emergency contraception, when discussing reproductive options.

Intrauterine Devices

Intrauterine devices (IUDs) have the distinct advantage of being completely reversible, highly effective, and have no need for regular administration. Adolescent patients should be counseled on their use as an option for contraception.

The levonorgestrel-releasing intrauterine system provides contraception for up to 5 years. Overall, it is as effective as tubal ligation in preventing pregnancy, but is reversible and not associated with a significant delay in fertility. It is safe to place in nulliparous patients, those with a contraindication to estrogen, and is not associated with increased rates of pelvic inflammatory disease. Due to the local release of progestin, many women have lighter menstrual periods and some have amenorrhea. Hormonal side effects include headache, acne, or breast tenderness. All IUDs should be placed by an experienced clinician due to the risk of uterine puncture and infection during placement. Expulsion can occur, but is rare.

The copper IUD offers a nonhormonal long-term option. It primarily acts as a spermicide (copper ions inhibit sperm motility and activation). It is effective for 10 years. Women may have heavier menses with more cramping, but hemoglobin levels are maintained and many do not notice significant changes in their menses.

394 Adolescent Gynecology: Menstrual Irregularities

Ann Giesel

Case: C.N., a 17-year old with primary amenorrhea with pubertal development beginning at age 11 years. Breasts are small, Tanner stage 4; genital exam shows pubic hair Tanner stage 5 with clitoromegaly. Laboratory evaluation shows negative pregnancy test, 17-hydroxy-progesterone is elevated at baseline and after cortrosyn-stimulation testing, and testosterone is elevated. Patient is diagnosed with late-onset congenital adrenal hyperplasia and referred to an endocrinologist for treatment recommendations.

Normal Menstruation

Irregular or heavy menstrual bleeding is a common complaint for adolescents. Knowledge of the normal range of flow is helpful in determining the cause of the menstrual irregularities. The mean interval of the menstrual cycle in adolescents is 28 days, ±7 days, with an average duration of 3–7 days. Median blood loss is 30–40 mL/month, with an upper limit of 60–80 mL. It is difficult to determine the amount of blood loss by teens' report and obtaining a hematocrit is important in assessing the amount of blood loss. *Oligomenorrhea* is infrequent periods, with intervals greater than 45 days. *Menorrhagia* is prolonged (greater than 7 days) or excessive uterine bleeding (greater than 80 mL) with a regular interval. *Metrorrhagia* is irregular menses with frequent intervals, and variable amount. *Amenorrhea* is absence of menses. *Menometrorrhagia* is prolonged uterine bleeding, with irregular intervals. *Polymenorrhea* is uterine bleeding at regular intervals of less than 21 days. *Dysfunctional uterine bleeding* is abnormal uterine bleeding unrelated to an anatomic cause.

Amenorrhea

Primary amenorrhea is defined as the absence of menarche by 14 years of age without secondary sexual characteristics, or the absence of menarche by 16 years of age in the presence of secondary sexual characteristics. *Secondary amenorrhea* is absence of menses for 3 months or more after having achieved menarche. There is some overlap between the etiology of primary and secondary amenorrhea. Primary amenorrhea with no pubertal development and uterus and vagina present may be due to genetic causes such as Turner syndrome (45 XO) or pure gonadal dysgenesis (46, XX), or isolated pituitary gonadotropin deficiency, hypothalamic failure with inadequate GnRH, constitutional delay of puberty, or premature ovarian failure, which may also be secondary to oophoritis (viral or autoimmune), or post therapy for cancer. Primary amenorrhea with breast development, but no uterus present may be due to androgen insensitivity syndrome (AIS) or Mullerian agenesis. Forty percent of those with Mullerian agenesis have associated renal anomalies. Rarely, a young woman with no breast development and no uterus may have an enzyme deficiency, or agonadism. When pubertal development is present with normal uterus and vagina, the cause may be pregnancy, hypothalamic, pituitary, ovarian, imperforate hymen, transverse vaginal septum, or vaginal agenesis. See *Table 394.1*.

Secondary amenorrhea may be caused by pregnancy, stress, exercise, weight loss or gain, eating disorders, systemic illness, drugs, partial gonadal dysgenesis or hormonal causes, such as polycystic ovarian syndrome, ovarian failure, prolactinoma, thyroid disease, adrenal or ovarian tumor.

In the evaluation of amenorrhea, it is important to take a careful history, including sexual history, history of illness, stressors, dietary history, exercise, drugs, and family history. Physical exam should include height, weight, blood pressure, Tanner staging, evaluation of signs of hyperandrogen including hirsutism, acne, clitoromegaly, and acanthosis nigricans. Consider pelvic exam or pelvic ultrasound, possibly rectal bimanual exam. The laboratory evaluation for secondary amenorrhea should include a pregnancy test, thyroid-stimulating hormone, free thyroxine, prolactin, luteinizing hormone, and follicle-stimulating hormone. Consider complete blood count, sedimentation rate, urinalysis, and androgens, including free and total testosterone, DHEAS, 17 hydroxy-progesterone as dictated by the history and physical examination. Karyotype, central nervous system imaging, and further evaluation for possible chronic illness may be done as indicated. The workup may proceed in a stepwise fashion, after initially ruling out pregnancy and

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_394,

Table 394.1
Etiology of primary amenorrhea

	No pubertal development	Some or normal pubertal development
Absent uterus and vagina	Enzyme deficiency agonadism	Androgen insensitivity syndrome (AIS) or Mullerian agenesis
Present uterus and vagina	Turner syndrome (45 XO), pure gonadal dysgenesis (46, XX) Isolated pituitary gonadotropin deficiency hypothalamic failure with inadequate GnRH constitutional delay of puberty premature ovarian failure	Pregnancy, low weight, weight loss, anorexia, hypothalamic, stress, pituitary, ovarian, CNS tumor, imperforate hymen, transverse vaginal septum, or vaginal agenesis

reproductive tract obstruction, which may be a gynecologic emergency.

Treatment depends on the underlying cause of the amenorrhea. In low estrogen states, it is important to support bone mass with estrogen replacement, however, in girls with amenorrhea caused by anorexia nervosa, estrogen replacement has not clearly been shown to affect bone density. Calcium intake of 1,300 mg/day is recommended. If the young woman is well estrogenized, monthly periods may be induced with daily progesterone for 12–14 days every 1–3 months to prevent endometrial hyperplasia.

Oligomenorrhea

Often adolescents are concerned about irregular and infrequent menses, occurring every few months. It is normal to have irregular menses in the first 2 years after menarche. The later the menarche, the longer it may take to achieve regular menses. Hypothalamic amenorrhea associated with change in weight or exercise is common, as is polycystic ovarian syndrome (PCOS) or other androgen excess syndrome. PCOS may present with menstrual irregularity more than 2 years after menarche, acne, hirsutism, or obesity. Other signs of virilism are clitoromegaly, deepening of the voice, increased muscle mass, widening of the upper torso, and loss of breast tissue. The anovulation and noncyclic production of estrogen and progesterone leads to amenorrhea or oligomenorrhea. Treatment is aimed at the underlying cause and, in the case of PCOS, treatment with combination oral contraceptive pills to decrease the risk for endometrial cancer. For those young women with hypothalamic hypogonadism, support of bone density acquisition is important, via improved nutrition or estrogen replacement.

Dysfunctional Uterine Bleeding

Dysfunctional uterine bleeding is defined as abnormal endometrial bleeding in the absence of structural pelvic pathology and usually is associated with anovulation, often due to immaturity of the hypothalamic–pituitary–ovarian axis. It is a diagnosis of exclusion and the differential diagnosis is extensive, including pregnancy and complications, trauma, coagulation disorders, benign and malignant neoplasms, genital tract infections, endocrinopathies, exogenous medications, and chronic systemic disease. Coagulation disorders include thrombocytopenia, von Willlebrand's disease, leukemia, or factor deficiencies.

Endocrinopathies include polycystic ovarian syndrome, hyperprolactinemia, hypothyroidism, or hyperthyroidism.

In obtaining the history for evaluation of the patient with heavy and/or frequent bleeding, it is important to note the timing of menarche, the menstrual pattern, the presence or absence of cramping and to take a careful sexual history. Inquire about nosebleeds, easy bruisability, or excessive bleeding with previous surgical procedures. Physical exam should include height, weight, vital signs, Tanner staging, thyroid gland examination, and evaluation of signs of hyperandrogen including hirsutism, acne, clitoromegaly, and acanthosis nigricans. Consider pelvic exam or pelvic ultrasound, possibly rectal bimanual exam. The laboratory evaluation should include a pregnancy test, complete blood count with platelet count, testing for Chlamydia and gonorrhea, thyroid function tests, prolactin, and coagulation studies. Consider luteinizing hormone, follicle-stimulating hormone, and androgens as indicated by history and exam. Type and cross if severe bleeding or significant anemia is present.

For treatment of mild dysfunctional bleeding, which may present with irregular bleeding and a hemoglobin greater than 12 g/dL, reassurance is indicated. Nonsteroidal anti-inflammatory drugs (NSAIDS) will decrease blood loss and help with symptoms of dysmenorrhea as well. Advise patient to keep a menstrual calendar, supplement with iron as necessary, and reevaluate periodically. Hormonal therapy may be considered.

For treatment of moderate dysfunctional bleeding, which presents with irregular, prolonged, and heavy bleeding with a hemoglobin of 10–12 g/dL, cyclic progestins

that stabilize the endometrium, or combination oral contraceptive pills, are indicated in addition to the above treatment for mild bleeding.

For treatment of severe dysfunctional uterine bleeding, with irregular, prolonged, and heavy bleeding, with a hemoglobin less than 10 g/dL, if the patient is not actively bleeding, combination oral contraceptive pills, iron supplementation, and close monitoring is indicated. If the patient is actively bleeding, hospitalize with preparation to transfuse if necessary. It is important to evaluate for a possible coagulation defect when the hemoglobin has dropped to this degree. Consider instituting hormonal therapy with conjugated estrogens intravenously along with progestins, or combination oral contraceptive pills given by mouth every 6 h, and then taper. Bleeding should stop within 24 h and if not, consider the need for surgical treatment with dilatation and curettage.

Continue oral contraceptive pills for at least 6–12 months, and reevaluate to see if continued treatment is desired for ongoing menstrual control or for contraception.

Dysmenorrhea

Dysmenorrhea occurs at some time in two-thirds of menstruating girls. Ten percent are incapacitated, and it is the leading cause of short-term school absenteeism in teens. Primary dysmenorrhea occurs 6–12 months after menarche, and the duration of pain is usually 48–72 h. Release of prostaglandins has been associated with the symptoms of dysmenorrhea including pelvic cramping, nausea or vomiting, fatigue, nervousness, dizziness, diarrhea, back pain, and headache. Secondary dysmenorrhea may be caused by endometriosis, pelvic inflammatory disease, adenomyosis, or uterine polyps or myomas. Recommended treatment of primary dysmenorrhea is with prostaglandin synthetase inhibitors (nonsteroidal anti-inflammatory drugs), or with oral contraceptive pills. Treatment of secondary dysmenorrhea is directed at the underlying cause.

Premenstrual Syndrome/Premenstrual Dysphoric Disorder

Premenstrual syndrome (PMS) is a recurrent luteal phase condition characterized by physical, psychological, and behavioral changes of sufficient severity to result in deterioration of interpersonal relationships and normal activity. Premenstrual dysphoric disorder (PMDD) is considered a severe form of PMS. Symptoms of PMS have been reported to affect as many as 90% of women of reproductive age sometime during their lives. Nearly 20% of women experience PMS; approximately 10% are affected severely with PMDD.

Healthy diet and exercise are recommended as they help to reduce stress as well.

Nonsteroidal anti-inflammatory drugs (NSAIDS) are useful for managing the general aches, pains, and dysmenorrhea associated with PMS.

Combination oral contraceptive agents also may help in the treatment of PMS, decreasing both mood and somatic symptoms.

Selective serotonin reuptake inhibitors (SSRIs) are the first-line drugs for severe emotional symptoms.

395 Adolescent Gynecology: Sexually Transmitted Infections

Taraneh Shafii · Gale R. Burstein

Adolescents and young adults have the highest sexually transmitted infection (STI) rates, with half of the almost 19 million STI cases in the USA diagnosed annually occurring in 15–24-year-olds. Among females, the highest reported gonorrhea and chlamydia rates are among 15–19-year-olds followed by 20–24-year-olds. Recent comparative international statistics are difficult to access. However, an extensive review of 17 developed countries using 1994–1996 data for 15–19-year-olds reported that Belgium, Sweden, and Switzerland had the lowest rates of gonorrhea with the Russian Federation and the USA having the highest. The lowest rates of chlamydia were found in Belgium, France, and Switzerland as compared to the highest rates in the USA and Denmark. Chlamydia rates for the Russian Federation were unavailable. Common to almost all countries was that adolescents accounted for 20–33% of all cases reported. These data do not account for differences between countries in reports and screening programs.

HIV/AIDS is now the seventh leading cause of US mortality in persons <25 years and accounts for 13% of all cases diagnosed annually; however, these numbers do not compare to the significant burden of HIV in Sub-Saharan Africa. Data from national adolescent surveys of Burkina Faso, Ghana, Malawi, and Uganda found that in 2006, 40% of new HIV infections were in 15–24-year-olds.

Adolescents are at High Risk for Acquiring STIs

Factors that increase adolescents' STI risk can be categorized as (1) biological susceptibility; (2) psychosocial development; (3) health-care utilization and compliance; and (4) confidentiality, ethical and legal issues. These four factors contribute to adolescent health risk and influence high-risk behavior in the setting of evolving sexuality and sexual behavior as youth progress through puberty.

Biological Factors

Due to developing physiologic characteristics, adolescent females are more vulnerable to STIs than adult females. The immature and incompletely estrogenized cervix is characterized by persistence of columnar epithelium extending to the ectocervix, referred to as cervical ectopy (*Fig. 395.1*). Columnar epithelium is more susceptible to invasion by pathogens, such as *Neisseria gonorrhoeae* and *Chlamydia trachomatis*, than squamous epithelium, which covers the vagina and the mature adult female cervix. Adolescent females tend to have thinner cervical mucus than adult females, thereby presenting a weaker barrier to pathogens infecting the cervix and upper reproductive tract.

Lower estrogen levels present in early adolescence results in thinner genital tissue. In addition, insufficient sexual arousal results in inadequate vaginal lubrication prior to penetration. This combination places adolescent females at increased risk for trauma and/or irritation to the female genital tissue creating potential portals of entry for pathogens.

Serial Monogamy

An interesting societal trend contributing to adolescent sexual risk is the adolescent relationship pattern, described as *serial monogamy*. Adolescents have relatively short-duration relationships (e.g., 2 weeks or 2 months) with an individual partner, and change partners more frequently. So while adolescents may be monogamous in each relationship, which they may interpret as a lower risk, as they accrue an increased number of partners over time, they accrue significant STI-exposure risk. To assess true STI-exposure risk and obtain a more valid assessment of sexual risk behaviors, providers should inquire about the number of partners in the past 3, 6, and 12 months.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_395,

Figure 395.1
Cervical ectopy (Source: Seattle STD/HIV Prevention Training Center at the University of Washington/Claire E. Stevens)

Trend for Earlier Puberty, Earlier Sexual Debut, and Delayed Marriage

In the USA, the median age of menarche is approximately 12.4 years (12.1 years in Black females); the median age of first sexual intercourse is 16.5 years and; the average age of marriage is the late 20s (an increase in approximately 5–8 years from the 1950s). Therefore, the average number of years when females are hormonally primed for sexual activity and not married has increased significantly over the past 50 years resulting in the potential for a higher number of lifetime sexual partners and increased likelihood for STI contact.

The Adolescent Female with Vaginal Discharge

Vaginosis, vaginitis, and cervicitis may present as a complaint of vaginal discharge changes. Infectious etiologies of vaginitis include *Candida albicans* (not considered an STI) and *Trichomonas vaginalis*. Bacterial vaginosis is predominantly caused by *Gardnerella vaginalis*. *Chlamydia trachomatis*, *Neisseria gonorrhea*, and *Mycoplasma genitalia* cause cervicitis presenting as vaginal discharge. If cervicitis remains untreated, it can progress to pelvic inflammatory disease (PID) and the possibility of future tubal infertility and ectopic pregnancy. PID is a clinical diagnosis, and in the absence of other diagnoses, can be confirmed by uterine, cervical, or adnexal tenderness with immediate treatment recommended.

Laboratory Tests to Evaluate Vaginal Discharge

CDC recommends using a nucleic acid amplification test (NAAT) for diagnosing genital chlamydia and gonorrhea infections. NAATs are the most sensitive chlamydia tests available. In addition to testing endocervical and urethral specimens, NAATs allow for noninvasive STI testing via the urine and self-collected vaginal swabs. Although not FDA approved, many clinical labs perform NAATs on rectal and oropharyngeal specimens. Microscopy of vaginal discharge identifies bacterial vaginosis, Candidiasis, and Trichomoniasis. More sensitive vaginitis tests include the OSOM Trichomonas Rapid Test and OSOM BV BLUE Test (Genzyme Diagnostics, Cambridge, Massachusetts), point of care tests providing results in approximately 10 min and the Affirm™ VP III (Becton Dickenson, San Jose, California), a nucleic acid probe test that evaluates for *T. vaginalis*, *G. vaginalis*, and *C. albicans*, providing results in 45 min. Culture is the most sensitive commercially available trichomonas test. There are currently no commercially available *M. genitalia* tests.

Adolescent Female with Genital Lesions

Infectious genital lesions in adolescents are most commonly caused by human papillomavirus (HPV) and herpes simplex virus (HSV). One in four to five Americans has genital herpes. In a study of American female college students, HPV infection incidence was 37% within 1 year of first intercourse. By adulthood, it is estimated that 80% of women will have been infected with HPV. An international prevalence study of over 15,000 women with normal cervical cytology from 11 countries reported the age-standardized prevalence for HPV ranged from a low of less than 2% in Vietnam to a high of more than 25% in Nigeria. Although syphilis rates are not as high in adolescents as in older age groups, any adolescent presenting with a genital lesion should be tested. Other common

etiologies of genital lesions include folliculitis from pubic hair removal, scabies (*Sarcoptes scabiei*), and molluscum contagiosum.

Laboratory Tests to Evaluate Genital Lesions

There is no commercially available genital wart screening test. Revised Pap testing guidelines recommend performing the first Pap test at age 21 years, regardless of age at coitarche (Cervical cytology screening (2009)). Herpes culture of genital lesions remains the standard HSV test. HSV DNA polymerase chain reaction (PCR) assays are more sensitive than culture and are increasingly used in many settings. Since herpes viral shedding is intermittent, providers cannot assume that a negative HSV culture or PCR tests confirm absence of HSV. The utility of herpes serology screening in young people has yet to be determined.

Screening Guidelines

Current adolescent primary care guidelines recommend yearly chlamydia screening of ALL sexually active females and gonorrhea screening adolescent females at risk. Syphilis screening should be based on local epidemiology. Currently, CDC recommends HIV screening for all Americans 13–64 years at least once and more often as indicated by sexual risk behaviors. Since reinfection is common, all adolescents testing positive for chlamydia or gonorrhea, and all females testing positive for trichomonas should return in 3 months for a test of reinfection.

Treatment

In all 50 states, adolescents may consent for their own, confidential sexual health care. However, states vary in minimum age to consent for STIs-related health care. Providers should check their state law for age-specific guidelines. CDC-recommended adolescent STI management does not vary from that of adults, except with the caveat of ensuring completed treatment and can be found in detail at www.cdc.gov/std/treatment. Since adolescents are notorious for poor compliance, single dose, directly observed therapy is recommended if available.

Uncomplicated chlamydia infection is treated with a single dose of Azithromycin 1 g. In light of gonorrhea resistance to fluoroquinolones and decreasing susceptibility to some cephalosporins, WHO and 2010 CDC guidelines recommend dual therapy with either a single dose of Ceftriaxone 250 mg IM if possible, or an oral cephalosporin of Cefixime 400 mg orally PLUS azithromycin 1 gram orally or doxycycline 100 mg twice daily for 7 days. Dual therapy for gonoccocal infections is recommended at all anatomic sites due to concerns about the possible emergence of cephalosporin resistance gonorrhea. PID may be treated as an outpatient with Ceftriaxone 250 mg IM in a single dose or another parenteral third-generation cephalosporin plus Doxycycline 100 mg orally twice a day for 14 days with or without Metronidazole 500 mg orally twice a day for 14 days in an adolescent who is nontoxic appearing, not vomiting, and reliable to return for follow-up care in 48 h and after completion of therapy.

Adolescents with laboratory-confirmed HSV infection may be offered suppressive therapy with Acyclovir 400 mg orally twice daily or Valacyclovir 500 mg or 1 gram daily. Daily suppressive therapy has been shown to decrease the number of outbreaks, severity, and duration of lesions in the index patient and also decreases their asymptomatic viral shedding, thus, decreasing the likelihood of infecting their sexual partner.

Management of Sex Partners

Providers should verify that all STI-positive patients' sex partners within the last 60 days have been tested and treated (or last partner if it has been longer than 60 days since last sex). One strategy to increase partner treatment and decrease reinfection rates of chlamydia, gonorrhea or trichomonas is expedited partner therapy (EPT): treating a partner of an STI-infected individual without requiring a prior clinical examination. EPT is usually practiced by patient-delivered partner therapy (PDPT). With PDPT, the provider gives the index patient medications or a prescription for medications to deliver to their partner(s). The medication is usually accompanied by a brochure describing the infection, the medication, and the need to see a clinician for a complete STI evaluation. As of November 2010, EPT is legally permissible in 27 states and 1 city for providers caring for heterosexual individuals infected with gonorrhea or chlamydia. For more information on EPT, including legal status, go to www.cdc.gov/std/ept.

Prevention of STIs

Abstinence from sexual contact is the only reliable means of avoiding infection with an STI. In lieu of abstinence, condoms remain the *best* protector against STI acquisition from an infected partner. In addition, male circumcision

has proven to be a significant prevention method against the transmission of HIV/STIs. Other preventive measures for adolescents include limiting their number of sexual partners and getting themselves and their partners tested before they initiate sexual contact and with each partner change.

396 Approach to the Adolescent Male and Reproductive Health Disorders

David J. Breland

Male health has become an emerging area of interest in an effort to improve the health status and quality of health care for men. Adolescent male health is particularly relevant, since many antecedents of adult illness originate in adolescence, such as alcohol and tobacco use. Many policies and programs have chiefly addressed young women's reproductive health needs and largely overlooked male health needs. Currently, it is recognized that adolescent male health is a vital element for all adolescent care. Data looking at health care utilization by adolescent males have found that, overall, the percentage of total healthcare visits by males were significantly less than that of females. In addition, there are age differences in the use of health care services. Older adolescent (16–20 years) males, as compared to young adolescent males, (11–15 years) show decreasing trends in hospital-based outpatient visits and increasing trends in emergency department visits. Adolescent female use of health care services is promoted by reproductive issues such as menarche, contraceptive needs, sexually transmitted infections (STIs), and pregnancy management. These health services are not readily available to adolescent and young adult males. There are fewer opportunities for preventive health messages for male adolescents. Boys often hold a more traditional "masculine" attitude that put them at increased risk for engaging in high risk behaviors such as having unprotected sex and illicit substance use. Nevertheless, male adolescents are often concerned about the same health issues as their female counterparts and are more likely to engage in health-compromising behaviors (i.e., substance abuse) and suffer serious health consequences (i.e., suicide completion). The clinician has to connect with them in a safe and unthreatening manner that will promote open and honest conversations about their fears and doubts.

As a clinician, it is important to realize that most male patients may not be upfront with any concerns they may have about their health. Boys will often have questions/concerns about growth/development and, therefore, it is an essential topic to raise. The health provider can introduce this topic by asking if he has any concerns regarding his athletic performance, strength, or endurance. These questions could lead the discussion of any feelings he may have about his changing body. Examples of such questions include, "Do you have any questions or worries about your height or physical appearance?" or "Are there any concerns about the development of your genitalia?" In addition, it is important to know that some male patients prefer a female provider to do the genital exam. Chaperones of the opposite sex of the health care professional should be utilized if the provider or the patient feels uncomfortable. Another important point is to normalize the genital exam and be comfortable performing this exam. One suggestion is to inform the young man before he changes for his physical exam that you will perform a head to toe examination that includes screening for genital abnormalities such as hernias and cancer. In addition, the provider should explain these conditions and why they are important to discover.

Pubertal Gynecomastia

Definition

Breast development in the pubertal adolescent male.

Etiology

It is thought to be the result of an imbalance of estrogen stimulatory effects relative to androgen inhibitory effects at the breast tissue level.

Epidemiology

Pubertal gyneconastia is thought to affect up to 60–70% of adolescent boys, beginning in middle adolescence. It can be unilateral or bilateral. Twenty five percent of cases may persist for $\geq$2 years and is called persistent pubertal gynecomastia.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_396,

Pathogenesis

It is characterized by ductal proliferation and formation of vascular connective tissue.

Clinical Manifestations

Predominantly, it is mild proliferation (less than 3–4 cm) of breast tissue under the areola. Many boys can find breast development embarrassing and wonder if something is wrong with them. Onset of gynecomastia correlates with pubertal development (*Table 396.1*). This condition will spontaneously resolve in 1–2 years without intervention.

Diagnosis

Neither laboratory nor radiologic studies are recommended unless the patient is prepubertal, undervirilized, has an eccentric mass or rapid progression of mass, or a testicular mass or persistence beyond the 12–18 month observation period. Initial laboratory tests are outlined in *Fig. 396.1*. Ultrasound is usually not indicated.

Differential Diagnosis

Pseudogynecomastia is seen in obese boys secondary to increased adipose tissue. The differential diagnosis also includes: lipomas, hemangiomas, neurofibromas, lymphangiomas, dermoid cyst, and breast carcinoma. Rarely, gynecomastia can be related to underlying conditions such as testicular cancer, Klinefelter's syndrome, chronic disease, medication (antipsychotic), or drug use (anabolic steroids or heavy marijuana use).

Treatment

Often, no treatment other than psychosocial support is needed. Antiestrogens, nonaromatizable androgens (including dihydrotestosterone), and first generation aromatase inhibitors have been used to treat gynecomastia with variable success. If it persists beyond 1 year, then chronic fibrous changes may occur. In persistent cases where there is a significant psychosocial problem, surgical reduction of the breast tissue is done. Options include open excision, conventional liposuction, or a combination of both. Caution is advised if performed before the completion of pubertal development to avoid the risk of recurrence.

Table 396.1
Genital stage at onset of Gynecomastia (Adapted from Neinsteins et al. 2008)

Genital stage 1–20%
Genital stage 2–50%
Genital stage 3–20%
Genital stage 4–10%

Genital Development/Circumcision

Adolescent males are often concerned about whether their penis size or shape is normal. They often have an unfounded perception of normal or even desirable penis size. Mean flaccid length of the penis is 8.2–9.7 cm (range 5.0–15.5 cm). The mean erect length is 15.1 cm (range 11.4–19.0 cm). No predictable relationship exists between the size of the flaccid penis and erect length. It is important to emphasize that men come in all shapes and sizes, and there is a relative unimportance of penis size for sexual function and pleasure. The young man should be warned against using any chemicals or mechanical devices that claim to change penis size. In addition to concerns regarding size, there may be questions/concerns regarding circumcision and its protection against HIV and other STIs. Circumcision has been found to provide partial protection for men against acquiring HIV infection through heterosexual sex. Countries in sub-Saharan Africa have developed prevention strategies involving male circumcision. Benefits have been found in developing countries, but whether the same benefits exist in develop countries is controversial. One study in the United States showed reduced prevalence in HIV risk in circumcised men. It is important for the clinician to know the risk and benefits of circumcision, in order to give comprehensive reproductive health care to the adolescent male.

Pearly Pink Papules

Definition

Pearly pink papules are a misnomer in that they are often pearly but can be flesh colored.

Clinical Manifestations

They are small papules, 1–3 mm that are found along the corona of the penis.

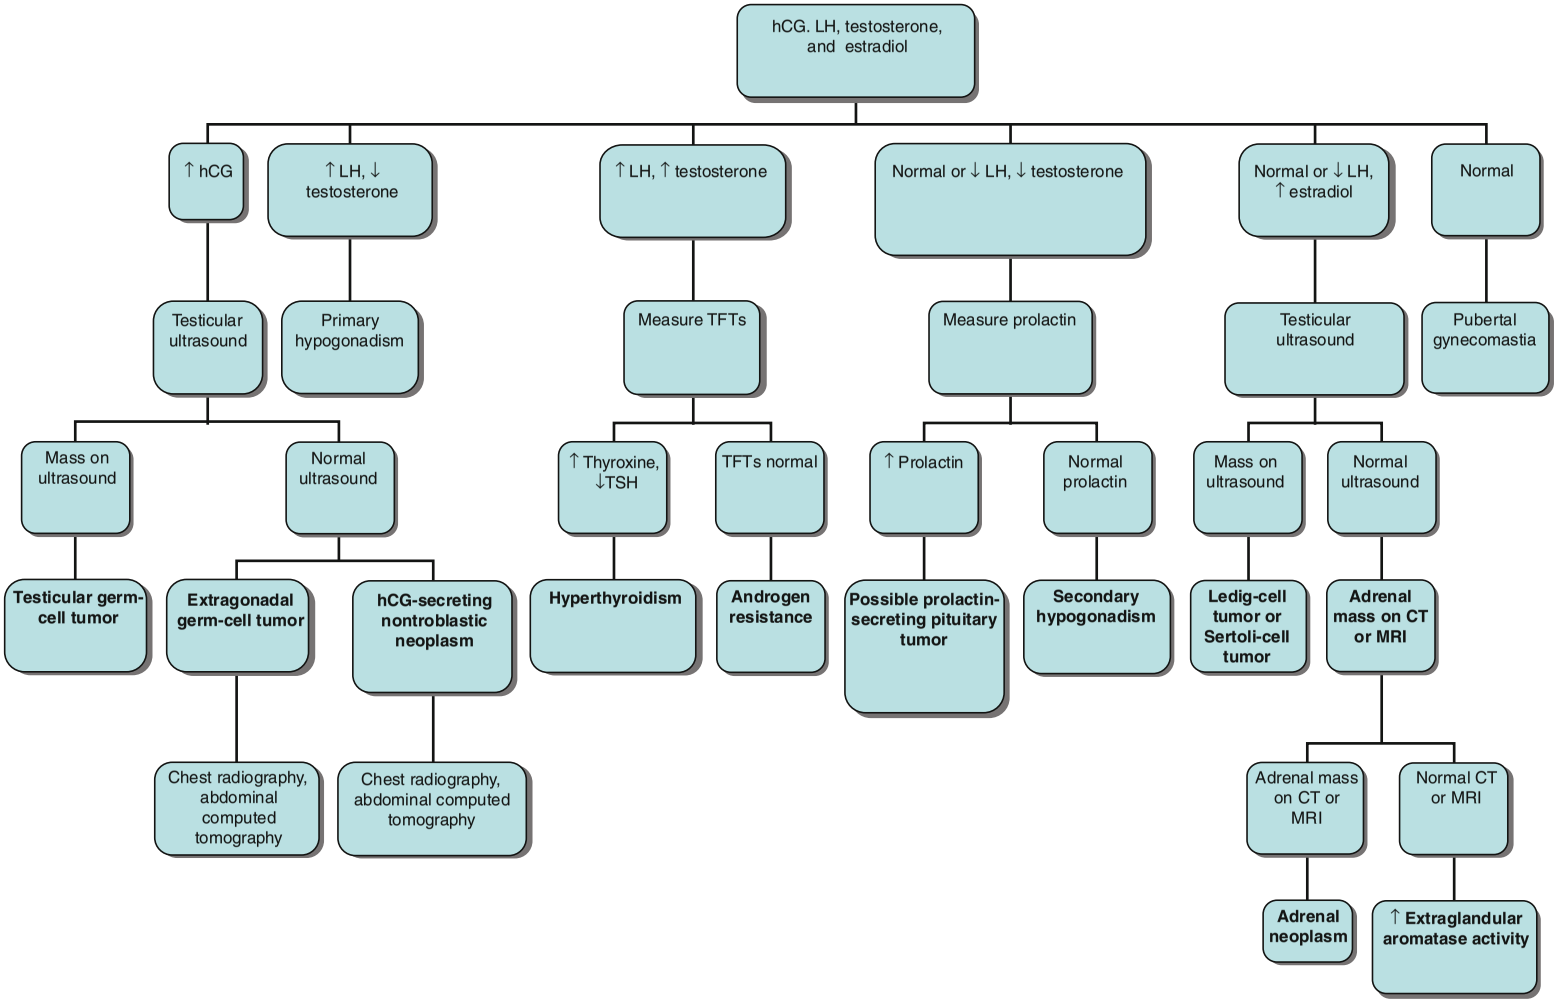

Figure 396.1

Serum hormone interpretation and recommendation for further evaluation of an adolescent male with gynecomastia. Diagnoses are presented in bold face type. CT, computer tomography; hCG, human chorionic gonadotropin; LH, luteinizing hormone; TFTs, thyroid function test; TSH, thyroid stimulating hormone (Adapted from Braunstein 2007)

Epidemiology

They are found in 15–20% of adolescents.

Treatment

They require no treatment, just reassurance.

Phimosis and Paraphimosis

Definition

Phimosis is the constriction of the prepuce orifice so as to prevent the foreskin from being withdrawn to reveal the glans penis.

Etiology

Commonly occurs when the foreskin experiences small amounts of inflammation such as normal erections, or from poor hygiene.

Treatment

Treatment can be conservative, such as Vitamin E creams and topical steroids to soften the phimotic ring. Significant phimotic rings will need definitive treatment, such as ring excision or conventional circumcision.

Definition

Paraphimosis occurs when the foreskin is tight but retractile and is pulled back but cannot be repositioned over the glans penis.

Etiology

Often paraphimosis is iatrogenic in the setting of a Foley catheter placed in an uncircumcised male patient.

Clinical Manifestations

Patients present with a tender, swollen penis with a large ventral penile skin bulge.

Treatment

This is an emergency and needs prompt attention. Urgent reduction is warranted, and usually a subsequent circumcision.

Prognosis

If untreated, edema causes constriction of the lymphatic and venous flow, leading to distal penile ischemia.

Testicular Torsion

Etiology

An exact etiology of testicular torsion is not known, but there is an anatomical abnormality that has been described that can predispose a patient to torsion of the testis.

Epidemiology

Incidence peaks at 15–16 years of age and 2/3 of cases occur between 12 and 18 years.

Pathogenesis

The abnormality that is implicated is called the "bell clapper" deformity. In this deformity, the tunica vaginalis is completely surrounding the testicle, including the posterior aspect of the testis. As a result, the testicle hangs within the scrotum by its vascular pedicle, which is analogous to a pendulum of a bell.

Clinical Manifestations

Clinicians must have a high index of suspicion for this condition, secondary to a short window of opportunity to salvage the testicle. Torsion commonly presents with an abrupt onset of scrotal pain. Associated nausea, vomiting, fever, and abdominal pain are also present. Often on physical exam, the scrotum is swollen, tender, and erythematous. The cremasteric reflex is almost always absent.

Diagnosis

The diagnosis can be made by physical examination and/or with the use of Doppler ultrasound. Doppler

ultrasound has a sensitivity of 89–100% and a specificity of 77–100%. Unfortunately, time is not on the side of the clinician. Viability of the testes declines to 0% after 24 h.

Differential Diagnosis

The differential diagnosis includes appendage torsion, epididymitis, trauma, and orchitis.

Treatment

Torsion of the testicles (*Fig. 396.2*) represents a surgical emergency. Therefore, treatment should involve prompt surgical exploration and ultimately detorsion of the testis. There is a high incidence of retorsion of the testis and also torsion of the contralateral testis. The testis along with the contralateral testis is fixed to the scrotum (scrotal orchiopexy).

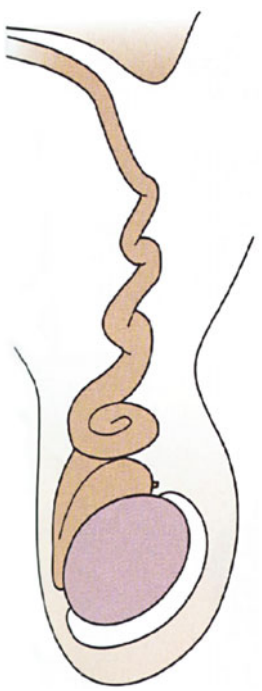

Figure 396.2
Testicular Torsion (From Zitelli and Davis 2007)

Torsion of Testicular or Epididymal Appendage

Epidemiology

Typically boys aged 7–12 years old.

Pathogenesis

The testis and the epididymis have remnants of the Wolffian and Müllerian duct system called appendages.

Clinical Manifestations

Boys present with pain, nausea, and vomiting. On palpation of the testis, there is tenderness over the superior or inferior pole of the testis with or without a palpable mass. Usually the cremasteric reflex is present. The characteristic "blue dot" sign, when present, will represent the infarcted appendage.

Diagnosis

Commonly made clinically. If torsion of the testis cannot be differentiated, then color flow Doppler examination is warranted.

Differential Diagnosis

Testicular torsion and trauma.

Treatment

Supportive treatment is indicated and includes analgesics, anti-inflammatory agents and elevation of the scrotum. If the pain persists for longer than 5 days, a consultation from a pediatric urologist is recommended.

Hernia and Hydrocele

Etiology

Two common congenital abnormalities in the inguinal canal include hernia and hydrocele.

Pathogenesis

When fluid tracks down the inguinal canal into the tunica vaginalis, it forms a communicating hydrocele. They may also occur secondary to other primary processes such as trauma, infection, testicular torsion, or neoplasm. Within the hernia sac, small intestine, omentum, bladder, or genital contents may be found.

Clinical Manifestations

Both hernias and hydroceles will present as scrotal swelling.

Diagnosis

Hydroceles are often found as an incidental finding on exam and often represent a benign mass in the scrotum. On exam, hernias are more firm and will not transilluminate, whereas hydroceles will transilluminate showing the presence of fluid. Hydroceles will often feel supple and fluid filled.

Treatment

Hernias may become incarcerated (twisting of a loop of bowl cutting off blood supply), and may need surgical repair. Hydroceles are often benign and are corrected electively, but a search for a primary cause should be performed.

Orchitis

Definitions

Orchitis or inflammation of the testis occurs in predominantly the pubertal males.

Etiology

There are multiple infectious causes of orchitis including mumps virus, coxsackievirus, echovirus, adenovirus, varicella, and tuberculosis, among other bacteria. Mumps virus is the most common cause of orchitis and usually follows parotitis by 4–8 days, but can present up to 6 weeks. If a bacterium is implicated, then it is often a consequence of a contiguous spread from an epididymitis.

Clinical Manifestations

Often associated with constitutional symptoms such as fever, nausea, lower abdominal pain, and can be both insidious and abrupt in onset.

Diagnosis

Exam may reveal unilateral or bilateral involvement and present with tenderness of the testis with edema and erythema of the adjacent skin.

Treatment

Bacterial orchitis is treated with an antibiotic in addition to supportive care. Viral orchitis is only treated symptomatically with rest and analgesics.

Prognosis

A rare but possible complication of orchitis is infertility.

Testicular Neoplasms

Epidemiology

Testicular neoplasms (TN) occur in prepubertal boys to postpubertal men. They represent 1–2% of neoplasms in men and boys. There has been increasing incidence worldwide, particularly in industrialized countries, but TN incidence varies in different geographical areas. It is highest in Scandinavia/Switzerland, intermediate in the USA, Australia and the UK, and lowest in Asia and Africa.

Etiology

Increased risk with a history of cryptorchidism.

Epidemiology/Pathology

Histologic types commonly found in adolescence are the germ cell tumors (seminoma, embryonal carcinoma, teratoma, and choriocarcinoma) and account for 95% of cases. Tumors that are of stromal origin are Leydig and Sertoli tumor cells, and can occur at any age.

Clinical Manifestations

TN present as painless scrotal masses that are of gradual onset. Pain is not a common feature, but if present may represent a hemorrhaged or necrotic tumor.

Diagnosis

On physical exam, there is usually a firm, irregular mass that will not transilluminate. They can also present as soft masses and represent cystic or necrotic areas of the neoplasm. The contralateral testis should be examined for comparison and to determine the presence of neoplasm. Once detected, a complete physical exam should be done looking for the following: gynecomastia, lymphatic or venous stasis in the genitalia or leg, prostatitis, epididymitis, and cervical or supraclavicular lymph nodes. Tumor markers can be useful tests for certain histologic types and should be obtained before orchiectomy. Human chorionic gonadotropin (hCG) is elevated in choriocarcinoma, nonseminomatous mixed germ-cell tumors, and seminoma with syncytiotrophoblasts. The α-fetoprotein (AFP) is elevated in nonseminomatous germ cell tumors, particularly yolk sac tumors and embryonal carcinoma. Note that 92% of pure seminomas produce no tumor markers. Imaging is done using either ultrasound or MRI and staging requires a chest and abdominal CT.

Differential Diagnosis

This includes orchitis, spermatocele, inguinal hernia, benign testicular cyst, and benign hydrocele. Any testicular mass is malignant until proven otherwise.

Treatment

Treatment is determined by staging and histology. It includes orchiectomy, retroperitoneal lymph node dissection, radiation, and chemotherapy.

Prognosis

The overall survival rate is greater than 95% of patients in Stage I or II.

Varicoceles/Spermatoceles

Definition

Varicoceles (*Fig. 396.3*) are defined as dilation of the pampiniform venous plexus within the scrotum.

Etiology

Is largely unknown yet there are several theories to its etiology. One theory is the presence of incompetent valves within the veins along the spermatic cord. Causing a back-up of blood and results in engorged veins. Another theory includes the "nutcracker effect." The left renal vein is compressed between the aorta and superior mesenteric artery resulting in an increase pressure that is transmitted to the left testicular vein. This theory is supported by the fact that varicoceles are present on the left side in 85–90% of cases.

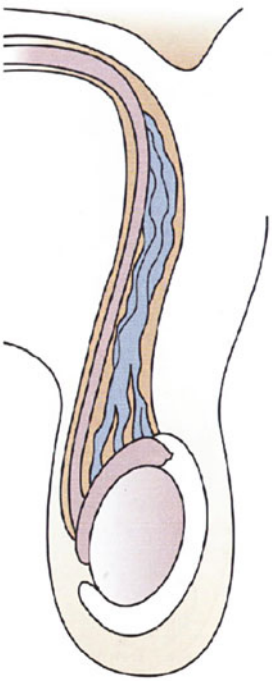

Figure 396.3
Varicocele (From Zitelli and Davis 2007)

Epidemiology

It is common in the 10–20 year age-group and has a prevalence of 15%. Most are clinically evident (85%) on the left side and 15% are bilateral. When a varicocele is found on the right, it is often associated with tumors and should be investigated.

Clinical Manifestations

Most varicoceles are asymptomatic in adolescents but can present with a dull ache after long periods of standing.

Treatment

Repair is offered to adolescents who show testicular growth arrest, abnormal semen analysis in those who have high grade varicoceles, bilateral varicoceles, and any symptomatic varicoceles.

Prognosis

There is controversy surrounding the clinical relevance of varicoceles and is related to the risk of infertility. There seems to be a time-dependent testicular growth arrest and abnormal semen analysis in adolescents.

Etiology

Spermatoceles (◉ *Fig. 396.4*) are found commonly on examination and represent an accumulation of sperm within the head of the epididymis.

Clinical Manifestations

They are soft cysts that are smooth and found on the superior pole of the testicle.

Diagnosis

A spermatocele will transilluminate on exam.

Treatment

Spermatoceles do not need treatment unless symptomatic.

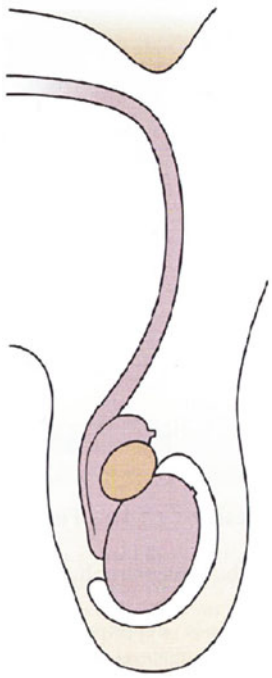

Figure 396.4
Spermatocele (From Zitelli and Davis 2007)

Epididymitis

Etiology

Epididymitis (◉ *Fig. 396.5*) is an inflammatory process of the epididymis that is commonly secondary to STIs (sexually transmitted infections) in adolescence.

Epidemiology

It is uncommon in prepubertal males and non-sexually active males without a history of genitourinary tract abnormalities.

Pathogenesis

Thought to be secondary to retrograde extension of *Chlamydia trachomatis* from the vas deferens. *Neisseria gonorrhoeae* is the second most common organism.

Clinical Manifestations

Commonly present with gradual onset of scrotal pain and swelling in addition to nausea, fever, abdominal or flank

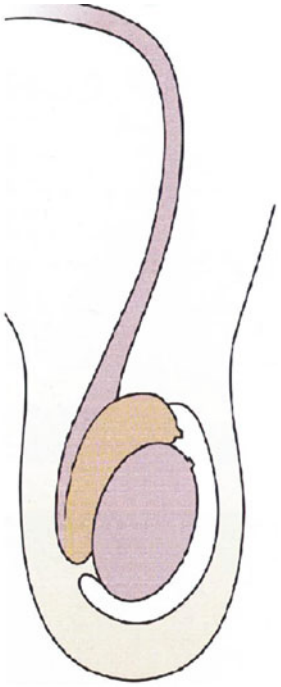

Figure 396.5
Epididymitis (From Zitelli and Davis 2007)

pain and urethral discharge. The scrotum is usually edematous and erythematous. The epididymis is often tender to palpation.

Diagnosis

A maneuver that can help distinguish epidiymitis from testicular torsion is the Prehn sign. The Prehn sign occurs when there is improvement in pain with scrotal elevation.

Treatment

The treatment includes the use of antibiotics directed at the most common etiologies (*Table 396.2*) and treatment should also be given to his sexual partners. If he fails to improve over 72 h, he must be evaluated for the possibility of an abscess.

Prognosis

Bilateral involvement has an increased risk of sterility.

Table 396.2
Treatment recommendations for epididymitis (Center for Disease Control and Prevention http://www.cdc.gov/std/Treatment/2006/updated-regimens.htm)

Ceftriaxone 250 mg IM in a single dose PLUS Doxycycline 100 mg orally twice a day for 10 days
For acute epididymitis most likely caused by enteric organisms or with negative gonococcal culture or nucleic acid amplification test
Ofloxacin 300 mg orally twice a day for 10 days OR Levofloxacin 500 mg orally once daily for 10 days

397 Behavioral and Mental Health Issues

Henry Berman

Behavioral concerns, including such problems as depression, anxiety, and attention-deficit/hyperactivity disorder, are among the most frequent problems seen in an ambulatory practice. Most physicians feel not enough time was spent in their training to make them comfortable with diagnosing and treating these problems, but a shortage (or, in some communities, a complete absence) of child psychiatrists plus the stigma that many teens and parents attribute to "needing to see a psychiatrist" lead to the need for many primary care physicians to be able to provide effective care for these adolescents.

Is This Normal?

Often, the first step for the physician is to determine whether the problem presented by the adolescent or the parent is normal adolescent development. Conflicts over curfews, privacy, rebellion, parental expectations, and peer relationships are to be expected. Problems with sibling relationships are common, if unpleasant for parents. The switch to middle school often brings problems, either in academic performance or in peer relationships.

Parental concerns over "time-wasting" activities, including playing video games, talking and texting on cell phones, and the use of online social networks, may be more common than in the past. And there are always ongoing concerns about ignoring household responsibilities, not keeping their rooms clean, and spending "too much" time in their room. Finally, and more importantly, parental concerns about drug experimentation and sexual activity are often in the fore. This chapter is not about such normal adolescent development, but rather about how to distinguish such concerns from those disorders that need a clinical intervention.

Depression and Risk of Suicide

Ten percent or more of teens seen in primary care may be depressed at a given time, with many more than that depressed over their teen years. The teen may present with deteriorating school performance, irritability, out-of-control behavior (e.g., truancy, running away from home, and theft), the use of drugs or alcohol, excessive self-criticism, expressions of hopelessness, or withdrawal from daily activities. A useful approach to screen for depression is to use the Patient Health Questionnaire 2 (PHQ-2). It consists of the following two questions:

In the past 2 weeks, have you been bothered by:

1. Little interest or pleasure in doing things?
2. Feeling down, depressed, or hopeless?

If the answer to either is "yes," a full PHQ-9 needs to be administered. The first step is to quantify the above questions by asking whether these feelings occurred for "several days," "more than half the days," or "nearly every day," scored as 1, 2, or 3 points. The remaining questions, scored as 0 (for "not at all") or 1, 2, or 3 as above are given in *Table 397.1*.

Scoring: One of the answers to first two questions must be a "2" or more, plus answers to 5 or more of the questions in all must be a "2" or more to make a diagnosis of significant depression. In addition, functional impairment must be "somewhat difficult" or higher. A total score of 5–9 represents minimal symptoms of depression; 10–14 is consistent with mild major depression, treated with watchful waiting, therapy, or medication; 15–19 is consistent with major depression, treated with therapy or medication, and 20 or higher is considered severe major depression, treated with both therapy and medication.

Since it can take some time to arrange for a referral for therapy and for therapy to be useful, many physicians choose to start medication for moderately severe depression, using a selective serotonin reuptake inhibitor (SSRI). Fluoxetine has the strongest evidence base for effectiveness in children and adolescents; other SSRI's that have been evaluated as effective in children and adolescents are sertraline, citalopram, paroxetine, and escitalopram. In all cases, the patient should be seen as often as weekly for the first 4 weeks of treatment, and frequently during the first 3 months. After 4–6 weeks, if the improvement in the PHQ-9 form is less than 5 points, the dose of medication should be increased. In addition to medication, counseling for patient and family as well as education about depression are important elements of treatment.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_397,

Table 397.1
The PHQ-9 form for diagnosing depression

During the last 2 weeks, how often have you been bothered by any of the following problems?	Not at all 0	Several days 1	More than half the days 2	Nearly every day 3
1. Little interest in doing things				
2. Feeling down, depressed, or hopeless?				
3. Trouble falling or staying asleep or sleeping too much				
4. Feeling tired or having little energy				
5. Poor appetite or overeating				
6. Feeling bad about yourself – or that are a failure or have let yourself or your family down				
7. Trouble concentrating on things, such as reading the newspaper or watching television				
8. Moving or speaking so slowly that other people could have noticed. Or the opposite – being so fidgety or restless that you have been moving around a lot more than usual				
9. Thoughts you would be better off dead, or of hurting yourself in some way				
Totals				
10. If you checked off *any* problems, how *difficult* have these problems made it for you to do your work, take care of things at home, or get along with other people?			Not difficult at all_____ Somewhat difficult____ Very difficult____ Extremely difficult_____	

A positive response of any kind to question 9 needs to be explored to assure current safety

Risks of treatment: There is evidence of an increased risk of thoughts of suicidality in adolescents treated with an SSRI (i.e., suicide ideation, preparatory acts, or suicide attempts, usually in the first few weeks of treatment). The United States Preventive Services Task Force states "conservative estimates from analyses show that treatment with antidepressants leads to a 1 percent or 2 percent absolute increase in the risk of suicidality. No suicide deaths are associated with these studies."

Another risk of antidepressant use is the risk of conversion from a unipolar depression to a *bipolar depression*. Symptoms of a bipolar disorder include, in addition to those of depression, *manic symptoms*. This includes severe changes in mood, either extremely irritable, prone to destructive outbursts, or overly silly and elated; grandiosity; increased energy; decreased need for sleep, with very little or no sleep for days without tiring; increased talking, changing topics frequently, cannot be interrupted; distractibility, with attention moving constantly from one thing to the next; hypersexuality in thoughts, feelings, behavior, or use of language; increased goal-directed activity or physical agitation; engaging in spending sprees; and excessive involvement in risky behaviors or activities.

Patients presenting with bipolar symptoms should not be started on an antidepressant, and should, if possible, be referred to a child psychiatrist for evaluation and treatment. Patients on an antidepressant who develop manic symptoms should have their SSRI discontinued, and be referred for further treatment.

Risk of suicide: Suicide is the third most common cause of death in adolescents, after unintentional accidents and homicide. A history of previous suicide attempts is the most important risk factor for subsequent suicide attempts. Approximately one-third of teens who die by suicide have made a previous attempt. Other common indicators of risk include depressive symptoms, severe anxiety, hopelessness, withdrawal, recklessness, suicidal ideation, having a family history of suicidal behavior, substance abuse, having a friend with a history of suicidal behavior, and the recent death by suicide by a family member or a close friend. Also, LGBTQ youth are at higher risk. Although many adolescents who die by suicide come from difficult family

circumstances, others grow up in supportive families. Many show problems in school or at home; others are excellent students, with many friends. The best summary statement may be "suicides are rare and unpredictable."

However, clinicians need to be alert to the possibility that teens presenting with any of the above risk factors may be contemplating suicide. A routine, confidential discussion of any previous history of self-harm, suicidal ideation, or present thoughts of self-harm may lead to a teen revealing that he or she has active thoughts of suicide. In that situation, emergency steps must be taken. In most cases, that would mean a visit to an emergency department of the nearest hospital that has mental health staff in the ED or on call. If no such hospital is convenient, the clinician needs to discuss with the family how to keep the teen safe until an evaluation by a mental health specialist can be done. Reducing access to lethal means, such as firearms, prescription medications, and alcohol (24% of those who die by suicide show alcohol intoxication) is very useful. A commitment on the part of the family to have an adult close to the teen at all times until an experienced professional can do a full evaluation can be lifesaving. Although adolescent girls are at higher risk for attempting suicide, adolescent boys are at six times the risk of completing suicide, given their propensity to use such lethal means as firearms and hanging.

Anxiety Disorders

Although all the anxiety disorders combined are more common than depression, they seem to be overlooked more commonly than depression (*Tables 397.2* and *397.3*).

Treatment: All of the anxiety disorders are best treated with cognitive behavioral therapy; more severe cases do better with medication in addition. For moderate or severe disorders, an SSRI is generally indicated, with

Table 397.2
Signs and symptoms of adolescent anxiety disorders (After Foa et al. 2005)

Anxiety disorder	Key diagnostic feature	Other criteria	Other
Social anxiety	Extreme fear in social situations that involve unfamiliar people	Must show the capacity for age-appropriate social relationships	Typically develops in late childhood or early adolescence
Generalized anxiety disorder (GAD)	Excessive worry on most days for 6 months	Apprehension when anticipating a feared event; often accompanied by somatic symptoms	Often occurs in association with other anxiety disorders, and with depression
Panic disorder	Sudden unexpected fear or anxiety along with somatic symptoms like palpitations or shortness of breath	Must be recurrent, and include concern about additional attacks or changes in behavior	Rare before puberty; may progress to agoraphobia
Separation anxiety	Related to being separated from home or a particular individual	Can include worry about harm to a specific individual	Typically develops in early childhood, may remit in adolescence
Specific phobia	Marked and excessive fear of a specific object or situation	Apprehension when anticipating an upcoming feared event	Generally lower level of impairment than other anxiety disorders
Post-traumatic stress disorder (PTSD)	Following a frightening exposure to trauma, development of recurrent experience of the event, with attempts to avoid stimuli associated with it	Can include flashbacks, nightmares, or images. Increased arousal can involve insomnia or irritability	Associated with many comorbid disorders, including major depression, other anxiety disorders, and behavioral disorders
Obsessive–compulsive disorder (OCD)	Recurrent, persistent, intrusive, anxiety-provoking thoughts (obsessions), or repetitive acts (compulsions) that the person feels driven to perform	The thoughts or acts are recognized as unreasonable, and consume at least 1 h per day	Stereotypical thoughts or acts, often involving counting or checking routines, or hand washing

Diagnosis. A brief screening tests can be useful in encouraging the clinician to consider an anxiety diagnosis. *The SCARED-5* (Screening Children for Anxiety-Related Emotional Disorders) has been validated in children and adolescents

Table 397.3
The SCARED-5 for screening for anxiety disorders

During the past 3 months, how true is each statement	Not true or hardly ever true	Somewhat true or sometimes true	Very often or often true
I get frightened for no reason at all	0	1	2
I am afraid to be alone in the house	0	1	2
People tell me I worry too much	0	1	2
I am scared to go to school	0	1	2
I am shy	0	1	2

A total score of $\geq$3 makes the diagnosis of anxiety likely

sertraline often a good choice. Specific phobias are generally treated with a desensitization approach, while OCD responds well to exposure and response prevention (ERP). For the latter, it is especially important for the patient to be treated by a therapist with specific expertise in using the ERP approach.

School Problems

Significant learning disorders should have been picked up long before adolescence; however, some bright teens may have a focused disorder that has been masked until the coursework gets more complex. There are a number of behavioral problems that can cause a teen with an acceptable, or even an excellent school record in elementary school to show deterioration in middle school or high school. Besides depression or anxiety, discussed above, substance abuse, family conflict, chronic illness, or ADHD are common causes of deteriorating school performance in middle school or early high school.

ADHD: This disorder is the behavioral problem that once diagnosed, is most easily treated by primary care physicians. Approximately 5–8% of adolescents, with a male to female ratio of 3:1, have this problem. Generally, the hyperactive type or the combined type is diagnosed at an earlier age. But children with inattentive ADHD do not cause problems for teachers, and many of them with above-average intelligence make their way through elementary school with good grades and no identified problems (Table 397.4).

Problems occur when the children, now adolescents, are promoted to a school in which they must change classes, no longer have a single teacher who recognizes what approach facilitates learning in a given child, and face more complex school subjects that require more focus. Their poor grades are often accompanied by behavior problems, including irritability at home and getting into trouble at school. Once a diagnosis such as depression, anxiety, or oppositional defiant disorder (ODD) has been eliminated, the next step should generally be to interview the parent, with the teen present, for the presence of inattentive ADHD. The following questions should be asked, with possible responses being "never or rarely," "sometimes," "often," or "very often."

Describe your child's behavior over the past 6 months. Then combine the "often" and "very often" answers; if they total at least 6 of 9 (some believe that for adolescents 5 of 9 is adequate), you can make a diagnosis of possible inattentive ADHD. To confirm the diagnosis, the behaviors must occur in at least two settings – generally in this age group that would mean home and school. Forms such as the Vanderbilt (which is also helpful in diagnosing ODD) should be completed by each teacher who has regular contact with the teen. If several teachers see the same problems the parent does, a diagnostic of inattentive ADHD can be made.

Treatment: The primary treatment for ADHD is a stimulant drug, preferably long acting. The recommended drugs are methylphenidate OROS, or mixed amphetamine salts, extended release. There are many other alternatives, including the non-stimulant atomoxetine, or the combination of a long-acting medication with an after school boost of a short-acting medication in the same family of drugs, to extend the effects of the medication long enough for homework to be completed. Studies show that medication plus parent education and behavior management is more effective than either treatment alone.

School refusal (also called school phobia): Frequent absences can sometimes be explained by any of the diagnoses discussed above, substance abuse, or other problems. Referral for psychological testing may be appropriate if there is no apparent behavioral cause of the problem, or poor performance is related to a specific

Table 397.4
Screening for ADHD without hyperactivity

	Never or rarely	Sometimes	Often	Very often
1. Fails to give close attention to details or makes careless mistakes in school work, work, or other activities				
2. Has difficulty sustaining attention to tasks or leisure activities				
3. Does not seem to listen when spoken to directly				
4. Does not follow through on instructions and fails to finish school work or chores				
5. Has difficulty organizing tasks and activities				
6. Avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort (such as school work or homework)				
7. Loses things necessary for tasks or activities (e.g., school assignments, pencils, books, or tools). (Note: ask about losing *completed* homework)				
8. Is easily distracted by extraneous stimuli				
9. Is forgetful in daily activities				

subject. However, some teens present with a puzzling history of missing many days of school with no clear diagnosis. At times, they present with fatigue and/or difficulty sleeping; it may be helpful to rule out chronic fatigue syndrome and/or a sleep disorder. In about one-third of these cases, no specific diagnosis can be made. The most common diagnosis that can be made is separation anxiety disorder, with all the anxiety disorders combined representing two-third of those who do end up with a diagnosis. Treatment with an SSRI can be helpful.

398 Substance Abuse

Michael J. Mason · Leslie R. Walker

Etiology

The initiation and establishment of adolescent substance use occurs as a result of many factors. In the past, attention was paid to environmental and physiologic factors, but increasing information is being uncovered about the genetic/biologic factors that play an important role.

There are different stages of adolescent substance use:

Experimentation – Using a substance for the first time and has a physical response to the substance; Of note, this response does not have to be a pleasant one, just one that elicits a new physical or mental response.

An example: Johannes takes his friends amphetamine to a party to see what will happen.

Misuse – Returning to a substance for a desired response; Johannes thought he was having a great time on the amphetamine and never got tired dancing. He decides at the next party he will take some again.

Abuse – Repeatedly using a substance or substances in order to get a desired effect even to his own detriment and in the face of severe consequences; Johannes has increased his amphetamine use to the point he had a near-death episode, where his friends had to drop him off at the hospital for care. He still uses amphetamines every chance he can get.

Drug Addiction and Dependency – Using substances now just to be "normal" no longer gets the desired effect; continued escalation of consequences but psychologically and or physically unable to stop; Johannes has been incarcerated for stealing to support his substance use and he has needed to use other drugs to augment his amphetamine drug of choice. He is no longer enrolled in school.

Epidemiology

Substance use disorders effect adolescents worldwide. Depending on the country, substance use patterns may differ. With over 72% of US high school youth reporting using alcohol and 47% reporting trying illicit drugs, the USA has the highest use of legal and illicit substances when compared to 17 other countries. Alcohol use is not uniform, with New Zealand, Americas, Europe, and Japan reporting much higher use than the Middle East, Africa, and China. An emerging problem worldwide is the misuse and abuse of prescription drugs. The abuse of these drugs has surpassed all illicit drugs combined except for cannabis. Internationally, 17% of adolescents are current tobacco smokers. In the USA, there has been a decrease in adolescent tobacco use over the last decade from 36.4% to 20%.

Marijuana and Alcohol remain the most commonly abused substances in this age group and they are responsible for the majority of adolescent drug dependence and treatment. Other substances that are abused but much less commonly during adolescence, are hallucinogens, cocaine, methamphetamine, anabolic steroids. Many of these other substances are used within the context of polysubstance abuse. While it is important that a provider stay current on the trends of specific substances adolescents are using in their community, what is more important is identification that an adolescent is abusing or dependant on any illicit or legal substance that is used for purposes other than what is prescribed. Any of these youth are at risk for poor health outcomes, school and job failure, poor family and interpersonal relationships, trauma, delinquency, and exploitation.

Substance abuse affects youth regardless of socioeconomic or ethnic or gender group status. All youth are potentially at risk for substance use and abuse, only screening those deemed to be high risk for this behavior will miss many who may be amenable to intervention and prevention.

Pathogenesis

Adolescent substance occurs through many pathways involving the environment, genetics and individual personality and resilience. While it would be hard to pinpoint a single direct pathway for a specific adolescent's initiation into substance use, there has been some exciting work that has begun looking at genetics and brain development in substance use and abuse.

The adolescent brain is still making new connections and pruning those it does not need, the areas that are most active during adolescence and young adulthood are those areas that govern emotions and executive functioning, these areas are also thought to be the most vulnerable to

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_398,

alcohol effects. Looking at genetic risk factors is beginning to show some important correlations as well, such as the relationship between nicotine receptors in the brain and Attention Deficit Disorders. Making it genetically more likely someone with ADHD would begin to use nicotine and have a harder time quitting when desired. Familial genetic predisposition is also apparent when statistics show that substance abuse and dependence run in families. It is nine times more likely for males and three times more likely for females to develop alcoholism when there is a positive family history of alcoholism.

It is commonly believed that substance use and ADHD are associated when a dual diagnosis of conduct disorder is present, but there is little evidence to suggest that substance use is associated with ADHD alone. While the relationship between ADHD and substance-use disorders may not be exclusive, it is likely that the severity of both ADHD and SUD will increase when the symptoms are combined. For instance, Biederman and colleagues found support for the theory of a causal pathway from ADHD to cigarette smoking to substance use, with ADHD youth who smoke significantly more likely to use substances compared to non-smoking controls. Manuza and Klein found that children with ADHD were four times as likely to develop an SUD by adulthood than those who had not been given an ADHD diagnosis (16% vs 4% of control subjects).

Child and adolescent substance abuse is inextricably linked to comorbid psychiatric conditions including ADHD, conduct disorder, depression, anxiety, a variety of stress disorders, oppositional defiant disorder, and reactive attachment disorder. The Substance Abuse and Mental Health Services Administration (SAMHSA) has further demonstrated the linkage and interactivity between emotional and behavioral problems and substance involvement. Adolescents who demonstrated behavioral and emotional problems were seven times more likely to be dependent on substances than those who presented with fewer symptoms. Finally, for those teens entering substance abuse treatment, 75% will have one or more psychiatric conditions, with 50% having three or more.

Clinical Manifestations: Symptoms and Signs

Symptoms and signs of substance abuse in adolescents include:

Physical	Personality	Home	School
Odors of marijuana, alcohol, solvents on clothes, in house or car	Sudden changes in mood, depression	Legal problems	Change in school performance
Decreased personal hygiene	Memory loss	Increased financial problems, i.e., selling of personal or family possessions	Truancy, dropout
Slurred speech or intoxication, lethargy	Increased belligerence and arguing	Increased family arguments	Change in interactions with teachers and students
Unsteady gait	Lack of motivation or interest	Less interested in family activities	Bringing alcohol or other substances to school grounds
Red eyes	Excessive energy, unusually talkative	Drugs or drug paraphernalia, matches, lighter in laundry, backpack, or bedroom, etc.	Increased disciplinary action
persistent coughing	Secretiveness	Runaway behavior, breaking curfew	Disengagement in school goals
Increased or slowed heart rate	Sudden paranoia, distrustfulness	Excessive sleepiness, decreased ability to get up in the morning	Sleeping in class
Sudden weight loss or weight gain	Hallucinations: auditory, visual	New group of friends and activities	Decreased interest in extracurricular school activities and sports participation
Increased or decreased blood pressure	Extreme opinions, language and dress	Prescription drugs missing from household	Stealing from school

Diagnosis

The substance use disorders can be divided into two categories: (1) substance abuse and (2) substance dependence. Substance abuse is more likely in individuals who have only recently started using a substance and is characterized by a maladaptive pattern of substance use observable by recurrent and significant adverse consequences due to repeated use of substances.

Criteria for Substance Abuse

1. A maladaptive pattern of substance use leading to clinically significant impairment or distress, as manifested by one (or more) of the following, occurring within a 12-month period:
   (a) Recurrent substance use resulting in failure to fulfil major role obligations at work, school, or home (e.g., repeated absences, suspensions, or expulsions form school; neglect of children or household)
   (b) Recurrent substance use in situations in which it is physically hazardous (e.g., driving an automobile or operating a machine when impaired by substance use)
   (c) Recurrent substance-related legal problems (e.g., arrests for substance-related disorderly conduct)
   (d) Continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance (e.g., arguments with spouse about consequences of intoxication, physical fights)
2. The symptoms have never met the criteria for substance dependence for this class of substance.

Substance dependence is characterized by a cluster of cognitive, behavioral, and physiological symptoms, indicating that the individual continues use of the substance despite recurrent and significant substance-related problems. Dependence is evidenced by a pattern of repeated substance use that can result in tolerance and withdrawal. Although not listed as a criterion, craving a substance (strong subjective drive to use the substance) is likely to be evident in most individuals with substance dependence.

Criteria for Substance Dependence

A maladaptive pattern of substance use, leading to clinically significant impairment or distress, as manifested by three (or more) of the following, occurring at any time in the same 12-month period:

1. Tolerance, as defined by either of the following:
   (a) A need for markedly increased amounts of the substance to achieve intoxication or desired effect
   (b) Markedly diminished effect with continued use of the same amount of the substance
2. Withdrawal, as manifested by either of the following:
   (a) The characteristic withdrawal syndrome for the substance
   (b) Substance is taken to relieve or avoid withdrawal symptoms
3. The substance is often taken in larger amounts or over a longer period than was intended.
4. There is a persistent desire or unsuccessful efforts to cut down or control substance use.
5. A great deal of time is spent in activities necessary to obtain the substance (e.g., visiting multiple doctors or driving long distances), use the substance (e.g., chain-smoking), or recover from its effects.
6. Important social, occupational, or recreational activities are given up or reduced because of substance use.
7. The substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance (e.g., continued drinking despite recognition that an ulcer was made worse by alcohol consumption).

Differential Diagnosis

Substance use disorders are differentiated from:

- Nonpathological substance use (e.g., "social" drinking)
- Use of medications for appropriate medical purposes

Repeated episodes of substance intoxication are almost always prominent features of substance abuse or dependence; however, one or more episodes of intoxication alone are not sufficient for a diagnosis of substance abuse or dependence. It is the presence of impaired psychosocial functioning that differentiates nonpathologic from pathologic use. Research has now established that substance abusing and dependent adolescents presenting with co-occurring psychiatric disorders are the norm, not the exception, with the majority of untreated adolescents likely to have a comorbid psychiatric disorder. These issues are clearly linked as adolescents with a substance use disorder are at a sixfold greater risk for co-occurring

disorders than those without a substance use disorder, with 78–90% of adolescents in substance abuse treatment programs endorsing internalizing or externalizing problem and 42–61% endorsing for both. The most common form of psychopathology observed in substance-dependent adolescents includes conduct disorder, ADHD, major depressive disorder, anxiety disorder, and posttraumatic syndrome disorder.

Treatment

General Care

In 2005, 1.5 million youths (6.1% youths aged 12–17) were classified as needing alcohol treatment in the past year and about 1,11,000 youths (7.2% of those needing alcohol treatment) received treatment for alcohol in the past year. About 1.4 million youths (5.4%) were classified as needing illicit drug use treatment in the past year and 1,24,000 (9.1% of those needing illicit drug treatment) received treatment for an illicit drug in the past year. As may be expected, most youths aged 12–17 who were in need of substance use treatment in the past year and did not receive treatment were not likely to perceive a need for substance use treatment. However, the good news is that within the last 10 years, the literature on adolescent substance abuse treatment has grown substantially in the quantity and in the quality of clinical studies. There is now a robust body of evidence to support evidence-based treatments that have demonstrated efficaciousness in addressing adolescent substance abuse.

Research has demonstrated that a quality treatment enables adolescents to offset addiction's powerful disruptive effects on their brain and behavior and to regain control of their lives. The specific type of treatment is dependent upon severity of symptoms and can be offered in formats such as typical outpatient settings, day treatment programs (partial hospitalization), and inpatient programs. Based upon the level of care needed and accompanying medical and safety concerns, the appropriate setting can be determined by a comprehensive evaluation of the adolescent and family. The types of effective treatment vary by their focus, style, and length. In general, no one treatment has emerged as superior to all others and no one treatment approach appears to be similarly efficacious for all adolescents. Recent research has demonstrated that the evidence-based treatments briefly reviewed below, have on average, produced large effects on substance-related outcomes across demographic differences.

Specific Treatment

Family Therapy Approaches

Brief Strategic Family Therapy is predicated on the assumption that the adolescent substance abuse is a product of maladaptive family interactions. Treatment focuses on enhancing family engagement, identifying maladaptive interaction patterns, and restructuring new, adaptive patterns.

Functional Family Therapy is an integrative ecological approach that combines a family systems perspective on family functioning with behavioral techniques. The focus is on enhancing treatment engagement and increasing family's motivation to change along with improving family communication and problem solving.

Multisystemic Therapy addresses the factors associated with serious antisocial behavior in children and adolescents who abuse alcohol and other drugs. By participating in intensive treatment in natural environments (homes, schools, and neighborhood settings), most youths and families complete a full course of treatment.

Multidimensional Family Therapy (MDFT) is a comprehensive and multisystemic family-based outpatient or partial hospitalization program for substance-abusing adolescents, adolescents with co-occurring substance use and mental disorders.

Individual Approaches

Cognitive behavioral therapy (CBT) is a behavioral model that assumes that cognition precedes emotions, which activate moods and behaviors. CBT identifies distorted thinking patterns and couples this with communication, problem-solving, and coping skills. CBT focuses on the acquisition of problem-solving, affect-regulation, and social skills.

Motivational Interviewing (MI)/Enhancement Therapy seeks to enhance readiness for change by helping clients explore and resolve ambivalence toward behavioral problems. MI is typically conducted in brief formats, one to five sessions, with some single session interventions being 20 min.

The Adolescent Community Reinforcement Approach to alcohol and substance use treatment is a behavioral intervention that seeks to replace environmental contingencies that have supported alcohol or drug use with prosocial activities and behaviors that support recovery.

Future Development

Drug-abusing adolescents have unique treatment needs. Research has shown that treatments designed for and tested in adult populations often need to be modified to be effective in adolescents. Due to the rapid changes occurring in adolescents' neurocognitive and psychosocial development, attending to the unique biopsychosocial needs of the adolescent is critical. The adolescent brain undergoes a critical process of development and refinement, during which a developmental shift occurs where actions go from more impulsive to more reasoned and reflective. For example, the areas of the brain associated with decision-making, judgment, and impulse control undergo a period of rapid development during adolescence, underscoring the unique developmental issues associated with adolescent substance abuse treatment. The future of adolescent substance abuse treatment will incorporate current neurocognitive developmental science with established evidenced-based treatment protocols to refine treatments that can be more individually tailored.

Prognosis

For some adolescents, experimentation with alcohol and other drugs of abuse can lead to substance abuse and for others, dependency. The progression and complexity of these disorders are now better understood making treatment more successful. If substance abuse has become chronic, relapses are probable, even after long periods of abstinence. Relapse occurs at similar rates to other chronic illnesses such as diabetes, hypertension, and asthma. Therefore, repeated treatment episodes are not uncommon for individuals seeking sustained abstinence and productive lives. Making ongoing lifestyle changes to support healthier living is critical for the long-term success of any individual dealing with an addiction. Often, this is most successfully accomplished with the support of others, just as individuals with diabetes need to make significant changes in their lifestyles and support systems.

In general, adolescents who get into and remain in effective treatment stop using alcohol and drugs, decrease their criminal activity, and improve their educational, social, and psychological functioning. Given that adolescents are particularly sensitive to social influences with peer groups and families, treatments that facilitate positive parental involvement integrate other systems in which the adolescent participates (such as school and athletics) and recognize the importance of prosocial peer relationships as among the most effective. Adolescents who have access to comprehensive assessment, treatment, case management, and family-support services that are developmentally, culturally, and gender-appropriate, are most likely to be successful in their treatment.

Prevention

The field of prevention science has produced a very solid knowledge base regarding the epidemiology, etiology, developmental timing, expression, and prevention of substance use and associated psychiatric and behavioral disorders. Prevention research is predicated upon a risk and protective model that identifies factors or processes that increase (risk factor) or decrease (protective factor) the likelihood of substance use. The most frequently identified protective processes against adolescent substance use are parental engagement and family functioning, self-regulation social competence, and school bonding and academic performance. The most effective evidence-based preventive programs are designed to focus on these protective processes and target interactions between the adolescent and these significant domains (family members, students, family–school interactions).

The U.S. National Registry of Effective Prevention Programs has recently developed a searchable database that contains detailed descriptions and evaluations of interventions for the prevention and treatment substance use and mental health disorders (see site at http://www.nrepp.samhsa.gov/index.asp).

399 Community Violence

T. Coyne-Beasley · Phillip W. Graham · Janelle Shumate

Introduction

There are many violence types in our community, including, but not limited to, suicide, bullying, sexual assault/rape, assaultive behaviors, gang, dating, school, media, and firearm violence. Many types of violence are interrelated and may occur simultaneously. Although homicide has declined over the last decade, recent violence in some of the nation's urban and rural areas and across socioeconomic classes reminds us that much work remains to be done by clinicians and others. Understanding community violence and its manifestations is an important step toward reducing its impact on young people's psychological and physical well-being.

Definition

The World Health Organization (WHO) and the Centers for Disease Control and Prevention define violence as: the intentional use of physical force or power, threatened or actual, against oneself, another person, or against a group or community that either results in or has a high likelihood of resulting in injury, death, psychological harm, maldevelopment, or deprivation. Community violence has been used to define violence that occurs in and around neighborhoods, schools, and the streets of communities. It typically excludes violence committed in the home such as child abuse or neglect. Community violence exposure has focused on experiences through direct and indirect victimization such as witnessing.

Epidemiology/Prevalence

The national prevalence of witnessed community violence in the USA is estimated at 38%. Internationally, this prevalence approaches or exceeds 90% in some war-torn regions; thus, community violence is a relevant global public health concern. In this chapter, the authors have limited the types of community violence exposure to interpersonal, bullying, intimate partner or dating, and firearm violence.

Interpersonal Violence. According to the Monitoring the Future Study of high school seniors, the violence index (hit an instructor or supervisor, got into serious fight at school or work, taken part in a fight where group of friends are against another group, hurt someone badly enough to need bandages or doctor, used knife or gun to get something from someone) has been at a high level for almost 20 years. Approximately 30% of high school seniors, age 13–18 years, reported having committed one of these violent acts in the past year. This estimate of 30% is only slightly higher than the available estimates of the violence index for youth in other countries. This estimate ranges from 16% to 26% in several European countries – England/Wales, the Netherlands, Spain, and Italy.

When examining homicide rates, most countries with rates higher than 10/100,000 are nonindustrialized or experiencing rapid social and economic transformation. The exception is the USA with an 11/100,000 homicide rate. Countries with low youth homicide rates tend to be in Western Europe – for example, France (0.6/100,000), Germany (0.8/100,000), and the UK (0.9/100,000) – or in Asia, such as Japan (0.4/100,000). Several countries such as Hong Kong, New Zealand, and Denmark had fewer than 20 youth homicides a year compared to 16 persons between the ages of 10 and 24 murdered daily in the USA. In addition to homicide, more than 780,000 United States youth aged 10–24 are treated in emergency departments annually for violence-related injuries.

Bullying. Bullying can be defined as a form of aggression, which involves one or more students verbally, physically, and/or psychologically harassing another student repeatedly. Prevalence estimates for bullying vary widely due to the lack of an agreed-upon definition and consistent measures. Some researchers focus solely on physical bullying, while others include nonphysical behaviors such as name calling. Despite these challenges, studies have produced useful estimates of bullying. One such study of middle school students found that 80% reported that bullying was a problem in their school, and 30% of students in grades 6–10 report moderate or frequent involvement in bullying, as a victim (11%), perpetrator (13%), or both (6%).

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_399,

However, bullying is not limited to the USA. One study, of students in 11 European countries, found that approximately 20% of students were bullying victims; the highest prevalence of 30% was in the UK. Interestingly, a separate study comparing rates of peer victimization in the USA and the UK found no significant differences. Finally, another study found that among the USA, Israel, Ireland, Portugal, and Sweden, students in the USA reported the second highest frequencies of bullying and other school violence (after Israel).

Dating or Intimate Partner Violence. Annually, 1 in 11 adolescents report being a victim of physical dating abuse. However, other prevalence estimates of psychological abuse range from 14% to 82%. Between 11% and 41% of adolescents report using some form of physical violence against their dating partners. Between 4% and 14% of adolescents report using forms of violence against dating partners that are likely to result in serious physical injury such as hitting a partner with an object, beating up a partner, and using a knife or gun against a partner. Approximately 3–10% of adolescents report perpetrating sexual violence against a date.

The prevalence of intimate partner violence in the UK is highest amongst women aged 16–24 years. A New Zealand study found that the rates of partner violence among women seeking emergency healthcare to be high at 20%. In the cohort of women aged 16–24 years, this statistic increased to 25%. Similarly, in the outpatient setting, 23% of women screened positive for dating or intimate partner violence.

Firearm Violence. Firearms are the major weapon used in the leading causes of death among adolescents and young adults – suicides and homicides. Homicides and suicides are the second and third leading causes of death, respectively among 15–24-year-olds in the USA. In 2006, firearms were used in 84% of homicides and 47% of suicides. Exposure to unsafely stored firearms is a major risk factor for childhood and adolescent injury. Parents of adolescents are actually more likely than other parents to keep household firearms stored unsafely.

Youth firearm death rates are not uniform in the industrialized world – the USA has the highest rate. Total firearm deaths among youth are approximately 12 times higher in the USA than in all of the other countries combined; homicide rates are approximately 5 times higher; and youth suicide rates are approximately twice as high. Five countries, three of which are in Asia, report none or few firearm deaths among children under 15 years old.

Armed conflict is a major cause of adolescent community violence worldwide. In armed conflict, there are also health consequences from the displacement of populations, breakdown of health and social services, and heightened risk of disease transmission.

The prevalence of community violence among youth continues to be a global public health concern that requires early detection and effective intervention. The following section highlights some of the most salient risk factors for violence perpetration and victimization. Early recognition of these factors can play an important role in addressing subsequent negative effects of exposure.

Risk and Protective Factors

Several factors are associated with a higher probability that an individual will engage in violent behavior. Such risk factors may differ depending on the age of the individual and onset of violence, circumstances, and social context. Protective factors that appear to decrease the probability of violence or buffer the individual against the potentially harmful effects of risk factors have also been identified.

The ecological perspective posits that many risk behaviors, and protective factors are influenced by factors that operate at different but interrelated dimensions starting with the individual as the central unit of interest out to the influence of the society. The domains include individual, family, peer group, school, and community. *Table 399.1* includes a list of risk factors associated with the violent behavior during different developmental periods and a list of protective factors for each ecological domain. As with any major public health concern, the underlying predictors of community violence exposure are multifactorial.

Although persons of color in the USA are disproportionately affected by community violence, race/ethnicity is not thought to be a risk factor but instead is considered a risk marker, because it is often highly correlated with known risk factors such as poverty, low socioeconomic status, neighborhood characteristics, and discrimination.

Impact

Youth exposed to community violence may be more likely to engage in fighting and aggressive behavior as a result of an arousal created by frustration. Children and adolescents who live with the constant threat of violence may also become desensitized to the threat and consequences of violence. These individuals may attempt to gain a sense of control over their lives through repeated encounters with life-threatening situations. Additionally, evidence

Table 399.1
Summary of risk and protective factors for violence, by domain

Domain	Risk factor Early onset (6–11 years)	Risk factor Late onset (12–14 years)	Protective factor
Individual	General offenses	General offenses	Intolerant attitude toward deviance
	Substance use	Substance use	High IQ
	Being male	Being male	Being female
	Aggression (males only)	Aggression (males only)	Positive social orientation
	Psychological condition (hyperactivity)	Psychological condition (restlessness, difficulty concentrating, risk taking)	Perceived sanctions for transgressions
	Antisocial behavior, attitudes	Antisocial behavior, attitudes	
	Medical, physical		
	Low IQ	Low IQ	
		Crimes against persons	
		Physical violence	
Family	Low socioeconomic status		Family connectedness
	Antisocial parents		Parental monitoring
	Poor parent–child relations		
	Broken home		
	Abusive parents		
School	Poor attitude, performance	Poor attitude, performance	Commitment to school
		Academic failure	Recognition for involvement in conventional activities
	Weak social ties	Weak social ties	Friends who engage in conventional behavior
	Antisocial peers	Antisocial, delinquent peers	
		Gang membership	
Community		Neighborhood crime, drugs	
		Neighborhood disorganization	

has consistently shown that witnessing gruesome acts of brutality as a bystander or a victim during the critical developing years has far-reaching negative consequences on adolescents' behavior and emotional and physical well-being. The psychological and physical impact of exposure is described below.

Psychological Impact. The psychological impact ranges from the traditional sequelae of depression, anxiety, and posttraumatic stress disorder (*Table 399.2*) to the more recently studied effect on identity development. Specifically, the exposed adolescent may struggle with coping in appropriate ways, defining a positive self-perception,

Table 399.2
Psychological impact of community violence

• Depression
• Anxiety
• Posttraumatic stress disorder
• Negative self-perception or identity
• Substance abuse
• Misplaced aggression
• Suicidal ideation

negotiating a moral compass, and attaining the altruism desired for his or her future. Exposure to significant community violence before or during adolescence can lead to the establishment of pathologic character traits.

Misplaced aggression is one of the most commonly cited coping mechanisms employed by the youth exposed to violence. In some environments, this aggression is simply a product of believing that hostility is the only means to achieving basic survival. In other settings, the aggression turns inward and manifests as suicidal tendencies. For example, at risk youth may solve the feeling of helplessness by owning suicidal ideation; thus the adolescent can manage the fear of death by controlling when and how it will happen.

A large multi-country study using WHO data found that women involved in intimate partner violence (including 15-year-old adolescents) were significantly more likely to report suicidal thoughts and attempts. The effects of physical intimate partner or dating violence are not restricted to females. Evidence suggests that both male and female victims have increased risk of depressive symptoms and developing a chronic mental illness. Finally, psychological effects may be a direct result of physical harm. A classic example involves females in abusive relationships, who sustain multiple untreated and unreported losses of consciousness. In these circumstances, eventual reports of memory loss and difficulty with daily activities or chronic headaches may actually represent inadequately diagnosed sequelae of neurologic damage from battering.

Worldwide, among child soldiers, the predominance of male exposure to violence is extremely high as well as the violent victimization experienced by many young girls and women. Some common psychological effects of war-related abduction, sexual assault, and child soldiering among adolescents in countries engaged in war are PTSD and depression.

Physical and Health-Related Impact. While the mental effects are well defined, the physical manifestations can be vague and variable in nature. These physical manifestations may also result in frequent visits to the physician, particularly through emergency visits. Postulated physiologic changes resulting from witnessed violence range from altered cortisol levels to worsening asthma morbidity. The reasoning for this depends in part on the hypothesis that chronic stress weakens the immune system.

Victims of dating violence are not only at increased risk for injury; they are also more likely to engage in binge drinking, drug use – including cocaine, unhealthy weight control, suicidality, physical fights, and sexual behaviors that can lead to unintended pregnancy, sexually transmitted diseases, and HIV infections. Rates of drug, alcohol, and tobacco use have been demonstrated to be more than twice as high in girls who report physical or sexual dating abuse than in girls who report no abuse.

To further complicate the matter, the clinical presentation can be quite unpredictable. Often, victims of dating violence do not present with noticeable trauma but rather with vague symptomatology. When injuries are present in battered young women, they are more likely to involve the face, head, neck, thorax, breast, and abdomen compared to women injured by other mechanisms.The sequelae of intimate partner violence and other violence types range from chronic pain to central nervous system effects to physical symptoms and disease (see *Table 399.3*). These consequences can be seen in both men and women who also have increased risk of: becoming a perpetrator, poor health, injury, and developing a chronic disease. Physical fitness of adolescents may also be affected. Adolescents in violent communities may avoid group recreational play.

School-Related Impact. Community violence can also impact school performance. For example, bullying victimization is associated with school absenteeism and feeling

Table 399.3
Physical and health-related manifestations

• Altered cortisol levels
• Worsening asthma
• Weakened immune system
• Injuries
• Chronic pain especially headache
• Syncope
• Seizures
• Chronic irritable bowel syndrome
• Decreased appetite
• Eating disorder
• Hypertension
• Abdominal pain
• Chest pain
• Back pain
• Gynecological symptoms (STIs, UTIs, dsypareunia, pregnancy)
• Loss of consciousness
• Memory loss
• Poor general health
• Poor physical fitness

unsafe at or on the way to school. Feeling unsafe at school and the resultant anxiety can lead to distraction and inability to focus and concentrate on school work.

Screening

Investigating exposure to community violence should be a standard part of health screening for all adolescents presenting at emergency departments and inpatient and outpatient settings. This screening should include questions about the school environment, neighborhood, and relationships. Many of the sequelae of violence exposure have a proven treatment record in the adolescent population, including depression, PTSD, and anxiety disorders. Thus, proper screening and identification of at-risk adolescents could lead to improvements in their health outcomes.

Screening Tools. Commonly used evidence-based screens for adolescent depression include the Beck Depression Inventory-Primary Care Version and PHQ-A (Patient Health Questionnaire for Adolescents). One tool appears to directly address the issue of community violence: the Screen for Adolescent Violence Exposure created by Hastings and Kelly. Also, the commonly used GAPS (Guidelines for Adolescent Prevention Services) questionnaire contains questions regarding violence exposure that help clinicians identify community violence to allow them to initiate a discussion such as: Do you or anyone you live with have a gun, rifle, or other firearm? Have you ever seen a violent act take place at home, school, or in your neighborhood? FISTS is a pneumonic that reminds clinicians to screen for violence risks and includes history of Fights, Injuries, Sexual violence, Threats, and Self-defense strategies. For example, have you ever been involved in a fight? Have you ever been hit, slapped, or physically hurt on purpose by your partner? Have you ever been injured in a physical fight or with a weapon? Have you ever been forced to have sexual intercourse or do something sexual when you did not want to? Have you ever been bullied or bullied others? Have you ever been threatened with a weapon? Have you ever carried or used a weapon?

Tools in international settings include the War Trauma Experience Checklist (WTECL-15) and the Adolescent Complex Emergency Exposure Scale. The UK reported the HITS (Hurts, Insults, Threatens, and Screams) scale to be the best of short screening tools used in their healthcare arena.

Timely use of screening provides the opportunity for intervention, prevention, and improvement in physical and mental health outcomes. The ideal screening tool is not only employed before permanent harm but must also be practical to implement.

What Clinicians Can Do?

Youth exposed to community violence are the patients of a broad range of clinical providers including pediatricians, family practitioners, internists, obstetrician gynecologists, emergency department (ED) physicians, physical therapists, nurse practitioners, and physician assistants. Each of these providers has the opportunity to advocate for violence prevention. For example, ED physicians can play an important role in the prevention of retaliatory violent acts amongst injured youth. For the purposes of this textbook, the chapter focuses on the unique role of the pediatrician.

Pediatricians not only have access to adolescents exposed to community violence but also have the opportunity to intervene during the early formative years. In fact, the American Academy of Pediatrics (AAP) offers relevant anticipatory guidance that begins at the age of 2 days through 21 years. In its publication entitled *Connected Kids: Safe, Strong, Secure*, the AAP specifically seeks to enable the primary health-care provider to use intentional violence and injury prevention strategies in daily practice. The adolescent portion of these recommendations is summarized in *Table 399.4*.

In 2009, an AAP policy statement updated the pediatrician's role in youth violence prevention with four areas of emphasis to focus preventive efforts:

1. *Clinical Practice*
   (a) Understand the *Connected Kids* protocol.
   (b) Have parent and youth education materials available.
   (c) Employ timely treatment and/or referral once violence-related problems are indentified.
   (d) Maintain current database of community-based counseling and treatment resources.
2. *Advocacy for*
   (a) Community-based behavioral health services
   (b) No firearm exposure amongst youth
   (c) Awareness of bullying
   (d) Multimedia responsibility to minimize violent images, messages, or themes
   (e) Role of health professionals as "public health messengers"
   (f) Electronic health records with content related to youth violence prevention

Table 399.4

Primary care guide to violence prevention strategies for adolescence (Training Resource, adapted from Sege et al. 2005)

Visit	Introduce	Reinforce	Brochures
Early	• Family time together	• Reducing access to firearms • Establishing routines and setting limits	Talking with your teen: tips for parents
11–14 years	• Peer relationships • Support system • Staying safe • Mental health • Conflict resolution • Healthy dating • Gaining independence • Plans for future	• Alcohol and drug abuse prevention • School performance	Staying cool when things heat up Expect respect: healthy relationships Teen dating violence: tips for parents
Middle	• Plans for future	• Alcohol and drug abuse prevention	Teen suicide and guns
15–17 years	• Firearms and suicide prevention, including reducing access to firearms • Depression prevention • Resiliency	• Peer relationships • Healthy dating • Gaining independence	Next stop- adulthood, tips for parents
Late	• Transition to independence	Peer relationships	Help stop teenage suicide
18–21 years	• Negotiating a new environment (Post-High School)	• Plans for future • Depression prevention	Connecting with your community

3. *Education*
   (a) Attend relevant CME or professional development programs.
   (b) Learn about resources in your community.
   (c) Get involved with providers in training, for example, elective work at medical school.
4. *Research*
   (a) Participate in practice-based research focusing on youth violence prevention.
   (b) Contribute data to existing surveillance systems.
   (c) Advocate for your local injury surveillance system to be municipally supported and legislatively mandated.

Summary

Exposure to community violence must be viewed as a preventable health problem. Pediatricians and Adolescent Medicine Specialists are an integral component of successful youth violence prevention. Although these providers are well trained in identifying the physical victimization, it is critically important that they become more astute at identifying the risk factors, psychological signs, and vague physical symptoms associated with direct and indirect victimization. The use and integration of valid and reliable screening tools during regular primary care visits could be beneficial in indentifying and intervening to reduce the short- and long-term effects of community violence exposure.

400 Delivery of Adolescent Health Care

Anisha Abraham · Kirsten Hawkins

Adolescence, the transition between childhood and adulthood, is defined by the World Health Organization as the time period between ages 10 and 18 and by the American Academy of Pediatrics as ages 11–21. Taking care of adolescents requires a different approach than caring for children or adults. The goals of an adolescent medicine provider are to oversee a teen's health care, provide support and counseling for the many issues that may arise during puberty, and enable an adolescent to segue successfully to adulthood. Visits should reinforce good health practices, while discouraging high-risk behaviors such as unprotected sexual activity or substance use. A comprehensive history is the most important aspect of the preventive service evaluation. Taking a thorough adolescent history can be time consuming and occasionally challenging but provides essential information for health maintenance and risk prevention.

Communication

The initial encounter with an adolescent sets the tone for future visits. Moreover, the ability to engage youth in health promotion is tied to a provider, forming an effective relationship. The following are the recommendations regarding communicating with adolescent patients. Attempt to greet the adolescent first before the parent and make the teen patient the primary historian. To increase a teen's willingness to communicate and feel comfortable, consider opening the discussion by asking the teen a nonmedical question. For example, ask about the book the adolescent is carrying, the outfit the teen is wearing, plans for upcoming holidays, etc. During the actual interview, sit at eye level with the patient and be attentive. Try to use understandable language and open-ended questions such as asking "what do like to do for fun?" Attempt to remain nonjudgmental and refrain from assessing behaviors in relation to one's own experiences. Also, avoid lecturing without regard to a teen's willingness to hear a message. Communication should be culturally sensitive with respect to different customs, traditions, and religions. Providers should try to listen to their adolescent patient, trust their intuition, and be open to "hidden agendas" that the adolescent patient may be reluctant to disclose.

A strength-based approach, highlighting the positives, creates a trusting relationship and helps teens develop their own solutions to problems. At the completion of the interview and examination, allow the teen to ask final questions. Prioritize problems by level of risk. While low-risk situations can be managed by dispensing health information and specific suggestions, high-risk situations may require return visit or more in-depth interventions. Attempt to focus counseling on key areas of need and involve the adolescent in developing the plan. Work with patients to incorporate cultural issues and preferences into the individualized care plan. Finally, inform the teen how to best obtain medical information and schedule follow-up appointments. Consider using electronic communication to facilitate the communication.

Clinical Approach to the Adolescent

Questionnaires and screening forms can help collect information prior to the actual interview. In fact, many patients may find it easier to disclose personal information through written or computer-based questionnaires. The American Medical Association has developed the Guidelines for Adolescent Preventive Services (GAPS) which are available for adolescents and parents and can be a useful screening tool.

The components of the adolescent history include the past medical history, family history, psychosocial history, and review of systems. The *past medical history* is best obtained from both the teen and parent/guardian and should include medications (including vitamins and over-the-counter/alternative medicines), allergies, developmental history, childhood illnesses, hospitalizations, surgeries, mental health history, and immunizations. The *family history* should be obtained primarily from the parent/guardian with the teen present and should include

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_400,

significant medical and mental health issues among family members such as hypercholesterolemia, hypertension, diabetes, and depression.

The *psychosocial history* can be taken mainly from the adolescent. Providers often use a standard screening format to ensure that they cover key issues. One such example is *SSHADESS*, an updated version of the widely used HEADSS concept. SSHADESS begins with general questions and progresses to ones which are more sensitive in nature and includes *S*trengths, *S*chool, *H*ome, *A*ctivities *D*iet/*D*rugs, *E*motions, *S*exuality, and *S*afety.

The institutional or office policy regarding confidentiality should be clearly reviewed with the teen and parent at the onset of an appointment. Information regarding confidentiality and legal issues is reviewed later in this chapter.

In conducting the SSHADESS psychosocial interview, begin by letting the teenager state their *strengths* or interests. If the teen has difficulty answering, then ask "What do you do best? What makes you proud? What would your friends say about you?" The strength-based questions focus on resiliency and can be useful in reinforcing a teen's ability to make healthy decisions and minimize high-risk ones.

After discussing strengths, progress to questions regarding school and employment. Poor attendance and grades have been shown to be risk factors for early sexual activity, teen pregnancy, and alcohol use. Employment can have both positive and negative effects on teens depending on factors such as hours worked and the reason for employment. Questions regarding *school* can include: What grade or level are you in? What are your educational and life goals? How many days have you missed in the past year and what was the reason? Have you ever had any educational setbacks? Adolescents are often employed either part-time or fulltime. Questions regarding *employment* include: Do you work after school? What type of work do you do? How many hours a week? Do you have any home chores or responsibilities?

Determining a teen's concept of their *home* and family is important. Questions regarding home include: Who lives in the home with you? How are your relationships with siblings, parents, and relatives? What are the rules like at home? Ever been homeless, in a shelter or foster care?

Worldwide, adolescents are increasingly using several forms of media each day. For a variety of reasons, teens often report inadequate sleep and sleep-related problems. Youth participation in extra-curricular activities such as after-school sports has been shown to be protective against violence and juvenile crime. Questions regarding *activities* include how many hours do you sleep every night? What do you do for fun? Are you involved in sports, religious activities, youth groups, music, and arts? How many hours per day do you watch TV? Use the Internet or computer? Play video games?

Body image disorders such as binge eating disorder and anorexia/bulimia often evolve during adolescence. Providers should screen for dietary practices and self-image. Questions regarding *diet* include: What do you think your ideal weight should be? What do you like about your body? How many meals do you eat per day? If there are concerns regarding low weight or weight restriction – do you exercise excessively, vomit, use diuretics or laxatives? If the concern is being overweight: What do you drink with meals and between meals? Do you skip meals? Do you exercise?

At this point in the interview, the provider should remind the parents about the importance of talking to an adolescent alone and review the policies regarding confidentiality. If the parents leave the room, the provider should reiterate confidentiality policies with the teen and progress to questions regarding drugs, emotions, sexuality, and safety. If the patient (generally a younger adolescent) prefers to have the parent present, a limited SSHADESS may be performed.

Most adolescents experiment with drugs at some point in their development whether limited to alcohol, caffeine, and cigarettes or extended to marijuana, cocaine, or other drugs. Adolescents who use *drugs* to manage stress are of particular concern as this can interfere with coping skills, responsible decision-making, and lead to lifelong addiction. Do you spend time with smoke, drink, or use drugs? How frequently and how much? Do you smoke or chew tobacco? Do you use anabolic steroids? Do you drink alcohol such as beer, wine, hard liquor? Do you use any illicit drugs such as marijuana or cocaine? Have you abused prescription drugs?

It is important to screen all teenagers for depression, not just those who may look depressed. Worldwide, suicide is the third leading cause of death in 15–34-year-olds. A sense of hopelessness, low self-esteem, and high self-blame are associated with the adolescent suicide. Questions regarding *emotion* include: What is your usual mood – happy, sad, both? What do you do to cope with or relieve stress? Have you ever received counseling and/or therapy? Have you ever tried cutting? Have you thought or tried to kill yourself? It is important to note that the screening for sensitive topics such as suicide does not increase the likelihood that a teen will actually become suicidal or engage in other high-risk behaviors.

As adolescents develop, many will have questions regarding their bodies, sex, pregnancy, and sexually transmitted infections, and the majority will begin sexual

experimentation. Less than half of US primary physicians routinely discuss sex, condoms, sexually transmitted diseases, contraception, and sexual orientation with their adolescent patients. However, discussing sex with adolescent patients in a clinic or office setting provides opportunities for personalized information, for confidential screening of risk status, and for health promotion and counseling. Questions regarding *sexuality* include: Are you attracted to males, females, or both? Have you ever had a sexual relationship with anyone? Have you been forced to have sex against your will? Do you use protection or contraception? What was the age of first intercourse? Sexual history should also include history of vaginal, oral, anal sex, number of lifetime sexual partners, and history of pregnancies and sexually transmitted infections.

Safety questions include screening for violence risks and should include history of fights, injuries, sexual violence, threats, and self-defense strategies. For example, have you ever been involved in a fight? Have you ever been bullied or bullied others? Have you ever used a weapon or witnessed violence? If the teen is driving, questions should also include do you drive after using alcohol or substances? Do you drive while talking on your cell phone or texting? Do you use a seat belt? Discussion should also include risks of Internet predators.

Teens are generally physically healthy but their needs vary by their developmental and physical circumstances. The *Review of Systems* should include vision, hearing, dental as well as specific questions regarding each organ system from ears, nose, and throat to musculoskeletal. The *Physical examination* allows the provider to determine the growth and pubertal development and detect abnormalities. Teens should be fully clothed for the interview portion of the visit. Before the start of the actual exam, the provider should leave the room and allow the teen to change into a gown with a screen or closed door to ensure privacy.

The height, weight, body mass index should all be obtained and plotted for age-specific norms. Blood pressure and pulse should also be obtained. Visual acuity often changes during adolescence, and teens should have vision tests during early, middle, and late adolescence. Hearing screening should be done at the baseline and repeated if there are any concerns. A dental visit should be encouraged at least once a year. In addition to the components of a routine physical, the adolescent-specific exam should include a complete assessment of sexual maturity rating, screening for scoliosis and overuse injuries (particularly prior to sports participation) and acne.

Developmentally delayed teens and young adolescents may want to have a parent with them during the exam. Chaperone policies should be well established. For example, providers may use a chaperone during the breast and genital exam of patients. *Lab tests* should be kept to a minimum. Screening for anemia, diabetes, and hypercholesterolemia should be considered based on risk factors such as poor nutrition, family history, and obesity. Screening for sexually transmitted infections should also be considered. Specific recommendations regarding adolescent screening tests and the physical exam can be found at Bright Futures: http://brightfutures.aap.org/web/

Legal Issues/Confidentiality

Adolescents can give independent consent for some health services if their capacities for understanding have sufficiently evolved. The International Convention on the Rights of the Child, almost universally ratified, limits parental powers, and duties, by adolescent's "evolving capacities" for self-determination. The Convention on the Rights of the Child (CRC) marks the age of 18 as the age of adulthood. Anyone below the age of 18 is a child unless the law applicable to the child, majority is attained earlier." Individual countries may establish an earlier age than 18 for adulthood. In 1986, the landmark British case of *Gillick v West Norfolk and Wisebech Area Health Authority* established the "mature minor principle," where an adolescent under the age of 18 years is capable of giving informed consent when she or he "achieves a sufficient understanding and intelligence to enable him or her to understand fully what is proposed."

The majority of legal systems recognize "mature minors" as enjoying adult rights of medical consent. Mature minors enjoy confidentiality and the right to treatment according to their wishes rather than their best interests. Minors incapable of self-determination may grant or deny assent to treatment for which guardians provide consent. Emancipated minors' self-determination may also be recognized, for instance, on marriage or default of adults' guardianship. Many adolescents are capable of giving consent for health problems that can occur in adolescence such as pregnancy, sexually transmitted infection (including HIV infection), mental disorders, and substance misuse.

Unfortunately, the majority of teens do not think that they have an access to confidential care. In a study of teens in the Caribbean, more than a third of respondents felt that they could not obtain confidential care from a physician. In a study of US girls aged 12–17 years, nearly 60% reported that if their parents were notified, they would stop using all or some sexual health services and

delay testing and treatment for sexually transmitted infections. Access to confidential care in most parts of the world is not well studied.

While courts have established the mature minor principle, they have not outlined what factors indicate sufficient maturity. Psychological research into adolescent decision-making has found that adolescents as least as young as 14 years are capable of making informed decisions. However, such capacities vary by the intelligence and social experiences of the individual. Health-care providers must be able to identify when a teenager can and cannot be deemed a mature minor. Parents of adolescents with intellectual deficiencies or with conditions affecting their cognitive abilities (such as brain wasting in severe anorexia or suicidality in a patient with severe depression) will often need to be involved in decision-making. Guidelines recommend that health-care providers maintain confidentiality with adolescents unless the adolescent consents to disclosure or disclosure is necessary to protect their well-being. Some states and countries have mandatory notification laws for adolescents in need of protection against neglect or abuse. Additional exceptions may arise when there is a serious or imminent threat to the life or health of an individual (e.g., suicide) or another person (e.g., transmission of serious infection or homicide). It is generally best to discuss the disclosure with the adolescent first.

Some clinicians themselves may not realize the decision-making capacity of their adolescent patients and may not be familiar with local laws and customs. Therefore, clinicians who work with teens must be familiar with local statutes and customs and advocate for enforcement of delegated responsibilities.

The emphasis that has been placed on the adolescent's growing need for privacy in these preliminary attempts at self-determination should not be seen as a denial of the role of parents in the lives of young people. The health-care team providing services to the adolescent needs to achieve a balance between supporting this important developmental task and encouraging the youth to involve parents or guardians or other trusted adults for the wisdom and experience they could contribute to the youth's decision-making. Young people who fear parental reaction to the decisions they are making about their sexuality may resist parental involvement. The reasons for resistance need to be carefully explored with the young person to facilitate self-examination. One study of unmarried pregnant teenagers found that a third of youth who did not want to inform their parents of the pregnancy had experienced family violence and feared it would reoccur if the pregnancy was shared with their parents.

Adolescents who have been granted the ability to consent may then decide whether their confidences can be shared with others such as their parents, teachers, and employers. Unfortunately, compromises of confidentiality may arise when adolescents are dependent on their parents or adults for payment of medical services. Involuntary disclosure can occur through billing or insurance records. Most countries and states do not have safeguards in place for prevention of such disclosure. However, some states in the United States and provinces in Australia have managed to provide confidential care through unique programs. In New York State, for example, the Family Planning Benefit Program provides publicly funded limited coverage for family planning services. Teens are eligible for services despite parental income or insurance status. Insurance bills are not sent to the patient so that adolescents can receive services and providers can seek payment without worrying about breaching confidentiality.

Summary

Although some teens suffer from chronic illnesses, the majority of teens are physically healthy and their interactions with the medical community are limited. The adolescent interview is a unique opportunity to reinforce good health practices, while discouraging high-risk behaviors. Prime consideration should be given to confidentiality, communication, and cultural sensitivity. The SSHADES is an example of a strength-based screening format for obtaining the psychosocial history, which focuses on the positive. During the course of the interview, teens should be empowered to develop their own solutions to problems and to take responsibility for their own health care.

401 Special Adolescent Concerns: Complementary and Alternative Medicine in Adolescents

Cora Collette Breuner

Complementary and alternative medicine (CAM) treatments are increasingly utilized in pediatric and adolescent medicine. Approximately 12% of teens in the general population use some form of CAM therapy. These therapies are more commonly used in children and adolescents with chronic illness.

Herbal Therapies

Herbal therapies and supplements are used for the prevention and treatment of upper respiratory tract infections, sleep issues, headaches, and depression/anxiety. The following is a brief description of a most frequently used herbal therapies and supplements.

Echinacea

Echinacea is widely popular as a natural immune booster and has been traditionally used to prevent and treat colds and other infections. In a Cochrane review, *Echinacea* preparations were found to be better than placebo for the treatment of upper respiratory symptoms. In the 2–11-year age group, Echinacea was not reported to decrease severity of upper respiratory infections.

Adverse effects may include skin rash in those allergic to ragweed, gastrointestinal (GI) upset, and diarrhea.

Chamomile

Chamomile has been used for GI discomfort, infantile colic, and mild anxiety. Chamomile contains chamazulene: an anti-inflammatory agent, apigenin: contains benzodiazepine properties, and bisapolol: an anti spasmodic.

Chamomile is regarded as safe although cases of contact topic allergic reactions have been reported.

Ginseng

Ginseng has been purported to enhance both mental and physical strength. In a meta-review, ginseng was noted to improve physical performance in young, active volunteers during cycle ergometer exercises.

Adverse effects may include nervousness, insomnia, bleeding, and GI disturbance. Importantly, ginseng may interact with oral anticoagulants, antiplatelet agents, corticosteroids, and hypoglycemic agents.

St. John's Wort

St. John's wort is currently used for depression and anxiety. Hypericin and hyperforin, two of at least ten active ingredients in St. John's wort, inhibit the reuptake of serotonin, norepinephrine, and dopamine. In mild depression, St. John's wort was superior to placebo.

Adverse effects include gastrointestinal (GI) symptoms, dizziness, phototoxicity, and serotonin syndrome when used with selective serotonin reuptake inhibitors (SSRIs). St. John's wort has been shown to induce the cytochrome P-450 metabolic pathway and therefore may interfere with metabolism of cyclosporine, oral anticoagulants, oral contraceptives, and certain antiretroviral agents.

Valerian

Valerian has been employed as a sedative agent, which may be due to its binding of gamma-aminobutyric acid (GABA) receptors. Efficacy of valerian as a sedative or anxiolytic has not been determined.

Adverse effects include headache, excitability, irritability, and cardiac disturbances. Valerian should not be taken when consuming sedatives and/or alcohol.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_401,

Melatonin

Melatonin is a neurohormone used in the treatment of delayed sleep syndromes. In one study in teens, participants had quicker sleep onset, longer sleep duration, and a decrease in school problems. In adults with primary sleep disorders, a meta-review showed a reduction in sleep latency. Melatonin is considered relatively safe when used for a period of days or a few weeks. The safety of long-term use is not known.

Feverfew

Feverfew is well known for its use the prevention of migraine headaches. 2 randomized trials have shown benefit of feverfew for the prevention of migraines.

Adverse effects include occasional mouth ulcerations, contact dermatitis, dizziness, diarrhea, and bleeding due to its inhibition of platelet aggregation.

Safety Issues

Adverse events associated herbal therapies should be reported as soon as possible to FDA MedWatch program (800)332–1088 or www.fda.gov/Safety/MedWatch/default.htm.

Acupuncture

Acupuncture originated as an ancient Chinese therapeutic treatment and is based on the theory that energy (*Qi*,Chi) flows along channels known as meridians, connected by acupuncture points. Disruption of the meridians may lead to disease; realignment of flow by acupuncture is felt to restore health. Acupuncture may be beneficial in patients who have dental pain, postoperative nausea and vomiting, or chemotherapy nausea and vomiting. Other opportunities for promoting use of acupuncture in the adolescent include migraine headaches, dysmenorrhea, and substance abuse.

Complications include pneumothorax, septic sacroilitis, epidural, and temporomandibular abscess.

Massage

Massage is commonly utilized in the pediatric and adolescent population and is thought to release muscle tension, remove toxic metabolites, and facilitate oxygen transport to cells and tissues. In the pediatric population, massage has been shown to be beneficial in preterm infants, ADHD, and juvenile rheumatoid arthritis. It may also decrease anxiety in those with eating disorders and improve postpartum depression. Massage can improve lung function in those with cystic fibrosis and asthma. In a Cochrane review on massage for adults with low back pain, massage was considered beneficial.

Adverse effects include temporary pain or discomfort, bruising, swelling, or sensitivity or allergy to massage oils.

Chiropractic

Chiropractors (DC) treat many conditions including low back pain, cervical pain, headache, otitis media, dysmenorrhea, and carpal tunnel syndrome. Chiropractic is based on the theory that most diseases can be traced to malpositioned bones in the spinal column called "subluxations" that lead to the entrapment of spinal nerves. Physical adjustment of the spine restores proper alignment of the spine by relieving nerve entrapments.

In an adult study comparing chiropractic spinal manipulation, sham manipulation, and a back education program, improvement was greater in the manipulation group than in other groups. In separate studies, the results were not as encouraging. Additional controlled studies are needed to evaluate the long-term cost-effectiveness of chiropractic in children.

Complications include strokes, myelopathies, and radiculopathies after cervical manipulation.

Homeopathic Medicine

Homeopathy aims to stimulate the body's own healing responses through the ingestion of extremely small doses of substances that when larger doses are taken, may produce characteristic symptoms of illness in healthy people. In a meta-analysis of 32 trials in adults, individualized homeopathy was significantly more effective than placebo in treating symptomatic seasonal allergies. However, when the analysis was restricted to the methodologically sound trials, no significant effect was seen. Complications are rare and include aggravation of symptoms.

Mind–Body Therapies/Yoga

Meditative interventions have been used to decrease symptoms associated with treatment of cancer, disordered sleep, diabetes, affective disorders, irritable bowel

syndrome, and eating disorders. More research is needed to support these therapeutic approachs to healing.

Spirituality/Reiki/Prayer

Pediatric patients and their families may bring their spirituality and faith into the office in regard to their children's health. In a thoughtful review by Barnes et al. (2000), providers are given suggestions on how to incorporate some approaches to spirituality in their practice. Also education and further research, opportunities are discussed.

Table 401.1

Talking with your patients about CAM (Breuner 2002 Complementary medicine in pediatrics: a review of acupuncture, homeopathy, massage, and chiropractic therapies. Curr Probl Pediatr Adolesc Health Care 32(10):353–384)

Be open-minded. Most patients are reluctant to share information about their use of CAM therapies because they are concerned their physicians will disapprove. By remaining open-minded, you can learn a lot about your patients' use of unconventional therapies. These strategies will help foster open communication
Ask the question. I recommend asking every patient about his or her use of alternative therapies during routine history taking. One approach is simply to inquire, "Are you doing anything else for this condition?" It is an open-ended question that gives the patient the opportunity to tell you about his or her use of other health care providers or therapies. Another approach is to ask, "Are you taking any over-the-counter remedies such as vitamins or herbs?"
Avoid using the words "alternative therapy," at least initially. This will help you to avoid appearing judgmental or biased.
Do not dismiss any therapy as a placebo. If a patient tells you about a therapy that you are unaware of, make a note of it in the patient's record and schedule a follow-up visit after you have learned more – when you will be in a better position to negotiate the patient's care. If you determine that the therapy might be harmful, you will have to ask the patient to stop using it. If it is not harmful and the patient feels better using it, you may want to consider incorporating the therapy into your care plan
Discuss providers as well as therapies. Another way to help your patients negotiate the maze of alternative therapies is by stressing that they see appropriately trained and licensed providers and knowing whom to refer to in your area. Encourage your patients to ask alternative providers about their background and training and the treatment modalities they use. By doing so, your patients will be better equipped to make educated decisions about their health care
Discuss CAM therapies with your patients at every visit. Charting the details of their use will remind you to raise the issue. It may also help alert you to potential complications before they occur

Conclusion

Health-care providers should ask about CAM use in order to help pediatric and adolescent patients navigate their own health. Improved communication can be addressed by following the recommendations in *Table 401.1*.

402 Special Adolescent Concerns: Military Service

C. Anita Robinson · Jeffrey W. Hutchinson · William P. Adelman

The opinions expressed herein are those of the authors and do not represent the official policy or position of the US Army, US Navy, US Air Force, US Department of Defense, or the US Government

Military Culture and the Adolescent

Across the globe, sovereign countries rely disproportionately upon their adolescents and young adults to make up their military population. Professional militaries have a service focus, an expert knowledge, a professional ethos, and a unique culture. Military culture is the common set of norms within the military that helps with organization and provides the individual with a sense of continuity and community. Military culture exerts great influence upon individual military members, with vast and sometimes conflicting data, supporting dual roles of military culture as protective against certain negative health outcomes (e.g., obesity), while contributing to others (e.g., tobacco use). Health-care providers of military adolescents must appreciate the influence of military culture upon adolescent development and health in order to provide optimal care to this population.

The form of military service influences the significance of service for the individual. For example, in countries with a compulsory military or national service (e.g., Austria, Israel, Norway), failure to perform military service due to health or other reasons places the adolescent outside of his or her peer norm and may have negative developmental consequences. In contrast, in large countries where military service is voluntary (e.g., the USA), the adolescent who chooses a military career may be part of a small minority and so may have difficulty finding a provider, outside of the military health-care system, who is culturally sensitive to his needs. The role of the military and its inherent culture influences health care among this adolescent population.

The adolescent health provider is likely to interact with two different adolescent populations associated with the military – dependent children of active duty or retired military personnel and the adolescent active duty member. Understanding the unique cultural milieu in which these adolescents live, work, and receive health care will assist the practitioner with directed, sensitive, and optimal health care. The purpose of this chapter is to review common military-specific adolescent health issues and offer an approach to adolescents associated with the military. While the topics addressed are applicable internationally, most examples provided are of the US military based upon the expertise of the authors.

Dependent Youth

A 13-year-old Colombian female, whose father is a member of the Colombian Armed Forces assigned to the Colombian embassy in Washington, DC, presents with a history of right-sided headache and jaw pain that began intermittently 6 months prior to relocation that progressed to constant pain since the move. There was no history of trauma, dental issues, previous headache, or family history of headache. This was the first move for the family. Despite having her parents and sister with her, she still missed her neighborhood, school friends, and family in Colombia. A careful psychosocial history revealed her anxiety since the relocation. She was diagnosed with temporomandibular joint disorder and anxiety. She was referred to oral surgery and counseling.

The Approach to the Dependent Adolescent

In general, dependent adolescents have similar medical illnesses as their civilian counterparts. Cultural differences not withstanding the provider's approach to the military dependent adolescent should be the same worldwide. The provider should approach each patient in a developmentally appropriate manner and interview the

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_402,

parent and teen together as well as the teen separately. In the USA, the rate of risk-taking behaviors is slightly less for the dependent youth of active duty military as compared with the youth not associated with the military community.

Unique Issues Affecting the Dependent Adolescent: Relocation and Deployment

The possibility and reality of relocation, frequent moves, and deployment of a parent to a combat zone presents unique cultural influences upon a dependent youth of active duty military. A military youth self-identifies as culturally separate from his/her peers in this context. Undergoing these stressors serves to build resilience in some youths and causes worsening health outcomes in others. An increase in somatic complaints and mental health issues can surface before, during, and after a relocation or deployment. Conditions such as school problems, learning disabilities, attention-deficient hyperactivity disorder, hypertension, eating disorders, anger, fear, anxiety, depression, substance use, and child abuse may be influenced by the military lifestyle.

The emotional adjustment for these life events has been described within the context of four discreet stages: *pre-deployment* (soldiers are notified of impending deployment and some are sent away from their families temporarily to train for the mission), *deployment* (soldiers are sent away indefinitely), *sustainment* (roles within the family unit change as new routines emerge), and *redeployment* (preparation to return home and readjustment for the returning soldier and the family). Reactive symptoms to deployment have been described in all four stages, and a youth may present at any stage with new somatic complaints, mental health concerns, or exacerbation of a chronic illness. The external environment heightens the internal stress of a youth during these times. Thus, the provider has to expand the psychosocial interview from school, home, and friends to include the role of community. For some adolescents, usually those with strong home and community supports, stressors of deployment and relocation builds resiliency, as adolescents adapt to new challenges. For other adolescents, such as those with difficulty at home prior to deployment, or who lack community support, stressors exacerbate baseline problems. When there are instances of problematic adjustments, the provider should review the questions in *Table 402.1* and gather detailed information regarding previous stressors with new situations, past and current school problems, mental health disorders, chronic illness, and undiagnosed family issues. A provider who is not familiar with the military culture must strive to understand the unique cultural milieu facing the dependent youth whose parents are associated with military service.

Table 402.1
Militaryspecific psychosocial screening questions

Family member adolescents	Active duty adolescents
How often have you moved? When was your last move? Who do you go to for support? Has anyone in your family deployed? How has your life changed during deployment? How has deployment impacted your roles and responsibilities at home, at school, with work, with free time? Have you noticed any changes in your family members before, during, or after deployment? Are there any deployments planned for the future? What have you learned from the last deployment that will help you with the next deployment?	Tell me about your experience in the military How long are you planning to serve in the military? Have you had any military experiences that affect your life now? Do you use anything to give yourself an advantage or to make your body or mind feel better or stronger? Why? Do you drink alcohol more than you want to? Do you use alcohol or drugs to feel better emotionally? (Substance use screening tool can be used here) Do you have anyone you can talk to? Do you feel like a valued member of your unit? Do you own a weapon?

Adolescents in Active Military Service

A 19-year-old female medic returned 6 months ago from Afghanistan after a 12-month tour with her unit. She comes to the office seeking contraceptive counseling. Her unit is tasked to deploy again in 6 months. She is in good health but upon psychosocial review of systems, she reports insomnia and binge drinking. During her prior deployment, she cared for critically injured military personnel and noncombatants and has not spoken with anyone at home because none of her other friends are in the military. She was diagnosed later with Post Traumatic Stress Disorder and referred for counseling. She returned to the clinic a month later with some improvement, though not in counseling.

The Approach to the Adolescent in the Military

Military leaders describe military culture as disciplined, loyal, hardworking, and honest, with members who value self-sacrifice, courage, and physical rigor. When these cultural influences combine with the developmental stage of late adolescence, there is potential for medical conditions to be minimized or hidden from the provider, especially if the condition is feared to influence military advancement or reputation within a unit. The military labor force, in direct contrast to the civilian labor force, is adolescent centric, with the largest group of those in the military under 25 years old. Some branches of service (e.g., US Marines) employ adolescents for almost half of their forces. Providers who care for those in the military should appreciate that many adolescents perceive invulnerability, while frontal lobe critical thinking is still in development.

In countries like the USA, with a comprehensive universal military health-care system, civilian providers are still likely to care for service members in areas of large military populations because Reservist, National Guardsmen, and a small number of adolescents, who have been medically retired because of disabilities, typically live away from major military facilities. The majority of service members seen are well, which allows health-care providers to focus on injury prevention and fitness in addition to treating acute and chronic illnesses. However, all aspects of medical care must be considered, including the impact of service. Like civilian adolescents, military members require psychosocial screening such as the home, education/employment, activities, drugs, sex/sexuality, suicide (HEADSS) and additional questions that are military specific. See *Table 402.1*.

Most service members are not directly involved in fighting, yet may experience emotional or physical trauma when deployed or while training. Assessment of preventable behavior and resilience can guide providers in appropriate anticipatory guidance. Suicide, depression, disordered eating, and substance use including tobacco are typically discussed with patients when there is a related chief complaint; however, the frequency of conditions and at-risk behaviors amongst active duty personnel suggests that these issues require more frequent discussions. An informal behavioral screening may identify highly visible issues such as suicidal thoughts as well as common issues such as stress and coping mechanisms. Providers can incorporate behavioral questions into visits, creating the opportunity to identify these significant behavioral issues.

Screening adolescents before military service is as important as providing comprehensive health care to the adolescents engaged in military service. In countries with mandatory service, physicians need to screen for conditions that may have a negative impact on their service or health while serving. In countries with voluntary service, screening determines if the applicant is fit to serve before training begins. Adolescents in both situations may benefit from withholding information. Those in a mandatory service circumstance can achieve a more desirable position by withholding information, and conditions like uncontrolled attention deficit hyperactivity disorder (ADHD), asthma, or depression may disqualify adolescents who desire to serve in a voluntary capacity. Providers should be aware of what service entails and approach the interview with the question of how this adolescent will cope with the stresses of being in the military. In the military, readiness to perform missions is a priority and central to the culture. The medical community is an essential element in maintaining a healthy force able to complete objectives. Health-care providers who care for military personnel and their families will do well to include educated questions about military service in their assessment of adolescents.

403 Special Adolescent Concerns: Transition to Adult Care

Anisha Abraham · Kirsten Hawkins

Transition is defined as the process of transferring care from a pediatric to an adult health-care practice or reorienting within a family medicine or internal medicine pediatrics practice, so that an adolescent assumes responsibility and management for his or her own health decisions. Transition is based on the teen's needs, taking into account individual strengths and interests as well as developmental status and age. Health-care providers are of unique importance in this process because of their contact with teen patients and the close relationships that often develop. A well-timed transition from child-oriented to adult-oriented health care, overseen by the provider, allows young people to optimize their ability to assume adult roles and functioning.

In the last several decades, survival rates associated with chronic illnesses have improved dramatically, so that a high number of children with chronic illnesses and/or disability now survive to adulthood. In the United States, for example, more than 90% of children with chronic illness survive beyond their 20th birthday. Most young people with special health-care needs are able to find their way into and negotiate through adult systems of care. However, some adolescents and young adults with severe medical conditions and disabilities experience difficulty transitioning from child to adult health care.

There are numerous potential barriers to achieving successful health-care transitions. For example, the patients, families, and health-care providers may be very reluctant to sever an established relationship and allow the transition to occur. Adolescents in transition may have difficulty obtaining adequate insurance and health-care coverage. There may be a lack of institutional support and inadequate time to address important transition issues. Finally, there may be difficulties obtaining a suitable health-care provider.

The goals of transition are to provide continuous, comprehensive, and compassionate health care. The following are the recommendations regarding transition:

1. **Start early:** The transition should be organized well ahead of time. Create a written individualized health-care transition plan by age 14 with input from the teen and family. The transition plan should be introduced as a normal part of growing up to lessen the likelihood that the teen and family feel they are being pushed out of the practice. The plan should include what services need to be provided, who will provide them, and how they will be paid for. The plan should be reviewed and updated annually and whenever transfer occurs. Ideally, the process should occur slow enough to allow the teen time to adjust and take responsibility for care.
2. **Provide a portable medical record:** Prepare and maintain an up-to-date medical summary that is portable and accessible. This information is the key to successful health-care transition and provides the common link for collaboration among health-care professionals.
3. **Identify knowledge and skills:** Self-evaluation should be an important part of the plan. Ensure that the patient and family (particularly those that are reluctant to transition) are involved in the process and understand the process of receiving adult-centered care.
4. **Create a health-care transition plan:** This applies to all adolescents but is of particular importance for patients with special health-care needs. Outline educational goals, steps to independent living, and emergency plans. Identify an adult health-care professional who is sensitive to the needs of young people and can assume responsibility for current health care, care coordination, and future health-care planning. Schedule an appointment with an adult practice prior to the patient transferring, leaving for secondary education or independent living. This ensures that if the teen encounters problems with the adult provider or practice, a backup is still in place.
5. **Review health insurance:** Depending on the country and health-care system, coverage for young adults may be vastly different than for children and adolescents. Ensure that the teen has access to an affordable and ongoing health care.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_403,

6. **Ensure consistent guidelines:** Apply the same guidelines for primary and preventive care for all adolescents and young adults. Recognize that young people with special health-care needs may require more resources and services than do other young people to optimize their health.

Transition involves a reorientation of clinical services to parallel the teen's increasing maturity and emerging adulthood. The purpose of transition is to maximize lifelong functioning and potential through the provision of developmentally appropriate health care that continues as the individual moves from adolescence to adulthood. There are a number of web-based resources available for providers, families, and teens such as the Health Care Transitions tool kit available at http://hctransitions.ichp.edu/. If done properly, transition of care can have a lasting impact on a teen's well-being.

404 About Children Bones

Elizabeth W. Weber

Lower-Extremity Alignment in Children – What Is Normal?

Lower-extremity alignment is a common cause for concern among pediatricians and families. The most common concern is rotational malalignment, which manifests as "intoeing" or less commonly "outtoeing." Often, parents will associate this with tripping commonly seen at this age as the child is beginning to walk, and a history of parental treatment with "special shoes" is common. There are three main causes of an internally rotated gait: metatarsus adductus, internal tibial torsion, and excessive femoral anteversion. These are all, to some extent, a result of "packaging" and in most cases will self correct with growth.

Metatarsus Adductus is characterized by a curved lateral border of the foot. It should be assessed for rigidity. Mild deformities that are passively correctable often require no treatment. Prior to walking age, parents may affect the resolution by stretching the foot to a corrected position several times a day. When the child begins walking, supportive leather shoes will maintain the medial border in a corrected position and the baby will experience corrective forces with each step. Multiple studies have shown prescription shoes to add no benefit to the resolution of flexible metatarsus adductus. In difficult, less flexible cases, short or long leg casting may be indicated. If shoe wear is not a problem, some amount of metatarsus adductus is acceptable at the conclusion of treatment.

Internal Tibial Torsion is physiologically normal in the 2–4 year-old child. It is more common in boys than girls. In early fetal development, the lower extremities are internally rotated and undergo "unwinding" throughout gestation and in the first several years of postnatal development. Depending on the degree to which the tibiae correct prior to weight bearing, the feet may be internally rotated during the first years of life. It is easy to quantitate tibial torsion by examining the child prone. With the knee flexed to 90°, the thigh–foot angle is estimated from above. While the growth plates at the proximal and distal tibia are responsible for longitudinal growth of that bone, there is some limited capacity for the same growth plates to correct the rotational deformity. Parents can expect to see torsional improvements in the tibia and the resultant intoeing gait pattern, up to age 4. Parents are cautioned that children may prefer to sit on the floor directly on top of their feet, but this creates an internal force on the tibia that the growth plate may be unable to overcome. The normal range for the adult foot is between 10° external and 5° internal. After the age of 4, if persistent tibial torsion exceeds this limit and the child has difficulty with gait due entirely to pathologic rotation of the tibia, surgical osteotomy and realignment can be performed, although it is rarely necessary.

Increased Femoral Anteversion results from a greater-than-average amount of internal femoral rotation. This results in an intoeing gait where the patellae can be seen to be internally rotated as well as the feet. These children often prefer to sit in a "W" position. Femoral Anteversion is best assessed prone. With the knees at 90°, it is easy to quantitate hip internal rotation and external rotation. This range should ideally be evenly split between the two. If there is significantly more internal range than external, excessive femoral anteversion is likely (see ❯ *Fig. 404.1a* and *b*). To estimate this version, the greater trochanter can be palpated as the hip is rotated. The position in which the trochanter is felt to be most prominent estimates anteversion. Excessive anteversion can be expected to grow out by age 8. If anteversion persists beyond that age and activities are difficult due to tripping, the femurs can be surgically realigned, although this is rarely required.

Outtoeing is a less common concern and is often due to an external rotation contracture of infancy. As the child begins to walk, this will usually resolve without treatment. After eliminating hip or neuromuscular etiologies for this gait, parental reassurance will suffice as treatment.

Frontal-plane deformities include genu varum (bow-legs) and genu valgum (knock-knees). As children first begin to bear weight, their centers of gravity must remain very low and their base of support must be very wide to provide the greatest stability for this new skill. The combination of subtly bent femora and tibiae with a broad, bent-knee posture gives the appearance of bowed legs. Internal tibial torsion, which is physiologic at this age, compounds this perception. The physician is advised to examine the child supine. Care should be taken to position the knee caps directly forward and then cover the feet. Often the apparent bow legs will then disappear.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_404,

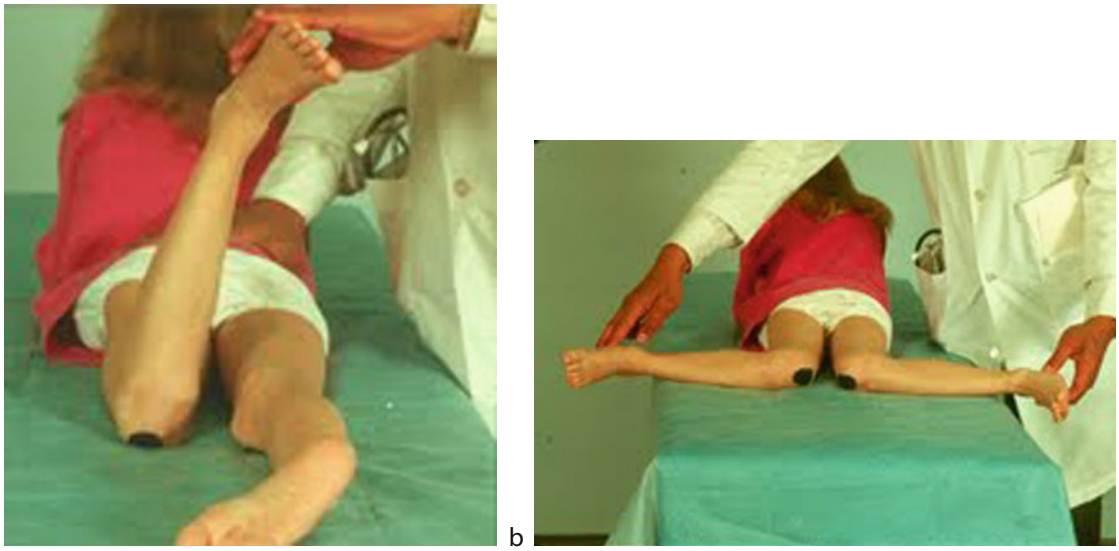

Figure 404.1

Some amount of bowing is expected prior to age 18–24 months, after which the lower-extremity growth plates tend to overcorrect this deformity such that children from age 3–5 tend to appear knock-kneed. The adult normal range is approximately 7° of valgus at the knees and will be attained by 7 years. In general, children may have bowing of the lower extremities as a physiologically normal phenomenon until about age 2. Persistent bowing should raise concern for Blount's disease or a metabolic syndrome such as rickets. Children with Blount's disease suffer from a poorly functioning medial growth plate that leads to progressive deformity. Bracing is often required in these cases, as severe deformity refractory to nonoperative treatment may develop. In general, heightened concern is appropriate in children with very short stature, dysmorphic features, family history of dwarfism, obesity, generalized osteopenia with wide physes, or extreme deformity. In the case of asymmetric genu valgum, obtain a fracture history for the involved extremity as proximal tibial metaphyseal fractures are known to grow into valgus for about 18 months after the injury and then tend to self correct.

Limb-length discrepancies less than 2 cm are common in the adult population. Discrepancies which are expected to be less than 2 cm at skeletal maturity are most often asymptomatic or can be treated adequately with an in shoe lift on the short side. Once a child has been identified as having a limb length discrepancy, it is important to attempt to determine the source of the discrepancy as well as the leg that is the pathologic leg (the long or the short). Depending on the etiology, a variety of patterns of progression can be anticipated. From serial examinations, the expected limb length discrepancy at skeletal maturity can be estimated accurately. The clinical examination includes assessment of pelvic obliquity done standing behind the patient with the patient's knees straight, ankles together, and examiner's fingers on the iliac crests. A gross estimate of discrepancy can be documented. If a discrepancy is noted, blocks are placed under the short leg to level the standing pelvis, which gives a more accurate estimate. With the patient supine, the examiner can measure the distance from the ASIS to the medial malleolus side to side. A Galeazzi test is performed by flexing the hips to 90° with the knees bent, which demonstrates a femoral inequality and then placing the heels on the exam table with the knees remaining bent to estimate the tibial contribution. Treatment options vary by estimated discrepancy at skeletal maturity.

Anticipated LLD at skeletal maturity	Preferred intervention
<2 cm	Shoe lift only if symptomatic
2–5 cm	Timed epiphysiodesis
5–15 cm	Lengthening +/− contralateral epiphysiodesis
>15 cm	Amputation

There are a variety of surgical techniques for epiphysiodesis. In general, approximately 9 mm of length can be gained from the distal femoral physis and 6 mm of length from the proximal tibia each year until the conclusion of growth. The surgery is aimed at ablating one or more growth plates in the long leg at a time calculated to correct the discrepancy at the conclusion of growth. Alternatively, if there is inadequate growth remaining or the discrepancy is too large to address with epiphysiodesis without compromising proportion, limb lengthening can be undertaken. Often the lengthening is limited by the soft tissue structures, including nerves, vessels, and tendons. Additionally, surgical lengthening is fraught with complications including pin tract infections, premature consolidation, fracture through regenerate, failure to obtain desired length, as well as lengthy encumbrance and unsightly scars. In the unfortunate rare patient who has a LLD at skeletal maturity anticipated to be greater than 15 cm, the most comfortable, predictable surgical option is definitive amputation.

405 Limping Child

John R. Fowler · James T. Guille

Musculoskeletal complaints are a common reason for presentation to the primary care physician, emergency department, and orthopedic surgeon. The limping child presents a diagnostic challenge with many nonspecific findings and the potential for significant morbidity if the diagnosis of a serious condition is missed. Efficient and cost-effective diagnosis and treatment of the underlying condition requires a systematic approach.

Definition/Classification

Limping is defined as the pathologic alteration of the smooth, rhythmic, and regular gait pattern. The evaluation of gait in a child is complicated by the observation that children do not achieve a mature gait until the age of 3 and an adult gait until the age of 7. Further confusion results from the observation that toddlers walk with a wide-based gait, increased flexion of the hips and knees, and spend an increased amount of time in double stance phase to maintain balance. To understand abnormal gait, the normal gait cycle must be defined.

Abnormal gait can be classified as either painful (antalgic) or painless (non-antalgic). Antalgic gait is a reflex response to prevent pain in an extremity and results in decreased stance phase on the injured side and decreased stride length on the contralateral extremity, allowing less time to be spent in stance phase on the injured extremity.

Etiology

Pain, weakness (neuromuscular problem), and structural/mechanical factors are the primary causes of a limp. Obtaining a thorough history and performing a careful examination can often identify the origin of the pain, and the differential diagnosis can be narrowed. Broadly, the etiology of limp can be broken into six major categories: trauma, infection, malignancy, inflammatory, congenital, and neurologic. The main concern in the child with a limp is not to determine an exact etiology, but rather to avoid missing serious pathology and expeditiously to begin appropriate management of the underlying condition. Oudjhane found that 20% of children less than 5 years old with an acute limp of unknown etiology had unsuspected fractures.

Clinical Manifestations

The specific etiology of the limp leads to different clinical manifestations. Infection or inflammatory conditions may manifest as systemic illness. Patients with septic arthritis will have fever, swelling, eyrthema, and decreased range of motion of the affected joint. Complete blood count (CBC), erythrocyte sedimentation rate (ESR), and C-reactive protein (CRP) will be elevated. Patients with inflammatory arthritis may have signs similar to septic arthritis, may have fever and elevated WBC, and elevated rheumatoid factor (RF) and anti-nuclear antibody (ANA). Diskitis may present with back pain and decreased spinal range of motion, although this sign is present in only 50% of cases. Diskitis in adolescents may manifest as buttock and leg pain as a result of nerve root irritation. Patients with underlying malignancy may have night pain and constitutional symptoms. Children less than 3 years old often present acutely with limp or a refusal to bear weight on the lower extremities. Overuse syndromes often manifest as pain with activities.

Diagnosis

Diagnosis begins with a focused history and physical examination that direct appropriate laboratory and radiographic studies. The history should focus on defining the character of the limp. An important distinction in evaluating a limp is the presence of pain. The absence of pain suggests a neuromuscular, metabolic, or congenital/developmental abnormality. A failure to achieve appropriate developmental milestones warrants a neuromuscular and/or metabolic workup. When pain is present, determining the duration and frequency is essential. Acute onset of pain over a few days is more indicative of trauma or infection, while a gradual worsening over weeks is more consistent with inflammatory disorders or mechanical

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_405,

symptoms. Malignancy may have either an acute or insidious onset of symptoms. Constant, unremitting pain is especially concerning, suggesting an intramedullary process such as tumor or infection. The temporal character of the pain is another important aspect. Morning pain may suggest an inflammatory disorder whereas pain after activity is more consistent with an overuse injury such as a stress fracture. Night pain is often attributed to "growing pains," but malignancy must also be considered. Conditions such as slipped capital femoral epiphysis and diskitis can result in referred pain to the leg. The anterior branch of obturator nerve passes close to the hip joint, and if irritated, can cause medial knee pain. A careful history should investigate for subtle trauma, mechanism of injury, and attempt to localize the problem to a specific area. Adolescents may need to be questioned separately from their parents to obtain a proper sexual history and assess risk for gonococcal arthritis. Pain that prevents children from participating in activities or play is worrisome.

After a careful history has been obtained, a focused physical examination is undertaken. The best opportunity to observe a true limp is by observing when the child does not know he or she is being watched, such as when the child is walking to the exam room with the parent. Most authors recommend adopting a systematic approach to analyzing gait, noting how the foot strikes the floor, any abnormal limb rotation, asymmetry of stance phase, and limited dorsiflexion of the ankle. Once in the exam room, the patient should be examined in the standing position. The spine should be examined, noting any signs of scoliosis, trunk shift, pelvic obliquity, and shoulder asymmetry. The skin should be examined for evidence of café au lait spots, hairy patches, and sacral dimples.

After the standing examination, the child should be placed on the table and examined. The lower extremities should be inspected for asymmetry, deformity, rash, swelling, and puncture wounds. The soles of the feet should be examined for the presence of foreign bodies. Note the resting position of the limbs (a child with septic arthritis of the hip will hold the hip flexed and externally rotated). Leg length should be measured from the ASIS (anterior superior iliac spine) to the medial malleolus. Inspect for muscle hypertrophy and/or muscle atrophy. An attempt should be made to identify a point of maximal tenderness and to localize the area of pathology. Take each joint through its full range of motion; note any pain, contracture, or muscle spasticity. Specifically examine the metaphyseal region of each long bone, as this is a common location of pathology. Test the patellofemoral joint for signs of apprehension and pain. Test the sacroiliac joint by direct percussion posteriorly and by stressing the joint with the FABER (flexion-abduction-external rotation of the hip) position. A child that will crawl, but not walk, localizes the pathology to an area below the knee.

Radiographic evaluation of the child with a limp begins with orthogonal plain radiographs of the affected limb, adding oblique views as needed. Plain radiographs may identify fractures, osseous lesions, and/or joint space widening consistent with effusion. MRI with and without contrast may be the most useful imaging study in the evaluation of pediatric patients suspected of musculoskeletal infection or malignancy. Bone scintigraphy has a role in the assessment of children who do not have obvious localizing signs of infection. The triple phase technetium 99 m bone scan has been demonstrated to be superior to other standard screening tests for infection. The triple phase bone scan, however, has a low sensitivity for septic arthritis, especially when there is adjacent osteomyelitis. Acute leukemia may also result in a cold scan. If the region of pain is easily identified, an MRI of the specific region is preferable for diagnosing infection. Ultrasound is used to detect an effusion in the patient suspected of having a septic joint, with a sensitivity of greater than 95%, although it is unable to differentiate between sterile effusion and sepsis.

Laboratory testing is indicated when a child presents with an acute, nontraumatic limp and signs and symptoms of fever, malaise, night pain, or localized complaints. Initial testing should include a complete blood count with differential, erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), anti-nuclear antibody (ANA), and rheumatoid factor (RF). Lyme titers should be obtained in any patient with acute arthritis who lives in an endemic area or has recently traveled to one. If septic arthritis is suspected, blood cultures should also be obtained, although they are positive in only 40–50% of cases. ESR becomes elevated within the first 24–48 h and returns to normal over 3 weeks whereas CRP rises within 6 h and returns to normal within 6–10 days of treatment.

Differential Diagnosis

The differential diagnosis for the child with a limp is extensive (see *Table 405.1*). The differential can be divided into six main categories: trauma, infection, inflammatory, neurologic, neoplasm, and developmental. The differential ranges from benign diagnoses such as transient synovitis to serious disorders such as malignancy and septic arthritis. The vast differential diagnosis can be narrowed by separating the conditions by the ages at which they most commonly occur (*Table 405.2*). The most likely diagnoses in patients less than 4 years old

Table 405.1
Differential diagnosis by category

Trauma	Infection	Inflammatory	Neurologic	Neoplasm	Developmental
Fracture	Septic joint	Juvenile rheumatoid arthritis	Cerebral palsy	Osteosarcoma	Legg–Calve–Perthes
Osteochondritis dissecans	Osteomyelitis	Lyme disease	Meningitis	Acute leukemia	Clubfoot
Stress fracture	Foreign body	Transient synovitis	Muscular dystrophy	Osteoblastoma	Congenitally short femur
Slipped capital femoral epiphysis	Diskitis	Sever's apophysitis	Myelomeningocele	Osteoid osteoma	Accessory tarsal navicular
Chondromalacia patellae	Appendicitis	Acute rheumatic fever		Ewing Sarcoma	Osgood–Schlatter
Sickle Cell Osteonecrosis	Psoas abscess	Reactive arthritis		Neuroblastoma	Sinding-Larsen–Johansson
Child abuse	Cellulitis	Systemic lupus erythematosus		Spinal cord tumor	Tarsal coalition
Sprain/strain					Developmental dysplasia of hip
					Leg length discrepancy
					Discoid lateral meniscus

include septic arthritis, diskitis, osteomyelitis, transient synovitis, developmental dysplasia of the hip, coxa vara, cerebral palsy, leukemia, and trauma from child abuse. The differential from ages 4–10 expands to include a variety of diagnoses. Infectious etiologies such as septic arthritis, osteomyelitis, and diskitis are still prevalent. Legg–Calve–Perthes disease is a common painless hip disorder responsible for limping in this age group.

The most common diagnoses in patients older than 10 years include fracture, slipped capital femoral epiphysis, transient synovitis, tumor, and osteomyelitis. Overuse syndromes such as Osgood–Schlatter syndrome, Sinding-Larsen–Johansson (SLJ) syndrome, and stress fractures are also common in adolescents. It is important to recognize that although these are the most common diagnoses in each age group, one should never exclude a diagnosis based solely on age.

Infection

A major objective of the treating physician is to differentiate between infectious and noninfectious causes of limp. Septic arthritis presents with rapid onset of joint pain, progresses to a febrile systemic illness, and leads to the child's refusal to use the extremity. The joint is tender and swollen and laboratory values will demonstrate obvious signs of infection. Transient synovitis also presents as acute onset of joint pain, limp, and restricted joint range of motion, but patients usually do not have fever or signs of systemic illness and it usually follows a recent respiratory illness. Transient synovitis is the most common cause of idiopathic limp in children and generally has a good outcome. Osteomyelitis, sometimes adjacent to a septic joint, is another infectious etiology that must be considered in the child with limp.

Bacteria most commonly gain access to joints by the hematogenous route and are deposited in the rich vascular network in the sub-synovial layer. The bacteria may then cross through permeable blood vessels into the joint space. In the acute inflammatory phase of septic arthritis, polymorphonuclear cells rapidly enter the joint, followed by the formation of a tense effusion. The increased capsular pressure caused by the effusion results in pain and decreased range of motion. Articular cartilage destruction occurs via degradation by proteolytic enzymes and activation of interleukin-1 to release acid proteases from chondrocytes and synoviocytes.

Table 405.2
Differential diagnosis by age

<4	4–10	>10 years
Toddler's fracture	Fracture	Stress fracture
Osteomyelitis	Osteomyelitis	Osteomyelitis
Septic arthritis	Septic arthritis	Septic arthritis
Diskitis	Diskitis	Diskitis
JRA	Legg–Calve–Perthes	Slipped capital femoral epiphysis
Lyme disease	Transient synovitis	Osgood–Schlatter
Discoid lateral meniscus	Discoid lateral meniscus	Sinding–Larsen–Johansson
Foreign body in the foot	Sever's apophysitis	Osteochondritis dissecans
Benign or malignant tumor	Accessory tarsal navicular	Chondromalacia patellae
	Foreign body	Lyme
	JRA	Gonococcal arthritis
	Lyme	Accessory tarsal navicular
	Tumor	Tarsal coalition
		Tumor

Patients with suspected septic arthritis should undergo routine laboratory testing, including a CBC, ESR, CRP, Lyme titer, RF, and ANA. An ESR >50 mm/h and CRP >2 mg/dL is indicative of acute inflammation and/or infection. In transient synovitis, the WBC is usually less than 15,000 cells/mL. Alternatively, juvenile rheumatoid arthritis (JRA) may present with moderate to severe anemia and leukocytosis. Lyme arthritis often mimics a septic joint, although a large effusion with seemingly little pain is the hallmark.

Plain radiographs may demonstrate a joint effusion, which can be confirmed by ultrasound. If the physician has a high index of suspicion for septic arthritis, joint fluid should be obtained by aspiration under sterile technique. Aspiration of a suspected septic hip is performed under sedation and with ultrasound guidance. A cell count with a WBC >80,000 cells/mL with >75% PMN is highly suggestive of joint sepsis.

Diskitis is a bacterial infection of the disc space and adjacent vertebral endplates. The most common cause of diskitis is hematogenous spread of infection through the nutrient arteries, usually with preceding or concomitant infections such as otitis media, urinary tract infections, and respiratory infections. The patient will usually have tenderness to palpation over the vertebral levels in question. Paraspinal muscle spasm, decreased range of motion, and hamstring tightness are common. Most patients will not have localizing neurologic findings. A good test for diskitis is to ask the child to pick an object up from the floor. If the child has diskitis, he or she will refuse to pick up the object or will bend only at the hips while holding the back straight.

Trauma

Occult fracture is another common cause of limp in children. Initial orthogonal radiographs may not identify a fracture. Oblique views are sometimes needed and often the fracture line is not visible until several weeks later when periosteal reaction is noted with fracture healing. The classic toddler's fracture, described by Dunbar, is a spiral fracture of the tibia without concurrent fibular fracture.

Slipped capital femoral epiphysis (SCFE) is a common hip disorder characterized by posteroinferior displacement of the capital femoral epiphysis on the metaphysis of the proximal femur. These patients are usually overweight, with at least half of patients in the 95th percentile for weight. Overuse syndromes such as stress fracture, Osgood–Schlatter disease, Sinding-Larsen–Johansson (SLJ) syndrome, and Sever's disease are common in adolescents and result from repetitive microtrauma. There is usually point tenderness over the affected area and compensatory muscle weakness. Confirmatory radiographic testing for stress fracture may include bone scan and MRI.

Neuromuscular

The muscular dystrophies are hereditary disorders of progressive weakness and muscle wasting that presents most commonly in males from age 2 to 5. Laboratory workup reveals elevated creatine phosphokinase (CPK) levels. Electromyography demonstrates myopathic features. The pathogenesis of muscular dystrophy is the deficiency of dystrophin protein in skeletal muscle. The child may have a history of delayed ambulation and now presents due to stumbling, falling, and difficulty climbing stairs. Patients demonstrate Gower's sign and often have calf pseudohypertrophy. Cerebral palsy is a nonprogressive, static encephalopathy resulting in abnormal motor control. Cerebral palsy may present as a limp with spasticity in the heel cord, resulting in equinus gait. A thorough history and physical examination should rule out progressive disorders of the nervous system such as muscular

dystrophy, spinal cord tumors, and metabolic syndromes before assigning a diagnosis of cerebral palsy.

Inflammatory

Juvenile rheumatoid arthritis (inflammatory arthritis of childhood) is characterized by synovitis of the peripheral joints, resulting in morning stiffness, limited range of motion, joint effusion, and often a limp. The patient may have systemic signs such as rash, fever, and swollen lymph nodes. Pauciarticular inflammatory arthritis is a specific form of the disease that mainly affects joints in the lower extremity, often with only a single joint initially involved. The acutely limping child may, therefore, represent the initial presentation of the disease. On physical examination, the joint demonstrates mild swelling, warmth, and restriction of range of motion that presents gradually. The subtalar joint, knee, and ankle are the most common locations. The male to female ratio is 1:4. The diagnosis is confirmed with laboratory tests, including CBC, ESR, ANA, and RF. Laboratory testing often reveals an elevated WBC, platelet count, ESR, and CBC. ANA is elevated in 40–80% of patients.

Neoplasm/Tumor

Acute leukemia is the most common neoplasm in children under the age of 16, with a peak incidence between 2 and 5 years old. Children with advanced disease typically present with pancytopenia, pallor, fatigue, easy bleeding, and bruising. Laboratory evaluation may reveal subtle abnormalities, but diagnosis ultimately requires a bone marrow biopsy. Osteosarcoma and related tumors predominantly arise in children and adolescents. The most common locations include the distal femur and proximal tibia, often resulting in limp as a presenting sign. Patients may have a localized mass with tenderness and overlying skin changes. Diagnostic workup should begin with plain radiographs and advance to MRI of the involved area with CT of the thorax for staging purposes. Spinal cord tumors usually present with a gait disturbance, sometimes described as a limp by the parents. Plain radiographs may demonstrate widening of the pedicles or neuroforamen and diagnosis is confirmed with MRI.

Congenital

Legg–Calve–Perthes disease is a common cause of usually painless limp in children ages 3–10 years. It is characterized by necrosis of the femoral head, followed by resorption, collapse, and repair. Although ischemia is thought to contribute to the disorder, experimental data has failed to show a direct correlation. Clotting factors, increased blood viscosity, and endocrine abnormalities have all been implicated as potential causes. Discoid meniscus is a common congential knee pathology known to result in limp.

Treatment

General Care

The most important aspect in the evaluation of the limping child is the efficient identification of conditions requiring immediate specialty consultation and/or intervention. These conditions include, but are not limited to: septic arthritis, osteomyelitis, slipped capital femoral epiphysis, developmental dysplasia of the hip, and tumor.

Specific Care

Discussion of the specific treatment of each condition in the vast differential for the child with a limp is beyond the scope of this chapter. Several conditions, however, do warrant further discussion. Septic arthritis requires urgent decompression, irrigation, and debridement to prevent further damage to the joint and articular cartilage. Acute infection causes synovial edema and increased synovial fluid production. Bacterial hyaluronidase decreases the viscosity and function of synovial fluid. Accumulating fluid and purulence rapidly increases the intra-articular pressure and can permanently injure vessels and articular cartilage.

Intravenous antibiotics should be initiated immediately in the toxic patients, but held until cultures are obtained in the stable patient. *Staphylococcus aureus*, Group A *Streptococcus*, and *Streptococcus pneumoniae* are the most common organisms overall, but each age groups has its own specific organisms. For children less than 3 years old, *Haemophilus influenzae* is common, but is decreasing due to vaccination. *Neisseria gonorrhea* and Group B *Streptococcus* must be considered in neonates. Sexually active adolescents are susceptible to *Neisseria gonorrhea* septic arthritis, while sickle cell patients are more likely to be infected by *Salmonella*. In cases of septic arthritis, empiric therapy is initiated with nafcillin, clindamycin, and gentamycin in the infant less than 3 months old and with ampicillin-sulbactam and clindamycin in the child

between 3 months and 4 years old. Methicillin-resistant *Staphylococcus aureus* (MRSA) has recently emerged as a community-acquired pathogen. Vancomycin should be added to the empiric regimen in any patient with a history of MRSA infection or with risk factors for MRSA colonization. Diskitis is treated with intravenous antibiotics for a duration of 4–8 weeks, followed by oral antibiotics for an additional 3–6 months. Bracing has not been shown to improve the clinical course, but may be indicated to decrease pain and minimize deformity.

Transient (toxic) synovitis is treated with symptomatic relief, rest, and anti-inflammatory medications. The symptoms often resolve in 1–2 weeks. Routine aspiration of effusions is not recommended. Children with oligoarticular juvenile rheumatoid arthritis often respond well to nonsteroidal anti-inflammatory medications. Patients with polyarticular disease require an additional anti-inflammatory, including methotrexate, infliximab, or etanercept. All patients require a referral to a rheumatologist for further evaluation and possible workup for pericarditis, myocarditis, and iridocyclitis as indicated.

Future Developments

Improved clinical decision models and more sensitive and specific diagnostic testing will improve the ability of physicians to more efficiently make the diagnosis and initiate treatment. These will not, however, replace a careful history and physical examination as the prime method for diagnosis.

Prognosis

The prognosis of the limping child depends greatly on the underlying etiology of the limp. The prognosis of selected disorders will be discussed. Patients with a diagnosis of transient synovitis often demonstrate a full recovery with no long-term sequelae, with a reoccurrence rate reported to be 4–17%. Patients with diskitis often experience full recovery with antibiotics alone, although a small minority require biopsy and surgical intervention. Patients with septic arthritis who receive expeditious decompression and irrigation often fully recover and experience a full recovery. Delayed diagnosis and treatment can lead to permanent joint destruction and early onset of degenerative arthritis. Risk factors for poor outcome in septic arthritis include: age less than 6 months, delay in treatment greater than 4 days, associated osteomyelitis, and infection with *Staphylococcus aureus.*

406 Orthopedic Management of Systemic Conditions

J. Channing Tassone

Cerebral palsy (CP), or static encephalopathy, is a central nervous system condition characterized by a disordered communication between the brain and muscles. The etiology is variable. Some cases have a specific prenatal or perinatal incident or a later hypoxic event that are believed causes for the condition. Other cases have no known etiology. The most involved infants first have feeding issues and hypotonia, which progresses to hypertonia with development. The diagnosis in the minimally affected cases may be unclear. Early signs are: (1) Early handedness – very young children showing hand dominance. (2) Velocity dependent tone – palpable muscle resistance during rapid joint range of motion. (3) Pathologic reflexes – presence (i.e., clonus) or maintenance (i.e., Babinski). (4) Posturing of an upper extremity with rapid gait or running. (5) Unilateral toe walking. The two basic types of cerebral palsy are spastic (difficulty controlling volitional movement) and dystonic (increased or constant nonvolitional motion). The subtypes of spastic CP are hemiplegia – one side affected more than the other, diplegia – legs affected more than arms, quad or tetraplegic – total body involvement.

The spine is often affected in CP. The level of involvement of the patient plays a role in how affected the spine is. Ambulatory hemiplegic and diplegic patients have fewer spine issues than wheelchair bound patients. Regular monitoring of the spine in more involved patients is important to diagnose scoliosis. The natural history of scoliosis in these patients is "relentless progression." This progression will also continue after skeletal maturity, in distinct contrast to idiopathic scoliosis. Treatment is controversial but includes wheelchair modification, bracing, growing devices, and fusion. Bracing yields questionable results and will not stop the progression of the curve. At best, bracing may slow the progression of the curve and improve seated posture. Bracing has also been criticized for decreasing patients' trunk strength and control. Surgical indications and outcomes are also controversial. Some believe that the risk of surgery is not warranted given the inconclusive outcomes benefits. Untreated scoliosis will eventually cause seating issues, pulmonary and cardiac compromise. The decision to perform surgery needs to be patient and family specific, taking into consideration a patient's pelvic obliquity and seating issues, their trunk position, and how it affects their ability to interact with their environment and communicate, and their medical comorbidities. Fusion surgery can be successful in achieving the goals of correction of curve, prevention of progression, and correction of pelvic obliquity. It is still debated whether or not this creates true quality of life improvements and eases long-term care. Various studies have come down on both sides of this question further making the decision as to whether or not perform surgery surgeon and center specific. Advances in technology have allowed for an increased number of posterior-only fusions, limiting the need for anterior/posterior combined surgery, which decreases the overall surgical morbidity.

The hip is also commonly affected in CP. The amount of pathology is related to the patients' global involvement with quadriplegic patients having more hip issues. With growth, tight adductor and flexor muscles can cause the hip to subluxate and eventually dislocate. A primary goal is to keep the hip from dislocating by preventing or treating contractures of the muscles. Physical therapy plays a role in achieving this during growth. Botulinum toxin (botox) can be used in conjunction to increase the range of motion and keep contractures from forming. Once contractures are present, then surgical lengthening of the muscles (often the adductors and hip flexors) can help to minimize or correct subluxation and prevent dislocation. Over time, bony changes occur, which lead to a loss of the normal angle of the femoral neck and an enlarged acetabulum with a more vertical orientation. These changes can become significant enough to warrant surgical intervention to prevent dislocation. The surgery involves the previously described muscle lengthening, along with a reorientation of the proximal femur and reshaping the acetabulum to a smaller size and horizontal orientation. CP patients may present with dislocated hips that are not painful. Surgery in this case is more controversial. While some believe that surgery is unnecessary as the condition may remain painless, others believe that

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_406,

reducing the hip prevents deterioration of the joint, which improves sitting balance and reduces the risk of the hip pain. Once a dislocated hip becomes painful, then reduction alone will not relieve pain and the patient will require additional procedures. In the ambulatory diplegic patient, tight adductors can also lead to a scissoring gait, which can also be addressed with the previously described modalities.

The most common deformity about the knee in CP is a flexion contracture, which may be progressive with growth. Tight hamstrings often lead to flexion contractures. This may be part of a larger constellation described as a crouch gate. Crouch gate is the result of a combination of hamstring contractures, hip flexor contractures, and ankle equinus secondary to a heel cord contractures. It is imperative that all three levels of deformity are appreciated and addressed. The treatment ranges from physical therapy and stretching, to botox for more significant tightness without contracture, and finally to surgical lengthening when the musculotendinous units are contracted to the point where they are unable to be stretched.

The foot and ankle in CP are a final lower extremity component of deformity that need be addressed. Equinus contracture secondary to tight gastro-soleus complex is often found as an isolated deformity. This is treated with stretching, botox, or surgery. Preventing this deformity or its recurrence can also be achieved with orthotics. An ankle foot orthosis (AFO) is utilized to keep the ankle in a neutral position. The foot can have several major deformities: equinovarus (foot down and in) or its opposite, calcaneovalgus (foot up and out). A tight heel cord and mid-foot collapse may lead to an equinovalgus foot. These deformities are primarily treated with orthotics. If the foot is too rigid to achieve a neutral position with bracing, then surgery is warranted. Tendon lengthening or transfer to alter the deforming forces or bony realignment may be necessary.

Spina Bifida

Myelodysplasia or Spina Bifida is caused by a failure of neural tube closure at varying levels of the spine. This is commonly associated with other conditions like hydrocephalus, Arnold–Chiari malformation, and other CNS lesions. The spinal cord level of involvement and the involvement of potential comorbidities determine a child's prognosis and treatment. The orthopedic treatment of these children revolves around the spinal deformity and the lower extremity deformities. Globally, the goal of treatment is to maximize function.

The lower extremity may have deformity at the hip, knee, ankle, and foot. There can be contrasting deformities (flexion or extension contractures, equinus, or calcaneus). If stretching does not allow the limb to achieve a position that enables bracing and an appropriate level of mobility, then surgery must be considered. The treatment of paralytic hip dislocation is more controversial. Studies have shown that except in the very high functioning patient with distal spina bifida, there is not a functional improvement from reducing the hip. In addition, the goal of maintaining flexibility may be hindered by surgical reconstruction.

The knee can be affected by either congenital or developmental flexion or extension deformities. Depending on the level of function and the amount of the deformity, either stretching or surgery may be necessary to appropriately position the knee. The foot and ankle can also be affected by a myriad of conditions ranging from clubfoot, congenital vertical talus, calcaneovalgus to equinus, varus, or valgus. Initially, stretching is a reasonable treatment plan, especially in the very young. Almost inevitably, surgical intervention should be undertaken early enough to attempt to place the foot and ankle in a neutral position for brace wear and ambulation.

Spinal deformities typically manifest as kyphosis or kyphoscoliosis. This is secondary to the inherent bony abnormalities involved in spina bifida or secondary to neurologic impairment. The spine must be monitored closely in this patient population as progression of the deformity is common. Progression can lead to sitting and balance issues or skin integrity issues. Bracing is an ineffective treatment for kyphosis or scoliosis in these patients and surgery may be necessary.

This population is particularly susceptible to pathologic fractures secondary to the combination of osteopenia and decreased protective sensation. Due to the lack of pain that spina bifida patients experience, it is important to always consider infection while evaluating for a fracture or musculoskeletal injury. Fractures are far more common than infection, and should be easily seen on a plain radiograph. Fractures heal well, but should be immobilized for as short a time as possible. The immobilization is necessary to avoid malunion, but prolonged immobilization may worsen contractures and have an adverse functional implication.

Neurofibromatosis

Neurofibromatosis (NF) is an autosomal dominant condition caused by a chromosomal abnormality leading to

the abnormal growth of cells originating from the neural crest. There are two types of NF. The most common is Type 1, or peripheral NF, which presents with café au lait spots, axillary and inguinal freckling, and a variety of other peripheral neurofibromas. Type 2, or central NF, presents with acoustic neuromas and little orthopedic concerns. NF should also be in the differential for patients being worked up for hemi-hypertrophy.

Most patients with NF need no orthopedic care, but those who do, have two primary associated orthopedic conditions: scoliosis and congenital pseudoarthrosis of the tibia. Scoliosis in NF is of two distinct varieties: dystrophic- and idiopathic-like. Idiopathic-like scoliosis in NF patients is treated in the same way as idiopathic scoliosis (see scoliosis section for treatment). These patients must be monitored to ensure the scoliosis does not become dystrophic. Dystrophic scoliotic curves are typically short, sharp curves. They are usually thoracic and may progress rapidly, carrying with them a higher neurologic risk. They must be monitored more closely than idiopathic curves. Bracing tends to be ineffective, so surgical fusion is often indicated to halt progression.

Congenital pseudoarthrosis of the tibia (CPT) is the other skeletal condition associated with NF-1. This is characterized by an anterolateral bow of the tibia and the leg. This is in contrast to the benign condition of posteromedial bowing of the leg associated with the calcaneovalgus positional foot deformity of birth that spontaneously resolves. CPT is characterized by structural and biologic abnormalities of the tibia, which increases the risk of fracture and causes poor fracture healing. The treatment ranges from bracing to prevent fracture to complex surgery to amputation if surgery fails.

Osteogenesis Imperfecta

Osteogenesis Imperfecta is an autosomal dominant condition caused by a mutation of type-1 collagen genes Col1A1 and 1A2 (on chromosomes 7 and 17). The classic classification described by Sillence subdivides OI into 4 types. More recently, Shapiro's modification of Looser's classification has better prognostic value.

The orthopedic treatment of OI primarily revolves around the treatment of fractures. A common dilemma that must first be delineated is the distinction between non accidental trauma (NAT) and OI. Young children presenting with stories of fractures from minimal trauma or suspicious circumstances must be evaluated for NAT before considering a diagnosis of OI. Diagnosing OI early in these children allows for appropriate interventions. Minor fractures are treated with reduction and casting. Fractures requiring surgical intervention are better served by intramedullary fixation with rods in contrast to plate and screw fixation. Limb deformity from recurrent fractures can also be addressed with this type of treatment. Curved bones can be cut and then straightened with a rod. Telescoping rods are utilized and remain in place growing with a patient providing continuing protection to the bone. Fortunately, children with OI have good fracture healing potential. Medications like pamidronate have also helped reduce the number of fractures. Children with OI have increased risk for scoliosis. Heightened awareness and appropriate monitoring for scoliosis is necessary in all patients with OI, and scoliosis treatment recommendations are similar to idiopathic scoliosis.

407 The Spine

Craig P. Eberson

Scoliosis

Scoliosis is classified as a lateral curvature of the spine greater than 10°, as measured by the Cobb method. A line is drawn parallel to the top endplate of the upper vertebra in the curve, and a second line drawn parallel to the lower endplate of the most caudal vertebra in the curve. The angle formed between two lines drawn perpendicularly to the first two lines is the Cobb angle (*Fig. 407.1*). Rotation of the spine in the axial plane results in the rib "hump" seen on exam. By definition, idiopathic scoliosis has no known cause, although recent evidence indicates a genetic inheritance. Other forms of scoliosis must be excluded via a thorough history and physical examination (*Table 407.1*).

Scoliosis can be classified by etiology and patient age in order to better guide evaluation and treatment. The three main categories of scoliosis are *idiopathic*, *congenital*, and *neuromuscular*. Idiopathic scoliosis can be subdivided by age into infantile (younger than 3 years of age), juvenile (age 3–10), and adolescent (older than 10). Congenital scoliosis implies an abnormal formation of the vertebral bodies, which leads to deformity, and is diagnosed at any age. Fused vertebrae, hemivertebrae (*Fig. 407.2*), or a combination of the two may cause curvatures of varying severity in the frontal, sagital, or axial planes and often are accompanied by abnormalities of the spinal cord (dysraphism), kidney, and heart, due to the temporal relationships of the organ systems with respect to intrauterine development. These other systemic abnormalities should be sought (MRI, renal ultrasound, cardiac evaluation) and prompt orthopedic referral made, as these deformities are often rapidly progressive, with many requiring surgery at a young age. Neuromuscular scoliosis is seen in patients with previously diagnosed conditions (i.e., myelomenigocele, neurofibromatosis, cerebral palsy, muscular dystrophy) as well as in "normal" patients whose scoliosis is the presenting symptom of an underlying disorder (i.e., syringomyelia, tethered spinal cord, Friedrich's ataxia). A thorough physical examination will reveal the presence of these disorders. Finally, other miscellaneous causes exist, such as connective tissue disease related (i.e., Marfan's syndrome), tumor related (i.e., osteoblastoma), and other syndromic causes of scoliosis. Of primary concern to the practicing pediatrician is adolescent idiopathic scoliosis, although the ability to rule out other causes is paramount. The remainder of the discussion will therefore focus on idiopathic scoliosis.

Patients with idiopathic scoliosis may present in one of several ways. Often a rib prominence is noted on a school screening examination or during a routine physical examination. The majority of cases of scoliosis are initially asymptomatic, although patients and their families may notice a waist asymmetry, a rib hump, or a difference in breast size resulting from the rotation of the curve. Infants are often diagnosed after a family member notices a spinal asymmetry while bathing. As with all conditions, a detailed history and physical examination will confirm the diagnosis of idiopathic scoliosis.

The history should focus on the presence of neurologic symptoms, pain, headaches, numbness, or weakness. Roughly 25% of patients with idiopathic scoliosis will complain of some pain, so its presence is not necessarily worrisome. Physical examination requires a systematic evaluation of the spine, as well as the skin and nervous system. The Adams forward bending test is performed by having the examiner sit behind the patient, who then bends forward at the waist with the arms hanging free. A prominence of the ribs or paraspinal muscles should alert the examiner to a curve. A scoliometer can be used to quantify the amount of rotation. Prior to bending, the patient's waist, scapulae, and shoulders should be examined for symmetry. The iliac crests should be palpated to look for evidence of pelvic obliquity from a limb length discrepancy. Skin exam can rule out systemic disorders (Marfan's syndrome, Ehlers Danlos syndrome, neurofibromatosis) or signs of spinal dysraphism (hairy patch or midline hemangioma), while neurologic examination seeks evidence of tethered spinal cord, or other underlying neurologic dysfunction. Reflexes should be checked (including the abdominal reflex), in addition to motor and sensory testing.

The diagnosis of scoliosis is confirmed by radiographs, ideally standing full-length x-rays of the entire spine. Most experts agree that a scoliometer reading greater than 7° should prompt radiographic evaluation. For patients with

a suspicion of neurologic dysfunction (young age, abnormal neurologic exam, left-facing thoracic curve, severe associated kyphosis, unexplained pain), magnetic resonance imaging (MRI) should be considered. Usually, this will be ordered by the specialist.

Treatment of scoliosis depends upon two factors: the age of the patient and the size of the curve. Skeletal maturity can be assessed in several ways; spinal growth usually ceases 2 years after the onset on menarche in girls. The Risser sign, which is determined by the percentage of the iliac apophysis which is ossified on the scoliosis radiograph, can be useful as well; girls spinal growth continues until Risser stage IV (100% ossification but not closure of the growth plate), boys can progress until Risser V (growth plate closed – "adult" pelvis). Patients with curves less than 25° usually do not require treatment, but must be followed through skeletal maturity. Radiographs taken every 6 months during rapid growth are helpful to identify curve progression. In general, curves greater than 20°

should be referred to a specialist for observation. For patients with at least 1 year of growth remaining with curves greater than 25–30°, bracing is often prescribed. The type of brace and wear schedule vary (Boston-full time, Providence and Charleston-nighttime only), but the concept is the same: to prevent curve progression in an at-risk patient. Curve correction is not usually seen, underscoring the necessity of early diagnosis to allow early brace initiation. DNA testing is currently available to help determine risk of progression and guide bracing recommendations. Bracing is continued until skeletal maturity, or until curve progression requires surgery. Operative intervention is usually undertaken for curves greater than 40–50°, due to the risk of progression after skeletal maturity and potential cardiopulmonary compromise.

Scoliosis in children less than 10 years old can be characterized as early onset scoliosis (EOS). Vigilance in looking for these curves is important, as the large amount of growth remaining portends a poor prognosis if untreated. Often bracing alone is insufficient to control the curve. Casting or "growing instrumentation" are two additional options for progressive curves. The latter technique involves inserting rods into the spine without a fusion, which are then lengthened at regular intervals until sufficient growth has been attained. Alveolar branching is complete by age 8, but more recent evidence suggests that fusion performed at that age significantly impairs pulmonary development, and the definitive procedure is usually delayed as long as possible. A recent technique, vertebral stapling, holds promise as a means of controlling or even correcting curves in these young patients.

Kyphosis

Kyphosis is defined as a curvature in the sagittal plane greater than normal (20–40°). Two types of kyphosis are seen: flexible and rigid. Flexible kyphosis is seen in patients with "poor posture"; they are able to actively correct their deformity if asked. Often, examination reveals tight hamstring muscles and poor flexibility in general. Physical therapy to increase flexibility and strengthen the spinal extensors is helpful, and specialist referral is usually unnecessary. Scheuermann's kyphosis is rigid and often painful, with radiographic changes consisting of increased sagittal angulation, wedging of three consecutive vertebral bodies, and vertebral endplate irregularities known as Schmorl's nodules. While physical therapy can be helpful for decreasing symptoms, the rare patient with a large progressive curve (greater than 75°), or who has pain recalcitrant to nonsurgical measures, often undergoes surgery to correct the deformity. Posterior osteotomy and pedicle screw fixation usually eliminates the need for an anterior procedure, which had been the standard of care in the past. Smaller curves in growing children may respond to bracing as is the case for scoliosis, although this is not universally accepted. Kyphosis in the presence of a significant scoliosis is not typical, and investigation for underlying neurologic abnormality should be undertaken.

Torticollis

Torticollis, or wry neck is a common entity in childhood. The differential diagnosis includes congenital muscular torticollis, ocular abnormalities, gastrointestinal reflux, posterior fossa brain tumors, rotary subluxation of C1–C2, and congenital spinal deformity. Definitive diagnosis is contingent upon a thorough history and physical examination.

Congenital muscular torticollis is the most common type. Often, this results from intrauterine positioning and can be associated with other "packaging" problems, such as metatarsus adductus or hip dysplasia. Because of this, imaging of the hips is recommended in children with torticollis. Alternately, traction during delivery may result in injury to the sternocleidomastoid (SCM) muscle. Hemorrhage and fibrosis may lead to a mass, or pseudotumor, which is palpable in the muscle. Treatment of torticollis consists primarily of physical therapy. Ocassionally, bracing with a collar may be helpful in older children. Neglected cases may require surgery; left untreated facial asymmetry will persist into adulthood. Early presenting cases may also be due to visual disturbance, so ophthalmologic consultation may be helpful. In addition, patients with gastrointestinal reflux may exhibit intermittent spasmodic posturing due to esophageal irritation (Sandifer syndrome). Cases presenting long after birth may be due to posterior fossa tumors, so MRI is warranted.

Acute torticollis in childhood may lead to atlantoaxial rotary subluxation. The inability to return the rotated head to the midline should raise suspicion for this condition. It can be seen after minor trauma, or occasionally after an upper respiratory infection due to the relationship of the retropharyngeal lymphatics to the C1–C2 joints. If symptoms exist for a short duration (less than 1–2 weeks), muscle relaxants and a soft collar may allow reduction and can be discontinued when full motion is achieved. Symptoms of longer duration may require halter or halo traction for reduction. Failure to achieve or maintain reduction, or symptom duration longer than 3 months, usually will require atlantoaxial fusion.

Spondylolysis/Spondylolisthesis

A common cause of low back pain in adolescents is spondylolysis/spondylolisthesis. In spondylolysis, a fracture exists in the pars intraarticularis region of the vertebra, usually L5. It may be acute from high-energy trauma, or more chronic, such as the case with stress fractures. Highly repetitive hyperextension activities (gymnastics, crew) are thought to play a role in the pathogenesis of the stress fracture, which may be uni- or bilateral. The initial workup should include anteroposterior and lateral radiographs of the lumbar spine, as well as oblique radiographs. In cases where plain films are normal, several options exist. MRI may show edema in the adjacent pedicle, pointing to the diagnosis, and is helpful in identifying stress reactions, i.e., a pre-fracture. Computed tomography is helpful for identifying fracture lines not seen on plain radiographs. Traditionally, SPECT scanning has been suggested to determine if the lesion is "hot," i.e., possessing adequate blood flow for healing. Treatment varies from activity modification to bracing or even surgery for cases failing to respond to conservative measures.

Spondylolisthesis (*Fig. 407.3*) implies a slippage forward of one vertebrae in relationship to the subjacent one. The cause may be a defect in the pars intraarticularis (isthmic), a dysplastic L5-S1 facet (dysplastic), or as a result of severe trauma (traumatic). Listheses are graded according to the percentage of slippage. Painless slips less than 50% (grade 2) are usually observed. Slips greater than 50% (grades 3–5) in skeletally immature patients are likely to continue slipping and are often treated with spinal fusion. Lower grade slips with symptoms uncontrolled by nonoperative measures also may benefit from surgery. Because in dysplastic spondylolisthesis the posterior elements of the vertebra are intact and slide forward with the vertebral body, there is a higher incidence of neurologic compromise from root compression in these patients. Signs and symptoms of neural dysfunction should be sought (numbness, tingling, bowel or bladder dysfunction).

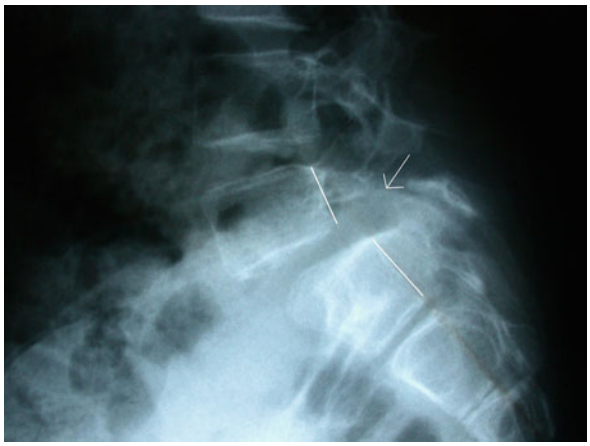

Figure 407.3
Spondylolisthesis. The L5 vertebral body has slipped anteriorly in relation to S1. The *arrow* points to a defect in the pars intraarticularis region of L5

Back Pain

Back pain in children and adolescence is a common complaint. Distinguishing minor ailments from significant pathology requires a thorough knowledge of potential etiologies. A stepwise approach is paramount.

The initial evaluation begins with the history. The location of the pain (localized versus diffuse) is important, as is any history of injury (minor injury versus major fall/accident). Radicular symptoms suggestive of a neurogenic etiology should be sought. Constitutional symptoms suggest leukemia, infection, or other multisystem disorder. Physical examination should include spinal range of motion in flexion/extension, tenderness to palpation, hamstring tightness, as well as a thorough neurologic exam, including straight leg raise.

It is helpful to consider potential causes of back pain when assessing the results of the history and physical examination. Trauma (compression fracture) often results in decreased range of motion and a history of a significant injury mechanism. Tumors (osteoid osteoma, osteosarcoma, leukemia, etc.) and infections often have an insidious onset, lead to severe pain, often at night, as well as fatigue and other systemic symptoms. While acute infections (disciitis, osteomyelitis) typically present with fever, chronic infections may not.

In general, patients with significant back pain should have plain radiographs. Those with suspicious histories should have appropriate bloodwork (complete blood count, erythrocyte sedimentation rate, c-reactive protein). If symptoms are mild, a short course of nonsteroidal anti-inflammatory medication, rest, and activity modification are appropriate. Physical therapy is appropriate for patients with tight hamstrings or generalized deconditioning. For patients who do not respond to simple measures, further imaging is helpful. Magnetic resonance imaging is helpful for ruling out infection, tumor, disk disease, occult fracture, or spinal cord pathology. Computed tomography can be helpful to evaluate for

spondylolysis. SPECT scanning can also be helpful in evaluating for occult pars fracture or stress reaction. Further evaluation is best done by a specialist.

408 Pediatric Upper Extremity

Julia A. Katarincic · M. Jason Palmer · Amir Mostofi

Brachial Plexus Injuries

The incidence of obstetrical brachial plexus injuries is reported in 0.4–2.5 per 1,000 births. Maternal risk fractures include maternal obesity and gestational diabetes with large birth weight. Women who have had a child with a brachial plexopathy have an increased risk with subsequent pregnancies. Shoulder dystocia may be related to an upper plexus injury because of traction on the shoulder inferiorly during delivery, causing a stretching of the upper plexus. A clavicle fracture in this situation is advantageous because it allows the shoulder to be compressed during delivery instead of getting stuck and stretching the plexus. Children delivered by caesarian section may also be at risk of a lower trunk injury if they are delivered head last. If the arms are over the child's head and traction is applied pulling the arms away from the body, there may be stretching of the upper trunk.

Most obstetrical brachial plexus injuries are upper or upper and middle trunk involvement. These injuries include muscles innervated by the fifth, sixth, and seventh cervical root. Limited shoulder motion is the biggest functional deficit of these children long term.

Referral within the first month to a surgeon or neurologist is appropriate. Approximately 90% resolve in the first 2 months. These children have almost normal shoulder function. If the children do not recover biceps function by 5–6 months, surgical intervention may be required. Those that show enough recovery to not require surgery may need prolonged physical therapy to ensure good shoulder motion.

Polydactyly and Syndactyly

Polydactyly is the duplication of parts. It can involve any part of the upper limb but most commonly the fingers. Preaxial polydactyly, or duplicate thumb, is most common in white or Asian children. Correction usually requires surgery at 6–24 months of age. Post axial polydactyly, an extra small finger, is most common in African-American children and there often is a strong family history. These can be tied off in the nursery if the skin bridge is small enough without significant bone involvement.

Syndactyly is the most frequent congenital limb deformity occurring in 1:2,000 births. It may be sporadic, inherited, or syndromic such as Apert's, Mobius, or Pierre-Robin syndrome. The syndactyly may be to the fingertip (complete) or just webbing (incomplete). There may be bone involvement (complex) or normal boney anatomy (simple). With the exception of a minimal web contracture, surgery is usually performed. If there is a significant length discrepancy between the digits with tethering, surgery may be performed as early as 6 months. Otherwise, surgery is typically performed at about 24 months of age. All of these children require a skin graft, typically from the groin. The advantage of waiting until about 2 years of age is that there is less web creep, or redevelopment of the webbing, the most common complication of the procedure.

Clinodactyly and Camptodactyly

These two diagnosis, angular deformities of the fingers, fall into the classification of failure of differentiation. Clinodactyly is a deformity of the finger affecting the middle phalynx of the small finger causing the tip to be deviated radially. There is a rare functional issue and no treatment is usually required. If there is a significant overlap of the fourth and fifth finger in flexion, an osteotomy of the small finger middle phalynx may be required in adolescence but is extremely rare. There is a strong family history of this deformity and there are no concerns for associated anomalies.

Camptodactyly means crooked finger. The deformity is a flexed position at the proximal interphalangeal joint. This deformity is typically diagnosed during the accelerated growth of adolescence. Full extension is the only functional deficit. Serial casting or splinting is appropriate treatment. Surgical treatment is rarely indicated for two reasons. Conservative treatment is usually very successful and the exact reason for the deformity is not clearly identified. Abnormal skin, flexor tendons,

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_408,

intrinsic muscles, or even a boney deformity. Because of the unknown etiology, surgical treatment has limited indications.

Pediatric Trigger Thumb

Pediatric trigger thumb, or "congenital trigger thumb," is triggering or catching of the thumb as in adults. It is a fixed flexion deformity of the thumb interphalangeal joint due to limited excursion of the flexor pollicis longus tendon at the A1 pulley. The parent's usually notice that the thumb does not fully extend with the interphalangeal joint held in flexion. Passive extension may produce pain or cannot be achieved. The differential diagnosis includes congenital clasped thumb, absent or aberrant extensor tendons, arthrogryposis, or spasticity. A nodule, termed a "Notta's nodule," is usually palpable over the volar portion of the thumb metacarpophalangeal joint in trigger thumb, which is not typically present in other diagnoses. This nodule moves as the tendon moves (*Fig. 408.1*).

The condition has been described to occur in newborns, often based on parental history or recollection, hence the original description as congenital trigger thumb (G). Other studies have suggested that the trigger thumb develops postnatal; thus, Slakey and Hennrikus recommend using the term "acquired thumb flexion contracture." Moon et al. examined 7,700 newborns prospectively and found no congenital cases. The origin remains unknown. The age at which symptoms first appear vary from birth to 4½ years.

Overall, pediatric trigger thumb is a rare condition, but still ten times more common than pediatric trigger finger. The incidence is reported to occur in 1–3.3% of children.

Unlike trigger thumbs in adults, pediatric cases are rarely seen to trigger or catch. More commonly, the condition is not noticed until there is a thumb interphalangeal flexion deformity. In contrast to adults, the pathology in the pediatric patient is more frequently found to reside within the tendon itself with thickening and synovial proliferation, resulting in a Notta node, as originally described in 1850.

Some have postulated that the condition may arise secondary to the common clasped thumb fisted posture of neonates. Patel believed this adducted thumb position caused tendon kinking at the A1 pulley with a resultant inflammatory reaction, which results in the thickened nodule. However, Buchman et al. performed electron-microscopic evaluation of tendon nodules and A1 pulleys in 11 trigger thumbs and showed that there were large amounts of mature collagen surrounding spindle-shaped fibroblasts in the tendon, with normal appearing A1 pulleys. They concluded that an infectious, inflammatory, or degenerative process is an unlikely etiology.

Reports differ regarding the optimum treatment. Some studies have shown spontaneous resolution whereas Ger et al. observed no cases of spontaneous resolution. Dinham and Meggitt observed a spontaneous recovery rate of 30% for congenital cases and 12% for patients presenting between 6 and 30 months of age. Other studies have shown 63% of cases resolving spontaneously.

Dinham and Meggitt's original algorithm for treating pediatric trigger thumbs recommended observation for deformities present at birth for 12 months and 6 months for cases noticed between the ages of 6 and 30 months. They suggested operative treatment before the age of 4 years to prevent residual flexion deformities; however, subsequent studies have shown no untoward events with operative treatment in the older child.

Observation, passive range of motion or stretching, and splinting have been reported to result in satisfactory trigger thumb improvement or resolution in 50–90% of patients in some series. However, these conservative treatment results are not always reproducible.

Most would recommend operative release of the A1 pulley overlying the flexor pollicis longus tendon in cases with painful triggering, severe compensatory hyperextension of the metacarpophalangeal joint, or in those cases

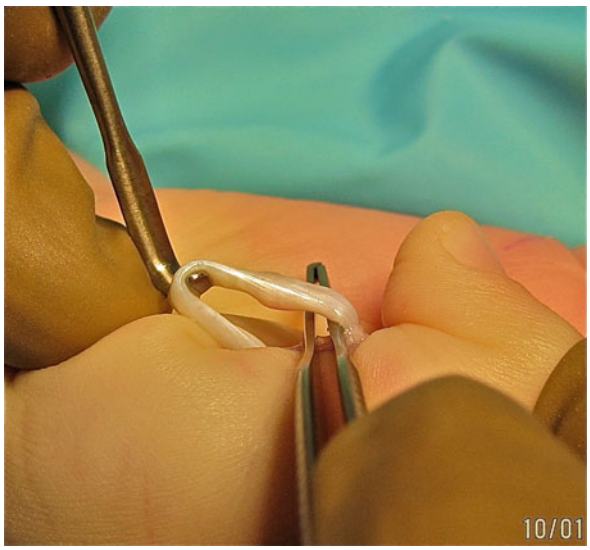

Figure 408.1
Thickening or "Notta's nodule" in the thumb flexor tendon

that have failed nonoperative measures. Historically surgeons excised the intratendinous nodule; however, current practice consists of pulley release alone for trigger thumbs. Recently, van Loveren et al. showed that release of the A1 pulley alone was sufficient to relieve the triggering in only 19% of their cases, suggesting either a separate annular pulley between A1 and A2, or a longer than normal annular pulley that extends into to proximal phalanx, which must also be divided.

Pediatric Trauma

As developing children begin to explore the environment around them, the hands they use to gather information are at risk for injury. The health care providers that encounter these injuries are faced with circumstances that are unique to the pediatric population. What may appear initially as a trivial injury may have significant consequences for the function of the hand. Children have an impressive ability to heal compared to the adult counterpart, but with this accelerated healing potential comes a narrowed opportunity to treat or alter treatment. In fact, within 5–7 days, the potential to treat injuries by closed means may be lost. Fractures can heal within 2–3 weeks, leaving treatment by open means impossible. Unless injuries are timely recognized and treated, one is left with the most common complication, malunion. Treating pediatric hand injuries requires consideration of the age at presentation, digits involved, presence of a growth plate injury, and fracture configuration.

Pediatric hand fracture occur more commonly in children younger than 2 years of age and those greater than 12. The female-to-male ratio is equal in toddlers and children, with increasing incidence in males during adolescent years. Border digits, the thumb and small finger, are more commonly involved. The mechanism for the majority of toddlers is a crush injury of the distal phalanges with associated nail bed injuries. Children and adolescents injure the hand more commonly during sports with a combination of twisting, bending, torquing, and axial loading of the digits.

Knowledge of anatomy can help in understanding fracture patterns. The growth plate of every phalanx is at its base, contrary to the metacarpals that have the physis in the metacarpal head. The exception is the thumb metacarpal where the growth plate is proximal. Salter and Harris classified growth plate fractures into five categories, determined by the fracture pattern around the growth plate. Non-epiphyseal, condylar fractures can be categorized as unicondylar, bicondylar (T or Y), or transcondylar. Shaft fractures can be described as transverse, short oblique, or spiral.

The developing child has an amazing ability to remodel fractures. Remodeling can occur if 2 years of growth remain; however, its potential decreases as the child reaches skeletal maturity. The further the fracture is from the growth plate, the less potential for correction of deformity over time.

The majority of pediatric hand injuries can be treated my closed means. Thick periosteum helps prevent significant displacement and often provides a thick tether to help hold fractures once reduced. Operative treatment is required in 10–20% of cases and is reserved for those that failed closed treatment.

The small finger metacarpal is the most commonly injured with the so-called "boxer's fracture" that occurs at the neck of the metacarpal because of an axial load from punching. Fractures that are further away from the physis, adolescents that are near the end of growth, coronal and rotational deformities are treated more like injuries in adults. Accepted sagital plane (flexion-extension) angulation is less than 15° in the neck and less than 10° in the shaft for index and middle finger metacarpals. The increased mobility of the fourth and fifth ray allows the small and ring finger to tolerate greater degrees of malreduction. Acceptable reduction in the small and ring finger is considered to be less than 30°–40° in the neck and 20° in the shaft. The Jahss maneuver is used for metacarpal neck fractures. A palmar force is placed on the proximal metacarpal fragment and PIP and MCP are bent at 90° and a counter force is created directed from the flexed PIP, axially and dorsally. Due to the mobility of the CMC joint, as much as 30° of angulation may be tolerated in the sagital plane of the thumb. No rotational deformity can be tolerated regardless of the digit involved.

In the proximal and middle phalanx, up to 10°–20° of angulation can be acceptable in the sagital plane, taking into consideration the impact on the flexor and extensor lever mechanisms. Coronal (medial-lateral) and rotational deformities are less forgiving and any malreduction leading to a clinically significant deformity should be treated with operative fixation and early range of motion after 2–3 weeks of immobilization.

Distal phalanx tuft fractures are the most common in toddlers due to crush injuries. Associated nail bed injuries are common and are considered an open fracture. Subungual hematoma greater than 50% requires removal of the nail, irrigation and debridement, and repair of the nail bed with 6–0 absorbable suture. Recently, the use of dermabond has been published as an alternative to suture fixation of the nail bed with good results.

Articular fractures, regardless if they are of the phalanx or metacarpal, usually require near anatomic reduction. Articular gap or step off of 1–2 mm and angulation of greater than 5° is generally considered an indication for surgical treatment. Phalangeal condylar fractures are intra-articular fractures that require near anatomic reduction and can be particularly unstable. Those that are displaced and shortened can lead to joint instability and arthritis. Dedicated lateral radiographs of the joint are necessary and double density sign of the condyles may indicate offset of a displaced fractured condyle. Subcondylar or transcondylar fractures of the phalangeal neck can also be unstable and typically have dorsal translation and extension angulation.

The "Seymour Fracture" is an example of a Salter Harris I or II injury of the distal phalanx with avulsion of the proximal edge of the nail from the eponychial fold (*Fig. 408.2*). This is an open fracture. Removal of the nail allows copious irrigation and reduction of the abnormally overlying nail plate underneath the eponychial fold. One example of a Salter Harris II fracture is the so-called extra-octave fracture of the small finger. Reduction can be achieved by using a pencil placed in the fourth webspace to apply counterpressure to the proximal fragment while

Figure 408.2

Seymour fractureThese (a) AP and (b) lateral radiographs show a typical Seymour fracture. Note the widening of the physis on the anteroposterior view and the flexion deformity and dorsal physeal widening on the lateral view. (c) The clinical appearance of the same fracture shows exposure of the proximal end of the nail plate from underneath the eponychial fold. Note the lack of skin laceration, which can lull the physician into believing the injury is closed. (d) After removal of the nail plate, the open physis is seen easily though the nail bed laceration

the metaphysis and shaft are brought radialward. Another reduction maneuver for proximal phalanx fractures is to bringing the small proximal piece into flexion. This places tension on the collateral ligaments that are attached to the proximal fragment and stabilizes it, allowing one to manipulate the distal fragment until reduction is achieved.

Carpal Fractures

Knowledge of the appearance of carpal bone ossification centers is important in evaluating pediatric hand trauma. The capitate is the first bone to appear at 6 months and the pisiform is the last to ossify at 6–8 years of age. The scaphoid appears at approximately 4 years of age and is the most frequently injured bone in children. As with adult fractures, any suspicion of a scaphoid fracture with tenderness at the snuffbox or distal pole of the scaphoid requires immobilization and repeat evaluation. The majority of these injuries can be treated in a thumb spica cast for 6–8 weeks.

409 Hip Pathology

Mark C. Lee

Transient Synovitis of the Hip (Toxic Synovitis)

Case: A 6-year-old boy presents with 2 days of low grade temperature with refusal to bear weight on the right leg. Exam demonstrates mild irritability and limitation of motion of the right hip. Labs reveal WBC of 10,000 cells/μL and ESR of 20 mm/h. X-rays of the right hip are negative but ultrasound shows a small hip effusion. The patient is given NSAIDs and symptoms improved markedly over 2 days, with complete resolution 10 days after presentation.

Transient synovitis is an idiopathic, self-limiting inflammatory condition of the pediatric hip that occurs in younger children. The etiology is unclear, but occasionally follows an upper respiratory infection. Incidence is estimated at 0.2% per year for children aged 1–13 years, with peak onset between 4 and 10 years of age. Boys are affected 2–3 times more frequently than girls.

Typically, a young child presents with a low grade fever and acute onset of limp or refusal to bear weight. The child is usually in mild distress with moderate limitations in hip range of motion.

The differential diagnosis for such a presentation is broad and includes septic arthritis, Lyme arthritis, deep pelvic or psoas abscess, femoral osteomyelitis, and fracture. Early Legg–Calvé–Perthes disease and juvenile rheumatoid arthritis (JRA) may also present in this fashion and should necessarily be excluded.

Of the utmost importance, the clinician must distinguish transient synovitis from a septic arthritis of the hip. Patients with septic arthritis are usually less comfortable and have greater restrictions in range of motion, but the presentation may vary. The following four criteria are used as a guideline for operative decision-making: fever $>38.6°C$, inability to bear weight, ESR >40 mm/h, WBC $>12{,}000$ cells/μL. If three or four of these criteria exist, then septic arthritis is likely and hip aspiration in the OR with the possibility of further operative drainage is performed. If septic arthritis is thought unlikely, then symptomatic management with an around-the-clock course of NSAIDs for several days is all that is required.

The prognosis for transient synovitis is excellent. Patients typically improve rapidly over the course of 2 days, with full resolution of symptoms by 7–14 days. No significant long-term clinical sequelae have been identified. This is in contradistinction to a neglected septic arthritis of the hip, where the long-term outcomes range from debilitating early onset osteoarthritis of the hip to fulminant sepsis with the possibility of death.

Developmental Dysplasia of the Hip

Case: A 6-week-old infant presents with a right hip "click" on exam. Physical examination demonstrates a positive Ortolani sign. Ultrasound of the bilateral hips shows mild right acetabular dysplasia with the femoral head in a subluxated position. The patient is placed in a flexion harness for 6 weeks with weekly physical examinations as well as monthly ultrasound examinations to confirm the congruence and the development of the hip. At 1 year of age, the hip is stable with a normal appearance to the acetabulum. However, follow-up continues to ensure appropriate hip development to skeletal maturity.

Developmental dysplasia of the hip (DDH) is a spectrum of disorders of hip development in which the femoral head and acetabular couple is disrupted, resulting in a mutual disturbance in development. Manifestations of the disorder are seen at all ages, but will most commonly be identified in the infant. Infantile DDH manifests as hip instability that is usually associated with poor development of the acetabulum. The infantile hip may be dislocatable, partly dislocatable (subluxatable), or reducible from a dislocated resting position.

The etiology is multifactorial and is influenced by hormonal and genetic elements. Numerous theories exist as to the exact cause of neonatal hip dysplasia. However, none have been definitively proven. The incidence varies with location and ethnicity, with a high incidence noted in a district of Manitoba, Canada as well as in the Navajo Native American children. The overall incidence varies from 1.7 per 1,000 live births to 188.5 per 1,000 live births. Known risk factors for DDH include female gender, first

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_409,

born status, family history of DDH, breech presentation, oligohydramnios, metatarsus adductus, and torticollis.

The clinical presentation depends on the age of the patient. The neonate will present with either a dislocatable hip (positive Barlow's sign or ability to dislocate the hip from a located position with hip flexion and posterior pressure on the knee) or a reducible hip (positive Ortolani's sign or ability to reduce the hip with gradual abduction of the hip and anterior pressure on the greater trochanter). The signs may be difficult to elicit in an uncooperative child and may change over the course of a week as the initial infantile ligamentous laxity from maternal hormones improves. As the child enters infancy, asymmetry in hip abduction becomes a more reliable finding in a unilateral hip dysplasia. When the hips are flexed to 90°, the height of the knee from the exam table may be less in the dysplastic hip (positive Galeazzi sign).

The differential diagnosis is broad and includes neonatal septic arthritis, teratologic dislocation with underlying neuromuscular disorder, fracture, or congenital femoral deficiency.

The initial treatment for DDH is Pavlik harness (flexion harness) application. The hip is closely monitored in the harness with serial ultrasound examination for improvement in the femoro-acetabular relationship. If no improvement is noted at 3–4 weeks, the harness is discontinued and surgical reduction, through closed or open means, is attempted after 6 months of life. Even if Pavlik harness treatment is initially successful, long-term follow-up is required to ensure that no residual hip deformity develops.

The short- to mid-term prognosis depends on the specific clinical instability. Up to 60% of Ortolani positive hips and >90% of Barlow positive hips will respond to Pavlik Harness treatment. Long-term outcomes are uncertain as it is unclear which patients will progress to adolescent or adult dysplasia despite acceptable short-term radiographs. Therefore, long-term clinical and radiographic follow-up is required to ensure that the patient does not develop residual hip deformity.

Preventative measures include screening of the neonate by physical examination. Universal screening of neonates with ultrasonography is a matter of controversy. Currently, ultrasound screening is recommended for female infants carried in a breech position or with a positive family history.

Legg–Calvé–Perthes Disease

Case: A 6-year-old boy without significant past medical history or antecedent trauma presents with a limp and mild right hip pain. Examination reveals mild limitation in range of motion, especially in abduction and internal rotation. X-ray of the pelvis demonstrates unilateral fragmentation of the femoral head sparing most of the lateral pillar. (*Fig. 409.1*) Labs demonstrate no evidence of infection. The patient is managed symptomatically and, by age 9, notes no hip pain and no residual limp. X-rays at that point show mild deformity in the femoral head and acetabulum.

Legg–Calvé–Perthes Disease is an idiopathic avascular necrosis of the femoral head. The most clinically useful grading is that of Herring, who divides the femoral head involvement into A, B, and C groups depending upon the involvement of the lateral column of bone along the femoral epiphysis, with the C group having <50% of intact lateral column structure.

The exact etiology continues to escape careful scrutiny, although a multifactorial cause is favored. It is postulated that there is an intrinsic propensity in affected individuals to abnormal clotting of small vessels through an abnormality in the clotting cascade. The worldwide incidence is approximately 1 in 1,200. The disorder is most prevalent in the 4–12 age group, but can be seen from 18 months of age to skeletal maturity. Boys are more frequently affected

Figure 409.1
Hip pathology – Perthes

than girls in a 4:1 ratio and bilaterality occurs in 10–12% of patients.

Patients typically present with complaints of a limp or hip or knee pain that is usually aggravated by physical activity and worse later in the day. The child is typically smaller in stature, thin, and reportedly hyperactive. The initial examination will reveal various degrees of loss in range of motion and guarding with a gait asymmetry manifested by an antalgic/Trendelenburg pattern.

The differential diagnosis for this clinical and radiographic presentation is broad. Avascular necrosis from specific etiologies (sickle cell disease, thalassema, steroid medication), epiphyseal dyplasias (multiple epiphyseal dysplasia), and syndromes (trichorhinophalangeal syndrome, osteochondromatosis) must be excluded.

No standard treatment protocol exists. Symptomatic treatment is practiced by most but surgical treatment remains controversial with disagreement between large centers. Surgical treatment focuses on containing the irregular femoral head in the acetabulum to maintain sphericity. The recommendations for surgical treatment are dictated by the age of onset and the relative involvement of the femoral head, as described by the lateral pillar system. Generally, the older the patient and the more involved the femoral head, the less efficacious is surgical treatment.

Prognosis depends on the radiographic involvement of the femoral head and the age of the patient. Patients <6 years of age generally fare well while patients >9 years of age generally fare poorly, although older patients with minimal head involvement can have excellent hip function. Long-term function of the hip is directly correlated to the degree of residual femoral head and acetabular deformity at skeletal maturity.

Slipped Capital Femoral Epiphysis

Case: A 12-year-old boy presents with groin and knee pain for 3 months and is still able to bear weight. Radiographs reveal posterior displacement of the femoral epiphysis with respect to the femoral neck and chronic, bony remodeling of the femoral neck. The patient is placed in a wheelchair and taken for in situ screw fixation that evening. At 2-week-follow-up, pain is significantly improved despite residual femoral deformity on radiographs.

Slipped capital femoral epiphysis (SCFE) is the posterior displacement of the femoral epiphysis relative to the femoral neck through the level of the proximal femoral physis. The condition may be classified temporally as acute (symptoms ≤ 3 weeks), chronic (symptoms >3 weeks), or acute-on-chronic (worsening symptoms for ≤ 3 weeks in the setting of chronic symptoms). The most clinically useful classification involves the ability to bear weight on the affected extremity. Patients unable to bear weight are termed "unstable" and those able to bear weight are termed "stable." Unstable slips have a high risk of subsequent femoral head avascular necrosis despite timely surgical intervention.

No clear etiology has been identified for SCFE. Hormonal predisposition is thought to play a factor as most slips occur in obese males with hypogonadal features during the adolescent growth spurt and slips occur in patients with known endocrine abnormalities. SCFE is a disease of adolescence and will uncommonly occur, in the absence of an endocrinopathy, in patients less than the age of 10 or greater than the age of 16. Incidence varies according to race, sex, and geographic region, with a range of 1–7 per 100,000 worldwide. Polynesian children have the highest prevalence of slips while Indo-Mediterranean children the lowest. Blacks have an approximately twofold greater prevalence than whites. Bilateral involvement occurs with a frequency of 20–25%, with symptoms in the contralateral hip appearing within 18 months of the initial presentation.

The patient presents with either acute or chronic complaints of hip or knee pain with an associated limp. An adolescent complaining of knee pain, particularly if overweight, has a SCFE until proven otherwise. If the slip is unstable, the ability of the patient to bear weight is compromised. For chronic SCFE, the hip will demonstrate little to no internal rotation and obligate external rotation with hip flexion. For unstable slips, any hip motion will cause the patient discomfort. An AP and frog lateral view of the pelvis typically reveals the deformity (*Fig. 409.2*).

Anteroposterior (AP) (a) and frog leg lateral (b) views of the hips demonstrating a left hip slipped capital femoral epiphysis. The blue line on the AP (Klein's line) drawn along the femoral neck demonstrates the relative varus of the femoral epiphysis. A similar line drawn on the lateral demonstrates the relative posterior displacement of the left femoral epiphysis compared to the normal right hip.

The differential diagnosis for this condition is limited. Unstable slips must be distinguished from a femoral neck fracture. Stable slips should be distinguished from late deformity resulting from Perthes disease or hip dysplasia as well as congenital conditions such as congenital coxa vara.

Surgical stabilization is required in all cases of slipped capital femoral epiphysis to prevent rapidly or slowly progressive deformity. Immediate non-weight bearing of

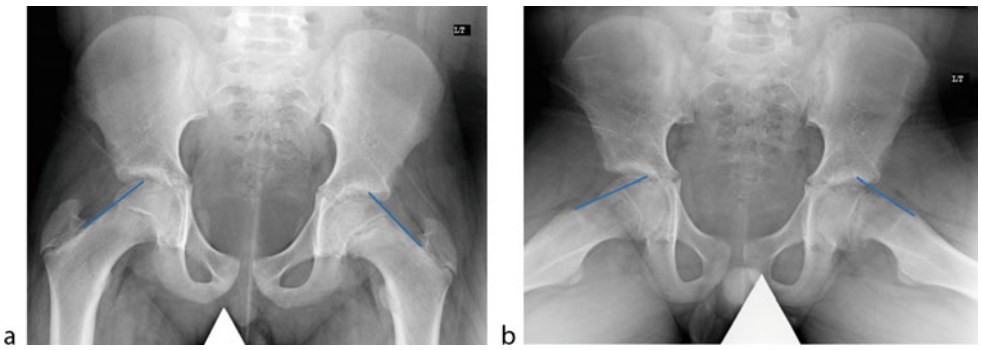

Figure 409.2
Hip pathology – slipped capital femoral epiphysis

the affected extremity is instituted and in situ screw fixation is performed. Open reduction with stabilization is sometimes recommended for acute unstable SCFE in the hopes of salvaging the tenuous blood supply.

Hip function and the risk of late degenerative hip arthritis is directly correlated to the residual deformity of the femoral head once healing has taken place. If avascular necrosis has occurred, the prognosis for good long-term hip function is poor. Of even greater import than appropriate surgical stabilization is early recognition of the SCFE diagnosis, so that the short-term and long-term consequences of the disease may be minimized or prevented.

410 Foot Pathology

Jonathan R. Schiller

Human walking begins as early as 10 months old and is subject to changes in the normal development of the foot. The foot comprises three divisions: the hind foot (calcaneus, talus, proximal cuboid, and proximal navicular), midfoot (distal cuboid and navicular, cuneiforms), and forefoot (metatarsals, phalanges). Soft tissue attachments of muscles, ligaments, tendons, and plantar fascia are responsible for maintenance of the longitudinal arch and normal joint biomechanics in all three divisions. Ossification begins in utero, starting with the talus, calcaneus, and metatarsals and finishing with the navicular at 3 years of age or later. Arrested development may delay ossification and alter intra-articular relationships, producing the relatively common presentation of foot deformities in children seen in 5% of newborns.

Polydactyly and Syndactyly

Polydactyly and syndactyly are common foot deformities in the pediatric population. Polydactyly is a duplication of one or multiple digits in the foot (*Fig. 410.1*). It may be bilateral up to 50% of the time, although not always symmetric. Observed in 1 in 1,000 live births, it is more frequent in blacks, up to 4 in 1,000 births. Syndactyly is observed in 20% of patients and one-third have polydactyly of the hand. Thirty percent of patients have a positive family history, and an autosomal dominance with incomplete penetrance has been described. The Hox genes have been cited as a possible cause, leading to apical ectodermal ridge disruptions in Bmp4. Polydactyly may be associated with syndromes such as Ellis van Creveld, Trisomy 13, tibial hemimelia, and Down syndrome.

Duplication may be on the great toe side (pre-axial) or the small toe side (post-axial), and may vary from a well-formed digit to a rudimentary "nubbin." Bone involvement may be a distal phalanx to a complete independent or connected duplication of the metatarsal. The majority of cases (80%) are post-axial, with duplication of the phalanx, metatarsal, or a wide metatarsal head.

Treatment is aimed to provide improved foot appearance and comfortable shoe wear. Suture ligation of duplicated digits is employed when only connected by soft tissue; radiographs are mandatory to determine osseous anatomy. Residual bone or cartilage will lead to future deformity and possible surgery. Surgery is recommended after 1 year of age to reduce anesthetic risk, as well as allow the child to begin walking. The most lateral or medial toe is removed with simple excision, whereas central digit duplication requires intermetatarsal ligament and capsular repair.

Syndactyly is congenital webbing of the toes (*Fig. 410.2*), most often involving the proximal portion of the toe (incomplete); however, it can involve the entire toe (complete) including the nail. Most frequently it is seen between the second and third toe, followed by the fourth and fifth toe. It may be seen with polydactyly and involve synostosis of the metatarsals as well. Isolated syndactyly is a cosmetic deformity and presents no functional problems. Parental counseling often alleviates concerns of cosmesis and functional limitation. When separated, a skin graft is usually required for closure. Except in cases of complex deformity, no surgery is usually the best option.

Metatarsus Adductus

Metatarsus adductus, metatarsus varus, and skewfoot are foot deformities characterized by forefoot adduction. Metatarsus adductus involves medial deviation of the forefoot and a neutral or slightly valgus calcaneus. Metatarsus varus, although similar, is characterized by forefoot supination in addition to medial deviation. Skewfoot is a rigid deformity characterized by forefoot adduction, cavus, equinus, and varus. Presentation varies from mild, moderate, to severe, determined by the ability to actively (mild) or passively (moderate) correct the foot, or without correction (rigid). Forefoot adduction is seen in 1 of every 1,000 live births, increasing to 1 in 20 for subsequent children. Considered to be secondary to intrauterine positioning, the increased incidence with subsequent children has raised doubt as to potential in utero packaging problems. To date, no genetic cause has been demonstrated.

Clinically, the forefoot is medially deviated on the hindfoot, most notable when examining from the plantar surface and following the lateral border. Assessment of

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_410,

Figure 410.1

Figure 410.2

forefoot motion is essential to determine flexibility. Flexible deformities actively correct to neutral when the lateral border of the foot is stroked and passively correct beyond neutral. Partly flexible deformities only correct to neutral, while rigid deformities do not correct to neutral. Frequently accompanying metatarsus adductus, internal tibial torsion is the most frequent parent complaint, though this is unrelated to the foot deformity and should be dealt with separately. Radiographs are not necessary as this is a clinical diagnosis.

Flexible feet, demonstrated by active correction require no treatment. Parents are taught home stretching and stimulation exercises to improve active correction, however, the deformity will resolve spontaneously in nearly 90–95% of patients. Debate exists whether to treat passively correctable feet. Serial casting is initiated in children less than 6 months of age to passively correct the foot. Casting is followed by reverse or straight last shoes to maintain correction and avoid recurrence. Rigid feet should begin with serial casting between 4 and 6 months of age followed by stretching, with gradual correction over a period of months. Surgery is rarely necessary, although older children with chronic deformity, pain, and difficulty in shoe wear may require intervention.

Talipes Equinovarus

Talipes equinovarus, or clubfoot, occurs in 1 to 2 in 1,000 births. Comprised of cavus, metatarsus adductus, hindfoot

Figure 410.3

varus, and equinus (*CAVE*), clubfoot is more common in males (M:F, 2.5:1) and may be bilateral 50% of the time. Usually recognized during the newborn exam (*Fig. 410.3*), clubfoot varies from a benign, flexible deformity to a severe, rigid foot. The etiology of clubfoot is multifactorial as numerous causes including intrauterine factors (positional compression, oligohydramnios), vascular abnormalities (hypoplasia or absence of the anterior tibial artery), abnormal muscle insertion and development (increase in the type I: type II muscle fiber ratio, muscle fibrosis, anomalous muscles), and environmental factors (amniocentesis, cigarette exposure) have been implicated. Genetic factors play a role in clubfoot development. A positive family history is present in 25% of children with clubfeet and both siblings are affected in 32.5% of monozygotic twins. More severe forms of clubfoot are seen in diseases involving the nervous system, most notably myelomeningocele and arthrogryposis, as well as rare disorders such as spinal muscular atrophy, sacral agenesis, Trisomy 18, and Larsen's Syndrome.

A complete physical examination is critical to discover associated conditions. Typically, patients present with a smaller calf and foot on the affected side, most notable in unilateral involvement. This is a permanent difference and will not change with intervention. Dimpling of the skin, due to loss of subcutaneous fat, and contractures suggest arthrogryposis. Hindfoot equinus and varus results from the calcaneus "locked" position under the talus and a tight heel cord. This results in talar deformity, evidenced by a foreshortened talar head, medial angulation of the neck, and tilting of the body. The forefoot is adducted as the navicular is situated medially relative to the talus. The Dimeglio classification system was developed to score to the physical findings of the foot (hindfoot varus, calcaneopedal rotation, equinus, forefoot adduction, medial and posterior skin crease, cavus, and muscle tone) and correlates with severity. Radiographic examination is usually not required and is limited secondary to difficulty positioning the foot, lack of ossification, rotational distortion, and inability to bear weight. Older children amenable to radiographs demonstrate on anteroposterior (AP) radiographs, a talocalcaneal angle (Kite's Angle) of less than 20° (normal 25–45°) and medial displacement of the cuboid ossification center, while the lateral talocalcaneal angle is less than 35° (normal 35–50°).

Nonoperative methods are the gold standard when initiating treatment for clubfoot. Two distinct modalities exist to treat deformity in the infant patient, the French physiotherapy method composed of stretching, manipulation, and taping, and the Ponseti method, which involves serial casting. Physiotherapy focuses on stretching the soft tissues through longitudinal traction, attempting to reduce the talonavicular joint. Taping and continuous passive motion maintains stretch and correction of the foot, with successful results 90–95% of the time.

The Ponseti method involves serial long leg plaster casting, changed weekly to gradually correct the deformity. Percutaneous Achilles tenotomy is required over 70% of the time. Ponseti casting yields over 90% success, although there can be up to 50% recurrence, despite casting up to 2 months. Some form of bracing is usually used for 2 or 3 years after casting to prevent recurrence. Results with bracing, casting, and percutaneous heel cord lengthening have increased success to greater than 95%. Nonoperative treatment is not without complications. Pressure sores are common, as are iatrogenic deformities such as a flat-top talus (excessive dorsiflexion compresses talus between tibia and calcaneus), rocker-bottom foot (forced dorsiflexion of forefoot attempting to correct equinus prior to forefoot adduction and heel varus), and a bean-shaped foot (correction of adduction is attempted before varus).

When nonoperative treatment fails, soft tissue releases are often attempted first to correct the deformity, especially in the skeletally immature child. Surgery may be performed anytime after 6 months, although, waiting until the child is a year old permits easier surgical anatomy and allows the child to be closer to walking age. Operative complications increase with the severity of deformity. Almost 10% of patients require revision surgery. This is often predicated on patient complaints of pain, cosmesis, or difficulty in shoe wear. Resistant deformities may require osteotomies of the calcaneus, cuboid, and cuneiforms in the near or skeletally mature foot. Triple arthrodesis, limited talonavicular arthrodesis, and Ilizarov external fixation are used for salvage reconstruction.

Sever's Disease

Calcaneal apophysitis is a common cause of foot pain in young immature athletes. The age of onset is 8–13 years old, coinciding with ossification and subsequent fusion of the apophysis to the calcaneus. Sixty percent of patients have bilateral involvement. The condition is more common in males, and can be as high as 4 to 1. The etiology of Sever's is unknown, although repetitive traction injuries at the Achilles tendon or plantar fascia insertion is thought to lead to disruption of endochondral bone formation as the apophysis attempts to heal, leading to inflammation and pain.

History and physical examination reveals complaints of pain after athletic activity, located on the plantar or plantar-medial aspect of the foot, especially with prolonged activity. Similar to plantar fasciitis, pain or stiffness upon awakening is also common. Symptoms are common at the start of the season or a new sport. Cessation of sports leads to immediate comfort. Squeezing the heel reveals tenderness of the plantar or medial aspect of the calcaneal apophysis. The Achilles tendon is almost always tight. The differential diagnosis includes stress fracture, infection, inflammatory arthropathy, and calcaneal tumor (unicameral bone cyst, osteoid osteoma). Radiographs are typically not necessary; however, weight-bearing radiographs are obtained to exclude other pathology, especially with a history of night or unilateral pain. Increased density and fragmentation of the calcaneal apophysis may be present, although the former is a normal radiographic finding in children.

Treatment involves activity modification, and Achilles tendon stretching. Some patients benefit from gel heel cups to decrease impact trauma to the plantar portion of the apophysis. Rarely is casting or discontinuation of athletic activity necessary except for extreme cases, although some patients may need to limit their participation during acute exacerbations. Immobilization with a cast or walking boot results in complete resolution in patients refractory to activity modification and physical therapy.

Kohler's Disease

Kohler's disease is an uncommon, self-limiting, avascular necrosis of the navicular. Affecting children between the ages of 2 and 9, this idiopathic condition is usually unilateral and more common in boys. The repetitive compressive forces on the navicular during weight bearing may lead to avascular necrosis, secondary to delayed ossification, and vulnerable peripheral blood supply.

Patients primarily complain of midfoot pain, often exhibiting a limp, and weight bearing on the lateral border of the foot to relieve pressure along the longitudinal arch. Navicular tenderness and swelling may be present, and contraction of the posterior tibialis tendon exacerbates pain. Radiographs of the navicular demonstrate sclerosis, flattening, and a loss of the normal trabecular pattern evidenced by a uniform increase in density, fragmentation, or collapse.

The mainstay of treatment is conservative, consisting of arch supports, medial heel wedge, and activity modification in symptomatic patients. Severe, persistent pain may be treated in a short leg walking cast for 4–8 weeks, followed by orthotics. Immobilization has decreased the duration of symptoms and morbidity and is universally effective in relieving symptoms. The prognosis is excellent as the navicular regains its normal architecture before the foot completes growth, thus patients can be expected to have a normal foot in adulthood. Operative treatment is rarely necessary.

Flatfoot

Flatfoot, or pes planus, is one of the most common conditions seen in pediatric orthopedic practice, present in 1 in 1,000 live births and nearly 25% of the adult population. It has been described as, "usual in neonates and infants, common in children, and within the normal range in adults." Characterized by loss of the medial arch and increased weight bearing on the medial border of the foot, children and adolescents are often brought in by parents, potentially under the perception the deformity will be associated with pain in adulthood. Differentiating the benign, flexible from the painful, rigid form is essential to determine the need for treatment.

Nearly all neonates and infants have the appearance of a flatfoot, owing to excessive fat and lack of development of the arch, which normally begins by age 5. The infant with a calcaneovalgus foot will have a flexible flatfoot that easily dorsiflexes against the tibia, and a heel in valgus. The anatomy is normal, however it is important to ensure the patient does not have a vertical talus or posteromedial bowing of the tibia. Gentle stretching into plantar flexion and inversion can be performed, and most deformities will resolve by 6 months. Patients with posteromedial bowing of the tibia will have a limb-length discrepancy, most likely not requiring treatment.

The older child and adolescent may not have an arch when weight bearing, however the flexible flatfoot arch reconstitutes when the child stands on their tiptoes. Heel cord tightness may be responsible for the deformity and make the hypermobile flatfeet symptomatic. Inspection of the shoes may demonstrate a lack of lateral heel wear, further indicating a tight heel cord. Gait should always be evaluated for suggestion of a neuromuscular cause (cerebral palsy, poliomyelitis, peripheral neuropathy, Duchenne's muscular dystrophy). Failure of the arch to reconstitute upon toe raising signals a rigid deformity, as seen with congenital vertical talus (rocker-bottom deformity more common), tarsal coalition, and skewfoot. Often, these conditions are typified by limited subtalar motion, pain, and difficulty with activity.

Diagnostic radiographs are rarely indicated for a flexible flatfoot. If radiographs are obtained, they should be weight bearing. The most important reason to obtain radiographs is to establish other diagnoses causing the deformity and not to relieve parental concerns when a flexible flatfoot is evident.

The majority of patients are asymptomatic, thus treatment is rarely indicated other than parental reassurance. Heelcord tightness can be stretched manually or with serial casting. Though many children rebuff inserts, orthotics are often tried despite evidence that the long-term outcome remains unchanged. The most inexpensive orthotics should be tried first since custom inserts can be costly and often are not covered by insurance. Surgical treatment has been described for pain and persistent deformity, although this is rarely required. Subtalar or triple arthrodesis has been effective in relieving symptoms, albeit at the expense of subtalar and hindfoot motion. Calcanealcuboid and medial cuneiform osteotomies, as well as lateral column lengthening, have yielded good results while preserving joint motion.

Accessory Navicular

The accessory navicular is an ossicle on the medial side of the midfoot, proximal to the navicular and in continuity with the tibialis posterior tendon. Commonly, 20% of normal feet have an accessory navicular, lending to the thought it is a normal anatomic and radiographic variant. Considered idiopathic, accessory navicular is frequently observed in multiple family members and an autosomal dominant inheritance pattern with incomplete penetrance has been described. Patients are typically active adolescents with a flexible flat foot, often presenting with a painful prominence and swelling on the medial arch of foot at the region of the navicular. The prominence may be associated with erythema, callus formation, tenderness, and a fluid-filled bursa. Inversion against resistance may elicit pain at the prominence and along the tibialis posterior tendon and is considered diagnostic. Shoe wear may become increasingly difficult, often aggravated by tight shoes. The differential diagnosis for medial midfoot pain should include: Kohler's disease, tibialis posterior tendon rupture, enthesiopathy of the tibialis anterior tendon, and navicular stress fracture.

Three types of accessory navicular have been classified. Type 1 has an ossicle within the tibialis posterior tendon, anatomically separate from the navicular; type 2, a cartilaginous bridge between ossicle and navicular; and type 3, where the accessory ossicle fuses to the navicular. Weight-bearing AP and lateral foot radiographs and an external oblique view demonstrate the accessory ossicle, aiding in classification and guiding treatment (*Fig. 410.4*). Computed tomography (CT) scans are used to differentiate the accessory ossicle from the navicular, although are not routinely needed. Bone scan and magnetic resonance imaging (MRI) may be helpful when the etiology of medial foot pain is unclear.

Treatment for asymptomatic accessory navicular is not required. A painful prominence or difficulty with shoe

Figure 410.4

wear should be treated initially with a doughnut-shaped piece of mole skin and comfortable wide-based shoes. Longitudinal arch supports may relieve pressure over the medial arch and resist pronation of the foot. Cast immobilization for 6–8 weeks may be warranted for severe pain. Although less than 1% requires surgery, failure of conservative measures leads to operative intervention to relieve the persistently symptomatic accessory navicular. Traditionally, excision of the accessory ossicle and transfer of the tibialis posterior tendon plantarly have been successful in relieving pain. A painful scar may result if placed directly over the symptomatic prominence, and care must be taken to keep the tibialis posterior tendon intact. Good results with pain relief and fatigue are expected in patients having undergone excision; however correction of the flatfoot may require a bony procedure such as lateral column lengthening to restore the medial arch. Percutaneous drilling of the accessory navicular bone has shown to be efficacious in young athletes, though most continue to advocate simple excision for a symptomatic accessory navicular.

Tarsal Coalition

Tarsal coalition is an abnormal connection in the hindfoot, a result of failure of segmentation of mesenchymal tissue with subsequent failure of formation of normal joints. Previously called the peroneal spastic flatfoot, the peroneals are neither a cause nor result in a coalition. Coalitions may be fibrous, cartilaginous, or osseous, and they are observed in 1–3% of the population. The etiology is unknown although a family history is observed and autosomal dominance with variable penetrance has been reported. Calcaneonavicular coalition occurs in 60%, while bilateral talocalcaneal coalitions occur in 50% of cases. Coalitions are associated with symphalangism, fibular hemimelia, proximal femoral focal deficiency, phocomelia, Apert syndrome, and Nievergelt–Pearlman Syndrome.

Symptoms typically develop during adolescence and skeletal maturity, appearing after a traumatic event or with increased activity, though many patients are asymptomatic. Ossification of a bony coalition may decrease subtalar motion, resulting in symptoms. Often there is a history of sprains, and walking over uneven ground exacerbates symptoms primarily through stressing the subtalar joint. Pain may be located in the sinus tarsi or along the peroneal tendons. Decreased subtalar motion is present as evidenced by decreased passive inversion and eversion, less evident with calcaneonavicular than talocalcaneal coalitions. The foot is often everted and pain is present with resisted inversion. Patients are unable to stand on lateral border of their foot and no inversion of the heel is evident when attempting to stand on the toes. Tarsal coalition is differentiated from a flexible flatfoot by examining hindfoot range of motion.

Radiographs should include weight-bearing AP and lateral foot films. For coalitions difficult to visualize on plain films, computed tomography (CT) is performed. A coronal CT scan is the preferred method of diagnosis for talocalcaneal coalition and a longitudinal CT scan is preferable to identify a calcaneonavicular coalition, and should include both feet since 50% will be bilateral.

Initially, conservative treatment is required for any patient. Patients with incidental findings do not require treatment, but should be followed. Patients with minor

pain may try orthotics. Short-leg walking casts are attempted for severe symptoms, often followed with a University of California Berkley Laboratory (UCBL) insert. Surgery is indicated for persistent pain and failure of conservative treatment. A calcaneonavicular coalition is treated with resection and interposition of extensor digitorum brevis or fat. This portends good results in 80% of patients. Younger patients fare better due to increased potential for return of joint mobility, with the best results observed in patients with a cartilaginous coalition less than 16 years old at the time of surgery. Anecdotal results of subtalar arthrodesis are good or excellent in nearly 80% of patients, though published reports have yet to support these results. Surgery of talocalcaneal coalitions are not as predictable as with calcaneonavicular coalitions. Subtalar joint motion needs to be assessed after resection as the goal of surgical treatment is to provide increased subtalar motion. Unresectable coalitions, commonly involving greater than 50% of the subtalar joint usually require triple arthrodesis. If coalition resection fails to relieve symptoms or degenerative changes are seen at presentation, a triple arthrodesis is the salvage procedure.

Pediatric Hip Disorders

Apophyseal Avulsion Injuries

Skeletally immature patients frequently suffer avulsion injuries about the pelvis due to weakness of the open apophysis. Avulsion fractures commonly occur at the anterior superior iliac spine (ASIS), the anterior inferior iliac spine (AIIS), and the ischial tuberosity as a result of sudden contraction of the sartorius, rectus femoris, and hamstring muscles, respectively. Patients often describe feeling a pop at the time of injury (e.g., kicking a ball) and frequently present with localized pain and swelling. Radiographic examination is important to determine the size and displacement of the avulsed fragment. These injuries are usually managed conservatively, including rest, ice, protected weight bearing with crutches, and gradual stretching and return to activity once symptoms resolve. Although most of these injuries can be treated non-operatively, large fragments displaced more than 2–3 cm may require surgical intervention.

Snapping Hip Syndrome

This syndrome has both external and internal etiologies. The *external form* is more common and involves snapping of the iliotibial (IT) band over the greater trochanter with hip flexion and extension. The snapping is further accentuated with knee extension and hip adduction, which serves to tighten the IT band. With the development of pain, conservative treatment is pursued, including rest, IT band stretching, and nonsteroidal anti-inflammatory medications. The *internal form* of this condition stems from the catching of the iliopsoas tendon on the pelvic brim (iliopectineal eminence) or the femoral head. This occurs with hip extension and may be associated with chronic bursitis. A similar treatment protocol is employed as for external snapping.

Iliotibial (IT) Band Syndrome

This condition commonly occurs in runners and dancers and is due to friction between the iliotibial band and the lateral femoral condyle. While some patients complain of knee pain, patients more often have tenderness localized to the greater trochanter due to rubbing of the iliotibial band. The ober test is used to evaluate for contracture of the IT band. During this test, the patient lies on the normal hip, while flexing the affected hip and knee. Abduction and extension of the hip from this position centers the IT band on the greater trochanter. Adduction will be limited in the case of IT band contracture. Patients often improve with conservative measures, including rest, iliotibial band stretching, and nonsteroidal anti-inflammatory medications.

Pediatric Knee Disorders

Osgood-Schlatter Disease

Osgood-Schlatter Disease (OSD) is a common knee problem in children between the ages of 10 and 15 years. The condition often occurs in sports such as soccer, basketball, gymnastics, and volleyball and is thought to result from repetitive microtrauma or a traction apophysitis of the tibial tuberosity. Athletes usually report intermittent anterior knee pain and swelling, made worse with activity. The low-grade ache is usually localized to the area of the tibial tubercle. Thirty to forty percent of adolescents with OSD report bilateral symptoms. Examination reveals tenderness and swelling over the tibial tubercle, while the remainder of the knee exam is usually normal. Radiographs are not generally indicated; however, they may reveal prominence or fragmentation of the tubercle or even a discrete ossicle. MRI or advanced imaging is rarely necessary.

Management consists largely of conservative measures including use of nonsteroidal anti-inflammatory drugs, rest from activity, and stretching of the thigh

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_411,

musculature. Patients may benefit from physical therapy at the time of diagnosis. If ambulation is difficult, crutch ambulation may be used with a knee immobilizer before the athlete initiates a stretching and strengthening program. If a patient experiences severe symptoms, a cylinder cast may be used with crutch ambulation for 2–4 weeks. OSD typically resolves within 6–18 months, coinciding with growth plate closure. Symptoms may recur with resumption of sports activities and can require a repeat cycle of rest from activity, stretching, and strengthening. The condition is usually self-limited, ceasing with the completion of growth and the fusion and maturation of the tibial tubercle. Following skeletal maturity, those patients with residual symptoms and loose fragments within the patellar tendon may require surgical excision.

Sinding–Larsen–Johansson Syndrome

Sinding–Larsen–Johansson Syndrome is thought to be due to an overuse injury at the junction of the developing patella and patellar tendon. It occurs most commonly in boys aged 9–13 years and is often associated with sports involving running or jumping, stair climbing, or repetitive kneeling. This condition is similar to jumper's knee (patellar tendinosis), which occurs in skeletally mature athletes. Jumper's knee involves a partial tear of the deep layers of the proximal patellar tendon and tends to be difficult to treat. Patients with Sinding–Larsen–Johansson Syndrome will often complain of anterior knee pain, worsened with activity. Physical examination reveals tenderness at the distal pole of the patella and insertion of the patellar tendon. As in Osgood-Schlatter disease (OSD), these athletes frequently have tight, relatively weak quadriceps. Radiographs often show fragmentation with ossicle formation, elongation of the distal pole of the patella, or small calcifications in the proximal patellar tendon. Fragmentation may also represent a patellar sleeve fracture, which is usually acute and associated with a specific traumatic event. Patients with patellar sleeve fractures require referral to a pediatric orthopaedist for surgical repair. MRI or other forms of advanced imaging are not necessary. Management is similar to OSD, focusing mainly on pain control, rest from activity, cross-training, and stretching and strengthening of the quadriceps. This condition is usually self-limited; however, severe symptoms may necessitate immobilization to promote healing prior to initiating muscular rehabilitation.

Patellofemoral Syndrome

Patellofemoral pain is extremely common in adolescent female athletes and may stem from conditions such as patellofemoral dysplasia or patellofemoral instability. This condition is often associated with activities that increase load across the patellofemoral joint, including squatting, running, stair climbing, and kneeling. The etiology of patellofemoral disorders is usually multifactorial. Several structures including the anterior synovium, infrapatellar fat pad, subchondral bone, and medial or lateral retinaculae are among those considered most likely to be the origin of patellofemoral pain. The development of this condition has also been associated with abnormal lateral tracking of the patella within the trochlea, creating areas of increased stress on the patellofemoral joint. Changes in forces across the patella may be related to rapid growth during adolescence, the strong lateral pull of the vastus lateralis and iliotibial band, or quadriceps tightness, all of which can lead to the onset of anterior knee pain and instability.

Athletes with patellofemoral syndrome usually describe a vague, aching pain on the anterior aspect of the knee, which is worse with sports activity or prolonged sitting with the knee flexed. There are rarely any associated mechanical symptoms of locking and catching. Patients often complain of pain with patellar compression during quadriceps contraction and pain with resisted extension. It is important to evaluate the alignment of the quadriceps, patella, and tibial tubercle both passively and actively, as malalignment problems are common, treatable causes of anterior knee pin. A line drawn through the center of the patellar tendon from the patella to the tibial tuberosity defines the patellar tendon vector; whereas a line from the anterior superior iliac spine to the patella defines the quadriceps vector. The angle formed by the junction of these two vectors is known as the quadriceps or Q angle. Several factors can influence the Q angle, including the patient's height, the degree of knee valgus, and the width of the pelvis. A Q angle of greater than 20° causes lateral patellar tracking and subsequent stress on the trochlear groove and the lateral aspect of the patella, often leading to anterior knee pain. In the office, these patients should undergo a thorough examination of the lower extremity evaluating specifically for femoral internal rotation, genu valgum (knock-knees), tibial external rotation, and pes planus (flat foot), since each of these conditions can lead to an increased Q angle (*Fig. 411.1*).

The mainstay of treatment for patellofemoral syndrome is nonoperative and requires avoidance of exacerbating activities. Ice and nonsteroidal anti-inflammatory

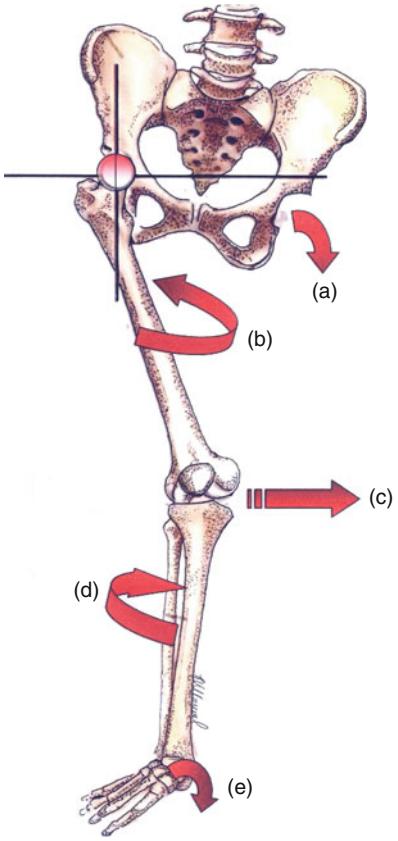

Figure 411.1
Schematic representation of potential causes of limb malalignment and malrotation, all of which can lead to increased Q angle: (a) hip adduction, (b) femoral internal rotation, (c) genu valgum, (d) external tibial rotation, (e) pes planus (flat foot)

drugs can be used to control pain. Physical therapy is frequently utilized to restore patellar alignment through quadriceps muscle strengthening exercises, stretching, patellar taping or bracing, biofeedback, and use of corrective foot orthoses. A neoprene knee sleeve or patellar stabilizing knee brace worn during athletic activity may be helpful. Surgical intervention is rarely warranted, usually reserved for those with a defined lesion that's amenable to surgical repair.

Patellar Dislocation

Patellar dislocation is a common acute knee injury in children and adolescents, with a peak incidence at age 15 years. There are several predisposing factors including a positive family history, patellofemoral dysplasia, and female gender. Acute patellar dislocation occurs more often in female athletes and is thought to be due to a higher incidence of lower extremity valgus and rotatory malalignment in women. Athletes will typically describe the injury as a "knee dislocation." The mechanism usually involves a flexion, twisting injury with the foot planted. Often, the patella will spontaneously reduce. When it remains dislocated, athletes will complain of extreme pain and an inability to extend the knee. The laterally displaced patella can usually be reduced with knee extension. Following reduction, physical exam often reveals significant swelling and tenderness along the medial aspect of the knee along the torn retinaculum. MRI is not required on initial presentation, although it can be useful to rule out cartilaginous fracture fragments. Radiographs of the knee, including Merchant or sunrise view, should be obtained to confirm reduction and to assess for osteochondral fractures. These injuries commonly occur on the medial side of the patella after lateral dislocation. Patellar dislocation can also lead to tearing of the medial patellofemoral ligament (MPFL), which is the primary restraint to lateral displacement of the patella.

Treatment following reduction should include a brief period of knee immobilization. A patellar stabilizing brace or taping can be substituted for the immobilizer after a period of 1–2 weeks. The athlete should begin a dedicated rehabilitation protocol immediately, including quadriceps strengthening, stretching, and coordination exercises. Gradual resumption of aerobic activities can follow with avoidance of activities involving twisting and cutting until full strength and motion have been attained.

Surgical repair is often recommended for recurrent dislocations, injuries with large associated osteochondral fractures or, rarely, in the high-demand athlete after a first-time dislocation. Patients with atraumatic patellar dislocations often have underlying ligamentous laxity or patellofemoral malalignment. Nonsurgical treatment is usually recommended in this group of patients, although surgery is required in extreme cases.

Baker's Cyst

The term "Baker's cyst" is commonly used to describe cysts occurring on the posteromedial aspect of the knee between the medial head of the gastrocnemius and the semimembranosus tendons. In adults, popliteal cysts have a high association with intra-articular lesions including rheumatoid arthritis, osteoarthritis, meniscal tears, and conditions that cause synovitis. In children, this is rarely

true, as most arise spontaneously. Baker's cysts commonly present as a mass in the posteromedial aspect of the knee. In children, these masses are usually asymptomatic and are brought to the attention of the pediatrician when the parent is concerned about the swelling or bulge in the popliteal fossa. Popliteal cysts can rupture suddenly, producing significant pain behind the knee and swelling extending down the calf region. Radiographs are frequently normal, but may occasionally reveal some soft tissue swelling. Ultrasonography is a common, noninvasive technique for evaluating popliteal cysts, and is helpful to rule out non-cystic masses. In children, popliteal cysts are often benign and self-limited, requiring no specific intervention.

Osteochondritis Dissecans of the Knee

Osteochondritis dissecans (OCD) can cause anterior knee pain in children and adolescents. OCD primarily affects subchondral bone, with secondary effects on articular cartilage. The etiology of this condition is unclear, but several hypotheses have been proposed including inflammation, genetics, ischemia, ossification, and repetitive trauma. The most commonly proposed etiology of OCD is repetitive microtrauma, which may stimulate a stress reaction, ultimately progressing to a stress fracture of the subchondral bone. Persistent loading may prevent the subchondral bone from healing, leading to fragment necrosis, dissection, separation, and nonunion. The "classic" location of knee OCD lesions is the posterolateral aspect of the medial femoral condyle (70–80% of cases), but it may also occur in the femoral trochlea (<1%), the patella (5–10%), and the lateral femoral condyle (15–20%). This condition most often presents in patients between ages 10 and 15 years, with a 2:1 male to female ratio. In 15–30% of cases, bilateral lesions are discovered, emphasizing the need to evaluate both knees in patients presenting with OCD.

There are two distinct forms of osteochondritis dissecans, juvenile (open physes) and adult. In the skeletally immature patient, there may be a disturbance in normal epiphyseal development, leading to formation of small areas of subchondral bone that separate from the main ossification center of the epiphyseal plate. Minimal trauma may then lead to osteonecrosis in this area. The adult form may result from a direct traumatic event or perhaps it represents a delayed presentation of a previously asymptomatic juvenile OCD that failed to heal. Fifty percent of patients with juvenile OCD demonstrate healing within 6–18 months of nonsurgical treatment; whereas, patients with adult OCD more often require surgical intervention to promote healing.

Patients usually present with vague anterior knee pain, occasionally associated with intermittent swelling. Adolescents with stable osteochondritis dissecans may ambulate with an antalgic gait; however, there is usually no effusion, crepitus, or pain through normal range of motion. Unstable lesions are often associated with persistent swelling and symptoms of catching, locking, or giving way. The Wilson test, which attempts to reproduce the knee pain by internally rotating the tibia during knee extension from 90° to 30° and subsequently relieving the pain with external rotation of the tibia, is often positive.

Standard weight-bearing anteroposterior and lateral radiographs of both knees should be obtained to assess growth plate status and to characterize the lesion. Since the "classic" location of osteochondritis dessicans can be difficult to visualize on the AP radiograph, tunnel views or flexed knee views can often provide valuable information. If patellar OCD is possible, skyline views should be obtained. Magnetic Resonance Imaging (MRI) has become a valuable tool in the diagnostic evaluation of OCD, providing an estimation of the size of the lesion as well as the status of cartilage and subchondral bone. Several additional findings including presence of loose bodies, extent of bony edema, and a high signal zone beneath the fragment are also important pieces of information revealed on MRI. The presence of an area of high signal intensity behind the osteochondral fragment is most indicative of an unstable lesion; whereas stable lesions are defined by the absence of any signs of dissection.

Skeletal age at the time of symptom onset is the most important factor in determining prognosis and guiding the overall treatment plan. Patients with open physes and stable lesions will likely recover with nonsurgical management, the goal of which is to promote lesion healing and to prevent fragment displacement. This treatment protocol consists primarily of activity modification, limited weight bearing (e.g., crutches or braces) for approximately 6 weeks, and non-steroidal anti-inflammatory medication (e.g., acetaminophen) for pain control. Immobilization in a cast should last no longer than 4–6 weeks and is reserved for noncompliant patients. Athletes are prohibited from participating in sports until they are pain free and physical examination as well as radiographs show evidence of healing. Surgical intervention is often required in unstable lesions or in stable lesions that have failed a period of nonsurgical management. Techniques such as in situ drilling, fixation, fragment removal, and chondral resurfacing are among the surgical procedures utilized.

Discoid Lateral Meniscus

Discoid meniscus, which refers to the presence of meniscal tissue across the entire tibial plateau, rather in a semicircular shape, occurs predominantly on the lateral side of the knee. Bilateral discoid menisci occur in approximately 20% of patients. Watanabe described a classification system for the discoid lateral meniscus. Type I menisci are complete, extending across the entire lateral tibial plateau. Type II menisci are incomplete, with the central portion of the meniscus stretching farther across the tibial plateau than normal. Type III menisci are referred to as the Wrisberg-ligament type, and lack attachment of the posterior horn of the meniscus to the tibia, resulting in instability.

Symptomatic discoid lateral meniscus occurs predominantly in children ages 10–15 years. Some athletes with this condition present with swelling, catching, popping, and tenderness over the lateral joint line. Symptoms are often related to the type of discoid meniscus, stability of the meniscus, and the presence or absence of a meniscal tear. Snapping knee syndrome is considered pathognomonic of a discoid meniscus and is often associated with the Wrisberg-ligament type. In these cases, the meniscofemoral ligament of Wrisberg provides the only stabilization to the lateral meniscus, which leads to increased mobility and shifting of the posterior horn of the meniscus into the femoral notch as the knee extends. Athletes often experience intermittent locking of the knee, as well as a palpable clunk as the knee moves through a full range of motion.

Plain radiographs of the knee are often normal, but may reveal a squared-off lateral femoral condyle, a widened lateral joint space, and cupping of the lateral aspect of the tibial plateau. Currently, MRI is the most accurate means of diagnosing a discoid meniscus. No treatment is indicated for asymptomatic discoid lateral menisci. For patients with stable, complete or incomplete discoid menisci, the first line of treatment is arthroscopy with partial meniscectomy or saucerization. Meniscal repair may also be indicated in the presence of a meniscal tear or instability. Traditionally, unstable discoid menisci were treated with complete meniscectomy; however, total meniscectomy in children has been shown to produce poor long-term results. Protected weight bearing and progressive rehabilitation is important to ensure complete recovery following surgical intervention.

ACL Injuries

Increased participation in high-demand sports by adolescent athletes has led to an increased frequency of ACL injuries in this patient population. Diagnosis has improved considerably with the heightened awareness of the injury and improved diagnostic tests. ACL tears in skeletally immature athletes occur secondary to both contact and noncontact mechanisms. Athletes often describe a "pop" with immediate inability to bear weight and swelling that resolves over several days. Patients may complain of diffuse pain; however, pain localized to the joint line or collateral ligaments may also be present in cases of associated bone bruise, meniscal or collateral ligament injuries. An effusion is often present as well as an inability to fully extend the knee. The anterior drawer and Lachman tests are usually positive, but can be difficult to elicit in an uncomfortable patient with muscle guarding.

On initial evaluation, plain radiographs are warranted to rule out physeal injury, osteochondral injury, fracture, or dislocation. MRI may be indicated to evaluate for ligamentous (*Fig. 411.2*), meniscal, and osteochondral injuries, especially in cases where physical examination is limited secondary to pain and swelling.

Nonsurgical management of ACL tears involves activity modification and a period of dedicated rehabilitation to restore knee range of motion. Several recent studies have indicated a failure of conservative treatment in this patient population, citing the risk for persistent pain and swelling, chronic instability, meniscal tears, chondral injury, and early-onset arthritis. For this reason, many surgeons support ACL reconstruction in skeletally immature patients.

Current recommendations for surgical reconstruction of ACL tears in skeletally immature athletes are based on

Figure 411.2
T2-weighted sagittal MRI image showing a proximal complete ACL tear in an 11-year-old male

skeletal age. Nonanatomic extraphyseal reconstruction is recommended in young children with substantial remaining growth; whereas partial transphyseal reconstruction is advocated in adolescents with decreased growth potential. Anatomic transphyseal reconstruction is recommended in adolescents nearing skeletal maturity.

Tibial Spine Avulsion Fractures

Tibial spine avulsion fractures result from a similar mechanism as with intrasubstance ACL tears and athletes may present with the same symptoms. Examination of the knee may reveal inability to fully extend secondary to both pain and displacement of the tibial spine into the femoral notch (*Fig. 411.3*). Displaced fractures require surgical repair. There is often residual laxity of the ACL following either nonoperative or operative fixation, secondary to stretching of the ACL at the time of injury.

Upper Extremity Injuries

Panner's Disease

Panner's disease, an osteochondrosis of the elbow capitellum, often presents in boys aged 5–12 without a history of repetitive throwing. This condition usually involves the dominant extremity and presents with symptoms of pain and stiffness in the elbow, aggravated by activity. This condition is not necessarily related to mechanical stress; however, adolescents may describe mild trauma or overuse. Examination reveals a small effusion and pain directly over the capitellum. Standard anteroposterior and lateral radiographs of the elbow may show fissuring or fragmentation of the capitellum. Panner's disease is often self-limited. Treatment includes cessation of activities that stress the radiocapitellar joint (i.e., throwing), immobilization, and anti-inflammatory medication. On resolution of Panner's disease, radiographs will reveal symmetrical ossification of the capitellum. Symptoms may persist for several months; however, adolescents usually have excellent long-term results.

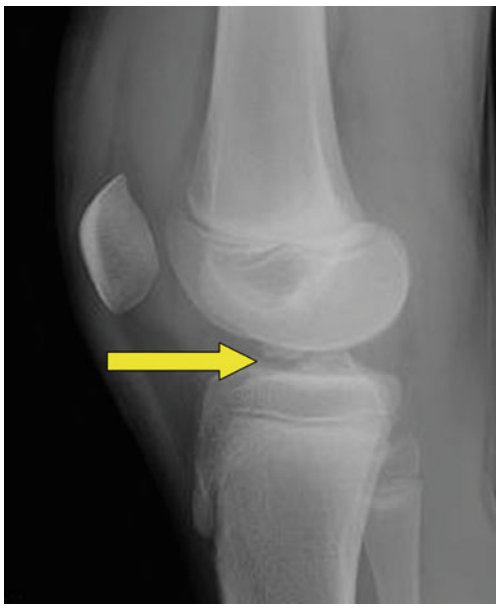

Figure 411.3
Lateral x-ray of the knee demonstrating a tibial spine avulsion fracture (*arrow*) in a 14-year-old male

Little Leaguer's Elbow

Little leaguer's elbow refers to a variety of conditions in adolescent throwing athletes, including osteochondritis dissecans (OCD) of the capitellum or radial head, olecranon apophysitis, and fragmentation or growth alteration of the medial epicondyle. The combination of a strong triceps contraction during the early acceleration phase of throwing and the movement of the olecranon into the humeral fossa during follow-through may lead to posterior elbow pain in throwing athletes (*Fig. 411.4*). Olecranon apophysitis, loose bodies, and avulsion fractures may occur as a result. OCD of the capitellum tends to occur in repetitive throwing sports, such as football or baseball. Frequent valgus stress, causing compression on the lateral aspect of the elbow, and pull on the flexor muscles in the forearm can lead to inadequate vascular supply of the subchondral bone and the development of OCD. Adolescents presenting with osteochondritis of the capitellum often complain of pain and an inability to fully extend the elbow. A report of catching or locking may indicate the presence of loose bodies within the joint. Examination may reveal a small effusion, tenderness directly over the capitellum, and crepitus with forearm rotation.

Radiographic evaluation includes anteroposterior and lateral radiographs of the affected elbow, as well as radiographs of the contralateral elbow for comparison. Findings on plain radiographs include irregular ossification of the capitellum, a fragmented border, subchondral lucencies, and loose bodies. In little leaguer's elbow, OCD typically affects the anterior aspect of the capitellum. MRI may be used in certain cases to completely define the lesion.

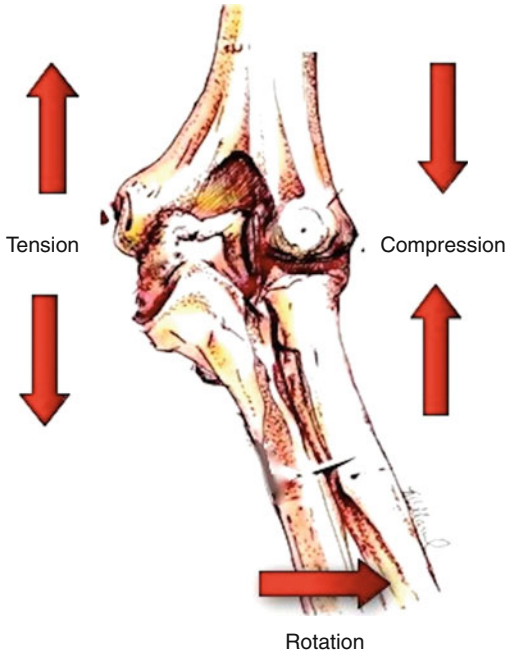

Figure 411.4
Schematic representation of the impact of valgus compression force on the elbow. The presence of valgus force pushes the olecranon against the medial aspect of the olecranon fossa, which may lead to osteophyte formation, chondral injury, and potentially the generation of loose bodies

For adolescents with a stable or mildly symptomatic lesion, conservative treatment is often appropriate, consisting of rest and immobilization. The athlete should refrain from all throwing activities until symptoms have resolved completely. Patients who continue to experience pain despite nonoperative treatment or those with displaced osteochondral lesions, loose bodies that cause catching or locking, or fractures of the articular cartilage will often require surgical intervention. Arthroscopy of the elbow is often performed to evaluate the articular surface and to remove any loose bodies. Subchondral drilling or fixation of the osteochondral fragment may also be performed at the same time. Rehabilitation following surgery includes strengthening and range of motion exercises.

Little Leaguer's Shoulder

Little leaguer's shoulder, also known as proximal humeral epiphysitis, occurs in male pitchers between the ages of 11 and 13. Although the exact etiology is unknown, it is thought to be related to repetitive overhead throwing and poor throwing mechanics. Patients complain of lateral shoulder pain with throwing. Examination may reveal tenderness and swelling over the lateral aspect of the shoulder as well as weakness with abduction and external rotation. Radiographs of the affected shoulder reveal widening of the proximal humeral physis. Treatment consists of activity modification and education on proper throwing techniques. Physical therapy is an important component of the rehabilitation and includes stretching and strengthening of the rotator cuff, periscapular muscles, and the shoulder capsule. Adolescent athletes can gradually return to play as symptoms resolve.

Shoulder Dislocation

Most shoulder dislocations in adolescent athletes are anterior and are due to trauma to the affected upper extremity. At the time of impact, the shoulder is usually in an abducted, externally rotated position. Prominence of the lateral acromion following shoulder dislocation may cause the shoulder to appear "squared off." The athlete often experiences severe pain and an inability to move the arm. In the absence of a physician or trainer with experience in shoulder reduction, the athlete's arm should be supported in a position of comfort for transport to an emergency room. Standard radiographs of the shoulder indicate the position of the humeral head as well as the presence of any fractures.

Management of a traumatic first-time dislocation in adolescents is controversial, although nonoperative treatment is the most commonly employed. Nonoperative treatment consists of immobilization in a sling for 1–2 weeks followed by 2–4 months of range of motion and strengthening exercises. Recurrence rates have been reported to be as high as 90% in patients younger than age 20, with rates dropping considerably for each subsequent decade. Rotator cuff tears occur very rarely in children or adolescents with shoulder dislocations. Patients experiencing recurrent instability or pain should undergo surgical repair consisting of either arthroscopic or open capsulolabral repair. Early specialty referral is important to discuss treatment options.

Although posterior dislocations are much less common, they can occur in collision sports (e.g., football, hockey) or following seizures. The mechanism of injury is a posteriorly directed force on a forward flexed upper extremity. Following dislocation, the arm is held in an internally rotated, adducted position. As with anterior

dislocations, reduction should not be attempted on the playing field in the absence of an experienced physician or athletic trainer. Nonoperative management is similar to that seen with anterior dislocations. Posterior shoulder dislocation can cause posterior labral tears, which may require surgical treatment.

Multidirectional instability is atraumatic and occurs primarily in adolescent female athletes (e.g., swimming, gymnastics). Patients report multiple episodes of painless subluxation with spontaneous reduction. Examination reveals increased shoulder translation in more than one direction as well as generalized ligamentous laxity. Radiographs are usually normal. Treatment consists largely of physical therapy, with a focus on strengthening the rotator cuff and periscapular muscles. A less commonly seen variation is the voluntary dislocator. These patients can control their dislocations and frequently are attention-seeking.

Growth Plate Fractures

Growth plate fractures involve physeal region at the end of the bone which is responsible for longitudinal development. Fractures involving the physis are common and occur due to the structural weakness of the cartilaginous growth plate relative to the adjacent bone. Like all fractures in the pediatric population, the capacity for successful healing is great, but the possibility of growth disturbance necessitates careful immediate and follow-up treatment. In addition, the proximity of growth plates to the end of the bone means that disruption of the joint surface can occur, and this requires careful reduction in order to prevent subsequent cartilage degeneration.

The physis consists of several layers of cartilaginous tissue that progress from a *resting zone* farthest from the center of the bone (diaphysis) to a *zone of provisional calcification* from which new bone arises. The physis thus allows for longitudinal growth by moving away from the diaphysis. A secondary center of ossification at the tip of the bone (epiphysis) gives the physis its characteristic radiolucent line appearance.

The Salter–Harris classification system is used to characterize physeal fractures (*Fig. 412.1*). Type I fractures occur through the plane of the physis, are typically not visible on x-ray, and heal predictably without growth disturbance or joint incongruity. Type II fractures begin through the physis and then exit through the flare at the end of the bone (metaphysis), leaving a fragment of bone that can generally be reduced back into place with manipulation. Type III fractures begin similarly through the physis but exit through the epiphysis, while Type IV fractures extend from the metaphysis to the epiphysis, crossing the physis. Type V injuries involve a crushing of the physis.

One large study of physeal fractures among American children found that the male-to-female incidence of fractures was 2 to 1 with the highest incidence among 11–12-year-old girls and 14-year-old boys.

Clinically, growth plate fractures present with pain, swelling, and deformity following a traumatic event. While at times the diagnosis is clear, sometimes the degree of deformity is not significant and adequate radiographs of the bone in question as well as joints above and below should be obtained to diagnose and characterize the fracture. For Type I and II fractures, x-ray imaging is usually sufficient, but Type III and IV fractures may require CT scanning to evaluate the degree of displacement and step-off of the articular surface. While Type I and II fractures can often be treated with cast immobilization (with or without manipulation), Type III and IV fractures may require operative reduction and fixation in order to maintain as close to an anatomic joint surface as possible.

Predicting growth plate injury is difficult but the likelihood increases with higher Salter–Harris classes. Physeal fractures require consistent follow-up in order to identify and monitor growth disturbance that can lead to angular deformity and/or limb length discrepancy. The degree of deformity is a function of the severity and location of injury as well as the years of growth remaining. Close monitoring will allow for interventions such as physeal bar resection or epiphyseodesis (induced growth plate closure) that can mitigate the functional impairment. Patients and their families should be counseled at the time of injury regarding the possibility of growth complications and necessity of vigilant follow-up.

Long Bone Fractures

Fractures of the shaft of the bone (diaphysis) in children are often amenable to closed manipulation and casting. Unlike adult bone, in which the surrounding periosteum is a thin soft tissue layer, pediatric periosteum is thick and robust, providing significant benefit in two key areas of fracture healing. First, it provides the underlying bone with a generous blood supply that brings the growth factors and signaling mechanisms necessary for the production of callus, or immature primary bone. Second, when a properly molded cast puts tension on the periosteum, it provides structural support to the fractured bone. High-energy injuries that significantly disrupt the periosteum, particularly in older children, may not have such advantages and therefore can require fixation to maintain an acceptable position until healing occurs.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_412,

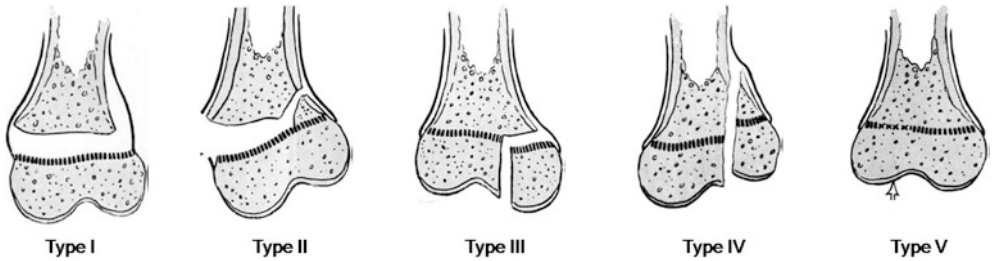

Figure 412.1
Salter-Harris classification system of physeal fractures

Table 412.1
Association with non-accidental trauma of various fractures

High specificity	Moderate specificity	Low specificity
Metaphyseal lesions	Multiple fractures	Clavicular fracture
Posterior rib fracture	Fracture of different ages	Long bone shaft fracture
Scapular fracture	Epiphyseal separation	Linear skull fracture
Spinous process fracture	Vertebral body fracture	
Sternal fracture	Digital fracture	
	Complex skull fracture	

The only absolute indication for surgery for a diaphyseal fracture is an open fracture, which requires adequate debridement and irrigation of the bone ends and often fixation as well. Otherwise, the need for surgery is determined by the ability to obtain and maintain a satisfactory reduction without an operation in terms of angulation, shortening, and rotation at the fracture site. Tolerance for deformity is a function the specific fracture site and the age of the child, with younger children more forgiving of deformity due to their ability to remodel bone with growth.

Options for fixation of long bone fractures include plate and screw constructs as well as flexible intramedullary rods that are inserted into the canal of the bone through small incisions away from the fracture site. Often, hardware is removed from pediatric patients following fracture healing although the necessity of this practice is controversial.

Non-accidental Trauma

Child abuse is an unfortunate reality in pediatrics, and orthopedic injuries are a common manifestation. The incidence of child abuse is difficult to establish and varies widely due to regional and reporting differences. The incidence of severe child abuse in one study from Wales (with fracture as an inclusive criterion) was 54/100,000 for children <1 year old, 9.2/100,000 for children 1–4 years old, and 0.47/100,000 for children 5–13 years old, while an Indian study of street children found that 36.6% of children reported severe or very severe abuse. In both studies, as in others, younger children experienced a higher incidence of child abuse.

In addition to a careful history surrounding the circumstances of an injury, certain findings should warrant extra vigilance in suspecting and reporting the potential for child abuse (*Table 412.1*). A retrospective study from Hong Kong found that of 29 patients with fractures from non-accidental trauma, 52% were under the age of 3, 38% had fractures of different ages, and 31% had inappropriate/contradictory histories. Many abused children will initially present with a fracture. There is a significant risk of further abuse, often resulting in further injury or even death. Lower extremity long bone fractures in children who are not yet walking, spiral fractures of the extremities, or unexplained injuries warrant referral to the appropriate child protective services.

413 Nasal Obstruction and Rhinorrhea

Mohamed O. Abuzeid

Introduction

Understanding nasal physiology and function is mandatory for the management of nasal obstruction and rhinorrhea. The nose plays a major role in the function of the respiratory system, including the warming, filtration, clarification, and humidification of inspired air. The nose is the sole area of olfaction and is also important in the resonance of the voice. When these functions are interrupted by disease, symptoms such as obstruction, rhinorrhea, anosmia, epistaxis, hyponasality, and cosmetic deformities result.

Several normal physiologic conditions of the nose are associated with obstruction and rhinorrhea without local or systemic diseases. They are seen more in older children and include paradoxic nasal obstruction, nasopulmonary reflex, puberty, menses, psychosomatic factors, and environmental causes. The etiology of nasal obstruction and discharge in disease includes congenital, inflammatory, traumatic (including foreign bodies), allergic, metabolic, neoplastic, and idiopathic causes. Other causes can occur in the nasopharynx.

Congenital Causes

Congenital disorders are caused by exogenous teratogenic elements or inherited genes. Two such disorders, total nasal agenesis (anasia) and proboscis lateralis, are very rare.

Choanal Atresia

This is the obstruction of the posterior nasal aperture. It is the most common congenital cause of nasal obstruction, with an incidence of one in 8,000 live births. A familial tendency has been noted. Choanal atresia may be unilateral or bilateral (*Fig. 413.1*), and complete or incomplete. The stenosis is bony rather than membranous in about 90% of cases. Unilateral atresia, usually recognized in later life, is twice as common as bilateral atresia.

As many as 50–70% of cases are associated with other anomalies as part of the CHARGE syndrome, which comprises

*C*oloboma of the iris and retina
*H*eart disease
*A*tresia choanae
*R*etarded development of the central nervous system
*G*enital hypoplasia
*E*ar anomalies with deafness

The diagnosis of CHARGE syndrome is made when four of the six categories are present. Other anomalies not included in the CHARGE categories are motor anomalies, seen in 26% of cases, and a single anomaly in 16%. Newborns are obligatory nasal breathers; therefore, cases with bilateral choanal atresia present with respiratory distress. Unilateral cases present with unilateral nasal obstruction and rhinorrhea.

The diagnosis of choanal atresia is suspected when a size five or six French feeding catheter fails to pass into the nasopharynx. Confirmation is obtained with a computerized tomography (CT) scan, which has superseded choanograms as the diagnostic imaging modality of choice.

Immediate therapy is mandatory. This involves placement of an oral airway such as a McGovern nipple and the institution of gavage feeding, followed by surgical intervention. Various surgical approaches, each with its own advocates, have been described. These include transantral and transnasal approaches using perforators and drills and, more recently, microscopic and endoscopic techniques. The transpalatal approach is the most common procedure used, despite the theoretical drawbacks of its adverse effect on maxillary development and the rare occurrence of oronasal fistulas.

Whatever method of approach is used, stenting the newly created passage is necessary. Stenting methods include placement of Silastic nasotracheal tubes fixed in different ways. The duration ranges from 4 week to 4 months. Endoscopic examination with frequent clearance and dilation has increased the success rate of patency and prevention of restenosing.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_413,

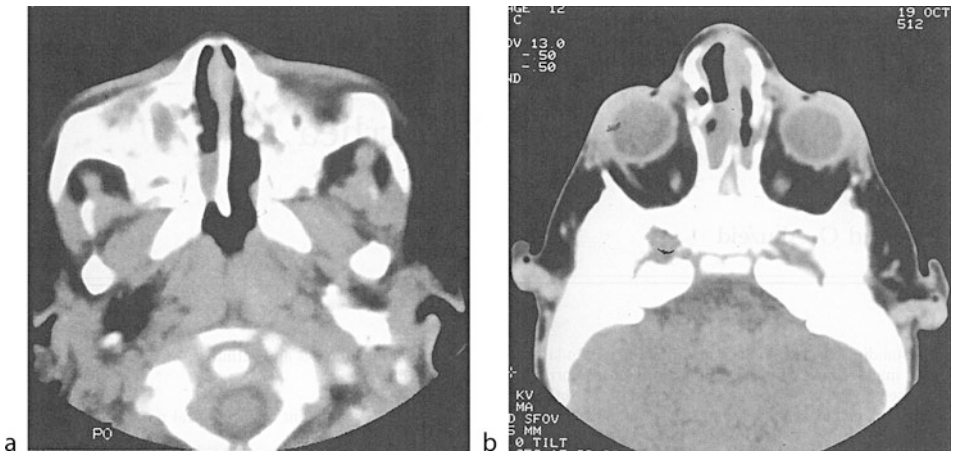

Figure 413.1
Axial computerized tomography scan of the choanal area showing (a) unilateral choanal atresia with fluid level in the left atretic side, and (b) bilateral bony choanal atresia with complete isolation of the nasal cavity from the nasopharynx

Congenital Nasal Deformity and Obstruction

Congenital nasal deformity and obstruction can occur as part of the various mandibulofacial dystocias, such as Crouzon disease and Treacher Collins syndrome. These are the result of intrauterine disturbance during the development of the first and second branchial arches. The obstruction occurs due to hypoplasia of the palate, maxilla, and molars. Nasoseptal deformities are seen in cleft palate deformities, causing alteration of endonasal structures.

Congenital Cysts

Congenital cysts, such as dermoid, nasoalveolar, nasolacrimal duct, dentigerous, and mucous cysts of the floor of the nose, can cause a degree of nasal obstruction. Nasal obstruction in the neonatal period can occur secondary to congenital cerebral herniation into the nose in the form of meningocele, meningoencephalocele, or encephalocele. These may lead to spontaneous cerebrospinal fluid (CSF) leakage.

Teratomas

Teratomas are congenital masses that contain ectoderm, mesoderm, and endoderm. These may include cartilage, bone, muscle, thyroid, and glial tissue. Radiologic evaluation is important before surgical removal is attempted.

Tornwaldt Cyst

Tornwaldt cyst is a diverticulum-like structure that lies in the midline of the posterior wall of the nasopharynx. It is seen in less than 3% of the population, and its origin may be related to the formation of a potential space between the pharyngeal epithelium and notochord remnants. The symptoms of nasal obstruction and headaches occur during periods of nasal inflammation. Lateral neck X-rays will show a distinct circumscribed soft tissue in the nasopharynx. Surgical excision or marsupialization is necessary for cure.

Traumatic Causes

Traumatic events are common causes of nasal obstruction in children, involving a blunt or penetrating trauma to the nose. It is important to diagnose and treat these deformities to prevent future complications, including nasal obstruction, possible malformation during facial and dental growth, and nasopulmonary pathophysiology.

Mucosal injury and mucostasis may lead to bacterial invasion, causing mucopurulent discharge with mucociliary damage and atrophic mucosa leading to rhinorrhea and nasal obstruction. This sequence, together with increased turbulence of the nasal air flow and stasis in the nose, results in the accumulation of allergens and other matter, causing more vasomotor, allergic, and inflammatory reactions.

Nasal obstruction can occur at any age due to traumatic events, but it may be asymptomatic in young infants

and neonates unless it is severe enough to cause respiratory distress in obligatory nasal breathers.

Perinatal Trauma

Nasal trauma may occur at birth during vaginal delivery with or without the use of forceps. Some septal deformity may be evident on careful examination in as many as 70% of newborns secondary to intrauterine or delivery trauma. In the acute traumatic period, intermittent bleeding, swelling, and nasal obstruction suggest the development of a septal hematoma. This is more common in children due to their thicker and more elastic mucoperichondrium, and is caused by the disruption of septal vessels. Throbbing pain and an elevated temperature indicate a septal abscess, which may lead to septal perforation if left untreated, due to the interruption of cartilaginous blood supply, leading to airway turbulence disturbance, obstruction, and rhinorrhea.

Foreign Bodies

Children younger than 3 years frequently stuff their noses with foreign bodies, causing intensive vasomotor reaction, rhinorrhea, and obstruction. If the object is left undetected for a period of time, purulent, offensive unilateral nasal discharge and obstruction are the main symptoms. Suctioning with the use of topical decongestants will make the diagnosis easier. If the removal of foreign bodies is not possible in an office setting, it must be done under general anesthesia. In all of these children, the other nostril and ears should be properly checked for further foreign bodies.

During the removal of a foreign body without a leading edge (e.g., a bead), the use of forceps will usually push it deeper into the nasal cavity rather than facilitate removal. The best method is to use a blunt hook, which can be slid along one of the nasal walls until the tip is beyond the foreign object, then turned 90° to pull the object out. Depending upon the type of the foreign body and the length of time, granulation tissue and concretions form around it, producing a rhinolith.

Differentiation of Cerebrospinal Fluid Leak

Special attention should be paid to differentiating between a CSF leak and rhinorrhea after trauma. A CSF leak usually occurs after skull base trauma and may be accompanied by CSF otorrhea presenting as rhinorrhea as it leaks along the Eustachian tube. Spontaneous CSF leak is not common. It indicates the presence of a variety of intracranial lesions (e.g., intrasellar tumors), and can be present in young infants secondary to congenital bone dehiscence.

The presence of CSF leakage is suggested by the history and nature of the nasal discharge. A unilateral clear, salty fluid after head injury is highly suggestive of this pathology, especially if it increases with change of position of the head, Valsalva maneuver, and internal jugular compression. The fluid can be tested rapidly using glucose oxidase-impregnated test sticks, bearing in mind that lacrimal or nasal secretions can give false-positive results. Biochemical analysis of the fluid for protein, glucose, and electrolytes will confirm the diagnosis. CT scans provide superior anatomic demonstration of the site of the bone dehiscence at the base of the skull. The treatment may be spontaneous healing, endoscopic repair, external exploration and repair, or neurosurgical approach and repair.

Inflammatory Nasal Disease

An inflammatory response of the nasal mucosa to infection, allergy, and chemical or toxic agents is the most common cause of nasal obstruction and discharge. The nasal response to this is a vasomotor reaction of the mucosa to bring specific antibodies, immunoglobulins, and lysozymes to the region as a defense action. The result of this response is an increase in surface area, congestion, and secretions, leading to obstruction and rhinorrhea.

An inflammatory response results in vasodilation and exudation of protein-rich fluid with migration of polymor-phonuclear leukocytes and monocytes into the nasal mucosal tissue. Recurrent episodes of infection result in abnormal motility and transport system of the cilia, with ultrastructural abnormalities; an increase in goblet cells and submucosal cells; and alteration of the periciliary fluid due to increased tissue leakage and increased mucous and purulent secretions due to microabscesses. These changes may take up to several weeks to heal after resolution of the inflammatory process. Chronic inflammation may be the end result.

Infectious Causes

Acute viral rhinitis or rhinopharyngitis (the common cold) is the most common cause of nasal obstruction and rhinorrhea in children. It is a self-limiting disease caused by a number of different viruses, including rhinovirus; adenovirus, which includes influenza and parainfluenza; respiratory syncytial virus; and Coxsackievirus A and B.

Chlamydia infection in newborns and infants can occur during birth, leading to conjunctivitis and pneumonia. A culture swab should be taken from children with nasal obstruction and rhinorrhea when *Chlamydia trachomatis* is suspected. Spirochetal infection is very rare nowadays, with the reduction of syphilitic cases caused by *Treponema pallidum*, either congenital or acquired. Other treponemal diseases, such as bejel, yaws, and pinta, are rare causes of nasal symptoms.

Fungal infection is more common than previously thought. Nasal and paranasal fungal infection should be suspected in debilitated, immunodeficient, or immunosuppressed children. Such infections occur more frequently with the use of chemotherapy or immunosuppressive drugs, as in organ transplantation. Mucormycosis and aspergillosis are the most common fungal infections. The diagnosis should be confirmed by biopsy and culture, as well as by microscopic examination. Early diagnosis and treatment are essential to prevent the serious complications of such infections.

Allergic Causes

Allergic rhinitis is another common cause of nasal obstruction and rhinorrhea in pediatric patients. It is due to the sensitized mast cells releasing mediators such as histamine, leukotrienes, thromboxanes, and prostaglandin. This response triggers the acute phase of allergic reaction, producing vasodilation, increased capillary permeability, and intense vasomotor reactions.

Nasal and Sinus Polyps

Nasal and sinus polyps are very rare in children and, if present, are the result of chronic inflammation of the mucous membrane of the nose and paranasal sinuses, manifested by hypersecretion and hyperplasias. This leads to polyp formation, representing a focal exaggeration of hyperplastic rhinosinusitis involving stromal binding of the intracellular fluids. Nasal polyps occur in allergies such as aspirin intolerance, intrinsic asthma, Young syndrome, cystic fibrosis, Kartagener syndrome, and ciliary dyskinesis syndrome.

Cystic Fibrosis

Cystic fibrosis (CF) is a generalized exocrinopathy that leads to pulmonary and pancreatic insufficiency. It is the most lethal genetic disorder in the white population. The CF gene has been localized to the q31 region of chromosome 7 and is responsible for the transportation of chloride in a transmembrane regulator. The sweat test is generally accepted as the most simple and reliable laboratory procedure for the diagnosis of CF. Sodium values in excess of 60 mEq/L are regarded as abnormal. A repeat test may be needed for highly suspicious cases with lower values.

Radiologic investigations include CT scan, which usually shows opacity with pansinusitis. A characteristic picture is an expanded maxillary sinus medially with accumulation of mucosequestral secretions, mostly in advanced cases. Medical treatment for nasal symptoms in CF includes the use of intranasal beclomethasone dipropionate.

Approximately 10–20% of CF cases will eventually require some form of surgical intervention for their sinus disease. The recurrence rate after nasal polypectomy alone is high, approaching 70% of cases. Combining nasal polypectomy with a sinus procedure such as Caldwell Luc, external ethmoidectomy, or endoscopic sinus surgery significantly reduces the recurrence rate. All of these measures result in symptomatic relief of nasal symptoms but do not eradicate sinus disease.

The most exciting area in CF research is gene therapy. The administration of CF transmembrane conductance regulator (CFTR) cDNA, using an adenovirus vector, offers promising results in correcting the CF genetic lesion and reversing the pathophysiologic abnormality of the nasal epithelium. It is anticipated that, with time, management of CF may be essentially medical except for management of disease-related complications, which will remain primarily a surgical matter.

Hypertrophy of Nasopharyngeal Adenoid Tissue

The most common cause of nasal obstruction in children is hypertrophy of the nasopharyngeal adenoid tissue. This part of the Waldeyer ring in the upper aerodigestive tract plays a key role in the development of the immune process. Adenoids are minimal at birth but rapidly increase in size, usually at 1–2 years of age, receding at puberty. They are continually exposed to nasal and paranasal secretions passing through the posterior choana to the nasopharynx, carrying antigens such as bacteria, viruses, and allergens. These lead to hypertrophy of the tissue as adenoids form their own complement of antibodies in response to these antigens. Such a reaction may occur with or without hypertrophy of the tonsils, and could lead to increased

nasal airway obstruction, resulting in alveolar hypoventilation. This results in a further pulmonary vasoconstriction with increased pulmonary vascular resistance and cor pulmonale.

Environmental Factors

Environmental factors are becoming increasingly important, especially in large, crowded, industrial cities. Inhaled substances act as chemical irritants, reacting with nasal mucosa and initiating a vasomotor response resulting in obstruction and rhinorrhea. Urban pollutants include carbon monoxide, ozone, nitrogen, aldehydes, ketones, chlorine, ammonia, sulfur dioxide, and hydrocarbons. The main sources of these chemicals are industrial waste, motor vehicle exhaust, and tobacco smoke.

Rhinitis Medicamentosa

Rhinitis medicamentosa is an iatrogenic cause of nasal obstruction in children. The causative over-the-counter medications include sympathomimetic agents and different topical decongestants that are applied locally. A nasal toxic reaction occurs due to the rebound phenomenon as the medications are used for longer periods than indicated in spite of enclosed labels and instructions. Examination of these patients usually demonstrates an edematous, erythematous, and thickened nasal mucosa. Therapy depends upon elimination of all vasoconstrictive nose drops and sprays, with an explanation of the problem to the patient and parents. Many patients could benefit from the institution of systemic antihistamines and a short course of topical or oral steroids. In patients with irreversible mucosal changes, turbinate surgery may be needed.

Neoplastic Diseases

Neoplasms of the nasal cavity are rare in children. These neoplasms may be ectodermal, mesodermal, neurogenic, or odontogenic in origin. Nasal obstruction and rhinorrhea with epistaxis are the most common presenting symptoms of nasal tumors, but are often overlooked because of their common occurrence in normal children. These symptoms occur early in nasal cavity tumors but are delayed in tumors of the nasopharyngeal and paranasal sinuses until the nasal cavity is affected. Primary congenital neoplasms such as angiomas, angiofibromas, hemangiopericytomas, and teratomas may present with these symptoms. Hamartomas, craniopharyngiomas, and chondromas are other recognized neoplasms, but they are quite rare in pediatric otolaryngology.

Juvenile nasopharyngeal angiofibromas are of special interest. These occur predominantly in males aged 7–17 years, with an average age of onset of 14 years. The symptoms are progressive obstruction and epistaxis of the involved side. CT scans with contrast and magnetic resonance imaging are essential for diagnosis. These modalities have eliminated the need for resorting to biopsy of the lesion, which could result in severe hemorrhage. The treatment of angiofibroma is primarily surgical, except when the cavernous sinus, pituitary gland, or optic chiasm is involved.

The incidence of nasopharyngeal carcinoma in childhood varies greatly according to geographic and racial factors. It represents less than 1% of childhood malignancy but constitutes 20–50% of pediatric malignancies of the nasopharynx (*Fig. 413.2*). The primary treatment is a full course of radiation therapy. The impact of chemotherapy on long-term survival remains uncertain.

Olfactory neuroblastoma is another rare tumor in pediatric patients. It presents with obstruction and epistaxis due to tissue destruction.

Figure 413.2
Axial computerized tomography scan of the nasopharynx showing a nasopharyngeal carcinoma in an 8-year-old child presenting with nasal obstruction

Miscellaneous Causes of Nasal Obstruction and Rhinorrhea

Rare causes of nasal obstruction include Wegener granulomatosis, systemic lupus erythematosus, scleroderma, rheumatoid arthritis, and psoriatic arthritis. Atrophic rhinitis (ozena, rhinitis fetida, or rhinitis crustosi) is a chronic progressive atrophy of the nasal mucosa leading to disturbance of normal streamlined airflow. It is characterized by a foul, smelly, green, crusted, and impacted nasal cavity. Nutritional deficiencies of vitamins and iron are blamed for this condition. Diagnosis is usually confirmed by isolation of *Klebsiella ozaenae* from the nasal cavity.

414 Pediatric Epistaxis

Mohamed O. Abuzeid

Bleeding from the nose (epistaxis) is a common pediatric problem. It can be slight but exaggerated by the patient and/or the parents, but it can also be severe and life threatening. It is usually a frightening experience for the patient and occasionally frustrating to the treating physician. In the majority of cases the bleeding is from the anterior part of the nose, mainly the septum, turbinates, and anterior two thirds of the inferior meatus. In most cases the bleeding stops spontaneously. Posterior epistaxis is usually from the nasopharynx, at the posterior edge of the septum.

Surgical Anatomy

The most common site of nosebleeds from the anterior septum is at the Kiesselbach plexus in Little's area. This area has an extremely rich blood supply, consisting of

1. The septal branch of the superior labial artery, a branch of the facial artery from the external carotid artery
2. Septal branches of the anterior ethmoid artery, a branch of the internal carotid artery
3. Septal branches of the sphenopalatine artery, the terminal branches of the internal maxillary artery
4. The anterior septal branch of the greater palatine artery

The next most common site is the anterior part of the inferior turbinate. The blood supply is also rich in this area, and consists of

1. Branches of the anterior ethmoid artery
2. Lateral nasal branches of the sphenopalatine artery
3. Nasal branches of the greater palatine artery
4. Nasal branches of the anterior inferior dental artery, a branch of the infraorbital artery

Posterior epistaxis is rare, occurring most often in juvenile nasopharyngeal angiofibroma, usually in teenage boys. The bleeding comes from the vascular distribution of the sphenopalatine artery (i.e., the nasopalatine, inferior, and middle turbinate arteries).

Regardless of the nerve supply of the nose, topical anesthesia is sufficient for freezing the bleeding area of the nose.

Etiology of Epistaxis in Children

Epistaxis in children can have many different causes (*Table 414.1*). The most common causes of nosebleeds in the pediatric population are idiopathic. The epistaxis occurs mainly during the night and, on waking up, the pillows and bed sheets are found to be soaked in blood. Nose picking is another common cause, which is usually denied by the patient and parents.

Upper respiratory tract infection may be acute or chronic, bacterial or viral with allergic rhinitis. Infection causes congestion of the nasal mucosa, which become more friable and irritable, leading to ulceration, erosion, and bleeding. Foreign body placement is a common problem in children, presenting with epistaxis and a purulent, foul-smelling discharge. This is usually unilateral.

Septal perforation from nose picking and repeated cauterization leads to nosebleeds. Environmental causes include dry air, which leads to ulceration and cracks to the anterior nasal mucosa, as in dry desert areas with low humidity. Forced-air heating with low humidity in winter leads to a similar effect.

Although neoplasm is a cause of nosebleeds, it is still quite rare, yet there are several cases of nasopharyngeal carcinoma in children and young adults in the Arabian peninsula. The most common cause of posterior epistaxis in young people is juvenile angiofibroma of the nasopharynx. This affects usually adolescent boys; therefore, any male patient in his teens who presents with posterior epistaxis should be suspected of having juvenile angiofibroma until proved otherwise. A computerized tomography scan with contrast is diagnostic (*Fig. 414.1*), and biopsy should be avoided. Embryonal rhabdomyosarcoma of the sinonasal tract can occur in children presenting with nasal bleeds as a symptom.

Vascular anomalies causing epistaxis include Osler-Weber-Rendu disease (hereditary hemorrhagic

Platelet abnormalities
Primary (idiopathic thrombocytopenic purpura)
Acquired (aspirin, leukemia)
Coagulopathies
Primary (von Willebrand disease, hemophilia)
Acquired (warfarin, liver diseases)
Drug-related thrombocytopenic purpura

telangiectasia), which is an autosomal dominant familial disease with a frequency of 1–2 per 100,000 population. More than 90% of patients will eventually present with recurring epistaxis, with a mean age of onset of 12 years and a mean number of epistaxis episodes of

Figure 414.1
Axial computerized tomography scan of the nasopharynx showing enhanced juvenile angiofibroma (the patient presented with severe epistaxis)

18 per month. Arteriovenous malformations are other causes of nosebleeds in children.

Nosebleeds can result from primary or acquired coagulopathies. The diagnosis in such cases is obvious from the case history and family history of hemophilia or von Willebrand disease, which is a combination of factor VIII defect and platelet abnormality. A history of unusual bleeding, bruises, recent use of platelets, use of inhibiting agents such as aspirin, or use of anticoagulants may be associated with nosebleeds. Rosenthal disease (factor XI deficiency) and Christmas disease (factor IX deficiency) are rare causes of nosebleeds.

Management

When a patient is first seen with heavy bleeding, a careful history is taken from the child or the parents, bearing in mind the previously noted etiology of nosebleeds. Physical examination is performed first by asking the patient to blow his or her nose to clear the blood clots if possible; if not, a suction device is used carefully to clear the nose. Then a suitable vasoconstrictor spray is used, or, cottonoids or ribbon gauze soaked in a vasoconstrictor combined with a local anesthetic (e.g., 4% lidocaine with epinephrine 1:100,000).

Table 414.2
Management of pediatric epistaxis

Anterior epistaxis	
Humidification: saline lavage to the nose, face, and cheeks	
Reflex vasoconstriction: ice to the nose, face, and cheeks	
External nasal compression: with the head down and breathing through the nose	
Cotton soaked in a vasoconstrictor agent	
Treatment of the underlying cause, if found	
Anterior nasal packing: gauze strips, Gelfoam, Avitene, Merocele, surgical, etc.	
Nasal cautery: chemical, electrocautery, argon or YAG laser	
Systemic evaluation of coagulopathy	
Posterior epistaxis	
Known diagnosis	**Unknown diagnosis**
Suction plus vasoconstrictor agents	Suction plus vasoconstrictor agents
Pressure	Endoscopic evaluation
Absorbable packing gauze	Computerized tomography and/or magnetic resonance imaging
Posterior tamponades	Arteriography plus selective embolization
Posterior and anterior embolization	Packing, embolization, or arterial evaluation
Endoscopy plus direct cautery: electric or chemical ligation	Systemic disorders
Correction of systemic causes such as coagulopathies	
Operative methods for anterior and/or posterior epistaxis	
Direct cautery	
Ligation of supplying arteries	
Septoplasty for deviated septum	
Closure of septal perforation	
Resection of neoplasm (e.g., angiofibroma)	

The management of pediatric epistaxis can be divided into that of anterior and posterior epistaxis (*Table 414.2*).

Anterior Epistaxis

The anterior nasal cavity is inspected using a xenon head light or a rigid 2.7-mm diameter telescope, first at 0° and then at 30°. These are usually tolerated well by most children. The inspection is first concentrated on the anterior septum, as most of the bleeding comes from Little's area. Active bleeding points can be identified and treated first with pressure using a cotton-tipped applicator or cotton ball or simply pressing the nasal ala against the septum for a few minutes. Silver nitrate sticks or electrocautery can be used to cauterize the point. The cautery should be applied to the exact site of bleeding, not to the whole nasal mucosa. Cautery should not be applied bilaterally at the same time; otherwise necrosis and septal perforation can result. The application of antibiotic cream or a similar petroleum-based ointment is effective in preventing further bleeding.

Recurrent Bleeding

In recurrent bleeding, the history may indicate an underlying cause such as allergic rhinitis. Suitable treatment, such as immunotherapy or drug therapy, can then be applied. In dry areas, suitable humidification of the nasal mucosa is effective in preventing further bleeding; for example, normal saline spray or drops, a humidifier, and application of ointment to maintain the humidity of the nasal cavity can be used. These measures also have mechanical actions, preventing sticky mucus and crust formation and washing out pollens, dust, and molds.

If sinusitis is diagnosed as the underlying cause, suitable measures, such as antibiotics, are indicated.

Hematologic investigations should be carried out, including blood count, platelet count, prothrombin and partial thromboplastin times, and bleeding times for primary or acquired blood disorders such as von Willebrand disease.

Anterior Nasal Pack

In rare cases when these measures fail to stop the bleeding, an anterior nasal pack is considered. Ribbon gauze soaked in suitable ointment can be used, but this has the drawbacks of discomfort, pressure, laceration, and nasal blockage with headaches. Several absorbable materials are available, such as oxidized cellulose (Oxycel), gelatin sponge (Gelfoam), and microfibrillar collagen hemostat (Avitene). There have been reports of toxic shock due to nasal packing, so nasal packs should contain antibiotic cream, with antibiotic administration and early removal of nonabsorbable packs, if use of this type of pack is unavoidable. This is more important and should be carefully considered in immunocompromised patients. Bilateral nasal packs can cause blockage of sinus ostia, nasal blockage with accumulation of secretions, sleep apnea, hypoxia, and possible death.

The gauze packing should be used precisely in a layer manner, starting at the floor to prevent it from hanging down to the oropharynx and hypopharynx and causing irritation, vomiting, laryngeal spasm, and suffocation. In some cases it is wise to remove the pack gradually over several hours to prevent further bleeding. If bleeding occurs after removal, pressure over the soft parts of the nose and application of ice packs over the nose will induce regional vasoconstriction. Usually these measures are enough to control the bleeding. This is also true after nasal surgery.

In severely deviated septum, the spur causes the overlying mucosa to be weak and friable. If simple measures do not control the bleeding, then septoplasty can be performed to stop further bleeding.

Posterior Epistaxis

Good vasoconstriction is needed to examine the posterior part of the nose and nasopharynx to find the bleeding point. The area supplied by the sphenopalatine artery and its branches is inspected. In modern practice, rigid or flexible fiberoptic nasopharyngoscopes are indispensable instruments for the diagnosis and management of endonasal conditions. If posterior epistaxis is expected, a rigid or flexible endoscope or a microscope is used in a cooperative child to inspect the posterior part of the nose and nasopharynx. A bleeding point can be identified at the maxillary ostium in the middle meatus or high in the vault. These are from branches of sphenopalatine or ascending pharyngeal vessels. If the patient is not cooperative, then examination and appropriate management can be applied under general anesthesia. Bleeding sites, foreign bodies, tumors, vascular anomalies, sinusitis, and nasal polyps can be diagnosed in a matter of minutes under reassurance or local or general anesthesia.

Similar treatment measures as in anterior bleeding can be applied in many cases. The visualized bleeding point can be cauterized. Posterior packing using ribbon gauze impregnated in antibiotic ointment is the traditional method. Nowadays, catheter balloons are applied to improve comfort and efficiency in managing nosebleeds in both adults and children. Similar devices include the Foley catheter, Fox balloon, Merocele Pope posterior nasal tampon, and Gottscholk nasostat and epistat. The patient is usually managed in the hospital because of risks of sleep apnea, suffocation, and further bleeding. Bed rest is available, and the patient can be sedated with replacement of intravenous fluids and/or blood, if needed, and further investigations may be carried out.

Arterial embolization is considered in cases of severe epistaxis refractory to other therapeutics, provided that an expert radiologist is available to avoid the risk of embolization of the internal carotid artery, with its devastating results (Fig. 414.2). By applying this technique, one avoids open surgery, with its obvious disadvantages.

Arterial ligation is rarely needed in children. In cases of posterior and superior nasal bleeding, ligation of the anterior and posterior ethmoidal arteries is needed. If the bleeding is from the posterior part of the nose, ligation of the terminal branches of the internal maxillary artery is required. The need for ligation of the external carotid artery is even rarer in the pediatric group. It is mandatory to identify at least two branches before the ligation as the internal carotid has no branches in the neck. These open procedures need to be done under general anesthesia and carry certain risks, such as denervation of the teeth, infraorbital nerve hyperesthesia or paresthesia, ophthalmoplegia, sinus complications, and inadvertent vidian nerve neurectomy.

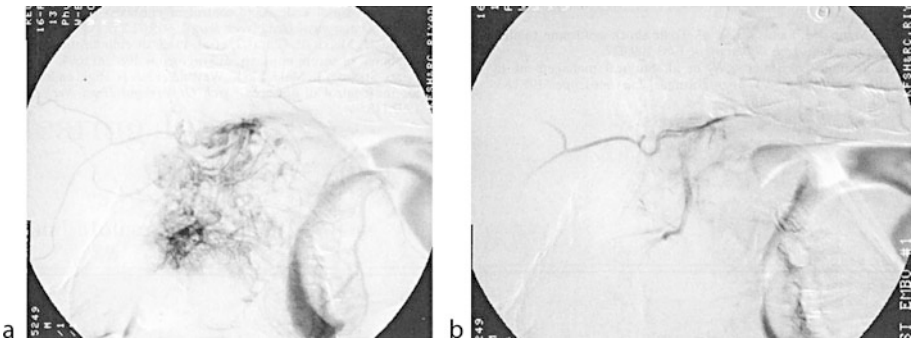

Figure 414.2
Angiogram of the nasopharynx (a) with blush in a child with juvenile angiofibroma of the nasopharynx prior to embolization, and (b) disappearance of the blush following arterial embolization

If the bleeding does not stop after arterial ligation of the internal maxillary artery, several options are available:

1. Return to the nasopharyngeal tamponade sequence
2. Ligation of the contralateral internal carotid artery
3. Ligation of the anterior ethmoid artery
4. Ligation of the external carotid artery

Conclusion

Most occurrences of epistaxis are controlled using simple measures. Step-by-step management is needed, starting with simple, uncomplicated methods. Severe and recurrent epistaxis warrant further investigation to exclude coagulopathies, tumors, and other recognized rare conditions. The physician should be aware of the complications of nose-bleeds as well as of the treatment.

Pediatric Ophthalmology

Selwa A.F. Al-Hazzaa

415 Ophthalmologic Disorders

Selwa A. F. Al-Hazzaa

Visual development is a highly complex maturation process. Healthy infants are born with the potential, but not the ability, to see. The eyes must be anatomically normal, and the media must be optically clear. The infant must have visual input for good vision to develop, and, if binocular function is to develop, the eyes must be aligned. Normal vision develops as a result of genetic coding and experience in a normal visual environment.

The infant eye is not simply a small adult eye. The pediatric eye is a growing eye, which differentiates it in many ways from the adult eye. At birth, the normal visual responses are to light or bright objects. At 6 weeks of age a normal infant is able to maintain eye contact, and, by 6 months small objects, toys, and fingers within several feet are seen. The infant's world of visual interest gradually expands, and, by $2\frac{1}{2}$ years, some children recognize Allen pictures equivalent in size to 20/20 Snellen letters.

The developing immune system predisposes children to reactions to inflammation and diseases that are distinctly different from those of adults. The central nervous system is in its formative period. It is particularly vulnerable to growth abnormalities and developmental interruptions.

No child is too young to have an assessment of vision. Children may pose a difficult visual assessment problem. In children less than $3\frac{1}{2}$ years, acuity may be evaluated by the CSM method: *C* refers to the normally reflected light from the center of the cornea, *S* to the steadiness of fixation to the examiner's light, and *M* to the ability of the strabismic patient to maintain alignment. Signs of poor visual development include nystagmus, wandering eye movements, lack of response to familiar faces and objects, staring at bright lights, and forceful rubbing of the eyes (oculodigital massage). Nystagmus secondary to decreased sensory input usually occurs at 2–3 months of life and not at birth. The most common causes of decreased vision in the pediatric age group are albinism, optic nerve atrophy and hypoplasia, cortical visual impairment, anterior segment anomalies, and retinal abnormalities.

Amblyopia

Amblyopia is a defect of central vision that cannot be attributed directly to the effect of any structural abnormalities of the eye or the posterior visual pathways in the visual cortex or in the lateral geniculate bodies. It is caused by abnormal visual experience early in life, usually resulting from ocular misalignment, uncorrected bilateral high refractive errors, difference in refractive error, or disorders that degrade the quality of images transmitted to the brain from the eye. Amblyopia is responsible for more reduced vision of childhood onset than all other causes combined. Nearly all amblyopia is reversible or preventable with appropriate treatment. The role of the pediatric ophthalmologist in identifying children with amblyopia or at risk for developing it at a young age (when the prognosis for successful treatment is best) is important and cannot be overemphasized. Voluntary vision screening programs are important in the detection of amblyopia. Treatment of amblyopia involves eliminating any physical abnormality of the eye, correcting the refractive error by optical prescription, or forcing the use of the poorer eye by occlusion therapy.

Cortical Visual Impairment

Cortical visual impairment (cortical blindness) may be congenital or acquired. Both prenatal and perinatal etiologies, such as intrauterine infection, cerebral dysgenesis, asphyxia, intracranial hemorrhage, hydrocephalus, infection, trauma, child abuse, shunt malfunction, meningitis, encephalitis, and asphyxia, may be found. Examination reveals normal ocular structure, normal pupillary responses, and searching eye movements. The electroretinogram is normal, while the visually evoked response may be abnormal. Neuroimaging may reveal changes in the occipital cortex. Cortical visual impairment can be transient or permanent and can be an isolated finding; it is more commonly associated with multiple neurologic handicaps.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_415,

Nystagmus

Nystagmus consists of rhythmic oscillation or tremors of the eyes that occur independently of normal ocular movements. Nystagmus in pediatric patients is divided into congenital and acquired types. A complete ophthalmologic examination and electrophysiologic testing are sometimes required for the evaluation of a patient with congenital nystagmus. The most common causes of congenital nystagmus are albinism and optic nerve pathology. *Congenital motor nystagmus* is a term applied to nystagmus of unknown etiology. The nystagmus may be either pendular, jerk, or both. No treatment has been found that is always successful. Surgical treatment has been advocated for nystagmus associated with abnormal head posture. Acquired nystagmus, at any age, requires thorough evaluation, including neuroimaging.

Strabismus

The term *strabismus* is derived from the Greek word *strabismos* (to squint or to look obliquely) and implies ocular misalignment. Defects of ocular motility constitute a large proportion of ophthalmic problems. A vast majority of children admitted to the ophthalmic service have strabismus that requires surgery for functional or cosmetic reason. Strabismus can be the first sign of retinoblastoma, and cataract must be excluded as a cause. The diagnosis and quantification of strabismus is the major focus of the pediatric ophthalmologic examination. No classification is perfect or all-inclusive. Strabismus may be classified on the basis of direction of the deviation: if the visual axes converge, there is esodeviation; if they diverge, there is exodeviation.

Esodeviations

Esodeviations are the most common form of misalignment and represent over 50% of ocular deviations in the pediatric population. They are caused by accommodative (most frequent), innervational, mechanical, refractive, and genetic factors.

Congenital Esotropia

Infants with congenital esotropia develop a large angle of esotropia at several months of age. Because it is not present at birth, some ophthalmologists prefer to name this condition infantile (early-onset) esotropia (◘ *Fig. 415.1*). The cause is unknown, and the abnormality is usually isolated. There is often a family history of strabismus, but well-defined genetic patterns are unusual. It occurs in otherwise normal infants, but it is quite common (up to 30%) in infants with developmental delay.

◘ **Figure 415.1**
A child with early-onset esotropia and large-angle esodeviation of the right eye

The angle of deviation is usually large. About one half of these infants see equally well with each eye. These infants alternate fixation from one eye to the other. In the other half of such infants, one eye sees better than the other. Amblyopia is present in the nonpreferred eye when there is constant in turning. The amblyopia must be treated by patching until the vision is equal, as determined by the infant spontaneously fixating with either eye.

The refractive errors in these infants, as determined by cycloplegic refraction, are the normal refractive errors of this age. Repeat refractions are essential. The treatment for this condition is surgery. However, surgery should be undertaken only after correction of significant refractive errors and treatment of amblyopia. Most agree that surgery should be performed early, before 2 years of age, to stimulate the infant to gain some binocular function and fusion. Most surgery is performed any time after the child is 6 months of age; this produces a better sensory and motor outcome when compared to surgery after 24 months. The success rate for surgery in the short term is quite high. Within the first years of life, some of these

children develop an abnormal head position: a face turn or a head tilt to either side. For most of these children, no cause can be found for the abnormal head position.

Pseudoesotropia

Pseudoesotropia, the illusion of esotropia, is a common reason infants are referred to ophthalmologists. Normal infants have a flat nasal bridge with prominent medial epicanthal folds and small interpupillary distance. As the infant looks straight ahead, it may appear that either or both eyes are turned inward. This illusion is aggravated in side gaze. As the child grows, the distance between the eyes increases and the nasal bridge grows forward, effectively pulling each medial canthus toward the midline. The pseudoesotropia then disappears. This underlies the old wives' tale that esotropia in infancy goes away spontaneously.

Accommodative Esotropia

Accommodative esotropia, the most common type, is produced by or caused by accommodation. Many of these cases occur as a result of uncorrected hypermetropia. The average age of onset is 2.5 years, and the condition develops between 6 months and 6 years of age. Treatment is by full hyperopic refractive correction as determined by cycloplegic refraction, visual rehabilitation if necessary, and surgical therapy. Initially therapy with spectacles may reduce the deviation, but, if esotropia persists, the clinician must decide whether it is sufficient to require surgery. The long-term use of miotic agents has largely been abandoned. Amblyopia must be fully treated prior to surgery.

Exodeviations

Most exodeviations develop in the first 4 years of life. Many children develop an exotropia that typically begins intermittently. The age of onset of exotropia varies but is often from infancy to 4 years. The cause is unknown. Amblyopia is uncommon, but photophobia is common. Exotropia may be induced by daydreaming, fatigue, illness, visual distraction, and distance viewing. Refraction of patients with exotropia reveals myopia. Exotropias are commonly associated with craniofacial anomalies and may be associated with neurologic impairment. Treatment is to maximize vision by treating amblyopia or anismetropia, by orthoptic exercises or surgery.

Infections and Allergic Ocular Disease

Prenatal and Perinatal Infections of the Eye

Maternally transmitted congenital infections can cause ocular damage in several ways: (a) through direct action of the infecting agent, which damages tissue; (b) through a teratogenic effect resulting in malformations; or (c) through a delayed reactivation of the agent after birth, with inflammation that damages developed tissue. The predominant organisms can be remembered by the acronym TORCHS: *to*xoplasmosis, *r*ubella, *c*ytomegalic inclusion disease (CID), *h*erpes simplex, and *s*yphilis.

Toxoplasmosis

In neonates, the disease occurs in a continuous clinical spectrum ranging from no signs or findings to severe necrotizing chorioretinitis that can usually be diagnosed from the typical fundus appearance. The animal reservoir is in the cat. Toxoplasmosis is found in about 80% of severely affected individuals with congenital infections of the eye. It is bilateral and frequently involves the macula, causing visual loss. *Toxoplasma gondii* is most often a congenital infection with lifelong ocular toxicity. Satellite foci are highly characteristic of toxoplasmosis. Scattered foci of calcification within the brain may be present in congenital cases and will be visible on computerized tomography (CT) scan. Hydrocephalus, mental retardation, and epilepsy can occur. Many authorities recommend treatment with sulfonamides and pyrimethamine or clindamycin to destroy the organism, together with steroids to suppress the inflammatory response. In newborns, the differential diagnosis of toxoplasmosis should include CID, herpetic infection, retinoblastoma, Coats disease, candidiasis, acquired immunodeficiency syndrome, and Aicardi syndrome.

Rubella

Rubella ("German measles") is caused by the rubella virus and is distributed worldwide. Rubella is typically a childhood disease. About 10–15% of women in the childbearing years are susceptible to rubella. The earlier in pregnancy the infection is contracted, the greater the risk to the fetus. Seropositive infants born to mothers infected between the first and eighth weeks of pregnancy

have about an 82% chance of developing severe defects. The most common cause of congenital cataracts is maternal rubella occurring during the first trimester of pregnancy. Other ocular manifestations consist of unilateral or bilateral microphthalmos, corneal opacification, chronic uveitis, congenital glaucoma, iris hypoplasia, and retinal degeneration. A diffuse salt-and-pepper retinopathy is often seen in rubella that does not significantly affect vision. The differential diagnosis includes syphilis, measles, varicella, and influenza. This syndrome has become rare with the advent of live attenuated virus vaccine.

Cytomegalic Inclusion Disease

CID is caused by cytomegalovirus (CMV), a virus of the herpes family. About 0.2% of all newborns are infected with CMV. The ophthalmic manifestations of CMV are highly variable and nonspecific. Strabismus, nystagmus, microphthalmos, cataracts, uveitis, optic disc anomalies, optic nerve atrophy, and anophthalmus are often seen. Retinochoroiditis occurs in 15–29% of severely affected neonates. Periventricular calcifications may occasionally be found on CT scans of the brain. CMV infection is usually subclinical in healthy children. Ganciclovir and foscarnet are currently the treatment of choice. Reactivation is treated with modest success with both drugs at the same time.

Herpes Simplex Virus

All members of the herpesvirus family have similar characteristics and infect a wide range of animals, including humans. There are two types of herpes simplex virus, herpes simplex virus type 1 (HSV-1) and type 2 (HSV-2). HSV-1 frequently affects the eye. The source of perinatal herpes simplex infection is usually maternal. Infection from the cervix is most common. Most neonatal HSV infections are acquired at the time of delivery, accounting for 50% of cases following vaginal delivery. The most common features of neonatal HSV infection are vesicular skin lesions, ulcerative mouth sores, and keratoconjunctivitis. HSV produces ocular symptoms in approximately 13% of infants with neonatal herpes; these include conjunctivitis, keratitis, cataracts, and retinochoroiditis. Eye involvement alone without other clinical manifestations may occur. The long-term prognosis for any infant with symptomatic HSV is poor due to serious neurologic sequelae.

Syphilis

Syphilis caused by *Treponema pallidum* is a reportable disease. Fetal infection occurs following maternal spirochetemia. If the mother contracts primary or secondary disease, one half of her offspring will be infected. Clinical signs develop during the first few months of life. Interstitial keratitis is seen secondary to untreated congenital syphilis in children who develop keratitis in the first decade of life. It presents as a rapidly progressive corneal edema followed by abnormal vascularization, giving the cornea a salmon pink color. Congenitally acquired infection can lead to neonatal death or premature labor. Salt-and-pepper retinopathy, glaucoma, and uveitis occur in some infants. Parenteral penicillin is given for 10–14 days to treat congenital syphilis.

Ophthalmia Neonatorum

Ophthalmia neonatorum, or neonatal conjunctivitis, is characterized by redness, discharge, and swelling of the conjunctiva in the newborn. It is uncommon in developed countries. Causes of ophthalmia neonatorum are *Neisseria gonorrhoeae*, trachoma inclusion conjunctivitis (TRIC), *Chlamydia*, chemical toxicity, and, rarely, HSV. Gonococcal and chlamydial infections are usually contracted from the maternal genital tract during delivery. Approximately 5–10% of maternal cervices harbor these infections.

Although gonorrheal conjunctivitis of the newborn is a vision-threatening conjunctival infection, it is rarely seen in the ophthalmologist's office. Its incubation period is so short that it is usually recognized in the newborn nursery and is diagnosed and treated by the pediatrician. It is characterized by marked purulent discharge and swollen lids, and is usually seen within the first several days of life. Appropriate smears and cultures should be taken. Systemic treatment is essential, and third-generation cephalosporins are mainstays of treatment. The patient should be isolated. Local treatment consists of irrigating or wiping away the purulent material.

Much more often seen is TRIC or chlamydial conjunctivitis in the newborn. The disease manifests at 1–2 weeks of age with marked swelling of the lids, copious mucoid discharge, and redness of the bulbar conjunctiva. The diagnosis can be confirmed by one of the commercially available rapid tests for *Chlamydia* infections. The treatment is 2 weeks of oral erythromycin (50 mg/kg/day in four divided doses), which greatly reduces the likelihood of pneumonitis and otitis media that may follow topical treatment only. The mother, father, and any sexual

partners should be treated. Fluorescent antibody staining and DNA probes of the patient's ocular surface and the cervix of the mother for *Chlamydia* have become important diagnostic tests.

Chemical conjunctivitis quickly follows topical silver nitrate instillation, and tends to be a mild conjunctivitis with watery discharge. Herpetic eye disease in the newborn can present as a blepharoconjunctivitis with herpetic vesicles of the lid margin. Diffuse chorioretinitis and encephalitis can result. This disease is associated with systemic illness. The overall mortality from neonatal HSV is 60%. Newborns may also develop a nonspecific conjunctivitis, usually from infection with *Haemophilus, Staphylococcus*, or *Streptococcus* organisms. Gonorrhea should be excluded by the appropriate smear and culture. Topical treatment is individualized based on the suspected organism and the results of the stain and culture.

Cellulitis

Cellulitis is divided into preseptal and orbital. *Preseptal cellulitis* is a common infection in children. It is an inflammatory process anterior to the orbital septum. Infections may be secondary to trauma, minor skin abrasions, insect bites, or spread from contagious structures. It can be associated with upper respiratory tract infections. Lid edema is common. Proptosis is not a feature, and the globe remains normal. Full ocular motility and absence of pain on eye movement distinguish preseptal from orbital cellulitis. *Staphylococcus aureus* and *Streptococcus pneumoniae* are the most common causes of preseptal cellulitis. Pediatric consultation is important in the management of *Haemophilus influenzae* cellulitis because a secondary meningitis can occur. Children less than 5 years of age are often admitted to the hospital. If there is no visible local source of infection, a CT scan is required to evaluate the paranasal sinuses. If positive, otolaryngologic consultation is required. Preseptal cellulitis is treated with systemic broad-spectrum antibiotics. Incision and drainage of the preseptal space may be required in severe cases with abscess loculation. There are usually no complications following mild preseptal cellulitis.

Orbital cellulitis is an infection of the orbit that involves the tissues posterior to the orbital septum. In children, it is a potentially fatal emergency that requires pediatric consultation, hospitalization, and intravenous antibiotics. It occurs in association with sinusitis in 90% of cases but can follow penetrating injury of the orbit. Signs include lethargy, fever, leukocytosis, headache, rhinorrhea, purulent nasal discharge, orbital pain, increasing proptosis, lid edema, and limitation of ocular motility. The etiologic agents responsible for orbital cellulitis vary with age. *Staphylococcus aureus, Escherichia coli*, and gram-negative bacilli are common in the neonate. *Haemophilus influenzae* and *S. pneumoniae* are common in children between 6 months and 5 years of age. *Staphylococcus aureus, Streptococcus pyogenes*, and *S. pneumoniae* are common in older children. Gram-negative organisms are common in immunosuppressed patients.

Paranasal sinusitis is the most common cause of bacterial orbital cellulitis. In children under 10 years of age, this is usually ethmoiditis. CT of the paranasal sinuses and orbit can determine and define the presence and extent of abscesses. Blood cultures should be obtained. Treatment includes emergent drainage of the sinuses and of any orbital abscess (Fig. 415.2). Parenteral third-generation cephalosporins, along with nafcillin, are given. Complications include cavernous sinus thrombosis or intracranial extension in the form of subdural or brain abscesses or meningitis, which may result in death.

Vernal Disease

Bilateral inflammation of the conjunctiva occurs on a seasonal basis during spring and summer. This is

Figure 415.2
Acute orbital cellulitis with a swollen and tender upper left lid and chemosis of the conjunctiva

a common but self-limiting disease. It occurs more commonly in boys between the ages of 6 and 20 years. It is thought to be due to an allergic diathesis. The most prominent features are photophobia and severe itching. The discharge is characteristically thick, filamentous, and gray and contains a large number of eosinophils. Vernal conjunctivitis is easily differentiated from other causes of conjunctivitis. The prognosis for recovery is excellent, although prolonged. Cold compresses and oral antihistamines may be helpful. Topical cromolyn sodium is the long-term treatment and reduces the need for steroids. Use of topical steroids should be limited to acute severe cases under an ophthalmologist's supervision. Long-term use of steroids may lead to complications such as glaucoma and cataract.

Congenital Ptosis

Conditions that cause ptosis (lid droop) can be divided into congenital and acquired. Healthy children may be born with one or both upper eyelids abnormally low. The most common cause of congenital ptosis is an isolated dystrophy of one or both levator muscles (*Fig. 415.3*). Some patients are born with a nondystrophic type of ptosis. Myasthenic syndromes must be excluded. If one or both ptotic lids cover the upper portion of the pupils, the infant or child must maintain a chin-up position to look at something straight ahead. If the lid margin occludes the pupillary axis, an urgent effort should be made to lift the eyelid to expose the visual axis in order to prevent amblyopia and stimulate normal visual development. In the majority of cases, surgery can often be deferred until the child is old enough for a more accurate assessment of his or her condition. This usually occurs around the preschool age (4–5 years old). In all cases of ptosis, refraction is mandatory as molding of the cornea by the lid may occur, causing anisometropia and secondary amblyopia. These patients must be followed by a pediatric ophthalmologist. Evaluation of ptosis includes a thorough history, a complete examination, and documentary photos.

Figure 415.3
A child with unilateral congenital dystrophic ptosis of the left eye in which the lid margin occludes the pupillary axis

Lacrimal Drainage System

Dacryocystocele

Congenital dacryocystocele is a rare condition in which cyst-like swelling of the lacrimal sac occurs as a result of obstruction of the lacrimal drainage system. Dacryocystocele presents at birth as a bluish swelling below and nasal to the medial canthus about 1 cm in diameter. Its appearance is quite distinctive. Digital massage coupled with topical antibiotic administration may lead to resolution of the condition without complications. If the condition does not resolve, infection and inflammation may develop (dacryocystitis), requiring systemic antibiotic therapy. Persistence of symptoms necessitates probing of the nasolacrimal canal (see "Nasolacrimal Duct Obstruction" below).

Nasolacrimal Duct Obstruction

Clinically evident obstruction of the lacrimal system is usually due to a thin mucosal membrane (Hasner valve) at the lower end of the nasolacrimal duct (NLD). Symptoms of NLD obstruction include epiphora and sticky mucoidal or mucopurulent discharge of the eye. NLD obstruction occurs in 5% of full-term newborns. Symptoms manifest by 1 month of age in 80–90% of cases. Bilateral involvement, though asymmetric, is common. There is no effect on visual development, although secondarily acute bacterial infections may have serious consequences. Culture of the discharge may reveal various strains of bacteria. Congenital NLD obstruction

resolves, spontaneously or with conservative management, in 90% of patients during the first 12 months of life. After 1 year of age, the chance of a spontaneous resolution decreases.

Conservative management of congenital NLD obstruction includes topical antibiotic (the choice is not critical) drops or ointment and frequent lacrimal sac massage. This management often provides substantial and complete relief of symptoms. When symptoms persist, surgical probing of the lacrimal system is indicated. The success rate of initial probing for congenital NLD obstruction exceeds 90% in infants up to 12 months old. Patients who fail one or two initial probings should have silicone tube insertion in the nasolacrimal duct for at least 9 months.

Diseases of the Cornea

Neonatal Corneal Opacities

Sclerocornea

Sclerocornea is a congenital condition in which the cornea is opaque and resembles the sclera. The central cornea is clearer than the periphery. It often occurs in association with other abnormalities of the eye.

Tears, Breaks, or Ruptures of the Descemet Membrane

Such injuries may be caused by a difficult delivery leading to a unilateral central opacity. They are sometimes associated with transient stromal edema, which invariably subsides. Severe amblyopia may result.

Mucopolysaccharidosis and Mucolipidosis

Mucopolysaccharidosis (MPS) is caused by abnormal carbohydrate metabolism. Mucolipidosis is a lysosomal disorder. Corneal clouding and haziness may be present in early life in MPS IS and mucolipidosis. The diagnosis is established by electron microscopic examination of a conjunctival biopsy. All of the mucopolysaccharides except MPS III (Sanfilippo syndrome) may have depositions in the cornea leading to some degree of corneal cloudiness. Mucolipidosis causes a cherry-red spot (*Fig. 415.4*).

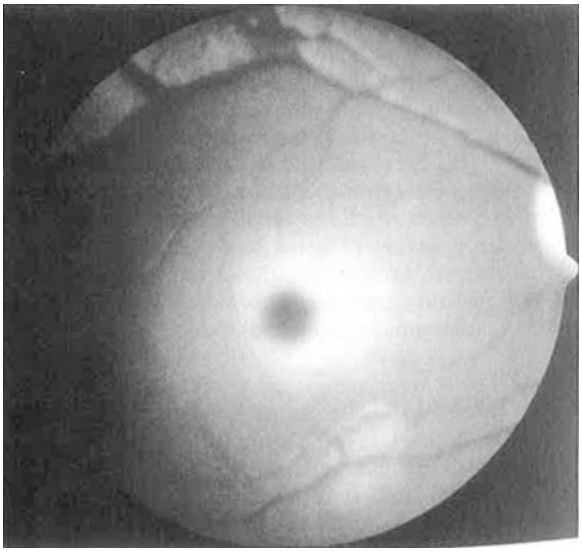

Figure 415.4
A fundus photo showing a characteristic cherry-red spot in mucolipidosis

Peters Anomaly

This anomaly causes a corneal opacity that can range from a faint stromal opacity to a dense, opaque central leukocoria that may be vascularized. In many cases, the stromal opacity decreases with time.

Dermoids

A corneal dermoid is a hamartoma that sometimes contains hair follicles, sebaceous glands, and sweat glands. They appear as raised, circumscribed, pale yellowish growths, and are usually present at birth. Limbal dermoids are often seen with Goldenhar syndrome.

Congenital Hereditary Endothelial Dystrophy

Congenital hereditary endothelial dystrophy is an unusual autosomal recessive condition that is noticed at birth. Both corneas are uniformly and diffusely hazy and edematous. The cornea is thicker than normal, with a normal diameter. The intraocular pressure is normal. These three findings differentiate this condition from congenital glaucoma. The condition remains unchanged, and vision is usually good.

Congenital Infantile Glaucoma

Glaucoma in an infant can make the cornea hazy, cloudy, opaque, or enlarged (see "Congenital or Infantile Glaucoma" below)

Systemic Diseases with Corneal Manifestations in Childhood

Mucopolysaccharidosis and congenital syphilis (see above) both have corneal manifestations in childhood. Other systemic diseases with such manifestations include cystinosis and Wilson disease.

Cystinosis

This is a metabolic disease characterized by elevated cystine within the cell. Cystinosis occurs in three forms, all of which have the characteristic corneal crystals (*Fig. 415.5*). The infantile form is associated with failure to thrive, renal failure, rickets, decreased pigmentation, and early death. The adolescent form has only the renal complications. The crystals in the cornea are mainly in the anterior stroma. Iridescent crystals, elongated and needle shaped, are distributed throughout the conjunctiva and the cornea (*Fig. 415.5*). The ocular findings are pathognomonic.

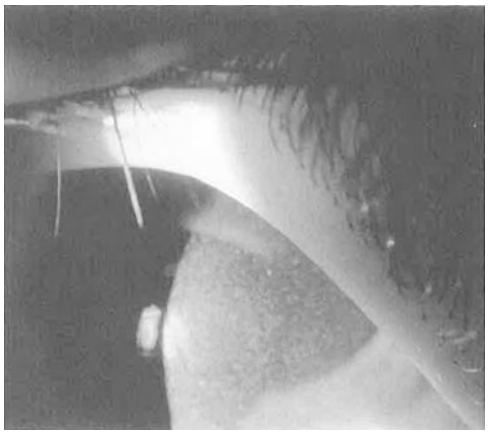

Figure 415.5
Slit-lamp photography showing elongated crystals in the cornea secondary to cystinosis

Hepatolenticular Degeneration (Wilson Disease)

Hepatolenticular degeneration is an autosomal recessive disorder of copper metabolism that affects the basal ganglia of the central nervous system, the liver, and the kidneys. Copper deposits in the periphery of the cornea in a copper-colored ring fashion referred to as a Kayser-Fleischer ring (*Fig. 415.6*). The stain is usually most marked near the upper and lower limbus of the cornea. This arc of deposition spreads, eventually encircling the entire cornea. This corneal finding is usually pathognomonic of Wilson disease. The ring resolves with treatment.

Iris Anomalies

Many pediatric patients present with congenital anomalies of the iris. Some of the most common anomalies are discussed below.

Aniridia

The condition is congenital, panocular, always bilateral, and often familial, transmitted in an autosomal dominant fashion with complete penetrance but variable. Expressively, two-thirds of all aniridic patients have affected parents. The iris is hypoplastic, often hidden behind the sclera on direct view, and visible only by gonioscopy. The sporadic form of aniridia is associated with Wilms tumor of the kidney in one-third of cases. The risk is increased

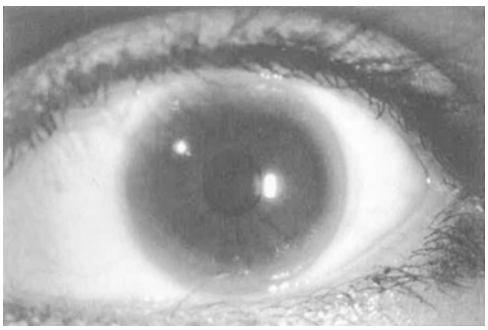

Figure 415.6
A copper-colored ring referred to as a Kayser–Fleischer ring encircles the cornea in Wilson disease

further if the patient has genitourinary anomalies or mental retardation (ARG triad). All patients with sporadic aniridia should have periodic ultrasound examinations of the kidneys to detect such tumors early; 80% of cases are diagnosed before the age of 5.

Typically, there is hypoplasia of the fovea and optic nerve resulting in nystagmus and decreased vision. In a sense, aniridia is a progressive disease. Photophobia and cataracts that are visually significant may develop, and the lens may partially dislocate. A major problem is the development of glaucoma, which is difficult to treat.

Coloboma of the Iris

A coloboma of the iris is considered typical if it occurs in the inferonasal quadrant. It is an external sign of a defect in the closure of the fetal fissure in the fifth week of gestation. The pupil is shaped like a lightbulb, keyhole, or inverted teardrop (*Fig. 415.7*). It may be unilateral or bilateral, sporadic or autosomal dominant. It may be an isolated ocular defect or associated with cardiac, hearing, anal, choanal, central nervous system, and probably other defects. If it is an isolated iris defect, it is compatible with normal or near-normal vision. It may involve the ciliary body, choroid, retina, and optic nerve. Nystagmus is usually present. Typically, an eye with a coloboma is smaller than normal, a condition called colobomatous microphthalmos. Many chromosomal abnormalities are associated with iris coloboma, as are many well-recognized syndromes.

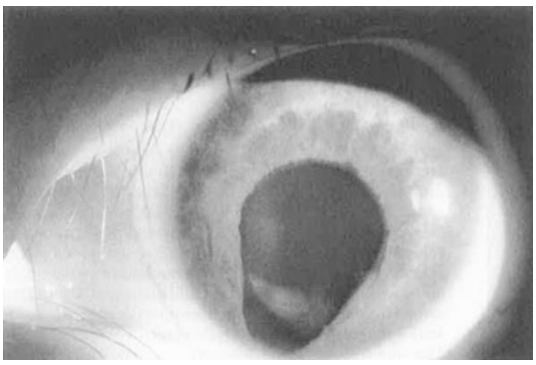

Figure 415.7
A lightbulb-shaped pupil showing a coloboma of the iris in the inferonasal quadrant

Lisch Nodules

Lisch nodules are common hamartomas associated with neurofibromatosis type 1. They are raised and tan in color. The prevalence and number increase with age.

Juvenile Xanthogranuloma

Juvenile xanthogranuloma is primarily a cutaneous disorder with a predilection for the head and face. Vascular iris lesions may occur as discrete yellowish nodules or as diffuse infiltration causing heterochromia. Spontaneous hyphema can occur.

Congenital or Infantile Glaucoma

The incidence of congenital glaucoma is about 1 in 12,500 births. It is not inherited as a simple mendelian trait but appears to be multifactorial. It is usually considered to be the result of maldevelopment of the angle. Infant and adult eyes react differently to raised intraocular pressure: the sclera of the younger eye is able to stretch more, and high intraocular pressures can produce ocular enlargement known as buphthalmos (ox eye) prior to 2 years of

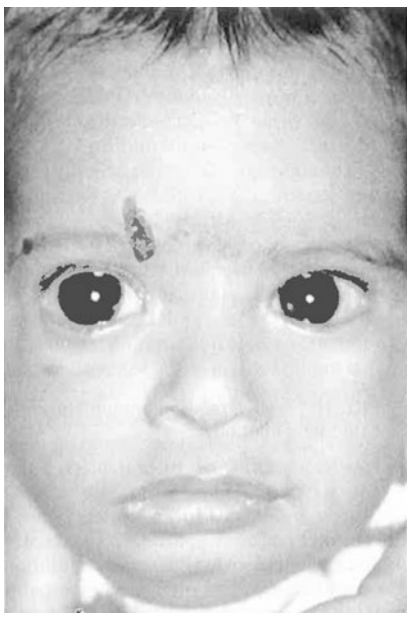

Figure 415.8
Congenital glaucoma of the right eye in an 8-month-old infant showing corneal enlargement and corneal opacity typical of buphthalmos

age (Fig. 415.8). Intraocular pressure is elevated in congenital glaucoma. The measurement of intraocular pressures in infants is difficult. Corneal changes are the earliest findings in congenital glaucoma. Any apparent difference in the diameter of the cornea should be considered to be congenital glaucoma until proven otherwise. The hallmarks of buphthalmos are corneal edema and corneal enlargement. Photophobia and reflex tearing are common symptoms. Vision is severely affected due to corneal edema, amblyopia, or optic nerve damage.

Congenital or infantile glaucoma can be divided into primary uncomplicated congenital glaucoma or secondary complicated glaucoma, which can be associated with several systemic syndromes and various ocular conditions. Systemic associations include Sturge-Weber syndrome, neurofibromatosis, oculocerebroneural syndrome, oculodentodigital syndrome, Rubenstein syndrome, and rubella. In general, surgery is the appropriate management for the childhood glaucomas. The prognosis is usually poor in the secondary type, but good results have been documented in the primary type.

Pediatric Lens Disorders

Cataracts

Certain types of lens opacities are common in pediatric ophthalmology and unique to infants and children, and are due to a variety of etiologies. Congenital cataracts are one of the leading causes of blindness in children. In bilateral cataracts, one-third are inherited, one-third are associated with other syndromes, and one-third are idiopathic.

The cause of poor vision in children with cataracts is irreversible amblyopia. They should be treated in the first months of life for optimal visual potential. Screening protocols are a must for all infants in the nursery stage and can be accomplished by evaluating the red reflexes by ophthalmoscopy. The gestational age of cataract formation determines the location of the lens opacity. Leukocoria is a common sign with complete cataracts (Fig. 415.9). Nystagmus usually develops due to poor visual development, especially with unilateral cataracts.

Hereditary cataracts are usually present at birth; others develop with time. They can be autosomal dominant, recessive, or X-linked. They can be associated with a variety of metabolic disorders, syndromes, and chromosomal disorders, such as trisomy 13, 18, and 21. A family history of cataracts and ocular anomalies can help in the diagnosis. Families with inherited cataract should receive genetic counseling. Surgical intervention (lensectomy) is essential and should be planned accordingly. Visually significant congenital cataracts should be removed urgently within 6–8 weeks of life. Aphakic optical correction, contact lenses, intraocular lens implantation, and keratorefractive surgery have all been utilized in the treatment of pediatric aphakia. The prognosis for children with congenital or infantile cataracts has improved markedly with early diagnosis and proper therapeutic technique.

Lens Dislocation (Ectopia Lentis)

Dislocated lenses (Fig. 415.10) cause decreased vision due to large errors of refraction. Diplopia and/or photophobia may be present. The condition is bilateral when

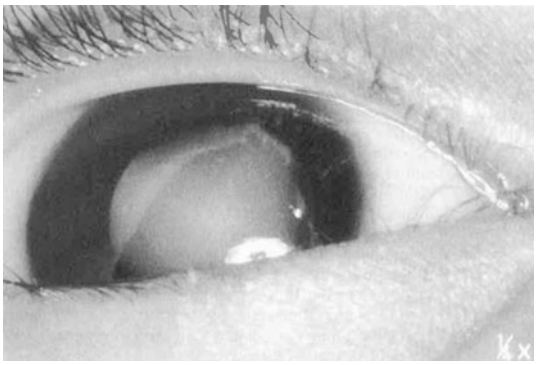

Figure 415.9
Congenital cataract in a 2-month-old revealing no red reflex and leukocoria

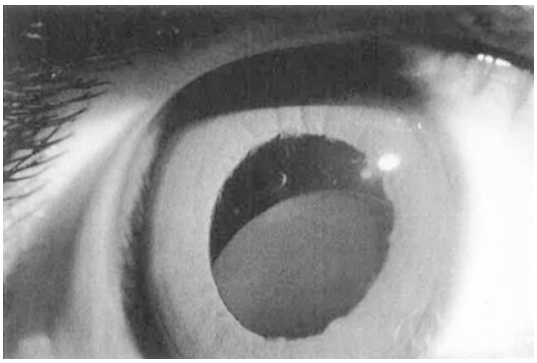

Figure 415.10
A slit-lamp photograph showing a dislocated lens inferiorly

inherited. There is usually a family history of decreased vision. Movement of the iris (iridodonesis) is common. Common ocular conditions associated with dislocated lenses include simple ectopia lentis, ocular trauma, aniridia, and ectopia lentis and pupillae. The associated systemic disorders include Marfan syndrome, homocystinuria, Weill-Marchesani syndrome, hyperlysinemia, sulfate oxidase deficiency, syphilis, and Ehlers-Danlos syndrome. A thorough history, physical, and ocular examinations are indicated.

Anterior Uveitis

Juvenile rheumatoid arthritis (JRA) is the most common cause of anterior uveitis in children. It is characterized by a chronic nonsuppurative synovial inflammation that includes low-grade fever, malaise, hepatosplenomegaly, lymphadenopathy, and anemia. Onset may be at any age but is rare before the second year of life. Several of the JRA subgroups have a genetic predisposition. Chronic iridocyclitis that is present in one or both eyes is most frequently associated with the pauciarticular forms of JRA. Individuals with JRA who are seronegative for the rheumatoid factor and positive for the antinuclear antibody are at increased risk for developing anterior uveitis.

Anterior uveitis, which can occur in a white eye, is detected with a slit lamp and can be seen at any time during the disease. Ocular inflammation often remains for years, frequently with long-term sequelae such as glaucoma and cataract formation. Suppression of the inflammatory process is the cornerstone of systemic treatment. Ophthalmic care of patients with JRA includes periodic examinations. The management is difficult in many cases. Topical steroids, cycloplegics, dilating agents, subconjunctival steroid injections, and systemic steroids have all been used. The parents should have a clear understanding regarding progress and prognosis. When the disease is chronic, vocational planning is indicated because the condition may lead to eventual blindness.

Leukocoria

The term *leukocoria* means white pupil. The differential diagnosis is important and includes retinoblastoma (until proven otherwise), retinopathy of prematurity (ROP), persistent hyperplastic primary vitreous (PHPV), retinal coloboma, Coats disease, posterior cataracts, uveitis, toxocoriasis, congenital retinal folds, vitreous hemorrhage, retinal dysplasia, and other tumors.

Retinoblastoma

Retinoblastoma is the most frequent intraocular malignancy of childhood. The disease is caused by a mutation in the long arm of chromosome 13. To initiate tumor growth, both chromosomes must contain a mutation. Single tumors occur in two-thirds of retinoblastoma patients (somatic form), and these mutations are limited to the retina. Multiple tumors occur in one-third of cases (germinal form) and are thereby reproduced in every cell of the body. A positive family history is present in 5–10% of retinoblastoma patients.

Retinoblastoma is diagnosed in the first year of life in the familial bilateral cases and between 1 and 3 years of age in the sporadic unilateral cases. The most common initial sign is leukocoria (white pupil), followed by strabismus. Retinoblastoma is usually diagnosed on clinical grounds by an experienced observer. This can be confirmed by demonstration of typical intraocular calcification with CT. All family members should be examined.

The preferred therapy for this tumor has undergone extensive changes. Enucleation is no longer the sole and immediate treatment. Treatment of large retinoblastomas, failure of conservative treatment, or extensive vitreous disease requires enucleation in the majority of cases. It is important to operate without unnecessary delays. Conservative management to salvage at lease one eye includes external beam radiation (for larger and posteriorly located tumors), brachytherapy (intermediate tumors), cryotherapy (small, anteriorly located tumors), photocoagulation (small posteriorly located tumors), and, more recently, thermal-enhanced chemotherapy. Chemotherapy remains investigational. The decision regarding the treatment of retinoblastoma is complex and is best approached by a team of experienced specialists.

Retinoblastoma patients with germinal mutation and unilateral involvement are at risk for developing additional ocular and nonocular tumors. Primary intracranial tumors originating in the pineal gland with retinoblastoma-like histopathology are described as "trilateral retinoblastoma." Sarcoma in the orbit and throughout the body occurs up to 30 years after retinoblastoma treatment. Primary extraocular tumors associated with retinoblastoma have a very poor prognosis for survival.

Retinopathy of Prematurity

ROP is an abnormal vasoproliferation in the retina of premature infants (see Chap. 304, "Proximal Renal Tubular Disorders"). Prematurity may trigger the onset

of ROP, causing abnormal neovascularization. With progression, fibroglial proliferation occurs that can lead to retinal traction or detachment. ROP is common in infants with birth weights of less than 1,500 g. As gestational age and birth weight decrease, the risk of ROP increases.

Supplemental oxygen has been implicated as a cause of ROP, although factors other than hyperoxia play a role in ROP. Gestational age and birth weight are inversely correlated to the development of ROP. The amount of time of oxygen therapy correlates well but the limit of oxygenation does not. Certain diseases are commonly seen in association with ROP, including respiratory distress syndrome, patent ductus arteriosus, apnea, bradycardia, intracranial hemorrhage, sepsis, anemia, and jaundice. An international classification of ROP has been developed that describes the disease in detail.

The initial fundus examinations of infants weighing less than 1,500 g is at 4–6 weeks after birth. The Cryotherapy for Retinopathy of Prematurity Cooperative Group study has shown that cryotherapy decreases visual loss by 46%. Laser photocoagulation is a newer treatment modality and considered by leading authorities as superior to cryotherapy. Vitamin E has been proposed as a treatment to reduce ROP, although no confirming data have been established. ROP regresses in most cases. Grave sequelae of advanced disease include retinal detachment, retinal folds, dragging of macula, amblyopia due to high myopia, microphthalmos, cataract, glaucoma, and phthisis bulbi. Enucleation is sometimes necessary.

Persistent Hyperplastic Primary Vitreous

PHPV is the most common cause of a unilateral cataract in a newborn or infant. An eye with PHPV is usually smaller than the normal eye. In mild PHPV, the only abnormality may be a persistent hyaloid artery, with or without a small opacity on the posterior surface of the lens. In a more advanced stage, an opacity is detected in the posterior portion of the lens cortex. The more advanced stage is characterized by a total cataract and a flat anterior chamber.

This condition is usually unilateral. It is not inherited, and it is not associated with any systemic condition or disease. In the extremely unusual event that PHPV is bilateral, Norrie disease should be considered in the differential diagnosis.

PHPV in the moderate or advanced stage is treated surgically by removing the lens and the retrolental membrane. The visual outcome can be poor because of the amblyopia characteristic of a unilateral cataract and the foveal hypoplasia that typically accompanies PHPV, although some reports have reported a good visual outcome.

Many eyes with PHPV can be saved by early surgical intervention followed by aggressive contact lens wear combined with eye patching.

Shaken-Baby Syndrome

Shaken-baby syndrome was first identified in the early 1970s. It became widely recognized as one of the most important forms of child abuse. These infants are victims of violent shaking by a parent and are always under 3 years of age. The characteristic clinical findings support the diagnosis of shaken-baby syndrome even in the absence of a history.

The most common ocular manifestation of shaking injury in most cases is retinal hemorrhage that is concentrated around the macula or involves nearly the whole retina. Vitreous hemorrhage may also develop. The vitreous becomes almost completely opacified by dispersed hemorrhage within a few days of injury, and this opacification may persist for many months or even years. The retinal hemorrhage in shaken-baby syndrome resolves over a week to several months. The mechanism of ocular injury in the shaken-baby syndrome is controversial. Some believe that intraocular hemorrhage results from increased pressure in the retinal veins secondary to increased intracranial pressure or increased intrathoracic pressure. Others have postulated that the shaking trauma itself causes retinal tissue damage and secondary hemorrhage. Retinal hemorrhage due to birth trauma is common in newborns but seldom persists beyond 1 month of age. Complete or near-complete recovery of vision is common in shaken-baby syndrome.

416 Surgical Conditions Presenting During Fetal Development

Rajan K. Thakkar · Francois I. Luks

As prenatal imaging techniques have evolved, so has the ability to diagnose and treat surgical conditions in the developing fetus. The prevalence of major birth defects is around 3% of live births, while the incidence of minor birth defects is at least three times as common. Surgically correctible births defects are seen in less than 1% of live births. Many surgical diseases arising in utero cause anatomic abnormalities that interfere with normal organ development. This makes in utero therapeutic strategies tempting and is one reason why fetal intervention continues to be an area of intense research. In utero imaging, in combination with molecular analysis, amniocentesis, chorionic villus sampling, fetal tissue biopsy, and other modalities, not only provides ever more precise diagnosis, but often prognostic information as well. This gives us the ability to counsel parents about therapeutic options and realistic outlook. While prenatal intervention may be entertained in certain cases, the vast majority of surgical conditions diagnosed in utero are best treated after birth.

Definition and Classification

A surgical condition can be diagnosed prenatally in three ways: First, the diagnosis can be suggested through genetic or biochemical testing. A classic example is open neural tube defect (spina bifida). Prenatal screening includes an elevated maternal serum alpha-fetoprotein (MSAFP) level. This suggests leakage of fetal proteins through an integumental breach (a neural tube defect, but also an abdominal wall defect such as gastroschisis). Second, the surgical condition itself may be visible on prenatal imaging. A typical example might be a large thoracic mass, an abdominal cyst, or a sacrococcygeal teratoma. Third, the mechanical effects of a surgical problem may become apparent. These secondary manifestations are relatively limited in number, and can give a clue as to the etiology and location of the primary defect. The most common of these signs is amniotic fluid volume. After the first trimester, amniotic fluid is mostly produced through fetal voiding. The fetus swallows the fluid, which is then absorbed through the small bowel and ultimately filtered and excreted through the kidneys, thus completing the cycle. Any interruption along this pathway can lead to abnormal amniotic fluid volume. Thus, interruption of the gastrointestinal tract proximal to the jejunum (such as duodenal atresia or complete esophageal atresia) will be associated with decreased intestinal fluid absorption and polyhydramnios. Polyhydramnios may also be due to kinking of the esophagus or gastroesophageal junction: This is often seen with congenital diaphragmatic hernia, when the intrathoracic stomach compresses the esophagus. Conversely, bilateral or distal obstruction of the urinary flow will cause oligohydramnios.

Surgical conditions can be classified as thoracic, abdominal, and parietal. They can be anatomic defects or proliferative lesions, both benign and malignant.

Thoracic Anomalies

Tracheoesophageal Fistula (TEF)/Esophageal Atresia (EA)

Esophageal atresia (EA) is a birth defect in which a portion of the primitive foregut is interrupted. The condition is most commonly associated with tracheoesophageal fistula (TEF), an abnormal connection between the trachea and esophagus. The trachea develops around the fourth week of gestation and disruption of the esophagus, with or without fistulization of the trachea, is believed to occur around this time. It is a defect of lateral septation of the foregut due to defective cellular signaling. Because of these improper cellular interactions, TEF/EA is often associated with other congenital anomalies. Grouping of these disorders makes up the VACTERL association (Vertebral, Anorectal, Cardiac, Tracheo-Esophageal, Renal, and Limb). The classification is based on the anatomic relationship between the esophagus and the trachea. The incidence is approximately 1 in 3,500 live births with a slight male predominance.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_416,

The presentation of TEF/EA depends on the type. If there is no esophageal atresia (type E), which occurs in 5% of cases, the diagnosis is often made long after birth. In cases with EA, the fetus cannot swallow amniotic fluid, which may lead to polyhydramnios, as is often seen in type A (isolated atresia). The combination of excess amniotic fluid, a visibly distended upper esophagus, and absence of gastric and intestinal fluid on prenatal ultrasound is highly suggestive of type A esophageal atresia. Type B, the least common variant, has an associated proximal TEF – the proximal esophageal pouch may therefore be decompressed and not visible, but polyhydramnios and non-visualized stomach are typical. The differential diagnosis in utero includes other causes of polyhydramnios, such as intestinal atresia, some neurological disorders with impaired fetal swallowing, and other, rare disorders of the oropharynx. Examples are laryngotracheoesophageal clefts, esophageal strictures, and tubular esophageal duplications. Most commonly, however, an associated distal tracheoesophageal fistula allows fluid to bypass the atresia and make its way into the distal esophagus. The most common form is a blind-ending proximal esophageal pouch and a fistula between the distal trachea and the distal esophagus (type C). Because amniotic fluid volume is typically normal and fluid is seen in the stomach and intestines, prenatal diagnosis is usually not possible.

Whether it was suspected prenatally or not, final diagnosis is made after birth. Excessive salivation and the inability to pass a nasogastric tube into the stomach is the main feature in the diagnosis of EA. A chest radiograph is obtained to demonstrate the nasogastric tube coiled in the proximal esophagus, but a contrast study (instillation of 1 mL of barium will coat the upper pouch) is rarely necessary.

The immediate care of a newborn with TEF/EA should be decompression of the proximal EA with a nasogastric tube to prevent aspiration and further respiratory compromise. Most newborns with TEF undergo an attempt at definitive repair within the first few days of life. A preoperative workup with a thorough physical exam is critical to detect other associated anomalies, particularly the VACTERL association. A preoperative echocardiogram can help detect cardiac anomalies, which are seen in 20% of patients. More recently, minimally invasive thoracoscopic repair of TEF and EA has been described, but it is not yet known whether its long-term results match those of traditional repair.

Survival of isolated TEF/EA is 90–95%, but this rate may be lower if there are associated anomalies (cardiac defects and chromosomal abnormalities in particular). Surgical complications include anastomotic strictures and anastomotic leak. These patients may go on to develop disorders of esophageal motility, gastroesophageal reflux, tracheomalacia, and reactive airway disease.

Laryngeal atresia and tracheal atresia are very rare foregut anomalies that lead to lung fluid trapping, causing dramatic distension of the lungs. On prenatal imaging, the lungs will appear very large and fluid filled, and the diaphragms flattened or inverted (concave). In some cases, the increased intrathoracic pressure may even lead to mediastinal compression and hydrops. If the anomaly is diagnosed prenatally and the atresia is high, emergency tracheostomy at the time of an Ex-Utero, Intrapartum (EXIT) procedure may be lifesaving. While rare, this anomaly (which some have dubbed Congenital High Airway Obstruction, or CHAOS) is the experiment of nature that formed the basis for fetal tracheal occlusion as a treatment for severe pulmonary hypoplasia (see under "Congenital Diaphragmatic Hernia").

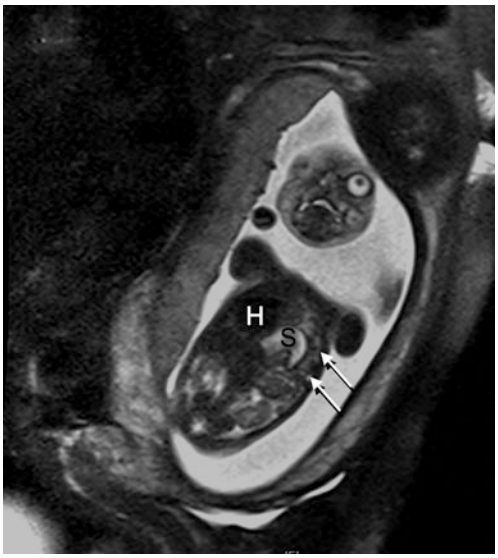
Congenital Diaphragmatic Hernia

In congenital diaphragmatic hernia (CDH), a defect in the diaphragm allows migration of abdominal contents into the thoracic cavity. The incidence of CDH is 1 in 2,000 to 3,000 live births. The most common and most frequently significant form is a posterolateral defect (Bochdalek). Herniation through a persistent foramen of Morgagni (an anterior, retrosternal defect in the diaphragm) is less common, and often diagnosed later in childhood. Posterolateral CDH is left sided in 80% and right sided in 20%. Bilateral CDH is extremely rare. The prognosis of CDH was long considered dismal, and severe forms are still often lethal. However, progress in neonatal management and respiratory care has significantly impacted the prognosis of CDH. Data from the CDH Registry show that isolated CDH (not associated with chromosomal or cardiac anomalies) now has an overall survival rate of greater than 70%. The pathogenesis of CDH is believed to occur from a failure of closure of the pleuroperitoneal folds during the fourth to tenth week of gestation. This time frame overlaps with a period of critical fetal lung development, from the 3rd to 16th week of gestation, suggesting a direct correlation between the severity of the diaphragmatic defect and the morbidity of this disease. Compression of the lungs by the abdominal contents causes pulmonary hypoplasia and interferes with the development of the pulmonary vasculature. This may ultimately lead to severe, refractory pulmonary hypertension after birth – the most common cause of death in CDH. Although early lung development and branching

morphogenesis may be seriously impaired by an intrathoracic mass effect, late lung maturation, at the end of the second trimester, is equally critical in ensuring normal postnatal pulmonary and pulmonary vascular function. The idea that mid-gestation reduction of the hernia or stimulation of accelerated lung growth (by fetal tracheal occlusion) may still reverse the effects of pulmonary hypoplasia lies at the basis of fetal surgery to treat severe CDH.

Diaphragmatic hernia can be diagnosed prenatally by ultrasound, which demonstrates abdominal viscera in the chest. In left-sided CDH, a fluid-filled stomach may be present in the same axial plane as the heart. In right-sided CDH, one may see a homogenous liver above the diaphragm. Because of the relatively solid appearance of fetal lung, it is not always easy to distinguish it from liver by ultrasound. Polyhydramnios may be present if there is compression of the esophagus or kinking of the gastroesophageal junction. However, hydrops (from compression of the mediastinum and impaired venous return) is rarely seen.

Magnetic resonance imaging (MRI) can be a useful diagnostic adjunct to confirm the diagnosis of CDH, to evaluate for other congenital anomalies, and to assess lung volume (◉ *Fig. 416.1*). The presence of abnormal structures in the fetal thorax can be a sign of CDH – or of other space-occupying thoracic masses. Differential diagnosis includes congenital pulmonary airway malformations (CPAM), bronchopulmonary sequestration (BPS), bronchogenic cysts, and, rarely, lymphangiomas, enteric cysts, and teratomas.



◘ Figure 416.1
Fetal MRI of a left-sided congenital diaphragmatic hernia. Coronal view of the fetus (T2-weighed image) showing small bowel loops (*arrows*) and stomach (S) in the left thoracic cavity, displacing the heart (H) into the right chest

Infants born with CDH most commonly present in severe respiratory distress. A chest radiograph typically demonstrates abnormal gas patterns in the left hemithorax, curling of the nasogastric tube in an intrathoracic stomach (left CDH), or presence of liver in the right hemithorax (right CDH). The mediastinum is deviated toward the contralateral side. Although the primary insult in CDH is pulmonary hypoplasia, it is rare for lung tissue to be so diminutive as to be incompatible with life. Rather, early hypoxia, hypercapnia, and acidosis all contribute to reflex vasoconstriction of the pulmonary arterial system and pulmonary hypertension (persistent fetal circulation), leading to refractory hypoxemia because of severe ventilation/perfusion (V/Q) mismatch. Right-sided heart failure may further complicate the infant's critical pulmonary condition. In severe cases, extracorporeal membrane oxygenation (ECMO) offers the only hope of temporary pulmonary rest and recovery from the cardiopulmonary insult.

Operative correction of the defect is never an emergency. Delayed repair allows stabilization of the infant during the transitional phase from fetal to adult circulation. Once surgical repair is indicated, it is typically performed through an abdominal incision, more rarely through the chest. During the procedure, the viscera are reduced into the abdomen and the diaphragm is closed primarily in most cases. If there is insufficient native diaphragmatic tissue, a synthetic graft is used.

No single prenatal factor to date can accurately predict survival in patients with CDH. There have been attempts at judging the degree of pulmonary hypoplasia and other perinatal factors, but they have had little success. However, the combination of several parameters, including early gestational age at diagnosis, polyhydramnios, mediastinal shift, a small lung-thorax transverse area ratio, left ventricle/right ventricle index, left heart hypoplasia, and the presence of stomach or liver in the chest, suggests a worse prognosis. The only parameter that comes close to predicting survival based on estimated fetal lung size is the lung-to-head ratio (LHR). It considers the surface area of the contralateral lung in a four-chamber view of the heart as a surrogate for three-dimensional lung size (volume), and is divided by the head circumference to normalize for gestational age. Normal LHR is greater than 2.5–3.5; an LHR greater than 1.4 is generally considered to indicate good prognosis, and an LHR between 1.0 and 1.4 considered an intermediate risk. Fetuses with an LHR

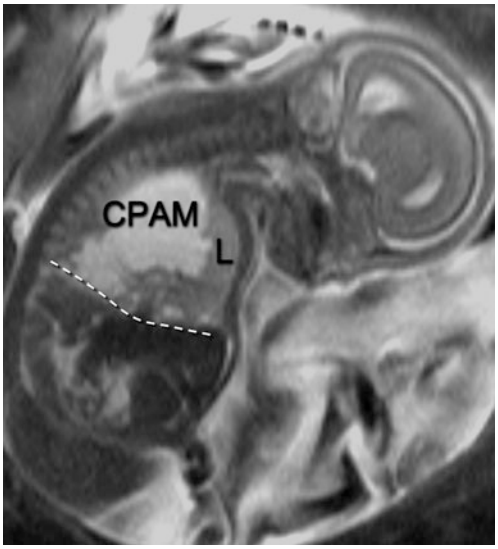
below 1.0 (most accurately measured at 26 weeks gestation) have the worse prognosis, with postnatal survival rates of 10–30% or less. Infants with CDH who survive the initial respiratory insult and management face many complications, including gastroesophageal reflux, foregut dysmotility, developmental delay, feeding difficulties, pulmonary hypertension, reactive airway disease, and chronic lung disease.

Bronchopulmonary Malformations

Congenital pulmonary airway malformations (CPAM) are a diverse group of rare developmental anomalies of the respiratory tract. The incidence of congenital lung cysts ranges from 1 in 8,300 to 35,000 live births. CPAMs, the more current term for what used to be called congenital cystic adenomatoid malformations (CCAM), are histologically divided into five types. The spectrum, from type 0 to type IV, is believed by some to mimic the normal bronchopulmonary anatomy from proximal airway to distal alveoli. A more practical classification considers their gross appearance: macrocystic (a few large cysts), microcystic or mostly solid. CPAMs usually have microscopic bronchial communications (pores of Conn) and arterial and venous branches that derive from the normal pulmonary circulation.

Bronchopulmonary sequestration (BPS) is another type of congenital pulmonary lesion. Intralobar sequestrations are found within the lung parenchyma, and resemble CPAMs. Extralobar sequestrations, by contrast, are invested with their own visceral pleura, are distinctly separate from the lung, and typically have an arterial feeder off the systemic blood supply. As these lesions typically occur in the lower thoracic cavity, the feeding artery comes off the descending aorta, often from its infradiaphragmatic portion. While sequestrations have a more homogeneous histology that resembles normal lung parenchyma, up to 50% of these also harbor CPAM elements.

The clinical manifestation can vary from a fatal condition in the fetus to a mild lesion in a child leading to recurrent pulmonary infections. Many CPAMs and sequestrations are diagnosed on routine prenatal ultrasound. Fetal MRI may be used to further define the lesion. The differential diagnosis includes bronchogenic cysts, congenital lobar emphysema, and congenital diaphragmatic hernia. The prognosis is largely based on the type of malformation and the extent of disease. Large lesions may cause severe mediastinal shift and even fetal hydrops, or lead to lung compression and pulmonary hypoplasia (◉ *Fig. 416.2*). In these situations, *in utero* intervention



◘ Figure 416.2
Large right-sided CPAM, compressing normal lung (L) and right hemidiaphragm, which is concave (*dotted line*). Sagittal view on fetal MRI

may be the only option: Large cysts can be decompressed with a needle or by cyst-amniotic shunt. If they are microcystic or solid in appearance, drainage is not an option and open fetal surgery with fetal thoracotomy and resection is warranted. Fortunately, more than 70% of CPAMs regress over the course of fetal development and never require fetal intervention. Most peak at 20–24 weeks gestation; if hydrops has not developed, observation is in order, and gradual decrease in size is typically observed by early third trimester. By then, late lung development can occur unimpaired, and most infants have no symptoms at birth.

Bronchogenic cysts are almost always unilocular, rarely become large enough to cause mediastinal shift, and have a very benign course. While they can be detected prenatally, many are found on a routine chest radiograph or unrelated chest CT scan later in childhood, and even in adulthood.

Postnatal management of congenital lung lesions is the subject of some debate. Due to their direct communication with the bronchial tree, some of these lesions can lead to air trapping, recurrent pneumonia, and abscess formation (◉ *Fig. 416.3*). In these cases, drainage may be warranted, followed by resection. Asymptomatic patients should be followed, and elective resection at 1–2 years of age is recommended by many. The risk of infection is

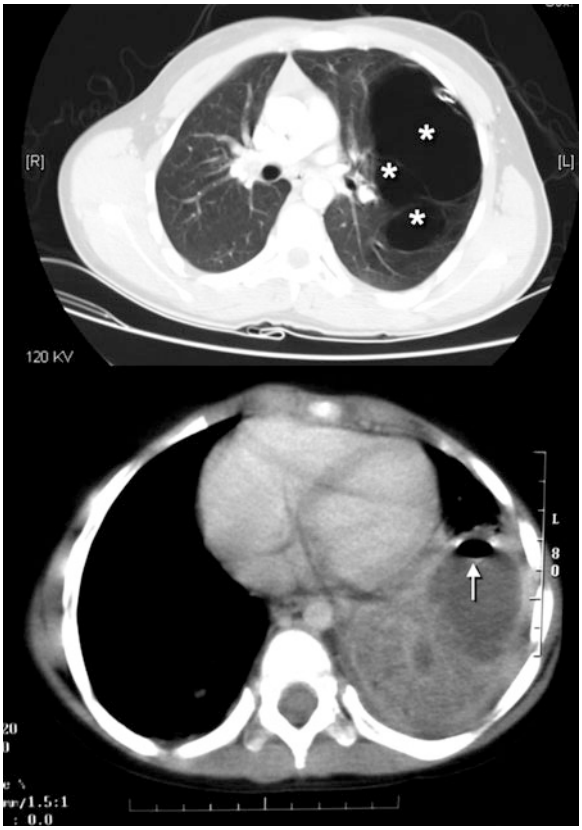


Figure 416.3
CT scan in children with CPAM. Top: several large air-filled cysts within the left lung (*asterisks*), suggesting communication with the tracheobronchial tree. Bottom: different patient with known CPAM of the left lower lobe, presenting with recurrent infections of the lesion (*arrow*: air-fluid level in an abscess)

most often cited as indication, but there appears to be a risk of malignancy as well, albeit very small. The controversy stems from the real malignant potential: Some lesions that were previously reported as malignant transformation in a CCAM were most likely pulmonary blastomas, a malignant tumor of early childhood that is radiologically and histologically similar to CPAM. Extralobar pulmonary sequestrations do not communicate with the tracheobronchial tree and are therefore not at risk of infection. However, 50% of these lesions contain some elements of CCAM – whether that increases the risk of malignancy later in childhood is a matter of debate. Today, elective resection of most of these lesions can be performed using minimally invasive techniques.

Abdominal Anomalies

Intestinal Obstruction

There are many causes of gastrointestinal obstruction in the developing fetus. While the exact nature of the obstruction may be difficult to diagnose in utero, certain patterns and association can help narrow the differential diagnosis. This rarely impacts on clinical decision making, but greatly helps counsel future parents regarding the need for postnatal intervention and long-term outcome. Obstructions can occur anywhere along the gastrointestinal tract, from the foregut to the hindgut, and may be due to atresia (intrinsic obstruction) or extrinsic compression (such as Ladd's bands or an annular pancreas).

Duodenal obstructions can be intrinsic or extrinsic. Duodenal atresia has an incidence of 1 in 30,000 live births and is thought to arise from incomplete vacuolization or recanalization around weeks 8–10 of gestation. This is in contrast to most other forms of intestinal atresias, which are believed to occur as a result of a vascular accident (see below). Recanalization of the duodenum, around the sixth week of gestation, occurs while the dorsal and ventral buds of the pancreas develop and ultimately fuse; this explains why duodenal atresia is often associated with an annular pancreas. Prenatal diagnosis of duodenal obstruction is relatively straightforward, even if its exact cause is not. Obstruction of the second part of the duodenum will cause distension of the proximal duodenum which, together with the stomach, creates a "double bubble" in the upper abdomen of the fetus. Because the obstruction is proximal, swallowed amniotic fluid cannot be absorbed and polyhydramnios is common. This, in turn, increases the risk of preterm delivery. While the majority of duodenal obstructions are isolated, up to 30% of duodenal atresias are associated with trisomy 21. Amniocentesis is therefore offered if the parents want to know whether there is a chromosomal anomaly.

At birth, the clinical features of duodenal obstruction, be it from an atresia or an annular pancreas, are bilious emesis without significant abdominal distension. This is due to the fact that most duodenal atresias occur just distal to the ampulla and the small and large intestine are collapsed. Characteristic imaging findings include gas distension of the stomach and proximal duodenum – the double bubble. If no distal gas is seen, the occlusion is complete – typically, an atresia. Annular pancreas more commonly causes a partial obstruction, and some scattered gas can be seen in distal bowel loops. A partial obstruction is also seen with a perforated duodenal web or extrinsic

compression by Ladd's bands in case of intestinal malrotation. With a classic double bubble and an otherwise gasless abdomen, no further studies are usually necessary, and surgical exploration should be performed. In cases of incomplete duodenal obstruction, the diagnosis may be more difficult as infants may be able to tolerate some feeds. If a partial obstruction is suspected, the patient should undergo an upper gastrointestinal contrast study to delineate the cause. Duodenal atresia itself is not a surgical emergency, but midgut volvulus is – and any suspicion of this requires a fast and efficient workup. Surgical repair can be done by open surgery or minimally invasive laparoscopic techniques. Long-term prognosis in patients with duodenal atresia is excellent and survival should exceed 90%. Mortality is generally due to associated anomalies.

Atresias and other forms of obstruction can occur along the entire intestinal tract, but small bowel atresia is much more common than colonic atresia. Unlike duodenal atresia, intestinal atresia is thought to result from vascular disruption during fetal life. This may be secondary to vascular occlusion, constriction, or even external compression of mesenteric vessels, leading to sterile necrosis of the affected intestinal segment – which in turn is followed by scarless resorption of the dead tissue and proximal and distal blind ends. The more proximal the intestinal atresia, the more likely it is associated with polyhydramnios. More distal obstructions are associated with multiple dilated loops of bowel, hyperechoic bowel, and ascites. The differential diagnosis of intestinal atresia includes malrotation, intestinal duplication, Hirschsprung's disease, and meconium ileus. Meconium ileus, in particular, must be ruled out as it is almost always associated with cystic fibrosis. Moreover, intestinal loops that are distended with thick, tenacious meconium may undergo volvulus, causing vascular occlusion and secondary intestinal atresia. In utero perforation of an intestinal loop secondary to volvulus may cause leakage of meconium into the peritoneal cavity. Although sterile, the meconium produces an intense inflammatory reaction (meconium peritonitis) characterized by ascites and, later, stippled calcifications of the peritoneum. It can also lead to a walled-off collection of meconium-stained fluid termed meconium pseudocyst.

Most cases of intestinal atresia are confirmed shortly after birth, when then infant presents with abdominal distension and vomiting. Passage of meconium in the first 24–48 h does not rule out an intestinal atresia, as the obstruction may be proximal. The diagnosis is typically suspected on the basis of history and physical examination, and confirmed by radiographic studies. The appearance of multiple loops of distended bowel and air-fluid levels suggests a distal obstruction, whereas few loops are seen in a proximal obstruction. A contrast enema can be done to evaluate and confirm the presence of an unused "microcolon" and to look for other, more distal segments of intestinal atresia (*Fig. 416.4*). As with all forms of obstruction, immediate treatment aims at hydration, correction of electrolyte derangements, and gastrointestinal decompression with a nasogastric tube. Operative repair is generally accomplished once the infant is hemodynamically stable and other associated anomalies are ruled out. A primary anastomosis is typically performed if the size discrepancy between proximal and distal ends is moderate. If the proximal pouch is much larger than the distal, collapsed bowel, a temporary stoma may be necessary.

If meconium ileus is suspected as the source of the obstruction, workup and treatment of the infant may have to be altered. An abdominal radiograph at birth will show numerous dilated loops of bowel, but because the thick meconium does not layer out, air-fluid levels will be absent. Instead, a "soap bubble" appearance is seen as a result of gas trapped in the viscous meconium. Patients with meconium ileus may present with severe dehydration, and intravenous resuscitation is crucial. If the infant is stable and in the absence of meconium

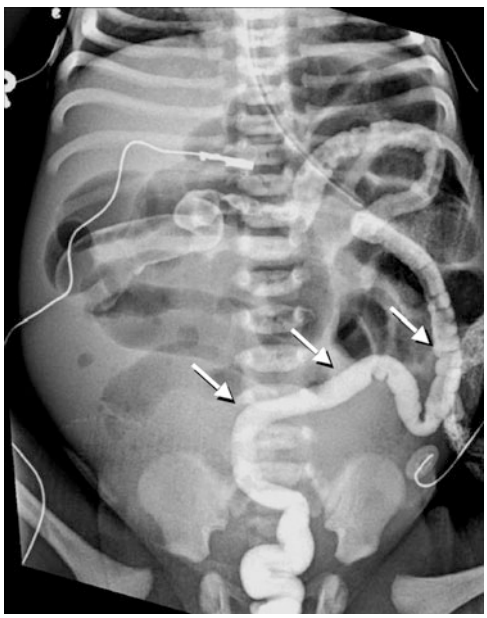

Figure 416.4
Intestinal obstruction in the neonate, secondary to meconium ileus. Note dilated gas-filled small bowel loops and a small, unused "microcolon" (*arrows*) on a contrast enema study

peritonitis, nonoperative treatment may be attempted. Retrograde rectal irrigation with hyperosmolar water-soluble contrast material may loosen the inspissated meconium. The need for adequate hydration cannot be overstated, as these agents have significant hygroscopic properties. If attempts at nonoperative management are unsuccessful, surgical intervention is required. The prognosis of meconium ileus is good, but the long-term outlook is determined by the underlying cystic fibrosis. Of note, the presence of meconium ileus does not represent a worse prognosis for cystic fibrosis – and may allow diagnosis and preventive measures even before any respiratory problems arise.

Hepatobiliary Anomalies

Choledochal cysts are congenital anomalies of the biliary tract characterized by either single or multiple cystic dilatations of the extrahepatic or intrahepatic bile ducts. The incidence of this disease ranges from 1:100,000 live births in Western countries to as high as 1:1,000 in Japan, with an overall female predominance. Most cases are diagnosed postnatally, sometimes in late childhood and even adulthood. However, with the evolution of ever-better fetal ultrasonography and magnetic resonance imaging, more cases are diagnosed *in utero*.

There are many theories to explain the pathogenesis of choledochal cysts. The most popular theory is that of an abnormal arrangement of the pancreaticobiliary ductal system in which the pancreatic duct enters the common bile duct at an abnormal angle. This allows reflux of pancreatic enzymes resulting in damage to the ductal wall and cystic dilation. Alternative theories implicate the common portion of the pancreatic and biliary ducts, which may be longer than normal and predispose to bile duct damage by pancreatic secretions, or a congenital defect in the proliferation of the bile duct epithelium. The most common clinical presentation is jaundice in the neonatal period or beyond, with or without a palpable abdominal mass. *In utero* detection of a cystic mass in the right upper quadrant may lead to the suspicion of a choledochal cyst. Fetal MRI may further delineate the hepatobiliary anatomy and confirm the diagnosis. This early detection can allow prompt diagnosis postnatally and lead to early referral to a tertiary care center. A cyst at the confluence of the right and left hepatic ducts may also be a sign of biliary atresia, which has a more guarded prognosis and requires expeditious workup after birth.

Postnatal ultrasonography of a suspected choledochal cyst may demonstrate dilated extrahepatic (and often intrahepatic) biliary ducts. The diagnosis may be confirmed by computed tomography with intravenous and oral contrast or, more commonly today, by magnetic resonance choledochopancreatography (MRCP). A technetium-99 m diisopropyliminodiacetic acid (DISIDA) scintigraphy can be performed to assess bile drainage. The differential diagnosis includes biliary atresia, hepatic cysts, and gallbladder duplication. Drainage of the cyst is no longer considered standard of care as patients may go on to develop cholangitis and biliary cirrhosis. Surgical resection of the cyst with enteric drainage via a Roux-en-Y hepaticojejunostomy is the most effective treatment. The prognosis of this disease largely depends upon the presence of cirrhosis or portal hypertension prior to surgical resection.

Genitourinary Anomalies

Obstructive Nephropathy

Fetal hydronephrosis is one of the most common findings on prenatal ultrasound. However, it is usually mild and its prognosis is excellent. Prenatal detection allows early postnatal diagnosis and management. In most cases, the condition is self-limited, but close follow-up by a pediatric urologist is necessary to protect against recurrent infections and deterioration. In some cases, the hydronephrosis is severe and surgical intervention is required in infancy or beyond.

In case of bilateral ureteral or renal disease, fetal renal function may be impaired. Since amniotic fluid is mostly fetal urine, bilateral urinary tract obstruction or anuria leads to oligo- or anhydramnios which, as outlined above, results in extreme pulmonary hypoplasia incompatible with postnatal life. The exact cause of the urinary obstruction is less important than its effect. Hydronephrosis and hydroureters in the presence of normal amniotic fluid volume is best monitored and left alone until after delivery. On the other hand, oligohydramnios and evidence of urinary obstruction can be treated *in utero* by vesico-amniotic shunting, typically under ultrasound guidance. Bilateral urinary tract obstruction occurs mostly in males, and is almost always due to posterior urethral valves.

While vesico-amniotic shunting theoretically bypasses the obstruction and relieves pressure on the urinary system, renal outcome is often compromised, and many of these infants go on to develop renal failure. However, restoration of amniotic volume can be lifesaving as it prevents the progression to pulmonary hypoplasia. The most difficult therapeutic decision is patient selection: If renal

failure is too advanced, urine production may no longer be sufficient to restore amniotic fluid volume. Several tests of fetal renal function exist, including ultrasound appearance of the kidneys and fetal urinary electrolyte and beta-2-microglobuline determination – but no test can predict renal function with sufficient accuracy.

Ovarian Cysts

The female fetus is sensitive to maternal hormonal stimulation, and small cysts of the fetal ovaries are not uncommon. With the dramatic improvements in fetal imaging, fetal ovarian cysts are diagnosed increasingly often. The differential diagnosis includes any other abdominal cyst, including choledochal cyst, intestinal duplication, mesenteric cyst and lymphatic malformation, and neurenteric cyst and liver cyst. However, the presence of a cyst in the pelvis in a female fetus is almost always ovarian in origin.

As long as it remains relatively small, observation is in order, and parents can be reassured that the cyst will regress after birth, once maternal hormones no longer stimulate the infant's ovaries. However, larger cysts are at risk of torsion and adnexal ischemia (*Fig. 416.5*). A cyst diameter of 4–5 cm has been used as predictor of torsion, but smaller cysts have been known to twist, while many larger ones have not. Fetal intervention, in the form of ultrasound-guided cyst aspiration, had been proposed in the past. Now, however, most specialists agree that the theoretical risk of torsion of one of two ovaries is not worth the risk of fetal complications, infection, or even pregnancy loss. Large cysts are best monitored closely, however, and ultrasound-guided aspiration after birth is recommended.

Torsion and necrosis of the right ovary and salpinx in a newborn (laparoscopic view). Prenatal torsion of a large ovarian cyst was suspected by ultrasound. U: uterus

Parietal Anomalies

Abdominal Wall Defects

Abdominal wall defects (AWD) are commonly diagnosed by prenatal imaging. The two most common types of AWD are gastroschisis and omphalocele. Other rare types include ectopia cordis (isolated, or as part of a pentalogy of Cantrell) and cloacal exstrophy.

Gastroschisis is a defect of the anterior abdominal wall, which allows evisceration of the intestines. The defect is typically small and is almost always located to the right of an intact umbilical cord. The incidence of gastroschisis is 1 in 3,000 live births. Males and females are affected equally, and most are born to young mothers. Gastroschisis is not typically associated with other congenital anomalies, except intestinal atresia, which occurs in 5–10%. Because atresia in this setting is likely the result of mesenteric vascular compromise through a small abdominal wall defect, it is more a complication of gastroschisis than an associated anomaly. In extreme cases, the vascular strangulation occurs at the root of the mesentery, leading to necrosis of the entire midgut (jejunum to mid-colon) and devastating short-bowel syndrome. The pathogenesis of gastroschisis is not clearly understood. Some have implicated early disappearance of a right umbilical vein (in the young embryo, umbilical veins are paired), or weakness of the umbilical cord at the site of the vitelline vessels. The pathogenesis is distinct from that of omphalocele, which is an abnormal herniation into the umbilical cord. Most cases of gastroschisis are diagnosed *in utero*. Ultrasonography demonstrates a cluster of bowel loops protruding into the amniotic cavity, lateral to a normal umbilical cord insertion. Early diagnosis allows referral to a tertiary care medical center for delivery. While altering the place of delivery ensures a smooth transition to postnatal care, altering timing (preterm) or mode of delivery (Cesarean section) has not proven beneficial. Some have even advocated aggressive fetal treatment by exchange amnioinfusions, in the belief that "caustic" amniotic fluid causes the typical damage to the intestinal wall and mesentery. However, the correlation between exposure to amniotic fluid and intestinal "peel" has never been confirmed, and prenatal intervention introduces a risk to the pregnancy that is difficult to justify.

At the time of delivery, these infants require neonatal intensive care monitoring. They have high sensible loss because of the exposed viscera, which also places them at high risk of hypothermia. The most expeditious and safe maneuver is to place the infant up to the chest into a sterile bowel bag. At the bedside, a silicone rubber (Silastic®) "silo" can be placed around the visceral contents and sealed intra-abdominally around the defect with a watertight spring-loaded elastic ring. The abdominal cavity adapts to the gradual reduction of the viscera (by gravity and gentle manual compression); once near-reduction of the visceral contents has been achieved (typically at 1 week of life), a delayed primary repair is performed in the operating room. Parenteral nutrition is crucial as these infants typically have an ileus, which may last for weeks. Rarely, the defect and the herniation are small enough so that primary repair can be achieved at birth. However, the wide availability of preformed spring-loaded silos, which do not require abdominal wall dissection or suturing, has made delayed repair the preferred approach in most cases. The survival rate for patients born with gastroschisis is greater than 90% for those who have adequate resuscitation, nutrition, and surgical intervention. Morbidity is largely due to sepsis (including necrotizing enterocolitis), short-bowel syndrome if multiple atresias are present, and TPN-related complications. An extreme form of abdominal wall defects is associated with extreme spine deformity and sometime grotesque truncal, facial, or limb anomalies. This limb-body-wall-complex or amniotic band syndrome (ABC) is due to early gestation amniotic disruption and is not compatible with life.

Omphalocele is also the result of an abdominal wall defect, but herniated viscera are typically covered by an umbilical membrane. The defect may be larger than that of gastroschisis, and the umbilical cord inserts into the sac. The incidence of omphalocele is 1 in 5,000 live births. In contrast with gastroschisis, infants with omphalocele are more likely to have other congenital anomalies. These include Pentalogy of Cantrell (omphalocele, diaphragmatic defect, sternal cleft, pericardial defect, and cardiac anomalies), cloacal exstrophy (also termed OEIS, for omphalocele-exstrophy-imperforate anus-spinal defects), and chromosomal disorders, including trisomies 13 and 18. The diagnosis of omphalocele is typically made on prenatal ultrasound, which demonstrates a mass anterior to the abdominal cavity at the site of cord insertion (*Fig. 416.6*). The abdominal cavity itself may appear scaphoid, and the relative paucity of abdominal contents accounts for a small abdominal circumference by ultrasound measurement. The presence of an omphalocele on prenatal ultrasound should raise the suspicion of other associated anomalies.

Figure 416.6
Small omphalocele. *Top*: prenatal ultrasound showing a small abdominal wall defect. *Bottom*: same infant at birth; note thrombosed umbilical arteries on the surface of the omphalocele sac

The clinical presentation and management varies with the size of the omphalocele. Omphaloceles that contain a large portion of the liver, in addition to hollow viscera, are termed "giant" omphaloceles and are more difficult to manage than those with a smaller defect. Herniation of the liver creates a tortuous and angulated inferior vena cava in which attempts at acute reduction can impair venous return and compromise the infant's cardiovascular function. These patients will require a more gradual reduction and possibly a staged abdominal wall closure. Morbidity varies based on the size of the defect and the presence or absence of liver within the sac. Mortality is most often related to associated congenital anomalies.

Open Neural Tube Defects (Spina Bifida)

The incidence of primary neural tube defects is around 1 in a 1,000 live births, but varies with ethnicity. There is

a higher prevalence in Americans than in Asians, and those of Irish descent have reported rates as high as 1 in 100 live births. The most common primary neural tube defect is a myelomeningocele (MMC), which is a lesion that contains both meningeal and neural components. It results from the failure of the neural tube to fully close during the fourth week of gestation. This leads to exposure of the neural plate along the midline of the back. Widespread prenatal screening with maternal serum markers (maternal serum alpha-fetoprotein, MSAFP) and ultrasonography have greatly increased prenatal detection, while vitamin B12 supplementation of a pregnant woman's diet has greatly reduced its incidence. Screening studies (MSAFP) and ultrasonography are typically followed by amniocentesis for karyotyping and to measure AFP and acetylcholinesterase levels. Fetal MRI offers higher resolution images of the defect. The majority of patients with myelomeningocele have a defect along the lumbar area and present with a cystic mass containing the neural placode, arachnoid, dura, nerves, and cerebrospinal fluid. The level of the lesion dictates the level of the corresponding motor dysfunction, which can range from mild gait problems to paralysis and stool and urine incontinence. Associated anomalies almost always include bifrontal indentation of the skull ("lemon" sign), changes in the cerebellar anatomy ("banana" sign), and some degree of hindbrain herniation (Chiari II malformation). While myelomeningocele is not a lethal condition, some of its complications (hydrocephalus and acute hindbrain herniation) can be devastating in infancy and early childhood. Prenatal diagnosis allows referral to a tertiary care facility with neurosurgical support, and discussions regarding timing and mode of delivery.

At birth, infants with an open neural tube defect need to be assessed for the level of the lesion, and care should be taken to keep the defect sterile. Treatment is aimed at early closure of the defect, typically within the first 72 h of life. The prognosis of patients born with spina bifida is highly variable and depends on the level of the lesion, along with the presence or absence of any other severe central nervous system anomalies. In 2011, the results of the 8-year randomized controlled "Management of Myelomeningocele Study" (MOMS trial) were published. It was revealed that *in utero* repair of the defect delayed the need for ventriculoperitoneal shunting and improved motor function at 30 months. However, infants who had undergone prenatal surgery were born more prematurely than controls, and maternal morbidity was not insignificant.

Fetal Tumors

Fetal tumors are very rare – and most are benign. They can cause serious harm to the fetus and the neonate, however, depending on their location and their size. The most common tumors are teratomas, neuroblastomas, and lymphatic/vascular malformations.

Teratomas

By definition, teratomas contain derivatives of all three primitive cell layers (endoderm, mesoderm, and ectoderm). They typically occur in the migration path of totipotential cells along the primitive streak – but they can also migrate cephalad of the umbilical cord, giving rise to thoracic and cervical tumors. Two major types have perinatal significance: sacrococcygeal teratomas and cervical tumors.

Sacrococcygeal teratomas arise from the primitive node of Hensen, and can be predominantly intrapelvic or external. The intrapelvic tumors may be diagnosed as a cystic mass and obstruct the urinary system, giving rise to bilateral hydronephrosis. Rarely, they may cause intestinal obstruction as well, as evidenced by dilated intestinal loops on prenatal ultrasound. Sacrococcygeal teratomas with a large external component can cause significant shunting of blood away from the fetus, leading to cardiac failure and hydrops. Often, placentomegaly is present, and the mother is at a higher risk of preeclampsia – a phenomenon dubbed "mirror syndrome," as both mother and fetus exhibit signs of cardiovascular failure. As long as hydrops is not present, no intervention is necessary and the course of pregnancy is typically benign. If the tumor is very large, Cesarean section may be indicated to avoid rupture and bleeding from the middle sacral artery (a branch of the aorta). Despite the sometimes disfiguring effect of the tumor on the perineal structures, complete surgical resection is almost always feasible and patients do well postoperatively. Gross continence problems are rare, but constipation is not uncommon. Up to 10% of sacrococcygeal teratomas contain malignant elements. This incidence increases with age, and recurrence must be avoided by complete excision of all external and internal tumor components, as well as the coccyx.

If the fetus shows signs of impending hydrops (typically, before 25 weeks gestation), or there is evidence of preeclampsia, urgent intervention is indicated. Open fetal surgery and resection of the tumor may be the only option, other than termination – but is a very invasive

undertaking, best performed in specialized centers. Attempts at endoscopic or ultrasound-guided occlusion of the tumor's feeding vessels have been described, but results have been disappointing.

The second most common location for fetal teratomas is the neck. Cervical teratomas, while mostly benign, can become very large and produce significant compression and displacement of neck structures. The biggest threat comes at the time of delivery – if the tumor is large enough to obstruct the airways, it is unlikely that the infant can be intubated in a timely fashion (◉ *Fig. 416.7*). In these cases, a planned, modified Cesarean section allows the team to secure an airway even before the umbilical cord is clamped. This approach, initially termed Operation On Placental Support (which makes for an unfortunate acronym), is now better known as EX-utero/InTrapartum, or EXIT procedure. It requires a lot of preparation and coordination between the obstetrical and neonatal teams to allow sometimes prolonged procedures while the uterus remains relaxed, the placenta functional, and the fetus partially exteriorized. EXIT procedures are also recommended for other forms of upper airway obstruction, including large lymphatic or vascular malformations, extreme hypognathism, and fetal tracheal occlusion to treat congenital diaphragmatic hernia (see above).

Figure 416.7
Large cervical teratoma distorting the normal head and neck anatomy. If diagnosed in utero, an EXIT procedure may be indicated to assure airway control before the umbilical cord is clamped

Neuroblastoma

Neuroblastoma is the most common of the very rare malignant tumors of the fetus. These are tumors of neural crest origin and may arise anywhere along the sympathetic chain, the most common site being the adrenal gland. The incidence of these tumors is about 1 in 10,000 live births, with a slightly higher rate in males. When detected prenatally, these are seen as adrenal masses, most often during the third trimester. The differential diagnosis includes adrenal hemorrhage and developmental anomalies such as intestinal duplications and subdiaphragmatic pulmonary sequestrations. Based on autopsy series, up to 1% of fetuses have foci of neuroblastoma within the adrenal glands; however, they usually undergo apoptosis during the third trimester and regress spontaneously. Although malignant, congenital neuroblastoma most often has a course that is even more favorable than infant neuroblastoma. The presence of an adrenal mass on fetal ultrasound warrants close follow-up throughout the pregnancy and once the infant is born.

Vascular and Lymphatic Malformations

Vascular and lymphatic malformations may be seen on prenatal ultrasound as complex cystic lesions. These vascular anomalies are some of the most common birth defects seen worldwide. During embryonic development, the vascular structures develop in close relation to the lymphatic system, and errors in development of these structures account for vascular and lymphatic malformations. Lymphatic malformations (also referred to as lymphangiomas or cystic hygromas) are most commonly located in the upper part of the body, with a predilection for head and neck. When they occur in the abdominal cavity, the differential diagnosis includes mesenteric cysts, enteric duplication cysts, choledochal cysts, teratomas, neuroblastomas, and urachal cysts. These lesions are classified according to the predominant vessel involved and mixed lesions are labeled with each involved channel. In extreme cases, large malformations can lead to fetal hydrops. These lesions do require close follow-up and further evaluation after birth.

417 Chest and Abdominal Wall Anomalies

Kenneth S. Azarow

Chest Wall Anomalies

Definition

Thoracic body wall anomalies have been grossly characterized into depressions: pectus excavatum, protrusions: pectus carinatum, and mixed deformities resulting in either protrusion or depression with rotation. Fusion deformities are those resulting in sternal cleft; the most severe form resulting in Cantrell's pentalogy: cleft sternum, ventral diaphragmatic hernia, omphalocele, and ecotpia cordis with the pericardial defect being at the apex, and intracardiac defects. Rib deformities can also be associated with soft tissue defects as in Poland's syndrome characterized by the absence of costal cartilages or portions thereof form the second to fourth ribs, hypoplasia and absence of the nipple and breast, minimal subcutaneous fat, absence of axillary hair, absence of the pectoralis minor muscle, and absence of the costosternal portion of the pectoralis major muscle.

Etiology

Although the etiology of these disorders was once debated in the literature, it is now generally agreed that pectus excavatum and carinatum deformities are a result of dysmorphic growth of costal cartilage, resulting in an abnormal position/rotation of the sternum. As a result, these defects may or may not be recognizable at birth and are often accentuated during growth spurts. Sternal cleft is an embryologic phenomenon caused by failure of lateral mesodermal plates to fuse during the first weeks in utero. This deformity is recognizable at birth, and usually presents in isolation and is not typically part of any syndrome.

Epidemiology

The prevalence of pectus excavatum is approximately 1/400 live births. There is no known genetic link, but 40% of patients with pectus excavatum (PE) report that a family member has a chest wall deformity. It is more common in males, with a male-to-female ratio of approximately 5:1. Most series report that excavatum is more common than carinatum at rates 6–10:1. A true incidence of sternal cleft cannot be accurately estimated as the condition is considered rare. Most series report only a handful of cases. Based upon the volume of reports and the extensive nature of the experiences published, the incidence of chest wall deformities appears to be higher in South America although specific epidemiologic data is lacking. One study estimates the incidence of pectus deformities as high as 2% in the city of Manaus, Brazil.

There is no known chromosomal abnormality associated with pectus excavatum, but it has been reported in conjunction with Marfan's syndrome, Ehlers–Danlos syndrome, osteogenesis imperfecta, syndactylism, club foot, and Klippel–Feil Syndrome. Of interest, over one fourth of these patients have scoliosis.

Pathology and Clinical Manifestations: Symptoms, Signs

Pectus deformities result in a significant cosmetic deformity with consequential psychological effects that affect social development. From a physiologic perspective, there is ongoing controversy on the relative impact of the restrictive components of the deformity. In pectus excavatum, the anterior-posterior diameter of the chest is diminished and the heart is often displaced to the left. Subjectively, patients complain of dyspnea with exertion, diminished exercise capacity, chest pain, palpitations, frequent upper respiratory infections, and wheezing. A disproportional number of patients are diagnosed with exercise-induced asthma based solely on subjective descriptions of possible symptoms. Pulmonary function testing usually reveals a mild restrictive pattern, with total lung capacity (TLC), forced vital capacity (FVC), and vital capacity (VC) in the low-normal range. The severity of the pectus deformity correlates roughly with the reduction in VC and TLC. The ratio of forced expiratory volume in 1s (FEV1) to FVC is normal, indicating absence of obstructive disease. Abnormalities on the electrocardiogram have

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_417,

been described, namely, right bundle block and right axis deviation. There is a known association between PE and mitral valve prolapse.

For the patients who complain of exercise intolerance, the results of exercise testing have been inconclusive. Some investigators found that upon exercise testing on a treadmill, there were no objective differences in cardiorespiratory function or aerobic capacity between patients with excavatum and control subjects. In fact, subjective exercise intolerance may be the result of physical deconditioning. Thus, others have controlled for level of conditioning and found the maximum oxygen uptake (VO2max) to be 75% of predicted, suggesting mild impairment. One theory suggests the right atrium and ventricle are compressed by the sternum when upright, causing decreased filling and subsequent inability to increase stroke volume and oxygen delivery during exercise. In fact, compression and reduced filling have been documented in several studies. In addition, others have demonstrated that the oxygen uptake (VO2) plateau in the supine position was higher than in the sitting position, and supine exercise stroke volume was higher than sitting exercise stroke volume. Therefore, it is likely that some patients with severe pectus excavatum have a real exercise limitation that is cardiac in origin. Contradictions in the literature are probably related to differences in conditioning based on psychosomatic limitations induced by the strong aversion to exposure and participation, differences in the severity of disease, and difficulty obtaining true exercise capacity independent of patient effort. Whether or not the situation is improved by surgery is discussed later in this chapter.

Although most patients with sternal cleft are asymptomatic, cardiopulmonary effects of cleft sternum may result from altered respiratory dynamics, as there is paradoxical motion of the anterior chest. Some have reported cyanosis, dyspnea, and recurrent pneumonia. However, the main impact of sternal cleft is the potential for mediastinal/cardiac trauma since the protective function of the "breast bone is absent."

Diagnosis

Excavatum and mixed deformities: Morphologic description has been helpful to classify the deformity. Terms such as cup or saucer refer to localized versus diffuse depression. Short versus long length of the depression can assist in determining extent of surgery or number of corrective bars to be utilized in the repair. Symmetry and torsion refer to the rotation of the sternum, while slope and position of maximal depth can imply the potential underlying malposition of the heart. Unique patterns such as "steer horn depression" have also been coined to describe these defects.

Carinatum and mixed deformities: One of several patterns may be noticed and are classified as follows: Type I or chondrogladiolar deformities are also known as keel chest and involve protrusion of the gladiolus and inferior cartilages. Type II or chondromanubrial deformities are much less common and are also called pouter pigeon breast. This type is described as prominence of the manubrium and protrusion of the superior costal cartilages. Type III or lateral pectus carinatum is asymmetric deformity characterized by unilateral protrusion or rotation of the sternum.

There are three types of sternal cleft that may be noted on examination. *Superior cleft sternum* is most common. It is an incomplete defect involving the upper sternum or manubrium. The inferior aspect of the sternum is fused, creating a "U" or "V" type of deformity. In the "V" deformity, there is often only a narrow bridge at the xiphoid process, and this is sometimes referred to as a *subtotal sternal cleft*. Patients with this abnormality may also have a midline raphe or band-like scar that extends to the umbilicus. *Complete cleft sternum*, also called bifid sternum or sternal fissure, is the rarest type, and the sternal bars are completely separate. There may also be diastasis of the rectus muscles. *Inferior cleft sternum* is also an incomplete defect: The upper sternum is fused, but there is a gap inferiorly. This type may be associated with other abnormalities of midline fusion.

Evaluation

One should obtain a history of the duration and progression of the sternal depression, family history, any other medical conditions, and a thorough review of systems, especially focused on cardiac and pulmonary symptoms/disease. Diagnosis is easily made on physical examination, with a prominent depression deformity of the sternum. One should also carefully note the presence or absence of scoliosis or a heart murmur. It is essential not to undertake a course of treatment until such associated conditions such as Marfan's are ruled out.

The deformity may be further characterized by a computed tomography (CT) of the chest. The most commonly used index is also known by some as the "Haller index," which is derived from a CT image through the deepest part of the pectus deformity. The transverse diameter of the chest is divided by the anterior-posterior diameter at this level. In Haller's original report, patients who had

operative correction of PE had an index greater than 3.25. Preoperative chest x-ray is mandatory, and the use of CT scan is dependent on individual practice. It rarely affects management and some argue that it exposes children to unnecessary radiation. However, some view it as a critical tool in preoperative decision making and planning as well as postoperative follow-up.

Further workup may include pulmonary function tests (resting spirometry), exercise testing, and echocardiography. Some order these tests as a matter of routine, while others selectively obtain them if the patient complains of significant respiratory symptoms or if a heart murmur is detected on physical examination.

Specific Treatment

For 50 years after Ravitch's paper in 1949, his technique was considered the standard for both excavatum and carinatum repair. The procedure is usually done through a transverse inframammary incision (vertical incisions in the midline have also been used). Skin flaps are raised, followed by subpectoralis flaps to expose the deformed cartilages. The deformed cartilage is resected in the subperichondrial plane, using care to leave some cartilage laterally near the growth plate and the entire perichondrium in place. This must be done bilaterally and symmetrically, even if only one side appears deformed. The retrosternal space is mobilized bluntly. A wedge-shaped transverse osteotomy is made on the anterior sternum at the superior aspect of the depression and carried down to the posterior table, which is then fractured. Some advocate the use of a retrosternal bar, first made popular by Rehbein and Adkins, while others oppose this technique. This splint or strut must eventually be removed (usually after 6 months) and has been known to dislodge and migrate. The sternal osteotomy is then closed with heavy nonabsorbable suture; to correct carinatum defects a wedge of cartilage or bone in the osteotomy to obtain a better contour. Subcutaneous or pleural drains (if the pleura are entered) are placed. The pectoralis muscles are closed in the midline and approximated to the rectus abdominus muscle inferiorly.

In 1998, Nuss and colleagues reported a new technique, the minimally invasive repair of pectus excavatum. By placing a convex steel bar under the sternum through small bilateral thoracic incisions, he was able to mold the chest wall over a 1–3-year period akin to braces molding a patient's bite. The placement was directed at the deepest point of deformity from mid-axillary to mid-axillary line. Initially, the bar was placed blindly through a substernal tunnel, but after one report of myocardial injury, many now perform the procedure using video thoracoscopy or with a third, subxiphoid, incision to manually guide the bar. Lateral stabilizers are now used to fix the bar and prevent displacement. More than one bar is used for severe deformities in older patients where cartilaginous ossification may have begun. Bar removal is performed after 2 years as an outpatient procedure.

The primary repair for sternal cleft varies somewhat based on the type of cleft. Vertical midline incision is made and the skin and sternal bands dissected away from the pericardium and pleura. In complete cleft sternum, the bands may usually be brought together as one closes a midline sternotomy. Superior cleft sternum requires separation of the inferior bridge, often excising a wedge of cartilage, thus converting the defect to a complete one, and then approximating the two bands. Division of the sternoclavicular joints may also facilitate primary repair. The pectoralis muscles are then united and closed in the midline.

Patients who have delayed referrals require more complex repairs. Young patients have pliable cartilage and may be manipulated so that sliding lateral chondrotomies followed by approximation of the sternal bands are possible. If the costal cartilages are not pliable enough, then it is not possible to approximate the sternum by mobilizing and advancing ribs; this can be circumvented by several other techniques that have been described. Gaps between the sternal bands can be filled with autologous chondral or rib graft. In cases where the pectoralis muscle does not come together in the midline, a sheet of Marlex mesh, pectoralis muscle flap, or acrylic plaque has been used.

The surgical approach to chest wall deformities has recently come full circle with the popularity of external bracing for the repair of pectus carinatum. First reported out of Brazil in 1992, the use of an external brace, in lieu of the Ravitch procedure described above, has gained popularity around the world. Using the brace to slowly remold the chest wall requires a schedule starting at 23 h/day for at least 3 months and then tapering down to 12 h a day over the next 1–2 years. If the patient complies with this schedule, a success rate of 80% is reported. However, approximately 20% of patients refuse to wear the brace outright and another 20% can be expected to be noncompliant.

Prognosis

Functional outcome after pectus repair has been the source of controversy and debate for years. As discussed above, patients have mild restrictive lung disease and diminished exercise tolerance, probably due to sternal

compression of the right atrium and ventricle. Anecdotally, some patients subjectively feel that their dyspnea, exercise tolerance, and chest pain improve after operation. However, it is not clear whether this is a psychological or a physical phenomenon. Several papers have compared cardiopulmonary parameters pre- and postoperatively. Most have found that pulmonary function tests worsen after open repair, with a decrease in TLC, residual volume (RV), functional residual capacity (FRC), and FEV1. This is likely due to a limitation of thoracic cage expansion and decreased chest wall compliance after operation. Others have reported that pulmonary function did not worsen in their patients post-op, perhaps because they did a less extensive operation. While pulmonary function does not improve with open pectus repair, several investigators have found that exercise tolerance, VO2max, and SV do increase after operation. However, this conclusion is not universally accepted. Most evidence seems to indicate that patients show physiological (as opposed to symptomatical) improvement after open pectus repair, not because of improvement in lung function but due to an increase in stroke volume during exercise. The cardiopulmonary effects of the Nuss procedure have now been reported and controversy still remains. Nuss' group reported that pulmonary function tests significantly improved in 72% with the bar in place and remained so after bar removal. Sigalet showed a sustained improvement in aerobic activity after bar removal. Aronson et al. found exactly the opposite: Pulmonary function was neither improved nor harmed by the procedure.

The conclusion that can be drawn at this time is that pectus excavatum patients have an aerobic limitation that can be measured. This limitation can be improved with surgical correction of the defect by objective measurements of pulmonary function and aerobic activity in a monitored setting. An unknown percentage of patients will achieve symptomatic relief and increase their exercise tolerance. However, whether the measured increase in pulmonary function or stroke volume during exercise relates to a true symptomatic relief that can be reliably predicted remains a controversy today.

Future Development

Despite its moniker of "minimally invasive," the post-procedure pain associated with Nuss bar placement for pectus excavatum can be significant. Given the success of external bracing in the treatment of pectus carinatum, the future of chest wall remolding for depression deformities may possibly be with an external approach that can reduce pain. Such a concept was introduced by Harrison in the form of magnetic energy to reposition of remold the chest. While in its infancy, this concept quite possibly represents the future direction of structural reshaping of the thoracic wall.

Abdominal Wall Anomalies

Definition/Classification

An umbilical hernia consists of protruding viscera through the umbilicus which is covered by normal skin. An omphalocele on the other hand is an opening bound by the umbilical ring with protruding contents covered by a double layer of cord material without any normal skin. The inner layer consists of peritoneum and the outer of amnion. In between these layers is the characteristic embryonic connective tissue ("Wharton's Jelly"). The cord and its vessels insert onto the membranous sac as opposed to the abdominal wall. The size of the defect subdivides omphalocele into hernia of the cord (<2 cm), omphalocele (2–5 cm), and giant omphalocele (>5 cm). Gastroschisis was classically thought to be a defect to the right of the umbilicus and not contiguous with the umbilical ring; however, now, that concept is being challenged through several embryologic and fetal observations. What is not challenged is the concept that the cord and its vessels insert onto the abdominal wall and the defect is usually within the right side of the umbilical ring. Typically, no hernia sac is present and the bowel is open to the air. Prune belly refers to muscular absence (either complete or partial) resulting in an inability to maintain a normal abdominal contour.

Etiology

Typically, omphalocele is thought to occur due to a genetic predisposition that makes the fetus arrest umbilical development secondary to some event that happens prior to the tenth week of life. This prevents the abdominal contents from returning to the abdomen and in doing so prevents the lateral body wall folds from closing. This theory also explains why omphalocele is associated (>75% of the time) with many other defects that result from developmental arrest during the first trimester.

The etiology of gastroschisis remains an enigma. Originally thought to be due to a ruptured omphalocele, over the years, it was realized that this was a separate entity. It is generally considered to be an isolated defect with an incidence of associated genetic anomaly of approximately 2%. Theories such as a defect in the dorsal myotomes

preventing complete rectus sheath formation to ischemic injury with the right umbilical artery or umbilical vein being implicated have been popular. Toxins and environmental influences have become popular as the incidence has increased among younger mothers without access to prenatal care. Finally, we have come full circle with the umbilical ring being implicated again. It has been observed that if left alone once the bowel is reduced, the umbilicus returns to its normal size over time and the abdominal wall defect will spontaneously close mimicking the umbilical ring closure during development.

Theories surrounding prune belly range from a secondary defect due to increased abdominal wall pressure from urinary tract anomalies to a first trimester event that prevents the lateral somatic mesoderm from invading the ventral body wall. In any event, there are no familial tendencies and most attention is focused on the development of the urinary system which is always anomalous.

Epidemiology

Historically, the teaching was that omphalocele was 3 times more common than gastroschisis with an incidence of approximately 1:3,000 live births for omphalocele. Worldwide this incidence for omphalocele remains stable. Gastroschisis on the other hand has increased in epidemic proportions in the USA and around the world. By 2000, the incidence was reported as 1:2,000, surpassing that of omphalocele. Furthermore, the incidence is continuing to rise: Over the past 20 years, it has increased at least by threefold. The true incidence is still changing and at present is unknown. Theories such as the increasing rates of teenage pregnancy, geographic epidemic tendencies, and increased use of recreational drugs during pregnancy remain inconclusive. What is clear is that the incidence of gastroschisis is higher with maternal age under 20 and increases with environmental exposures. Smoking and other vasoactive substances (cocaine and pseudoephedrine) have been classically implicated. In the state of Washington, when women resided within 25 km of known surface water impregnated with atrazine (a common agricultural chemical), there was an increased prevalence of gastroschisis with an odds ratio of 1.6.

Pathogenesis

Gastroschisis usually presents as an isolated defect. Any associated anomalies are usually gastrointestinal in nature and directly related to the abdominal wall defect. IUGR is a common association however. Approximately 10–15% of these infants will have an associated bowel atresia that is caused by an ischemic event secondary to a tenuous blood supply coursing through the abdominal wall defect. Complete bowel loss is also seen in the instance of umbilical ring closure around the defect, thus cutting off all mesenteric flow to the protruding GI tract. The incidence of an associated anomaly outside of the GI tract is under 2% with gastroschisis.

Omphalocele on the other hand has a strong genetic association. Approximately 75% have associated anomalies. In 30% of cases, a trisomy will be present. Trisomies 13, 14, 15, 18, and 21 are all reported to have omphalocele associated with them. Ten percent of cases are associated with Beckwith–Wiedemann syndrome (macroglossia, organomegaly, hypoglycemia, and an increased risk of developing childhood tumors). The most commonly associated anomaly is an intracardiac defect.

Pathology

The primary pathologic process in gastroschisis is gastrointestinal dysfunction. Decreased absorptive capability and decreased motility is the hallmark of the disease. The predominant theory explaining this dysfunction is an abnormally high level of inflammatory cytokines in the amniotic fluid that comes into direct contact with the bowel. Some feel the length of time the bowel is in contact with the amniotic fluid determines the severity of the GI dysfunction, while others dispute this claim. As a result there is an ongoing debate about the timing of delivery in this disease. Once delivered, the bowel loses fluid at an extraordinary rate since it is exposed to the air. This represents a surgical emergency, and either primary closure or silo covering of the bowel needs to be done as soon as possible.

In omphalocele, there may be no GI dysfunction despite the enormity of the defect. Patient can be fed immediately, and the most significant GI concern is that of reflux. All abdominal defects to include congenital diaphragmatic hernia have variable expressions of foregut dysmotility. Attention should be paid to the associated anomalies with omphalocele leaving the defect repair to a more elective situation. IUGR is less common in omphalocele and is probably due to associated anomalies.

Diagnosis

Prenatal diagnosis has become standard in the United States. Serum maternal Alpha fetal protein levels are almost ten times the normal in gastroschisis and are five times the normal in omphalocele. An elevated AFP usually

triggers a prenatal ultrasound. Position of the cord alongside the bowel (gastroschisis) or coming of the end of a sac separated from the bowel (omphalocele) distinguishes between the two diagnoses; however, this differentiation is not always clear.

After delivery, the diagnosis is obvious with the cord coming of the end of the omphalocele sac or in gastroschisis an intact cord with a defect to its right.

Treatment

As mentioned, the timing and method of delivery have triggered an emotional debate among perinatologists, pediatric surgeons, and neonatologists. Excluding maternal factors, there is evidence to support recommendations ranging from full-term (>36 weeks) vaginal delivery to timed elective c-section as soon as lung maturity is determined by amniocentesis. Most evidence supports the concept that neither early delivery nor elective c-section confers any outcome advantage.

General Care: For an omphalocele, review of a complete history and physical examination to identify all associated anomalies along with genetic counseling is warranted. The omphalocele is then sized with hernias of the cord being repaired electively in the first week of life. Omphalocele of 4–8 cm may be repaired electively based upon other anomalies, and giant omphaloceles should be delayed by up to 1–2 years prior to potentially staged repair. There have been recent reports of rapid closure (2–8 months) with techniques utilizing intra-abdominal l tissue expanders to achieve adequate abdominal compartmental domain. Resection of the sac or rupture of the sac creates a surgical emergency where repair of the sac, primary closure, or prosthetic covering will be required. The sac should be protected by a number of methods during the period of delay.

Upon delivery, gastroschisis patients need to have the bowel covered and kept warm assuring inspection to determine that there is no torsion of the delicate vascular pedicle. A material that is transparent is best so that the bowel can be continuously assessed. The use of a bowel bag has become popular in many centers. The infant is placed in the bag entirely up to the level of the axilla. The bowel should be oriented off to the right to prevent kinking of the mesenteric blood supply. Expeditious primary repair or silo placement needs to be performed to avoid excessive hypothermia and fluid loss. Most infants will require isotonic fluid at least two times their calculated maintenance.

In addition, the placement of a PICC line or central line in the first 48 h will be critical as these children will be completely dependent upon TPN until bowel function develops. Whether or not the infant should have a planned staged repair vs. an attempt at primary repair has been a great source of debate. Arguments supporting attempted primary repair include shorter time to regain intestinal function and shorter hospitalizations. Arguments supporting routine silo placement and staged repair include decreased incidence of abdominal compartment syndrome and improved renal and splanchnic blood flow during a period of extreme fluid shifts.

Specific Treatment

Omphalocele closure is usually very straightforward in the case of a hernia of the cord. A standard umbilical hernia repair can take placed with adequate skin coverage. Giant omphalocele is also straightforward in the newborn period. An inflammatory topical agent (most commonly silvadene) is applied several times daily until a pseudo skin develops. Having the infant constantly on its back while sleeping will allow gravity to slowly reintroduce the bowel and abdominal organs back into the peritoneal cavity. One determination that an attempted repair is indicated the decision process becomes more complicated. This situation is identical to the primary repair of a standard omphalocele. Once the sac is resected, a bridge has been crossed that cannot be regained, thus many elect to attempt closure over top of the sac. Thus, if the repair does not hold the bowel, it is still covered. However, once there is no longer a covering sac, several options have been described from primary skin coverage to component separation of the lateral musculature, to prosthetic mesh placement (now more popular than ever due to the development of biologic mesh materials), and tissue expanders. Most recently, negative pressure dressings have been incorporated into the management of difficult abdominal wall closures with excellent results.

Operative decision making in gastroschisis can be life altering for these infants. Mesenteric blood supply must be maintained at all costs. If the bowel is reinserted into the abdomen, care must be taken to maintain perfusion. Measures of peak pulmonary pressure, intra-abdominal pressure, and splanchnic perfusion pressure have all been used. However, surgical judgment still is the critical factor in this decision. In cases of closed gastroschisis, the fascia will have to be opened prior to any primary closure attempt or silo placement. If the bowel cannot be safely replaced into the abdomen, a prosthetic material (classically siliconized Teflon) is placed to cover the bowel and to continuously reassess. Approximately 15 years ago, preformed, spring

loaded silos became available. They have now been extensively studied and are considered standard when secondary closure is undertaken.

It is important to mention the surgical treatment of prune belly. That is simply because the urologic consequences of this anomaly take precedence. The surgical management is undertaken electively or in combination with a urologic procedure: Typically Fowler-Stephens staged orchiopexies, ureteral reimplantations, bladder augmentations, etc. The functionality of abdominal reconstruction has never been proven; however, it is considered to be a cosmetic benefit to abdominoplasty.

Future Development

Sutureless gastroschisis repair is now being popularized. Primary or secondary closures are being done by simply covering the defect with remaining umbilical cord and sterile dressing. Over time the umbilical ring closes down. Approximately two third of the patients will have their umbilical hernias resolved and the remaining will require delayed repair.

Prognosis

Prognosis for both omphalocele and prune belly is specifically related to the anomalies they are associated with. The exception to this is a giant omphalocele that ruptures. The survival in gastroschisis has gone from below 30% 50 years ago to now over 90%. The seminal advancement that has made this possible is the development of TPN. A lifelong risk for adhesive obstruction exists and has been estimated to be as high as 18%. In the 5–10% of nonsurvivors, there are usually sequelae of multiple atresias or extensive bowel necrosis at birth resulting in short gut and sepsis. Gastroschisis is a major etiology contributing to the pediatric short gut population and the intestinal transplant population. However, for children who undergo intestinal transplantation, there is a worse prognosis for those with gastroschisis as their underlying diagnosis than for other etiologies.

418 Congenital Intestinal Obstruction

Deepika Nehra · Allan M. Goldstein

Introduction

Vomiting, abdominal distension, and failure to pass meconium in the newborn period all suggest the possibility of intestinal obstruction. The cause of the obstruction can be mechanical or functional (❯ *Table 418.1*); but regardless of the final diagnosis, prompt assessment is essential in order to avoid treatment delays that can have catastrophic consequences for the infant. The initial management of neonatal bowel obstruction includes resuscitation with intravenous fluids and broad-spectrum antibiotics. Nasogastric suction is important in order to decompress the stomach, which can improve diaphragmatic excursion and ventilation while reducing the risk of pulmonary aspiration. Once resuscitation is underway, a detailed history and physical examination are essential. Based on the differential diagnosis thus generated, targeted imaging studies will usually lead to an accurate diagnosis. Occasionally, a plain radiograph may be the only study necessary prior to operative exploration in a critically ill child. Because of the time-sensitive nature of some causes of bowel obstruction, early consultation with a pediatric surgeon is important.

The history should begin with the findings on prenatal ultrasound. The presence of dilated echogenic loops of bowel is suggestive of fetal intestinal obstruction. Polyhydramnios also occurs in bowel obstruction, especially in more proximal obstructions, like esophageal, duodenal, and jejunoileal atresia. Meconium peritonitis, diagnosed when intraperitoneal calcifications are identified on fetal ultrasound, indicates prenatal intestinal perforation and can be seen in association with intestinal atresias, volvulus, and meconium ileus. Nonintestinal anomalies seen on prenatal ultrasound are also important as they may direct the physician toward specific syndromes or associations. A maternal history, including a history of diabetes or drug use, is helpful, as is a thorough family history for cystic fibrosis, Hirschsprung's disease, and any intestinal anomalies.

The presence of prematurity is important as these infants often have delayed passage of meconium. Other important aspects of the newborn history include the ability to tolerate feedings at any point postnatally. If feeds were initially tolerated, a proximal atresia is unlikely. The presence of emesis, and whether it is bilious or not, may be the most important question, since bilious emesis in a newborn must be assumed to be caused by midgut volvulus until proven otherwise. The timing of onset of emesis is also important, as proximal obstructions cause emesis earlier than more distal obstructions. The timing of passage of the first meconium stool is critical. Delayed passage beyond 24–48 h suggests a distal, often colonic, process, such as Hirschsprung's disease. If meconium passes but looks like white mucus rather than bile-stained, then an intestinal atresia should be suspected. If meconium is seen coming from the urethra or from the perineum, then the infant likely has an anorectal malformation with a rectourethral or rectoperineal fistula, respectively.

Physical examination should be thorough in order to identify associated anomalies or syndromic features. The abdominal examination is paramount. Is the abdomen distended, flat, or scaphoid? In general, more distal obstructions cause more prominent distension. Is there tenderness or even peritonitis? The presence of bilious emesis in a newborn with abdominal distension and peritonitis is ominous, raising concern for midgut volvulus with compromised bowel. The presence of an incarcerated inguinal hernia could explain bowel obstruction. Anal examination is critical in order to determine whether there is an anal opening that is in the normal position, patent, and normal in caliber.

A plain abdominal radiograph is a very useful first test, and in some instances, such as in duodenal atresia, may be sufficient alone to make the diagnosis. Depending on the suspected level of obstruction based on the clinical history, physical examination, and initial abdominal radiograph, an upper gastrointestinal series or contrast enema usually follows. In the majority of cases of neonatal bowel obstruction, these studies will suffice to direct medical and surgical therapy. Additional imaging will be guided by the specific diagnoses being considered.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_418,

Table 418.1
Causes of neonatal intestinal obstruction

Mechanical causes	Functional causes
Malrotation with midgut volvulus	Prematurity
Duodenal atresia	Sepsis
Annular pancreas	Maternal narcotic use
Jejunoileal atresia	Magnesium use
Colonic atresia	Congenital hypothyroidism
Meconium ileus	Small left colon syndrome
Anorectal malformation	Meconium plug syndrome
Presacral mass	Hirschsprung's disease

Duodenal Atresia and Stenosis

Duodenal atresia (DA) and stenosis is a cause of intestinal obstruction in neonates that occurs with a reported incidence of 1:5,000 to 1:10,000 births. DA is thought to occur as a result of failure of vacuolization of the duodenum following its solid cord stage during weeks 8–10 of gestation. Although DA is an isolated finding in 30–50% of cases, it can be associated with cardiac (38%), renal (14%), esophageal (6%), anorectal (5%), and vertebral malformations (6%). Other anomalies of the midgut, including annular pancreas, anterior portal vein, choledochal cyst, biliary atresia, malrotation, and jejunoileal and colonic atresia, can also occur in children with DA. Approximately 20–25% of infants with DA have Down syndrome and up to 38% have associated cardiac anomalies.

DA is classified into three types of defects. Type I defects are the most common and consist of a mucosal diaphragmatic membrane that occludes the duodenal lumen. In some cases, this membrane may resemble a "windsock," in which the site of origin of the web may be a few centimeters proximal to the perceived site of obstruction. This web frequently involves the opening of the bile duct at the ampulla of Vater, an important consideration for the surgeon. Additionally, this luminal membrane or web may have an opening of variable size resulting in a congenital intrinsic stenosis. Large openings may provide a large enough conduit to delay symptoms until later in life. Type II defects consist of a short fibrous cord connecting two ends of atretic duodenum. Type III defects, which are the least common, have a complete separation of the two ends of atretic duodenum and an associated mesenteric defect.

DA is often diagnosed antenatally by the presence of the characteristic "double-bubble sign" on prenatal US in which the stomach and duodenal bulb are seen as two bubbles. Other ultrasound findings suggestive of DA include polyhydramnios, noted in 50% of patients with DA, a dilated loop of bowel, hyerpechoic bowel, and ascites. Generally, proximal atresias such as DA are more likely to be detected on prenatal ultrasound than more distal atresias. If DA is diagnosed prenatally, a detailed evaluation for other associated anomalies should be performed, as well as an amniocentesis for chromosomal analysis. Several studies have demonstrated that prenatal diagnosis improves outcomes by allowing earlier recognition of the defect, which leads to prompt surgical intervention and fewer metabolic complications.

Neonates with DA are often born premature (46%) and almost all are small for gestational age (90%). In approximately 80% of cases of DA, the obstruction occurs distal to the ampulla of Vater, typically resulting in bilious emesis and feeding intolerance within the first few hours of life. Although generalized abdominal distention is not commonly seen due to the proximal location of the obstruction, a fullness in the upper abdomen may be appreciated. Affected infants may pass meconium after birth if the distal intestinal tract is normal.

The classic abdominal radiographic finding in a neonate with DA is the "double-bubble sign" in which an air-filled stomach and duodenal bulb are seen as two bubbles separated by the pylorus (*Fig. 418.1*). If no air is present in the intestine distal to the duodenal bulb, then the diagnosis of DA is secured and no further diagnostic studies are necessary. The presence of air distal to the duodenum may indicate an incomplete obstruction due to duodenal stenosis or a fenestrated web. However, of major concern is the possibility intestinal malrotation with midgut volvulus, which would require emergent surgical intervention. Therefore, the presence of air distal to a "double-bubble" mandates a prompt upper gastrointestinal series to exclude malrotation. All newborns with duodenal atresia need specific diagnostic tests to evaluate for associated anomalies. An echocardiogram should be performed to look for congenital heart disease (patent ductus arteriosus, atrio-ventricular canal defect, atrial or ventricular septal defect, tetrology of Fallot), a chest radiograph to assess for vertebral anomalies, and a renal ultrasound to rule-out renal anomalies (renal agenesis or dysplasia, ectopic kidneys, duplicated or incomplete collecting system). A rectal biopsy should be considered if there is any suspicion of Hirschsprung's disease, which is of particular concern in the neonate with both DA and Down syndrome.

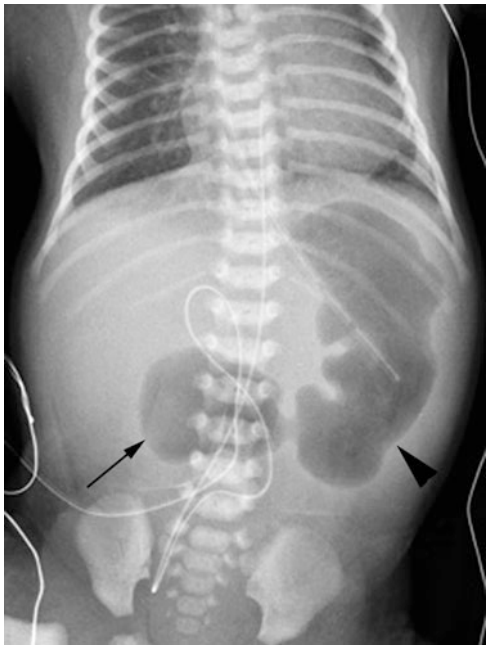

Figure 418.1
Abdominal radiograph showing the classic "double-bubble sign" of duodenal atresia. Note the dilated gas-filled stomach (*arrowhead*) and proximal duodenum (*arrow*) with an otherwise gasless abdomen consistent with a complete obstruction

DA requires operative correction. Preoperative management includes intravenous hydration, correction of electrolyte imbalances, and placement of a nasogastric tube to decompress the stomach and decrease the risk of aspiration. DA is not a surgical emergency and the infant should not undergo operative repair until hemodynamic and fluid and electrolyte status are stable. Additionally, in the case of a very premature infant, consideration must be given to delaying operative intervention, while continuing nasogastric decompression and parenteral nutrition, to allow the child to gain weight to reduce the risk of operative intervention. The ideal timing of surgery in such instances is determined on a case by case basis. Additionally, preoperative consultation with a cardiologist and cardiac surgeon should be considered in any infant with DA and a concomitant cardiac defect to determine the need for and optimal timing of operative correction of the cardiac defect and any preoperative steps necessary prior to correction of the DA.

DA is approached through a transverse right upper quadrant incision. The surgical treatment for Type II and III defects involves a bypass of the obstructed segment of duodenum with a side-to-side or proximal transverse to distal longitudinal (diamond-shaped) duodenoduodenostomy. In cases where the proximal duodenum is markedly dilated, a tapering duodenoplasty may be necessary to reduce the duodenal caliber, which may improve postoperative duodenal emptying. A Type I defect can be corrected with a transduodenal web excision or a duodenoduodenostomy. The ampulla is often closely associated with the web and must be carefully identified and preserved. Identification of the ampulla can be facilitated by gentle compression of the gallbladder, which releases bile in the region of the ampulla. During the procedure, it is imperative to examine the distal bowel for other intestinal atresias, as these are associated with DA. This can be accomplished by passing a catheter into the distal bowel and insufflating air or saline to distend the small intestine.

Neonates generally do well following surgical correction of DA with an operative mortality of <5% and reported 15-year survival of 86%. The majority of the early and late deaths in infants with DA occur secondary to severe associated cardiac defects. Commonly reported late complications include adhesive bowel obstruction, megaduodenum with abnormal motility often requiring tapering duodenoplasty, and gastroesophageal reflux that is often unresponsive to medical management and may require antireflux surgery.

Jejunoileal Atresia

The small intestine is the most common site of intestinal atresia in neonates, and the incidence is higher in the ileum than in the jejunum. The reported incidence of jejunoileal (JI) atresias ranges from 1:1,500 to 1:5,000 births. JI atresia is an acquired lesion thought to result from a vascular accident resulting in ischemic necrosis of a segment of fetal intestine. This vascular accident may be secondary to intestinal volvulus, intussusception, internal herniation, or strangulation of bowel in a tight abdominal wall defect. The necrotic segment of intestine resorbs, resulting in a blind proximal and distal end often with a gap in the associated mesentery. Interestingly, maternal smoking and use of vasoconstrictive medications in the first trimester of pregnancy, in addition to inherited thrombophilias, increase the risk of small intestinal atresia. Although most cases of JI atresia are sporadic in nature, some familial cases of Type IIIB and Type IV atresias have been reported, suggesting a genetic component.

JI atresias are classified into four types based on their anatomic characteristics (*Fig. 418.2*). In Type I atresias,

the lumen is obstructed by an intact membrane composed of mucosa and submucosa while the outer muscularis and serosa are intact. This results in no obvious external discontinuity of the bowel, but an obstructed lumen (Fig. 418.3a). Type II atresias involve a gap in bowel continuity with the proximal and distal ends connected by a short fibrous band. Type III atresias are subdivided into Types IIIA and IIIB. Type IIIA atresias consist of a gap in intestinal continuity with no tissue connecting the two blind ends and a mesenteric defect between them (Fig. 418.3b). Type IIIB atresias are characterized by a proximal small bowel atresia and the absence of a large segment of bowel that is normally supplied by the distal superior mesenteric artery, resulting in a large gap in the small bowel mesentery. The small bowel distal to the atresia is foreshortened and coiled, leading to the designation "apple peel" or "Christmas tree" deformity. Type IV atresias refer to the presence of multiple Type II or IIIA atresias, giving the bowel the appearance of a "string of sausages" (Fig. 418.3c).

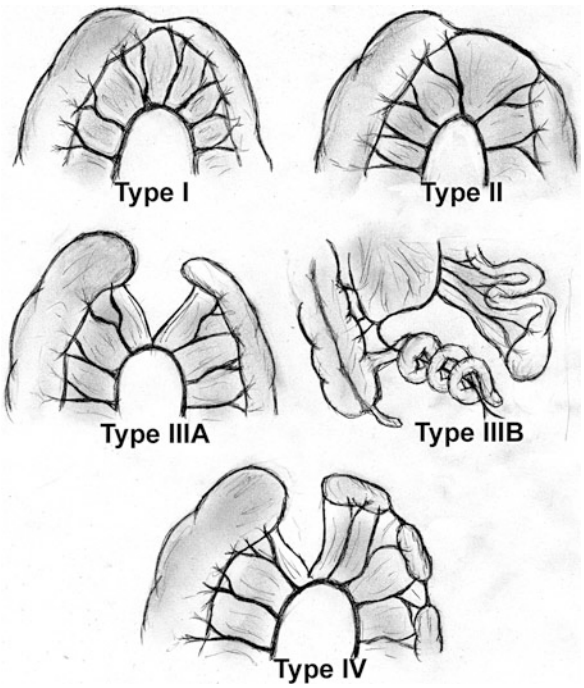

Figure 418.2
Classification of intestinal atresia

Fewer than one-third of all JI atresias are diagnosed prenatally. Maternal polyhydramnios is a common finding with intestinal atresia. Other prenatal findings include ascites, dilated loops of bowel, and increased bowel echogenicity. Generally, proximal jejunal lesions are more likely to be detected antenatally as they result in more severe dilation of the proximal bowel due to continued fetal swallowing of amniotic fluid without the potential for intestinal absorption. Neonates with JI atresia have a high incidence of prematurity (44%) and being small for gestational age (25–50%).

Neonates with JI atresias typically develop obstructive symptoms, including abdominal distention and bilious emesis, within the first 48 h of life. These infants usually do not pass meconium. Infants with JI atresias can have associated gastrointestinal anomalies including abnormalities of intestinal rotation and fixation (13%), gastroschisis (16%), duodenal atresia (4%), and colonic atresia (2%). Associated extra-abdominal anomalies are rare but include cardiac defects (8%), skeletal anomalies (2%), and renal abnormalities (4%). JI atresias may also occur

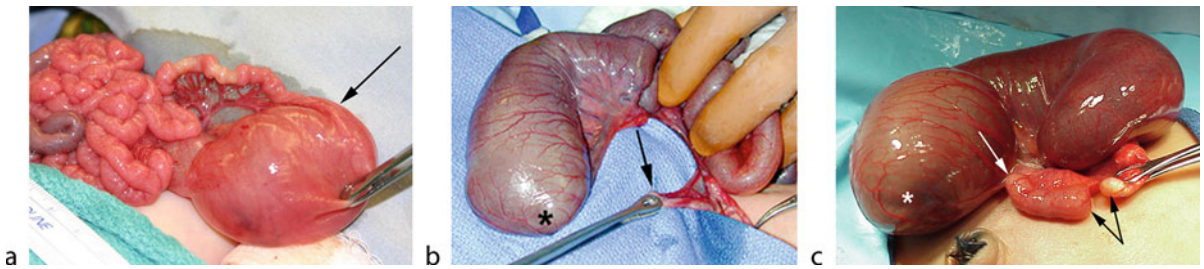

Figure 418.3
Jejunoileal atresias. (a) Type I atresia. Note the lack of external discontinuity of the bowel and the notable size discrepancy between the proximal dilated and distal decompressed bowel (transition point marked with an *arrow*). (b) Type IIIA atresia with a very dilated proximal end of the bowel (*asterisk*) compared to the distal end (*arrow*) and a mesenteric defect between the two blind ends. (c) Type IV atresia with a very dilated proximal end of intestine (*asterisk*) and multiple blind-ending segments (*arrows*) giving the bowel an appearance resembling a "string of sausages"

in association with meconium ileus, which is almost always due to cystic fibrosis (CF). The inspissated meconium associated with CF may cause intestinal dilation and can lead to a localized volvulus which results in ischemic necrosis of a segment of bowel, thus forming an atresia. Among neonates with JI atresia, 12% are found to have cystic fibrosis.

Plain abdominal radiographs in the setting of JI atresias are notable for dilated loops of bowel (*Fig. 418.4*). The number of dilated bowel loops is indicative of the level of obstruction. The presence of intraperitoneal calcifications is indicative of meconium peritonitis, suggesting an intrauterine intestinal perforation. Although a contrast study is not necessary to make the diagnosis of a proximal atresia, a contrast enema is useful to rule out an associated colonic atresia. For patients with a suspected distal atresia, a contrast enema can help define the level of obstruction and identify the location of the cecum to rule out abnormalities of intestinal rotation and fixation. The contrast enema in a newborn with JI atresia often reveals a microcolon, resulting from lack of use of the distal bowel. Neonates with JI atresia in association with meconium ileus or meconium peritonitis should undergo mutation analysis for CF. In the absence of signs or symptoms of a cardiac anomaly, routine echocardiography is not necessary for patients with JI atresias due to the low incidence of associated congenital heart disease.

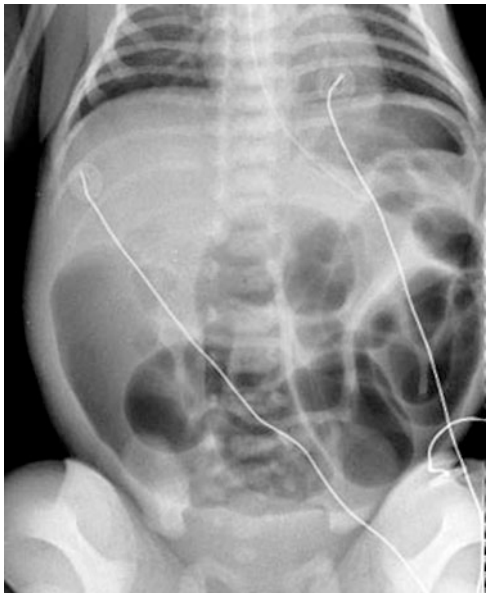

Figure 418.4
Abdominal radiograph in JI atresia. The x-ray shows multiple dilated loops of bowel consistent with an intestinal obstruction. The number of dilated loops can provide an indication of the level of obstruction

JI atresias require operative correction. Preoperative management, as with any intestinal obstruction, includes hydration, correction of electrolyte abnormalities, and nasogastric decompression. Complicating factors, such as prematurity or congenital heart disease, should be recognized and included in preoperative planning. The surgical approach and technique vary depending on the level and type of atresia present. However, several principles are constant, including judicious use of resection to preserve maximum bowel length, restoration of intestinal continuity, and careful inspection of the entire bowel to rule out associated atresias. Primary anastomosis can be challenging due to the marked size discrepancy between the proximal and distal segments. In patients with an isolated atresia and a short segment of dilated proximal intestine, resection of the excessively dilated segment with a primary end-to-oblique anastomosis can be performed. In cases with a long segment of very dilated proximal bowel, antimesenteric tapering enteroplasty or imbrication of the proximal bowel should be considered in order to reduce the caliber of the proximal bowel while preserving intestinal length. Tapering enteroplasty or imbrication is required in less than one-third of JI atresias. In some cases, a Type I atresia or web can be treated by simple web excision or stricturoplasty. The evaluation for associated distal atresias can be facilitated by flushing the intestine distal to the site of obstruction with saline. Intestinal atresia in the setting of gastroschisis can be a challenging problem. Identification of the atretic segment is particularly difficult in the setting of thickened and inflamed bowel, and healing of the intestinal anastomosis can be tenuous under these conditions. For these reasons, for JI atresias in the setting of gastroschisis, consideration should be given to reduction of the viscera into the abdominal cavity followed by definitive repair of the JI atresia after the acute inflammation has subsided.

The reported operative mortality associated with repair of a JI atresia is 0.8% and the long-term survival is 86–92%. Postoperative complications include adhesive bowel obstruction, prolonged ileus, anastomotic leak, and short bowel syndrome, which is most common in Type IIIB and Type IV atresias. The long-term survival of children with JI atresias has increased markedly over the last 40 years most notably due to the ability to provide these infants with long-term parenteral nutrition, which can be necessary for weeks to months following surgical repair. Currently, the late mortality is most commonly related to complications of short bowel syndrome including liver disease and sepsis.

Intestinal Malrotation and Midgut Volvulus

The incidence of rotational abnormalities of the midgut is difficult to determine, but autopsy studies indicate an incidence as high as 1% of the population. In contrast, symptomatic malrotation is estimated to occur in 1:6,000 births. Intestinal malrotation results from a failure in the normal embryologic sequence of bowel rotation and fixation. In a landmark article in 1923, Norman M. Dott first described intestinal malrotation by applying embryological observations to his clinical experiences treating five patients. Intestinal rotational disorders can encompass an array of anatomical abnormalities including nonrotation, reversed rotation, and varying degrees of incomplete rotation. The classic appearance of intestinal malrotation is depicted in *Fig. 418.5a*.

Two anatomic features of malrotation are responsible for the clinical symptoms that occur. First, the malrotation often positions the duodeno-jejunal junction very close to the ileocecal valve. Since these represent the proximal and distal ends of the small intestinal mesentery, respectively, their abnormal proximity creates a narrow mesenteric base that allows the root of the mesentery to twist, resulting in midgut volvulus. Second, duodenal obstruction can result from Ladd's bands, which are abnormal attachments that typically develop between the ascending colon and the right abdominal sidewall, crossing over and constricting the duodenum. Neonates with intestinal malrotation typically present with bilious emesis. The abdominal examination is often initially benign. However, a benign exam should not lead to complacency. Midgut volvulus can rapidly lead to intestinal ischemia and the infant can develop abdominal distention, tenderness, hematemesis, hematochezia, hypotension, and shock. These findings are ominous in the setting of bilious emesis as they are highly suggestive of intestinal ischemia. Although bilious emesis in a newborn can be due to other surgical or nonsurgical causes, it is imperative that intestinal malrotation with midgut volvulus be ruled out before other diagnoses are considered due to the potentially devastating complications of intestinal ischemia associated with delaying this diagnosis.

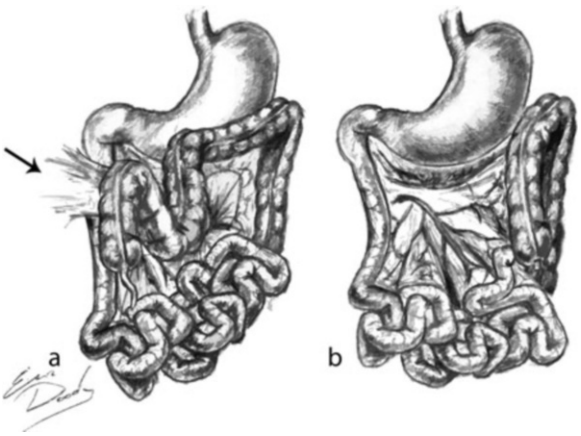

Figure 418.5
Intestinal malrotation. (a) The duodenum courses down the right side of the abdomen and the ligament of Treitz fails to cross the midline to the left side. Ladd's bands (*arrow*) are seen extending from the right colon, across the duodenum, to the right lateral abdominal wall. (b) After Ladd's procedure for malrotation, the small bowel is predominantly on the right side, with the colon on the left. Ladd's bands have been divided, the base of the mesentery broadened by lysing adhesions, and the appendix removed (Reprinted from Nehra D, Goldstein AM (2011) Intestinal malrotation: varied clinical presentation from infancy through adulthood. Surgery 149(3):386–393, Copyright 2011, with permission from Elsevier)

Approximately 30–60% of neonates with intestinal malrotation have an associated congenital anomaly, the majority of which are related to the gastrointestinal tract. Rotational defects are known to be present in all patients with congenital diaphragmatic hernia, gastroschisis, and omphalocele although volvulus is less common in these conditions. As many as 50% of children with duodenal atresia and 10–20% of children with jejunoileal atresia may have associated intestinal malrotation. Other associated anomalies involving the cardiac, respiratory, genitourinary, and central nervous systems have been reported but are much less common. It is important to note that although intestinal malrotation is classically thought to be a disease of neonates and infants, malrotation can present at any age and with a variety of acute and chronic symptoms. A recent report on intestinal malrotation found that fewer than 50% of all patients with malrotation are diagnosed prior to 1 year of age.

If there is clinical suspicion of intestinal malrotation with midgut volvulus in a newborn with peritonitis, hemodynamic instability, or any clinical deterioration, valuable time should not be wasted on radiographic imaging and the focus should be placed on aggressive resuscitation and prompt surgical exploration. In a stable child, upper gastrointestinal series is the gold standard to evaluate for malrotation. The ligament of Treitz, which is located at the duodeno-jejunal junction, should normally be located to the left of midline and roughly at the level of the pylorus. An abnormal position of the ligament of

Treitz indicates malrotation. The presence of a "corkscrew" appearance to the duodenum and proximal jejunum is consistent with volvulus. Duodenal obstruction, often with a "bird beak" appearance, is also concerning for volvulus (*Fig. 418.6*). Plain radiographs are not usually helpful in the diagnosis of malrotation and volvulus, but may demonstrate a gasless abdomen, intestinal dilatation, or may be completely normal. Findings that are suggestive of malrotation on plain radiographs include a nasogastric or orogastric tube that extends into an abnormally positioned duodenum or a "double-bubble sign," signifying duodenal obstruction, with the presence of distal gas. Ultrasonographic findings suggestive of malrotation include abnormal position of the superior mesenteric vein either anterior or to the left of the superior mesenteric artery, the "whirlpool sign" of volvulus (caused by twisting of the mesentery and vessels around the narrow mesenteric base), or a dilated duodenum indicating obstruction from Ladd's bands or volvulus. Additionally, an abnormally placed cecum on barium enema may indicate a rotational abnormality, but this study is of limited benefit as an abnormally placed cecum is not pathognomonic of malrotation and a normally placed cecum does not rule out malrotation since the cecum is in a normal location in 20% of individuals with malrotation.

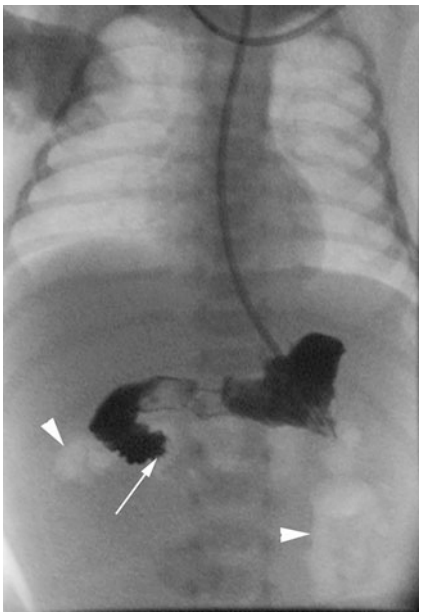

Figure 418.6
Upper gastrointestinal series (UGI) demonstrates an abrupt cutoff at the level of the duodenum (*arrow*) with visible distal gas (*arrowheads*). This constellation of findings is concerning for malrotation with midgut volvulus

Intestinal malrotation with or without volvulus is treated surgically. Malrotation with midgut volvulus is a surgical emergency. In contrast, asymptomatic malrotation, which may be discovered incidentally on an imaging study performed for other reasons, can be approached in a less urgent fashion. Midgut volvulus is present in up to 50% of patients operated on for malrotation and is more common in neonates with malrotation than it is in older children and adults. In 1936, William Ladd wrote the classic article on the treatment of intestinal malrotation describing the corrective procedure that now bears his name. The Ladd's procedure involves counterclockwise detorsion of the midgut, division of bands crossing from the cecum to the lateral peritoneal gutter, and widening of the mesenteric base with placement of the colon in the left side of the abdomen and the small bowel in the right. The appendix is removed to prevent future diagnostic confusion due to its abnormal location. *Figure 418.5b* depicts the anatomy after a Ladd's procedure for intestinal malrotation. If the viability of a portion of the bowel is questionable following detorsion of the midgut, warm sponges and observation for a period of time may allow reperfusion of the intestine and improvement in its appearance. If segments of bowel with questionable viability remain, the abdomen can be closed and the intestine re-evaluated at a second operation performed 24–36 h after the initial procedure. Complete necrosis of the midgut in cases of severe or prolonged volvulus is catastrophic.

Complications following the Ladd's procedure are uncommon in the absence of compromised bowel. Patients with volvulus may require extensive bowel resection resulting in short bowel syndrome. These complications are preventable by prompt recognition and operative intervention for symptomatic malrotation. The mortality rate after surgical intervention for malrotation is 3–9% and is higher in the setting of volvulus, intestinal necrosis, prematurity, and other associated anomalies. It is important to recognize that a history of a Ladd's procedure does not rule out the possibility of future volvulus. Recurrent volvulus is estimated to occur in 2–7% of children following a Ladd's procedure.

Colonic Atresias

Atresias of the colon are rare, with an incidence of approximately 1:20,000, accounting for about 5–10% of all intestinal atresias. Colonic atresias are classified using the same

classification system used for small intestinal atresias (Fig. 418.2). Type III defects are the most common and usually occur proximal to the splenic flexure. Type I atresias are the second most common type encountered in the colon (Fig. 418.7).

The clinical presentation of a colonic atresia is consistent with that of a high-grade distal intestinal obstruction and is characterized by severe abdominal distension, bilious emesis, minimal or no passage of meconium, and feeding intolerance. Neonates with colonic atresia are often premature (29%).

Plain abdominal radiography will show very dilated loops of bowel, often with air-fluid levels and absence of air in the rectum. Pneumoperitoneum can occur. In the absence of intestinal perforation, a contrast enema is obtained. In the setting of colonic atresia, contrast will fill a distal microcolon and stop at the level of the atresia. Proximally dilated air-filled bowel will be seen.

Colonic atresias are associated with several anomalies, including gastroschisis, skeletal abnormalities, congenital heart disease, and jejunoileal atresias. The coexistence of colonic and jejunoileal atresias supports the importance of preoperative contrast enemas in all neonates with atresias of the jejunum or ileum in order to avoid missing a colonic obstruction following operative repair of the small intestinal atresia. The association of colonic atresia with Hirschsprung's disease has been reported, but is rare. At the time of surgery, the resected atretic segment should be sent to pathology with the specific request to evaluate the distal end for the presence of ganglion cells.

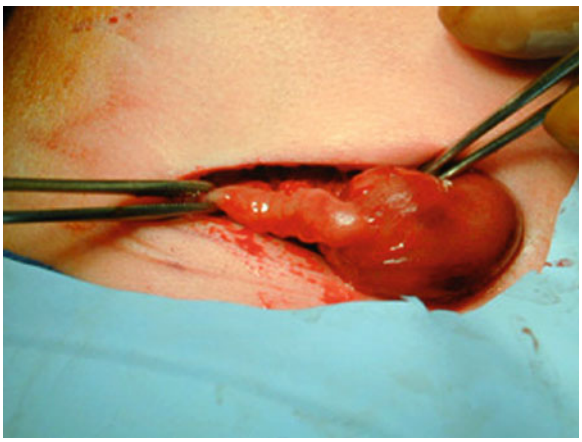

Figure 418.7
Type I colonic atresia. The sigmoid colon proximal to the atresia is dilated, while the distal segment distal to the atresia is narrow

Surgical treatment of colonic atresia involves resection of the atretic segment along with any excessively dilated proximal bowel. The length of resection is minimized and effort is made to preserve the ileocecal valve when possible. Primary anastomosis can be performed safely regardless of the level of the atresia. However, some authors have reported high rates of anastomotic leak and recommend initial diverting colostomy. This is a safe alternative and should be considered in more complex cases, such as those associated with gastroschisis, Hirschsprung's disease, or in critically ill newborns.

Hirschsprung's Disease

Hirschsprung's disease (HD), or congenital megacolon, is characterized by the absence of ganglion cells (aganglionosis) extending from the distal end of the rectum proximally for a variable distance. Named for the Danish pediatrician, Harald Hirschsprung, who first described the disease in 1886, HD disease occurs in 1:5,000 live-births, with a male to female ratio of 4:1. In 80% of cases, the aganglionosis is limited to the rectosigmoid colon, and this is referred to as "short-segment" disease. The remaining cases have "long-segment" disease, in which the aganglionic segment extends proximal to the sigmoid colon. Total colonic aganglionosis occurs in about 5% of cases, and total intestinal aganglionosis is quite rare, occurring in <1% of all cases.

The enteric nervous system (ENS) is made up of a complex network of neurons and glial cells that are located in the wall of the gastrointestinal tract and comprise the largest component of the autonomic nervous system. The ENS regulates critical functions of the gut, including intestinal motility as well as absorption and secretion across the mucosa. The ENS is organized into two concentric rings of ganglia situated on either side of the circular smooth muscle layer, with the submucosal plexus located on the inner side of this layer and the myenteric plexus located between the circular and longitudinal muscle layers. When the ENS is absent, as it is in the aganglionic bowel of HD, normal motility cannot occur and a functional bowel obstruction develops. The cellular and molecular etiology of intestinal aganglionosis is an area of intense scientific interest. The cells that comprise the ENS arise from the neural crest along the dorsal aspect of the embryonic neural tube. Those neural crest-derived cells that will form the ENS originate in the vagal region of the neural tube, from where they migrate to the foregut and then proceed in a proximal-to-distal direction along the entire length of the gastrointestinal tract. This process occurs during weeks 4–7 of human gestation.

In rodents and avians, a smaller contribution of cells arises from the distal (sacral) region of the neural tube and contributes cells to the colorectal ENS. Whether the sacral neural crest contributes cells to the human ENS is unknown. Formation of a mature and functional ENS requires that the neural crest-derived cells undergo extensive cellular proliferation to generate a sufficient number of cells to colonize the entire bowel. These cells must also be capable of migrating distally and of differentiating into neurons and glial cells. The cells must cluster to form ganglia and pattern into two concentric plexuses. Hirschsprung's disease, in which there is aganglionosis of the distal colorectum, has several potential etiologies, each of which has experimental support. These possibilities include (1) inadequate proliferation of neural crest-derived cells to complete colonization of the distalmost bowel, (2) premature differentiation of ENS precursor cells into a neuronal phenotype, thereby preventing their continued proliferation and migration along the gut, and (3) death of enteric neurons either along their normal migratory path or after they have colonized the colon.

Several genes are essential for normal ENS development. The most important gene in the etiology of HD is Ret, a receptor tyrosine kinase expressed on the surface of enteric neural crest cells. Its ligand, glial-derived neurotrophic factor (Gdnf), is expressed by the intestinal mesenchyme. Gdnf-Ret signaling regulates proliferation, migration, differentiation, and survival of enteric neural crest cells. Null mutations of Gdnf or Ret in mice lead to total intestinal aganglionosis. Nearly all patients with HD have a mutation in the Ret gene, either in the coding sequence or in a noncoding regulatory region. Other important genes in the pathogenesis of HD include endothelin-3, endothelin receptor B, and Sox 10.

While most cases of HD are isolated and sporadic, familial cases can occur. However, the pattern of inheritance in these cases is not Mendelian. One of the interesting hallmarks of this complex genetic disorder is that the recurrence risk within a family depends on gender and the length of aganglionosis. For example, the risk for HD is 1% for a female sibling of an affected male with short-segment disease, while it is 33% for a male sibling of a female patient with long-segment disease. Syndromic cases comprise a minority of Hirschsprung's patients. About 2–8% of patients with HD have Down's syndrome. Shah–Waardenburg's syndrome represents the association of HD, sensorineural deafness, and pigmentation abnormalities. Haddad syndrome refers to the coexpression of Ondine's curse and HD. Mowat–Wilson syndrome is the association of HD, mental retardation, microcephaly, and dysmorphic facial features.

HD presents in the newborn period in 90% of cases. The disease is suspected when a neonate fails to pass meconium within the first 48 h of life and is often associated with abdominal distension and vomiting. In healthy newborns, 94–99% pass meconium within 24 h of life, and 100% pass meconium by 48 h, so a failure to pass meconium by 48 h of life should prompt further investigation. In patients presenting outside the newborn period, typical symptoms include longstanding constipation, abdominal distension, and failure to thrive. Up to 12% of patients will present with vomiting, distension, loose stools, and fever. This constellation of symptoms should raise concern for Hirschsprung's-associated enterocolitis, the most serious source of morbidity in HD. The presence of diarrhea in these patients should not distract the clinician from including HD in the differential.

Several conditions need to be considered in the differential diagnosis of a child being evaluated for HD. Examination of the anus is important in order to rule out anal stenosis or an anoperineal fistula, both of which can cause significant constipation. In neonates, other causes of distal bowel obstruction should be considered. *Meconium ileus* can present similarly to HD. Imaging can distinguish the two, showing a ground-glass appearance in the right lower quadrant on plain abdominal radiography (◉ *Fig. 418.8*)

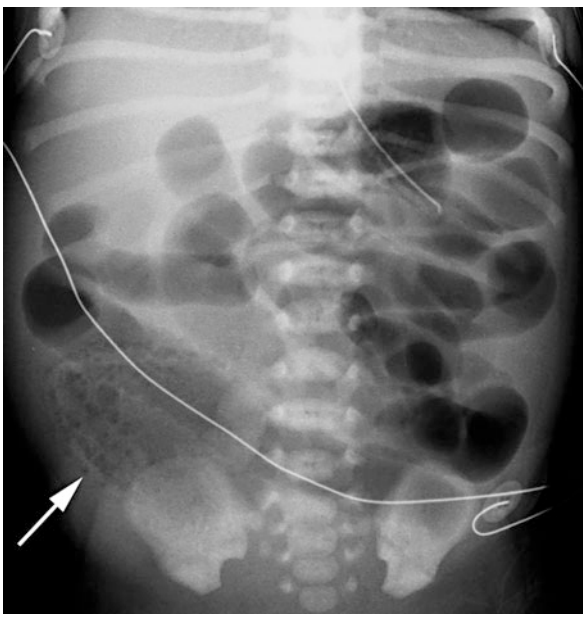

Figure 418.8
Abdominal radiograph showing distended loops of bowel and a ground glass appearance in the right lower quadrant (*arrow*) secondary to inspissated stool mixed with air, a classic finding in meconium ileus

and a microcolon on contrast enema in meconium ileus. *Small left colon syndrome* is a condition that is associated with maternal diabetes in about 50% of cases. It is due to transient dysmotility in the left colon and is hypothesized to be caused by release of glucagon in the neonate in response to hypoglycemia. It has a clinical presentation similar to HD, including distension, vomiting, and failure to pass meconium. The contrast enema often will show a narrow descending and sigmoid colon with the transition at the splenic flexure. Unlike in HD, the rectum is often normal in caliber in small left colon syndrome (Fig. 418.9). *Meconium plug syndrome*, which has an incidence between 1:500 and 1:1,000, also presents as a distal intestinal obstruction. Contrast enema will show many filling defects in the colon, consistent with retained plugs of meconium (Fig. 418.10). The cause appears to be transient colonic dysmotility and/or abnormal meconium. In all three conditions – meconium ileus, small left colon syndrome, and meconium plug syndrome – contrast enema is both diagnostic and therapeutic. Surgery for these conditions is rarely necessary and is indicated only in cases of intestinal perforation or cases refractory to radiologic resolution. Rectal biopsy should be performed in children with small left colon syndrome and meconium plug syndrome to rule out coexisting HD.

A plain abdominal radiograph may demonstrate findings suggestive of HD, including multiple dilated loops of bowel consistent with a distal bowel obstruction and the absence of gas in the rectum (Fig. 418.11a). When the diagnosis of HD is suspected, a contrast enema should be obtained. The proximal (ganglionated) colon will be distended, while the distal (aganglionic) colon will be contracted. Between dilated and contracted colon there is classically a funnel-shaped transition zone (Fig. 418.11b). These features may not be present in the neonate, where proximal dilatation has not yet developed, or in cases of total colonic aganglionosis. Finding retained contrast in the colon 24 h after the contrast enema is highly suggestive of HD.

Rectal biopsy is required to make a definitive diagnosis of HD. Suction biopsy can be performed at the bedside and is successful in the majority of young children. If the sample is not diagnostic, or in older children, full-thickness biopsy can be performed under anesthesia. The most important and diagnostic histologic feature of HD is the absence of ganglion cells. Additional features often seen include the presence of hypertrophic nerve fibers,

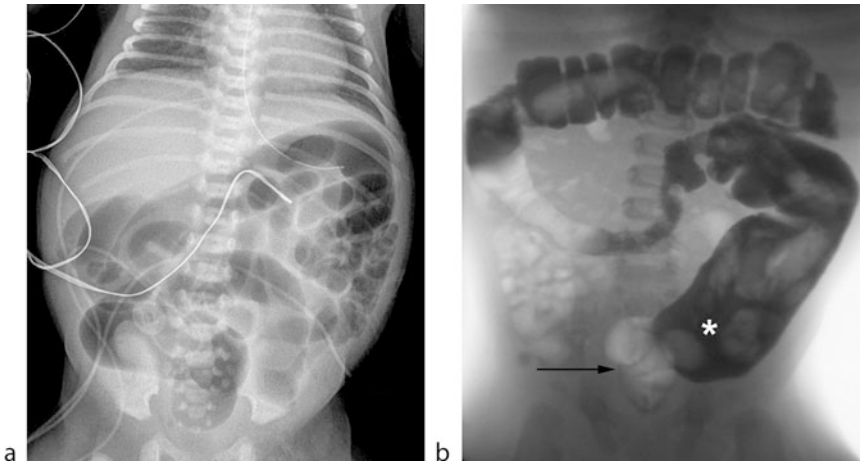

Figure 418.11

Hirschsprung's disease. (a) Abdominal radiograph with multiple loops of dilated bowel and the absence of gas in the rectum, suggestive of a distal bowel obstruction, such as Hirschsprung's disease. (b) Contrast enema of a patient with Hirschsprung's disease demonstrates a dilated proximal segment of colon (*asterisk*) with a classic funnel-shaped transition zone (*arrow*)

increased acetylcholinesterase staining of thickened submucosal nerves, and decreased calretinin staining.

Anorectal manometry can be used to support the diagnosis of HD. Normally, distension of a balloon in the rectum leads to reflex relaxation of the internal anal sphincter. This recto-anal inhibitory reflex (RAIR) is absent in HD. Anorectal manometry may be particularly helpful in cases of ultrashort segment disease, also referred to as anal sphincter achalasia. In these cases, rectal biopsy, which is performed at least 2 cm above the dentate line, may demonstrate ganglion cells. However, these children, who often suffer from chronic, refractory constipation, will have an absent RAIR. Treatment for this condition includes injection of botulinum toxin into the internal anal sphincter or sphincter myotomy.

Once the diagnosis of HD is made in a neonate, surgery is planned. The surgical approach depends on the level of aganglionosis. In all cases, the operation generally begins with multiple seromuscular biopsies, either laparosopic or through a small laparotomy. Frozen section evaluation identifies the level at which ganglion cells are present. If the patient has short-segment disease, then a one-stage transanal pull-through procedure can be performed. In long-segment disease, a diverting colostomy or ileostomy at the level of normal ganglion cells is made and the patient is brought back at a later date for an elective pull-through. In all cases, the definitive procedure involves resection of the distal aganglionic bowel and anastomosis of proximal, normally innervated bowel to the distal rectum or anus. The three most commonly used operations are Soave, Duhamel, and Swenson procedures, all of which yield similar results. The choice of procedure is based on surgeon preference.

Postoperative complications include anastomotic leaks, strictures, abscess formation, and intestinal obstruction, as can be seen following any intestinal surgery. Specific to HD is the possible development of Hirschsprung's-associated enterocolitis (HAEC). HAEC can occur either before or after definitive pull-through surgery. The typical presentation includes abdominal distension, loose stools that are often explosive and foul-smelling, fever, and vomiting. Lethargy and bloody stools can also occur. However, HAEC is highly variable and can present with only mild diarrhea and distension or with septic shock. HAEC remains the leading cause of morbidity and mortality in HD. Mild cases are treated with oral metronidazole and anal dilations. Severe HAEC requires hospitalization, bowel rest, rectal irrigations, and broad-spectrum antibiotics. Another complication specific to HD is the development of obstructive symptoms, which occurs in at least 10% of patients. These patients present with chronic constipation or recurrent episodes of enterocolitis. Possible causes for obstructive symptoms include (1) mechanical obstruction, (2) persistent or acquired aganglionosis, (3) intestinal motility disorders, (4) internal sphincter achalasia, or (5) behavioral disorders. Diagnosing the cause allows targeted therapy, although in some cases no etiology is identified.

Anorectal Malformations

Anorectal malformations (ARMs) represent a spectrum of anomalies characterized by an ectopic, stenotic, or absent opening of the anorectal canal. Considered the most common gastrointestinal anomaly at birth, the worldwide incidence of ARM is reported to range between 1:1,500 and 1:5,000 births. In a large Canadian study, the incidence was 1 in 2,524 live-births, with a similar incidence of 1 in 2,295 in Poland and 1 in 2,500 in the USA. Available data support a slight male predominance at 1.55 males for each female affected.

The embryologic cause of ARMs remains unclear, largely due to a poor understanding of normal anorectal development. Classic teaching held that the cloaca is divided into a ventral urogenital sinus and a dorsal anorectal canal by descent of the urorectal septum and its fusion with the cloacal membrane. ARMs were believed to be due to abnormal partitioning of the cloaca. However, several studies on human embryos have found no evidence that the urorectal septum fuses with the cloacal membrane. Instead, as the septum gets close to the cloacal membrane, the membrane undergoes apoptosis and ruptures, leaving a dorsal anal opening and a ventral urogenital sinus, with the end of the urorectal septum forming the perineum. ARMs are now thought to be due to abnormal development of the dorsal cloacal membrane, which normally gives rise to the anal orifice. A short or absent dorsal membrane leads to a deficient dorsal cloaca. As a consequence, the anal orifice is shifted anteriorly, causing it to enter the urogenital tract in severe cases or the perineum in milder cases. Targeted mutations of the Sonic hedgehog or Wnt signaling pathways lead to ARMs in mice, suggesting critical roles for these pathways in cloacal morphogenesis.

Classification of the various forms of ARMs traditionally separates them into high, intermediate, and low anomalies, as in the commonly used Wingspread classification. Based on the embryologic origin of these defects, the abnormal communication of the distal anorectum with the urinary or genital tract is best perceived as an ectopic anal orifice. The location of that orifice is critically important in determining treatment and prognosis. Therefore, a clinically relevant classification system describes the anomaly entirely based on the location of the anorectal fistula (*Table 418.2*).

Table 418.2
Classification of anorectal malformations

Males	Females
Rectoperineal fistula	Rectoperineal fistula
Rectourethral fistula	Rectovestibular fistula
Rectobladder neck fistula	Rectovaginal fistula
Imperforate anus without fistula	Cloaca
Rectal atresia	Imperforate anus without fistula
	Rectal atresia

In males, the anorectal fistula can open into the perineum, the urethra, or the bladder. The lowest fistulas are rectoperineal and these have a variety of presentations. They can present as (1) an anal orifice, often stenotic, anterior to the normal anal position (*Fig. 418.12a–b*) or (2) a subepithelial tract with the fistula opening along the midline raphe. A "bucket-handle" deformity can be seen in a male with a rectoperineal fistula (*Fig. 418.12c*). Rectoperineal fistulas are associated with a well-developed buttocks and gluteal cleft, normal sacrum, good muscle development of the anal sphincter, and a low incidence of associated anomalies. The most common ARM in males is the rectourethral fistula, which can open into the bulbar (distal) or prostatic (proximal) urethra. Rectourethral fistulas account for about 50% of cases in boys. The highest fistula in males is the rectovesical fistula, which enters at the bladder neck and occurs in only 10% of cases. The higher fistulas are associated with flatter buttocks (*Fig. 418.12d*), poor midline cleft development, abnormal sacrum, poor sphincter muscle development, and an increased risk of associated defects. While the vast majority of ARMs have an anorectal fistula, about 2% of patients with ARMs, including boys and girls, present with imperforate anus without a fistula. These cases are usually associated with Down's syndrome. Even rarer, occurring in only 1% of cases, is rectal atresia. In these cases, the anus appears grossly normal. However, upon attempting to pass a thermometer or catheter into the anal canal, one finds that it ends blindly at about 1–2 cm and does not communicate with the rectum immediately above it.

In females, the lowest fistula, as in males, is the rectoperineal fistula (*Fig. 418.12e*). Often referred to as an "ectopic" or "anterior" anus, these anomalies should be considered ARMs with a rectoperineal fistula. The most commonly encountered ARM in females is the rectovestibular fistula, in which the anorectal orifice is located at the posterior end of the vaginal vestibule. Diagnosis is made by clinical examination with careful inspection of the introitus in a newborn female with an imperforate anus. Fistulas to the vagina are rare. The highest and most complex ARM in females is the

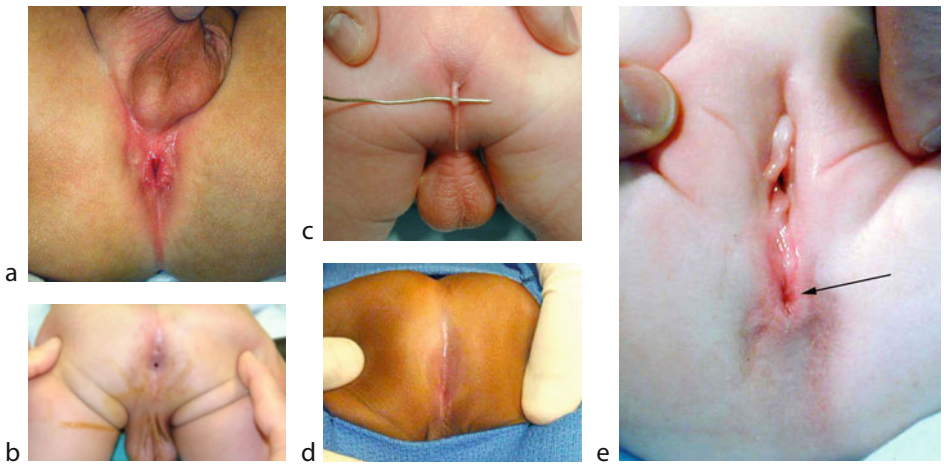

Figure 418.12

Anorectal malformations. (a) Abnormally positioned anal orifice located anterior to the normal anal position. (b) A rectoperineal fistula presenting as a stenotic anal orifice anterior to the normal anal position. (c) A "bucket-handle" deformity in a male with rectoperineal fistula. (d) Absence of the anal orifice in association with a flat buttocks and poor gluteal cleft development are consistent with a high fistula, in this case a rectourethral fistula in a male. (e) Rectoperineal fistula in a female with the anal orifice anterior to the normal anatomic position, leaving a very short perineum

persistent cloaca, in which the rectum, vagina, and urinary tract all fuse and exit as a single channel. The incidence of this rare anomaly is about 1:50,000 births. The anatomy of the pelvic organs in these patients is highly variable and very complicated. Careful physical examination is critical to distinguish this from the rectovestibular fistula, as only a single common orifice will be seen in the cloaca.

ARMs are associated with other congenital anomalies in approximately two-thirds of children. The higher the fistula, the greater the likelihood that the child has an associated anomaly. The anomalies most commonly encountered are listed by organ system in *Table 418.3*. The incidence of these associated anomalies varies widely in the literature, likely due to the vigilance with which each anomaly is sought and also to the relative numbers of high versus low ARMs in a given series. Nevertheless, the incidence of a given anomaly is not critical. What is important is to be familiar with the potential coexistence of specific anomalies in order to guide a thorough physical examination and targeted imaging of the newborn to prevent missed or delayed diagnoses. Preoperative imaging should include plain abdominal radiography to evaluate the lumbosacral spine, abdominal ultrasound to rule-out hydronephrosis or other renal pathology, and echocardiography to assess for congenital heart disease. Voiding cystourethrography and spinal ultrasound should also be performed to rule out vesicoureteral reflux and tethered cord, respectively. Pelvic ultrasound is important in girls with cloacal defects, as these are highly associated with genitourinary anomalies, including hydrocolpos and hemivaginas. The possibility of syndromic disorders should also be considered, as ARMs are known to occur in the setting of several syndromes. For example, Currarino's triad consists of an ARM (usually anal stenosis) with a sacral defect and a presacral mass. ARM is also a feature of Pallister–Hall syndrome, which is due to a mutation in Gli3, a gene downstream of Sonic hedgehog. The VACTERL association includes *V*ertebral defects, *A*RMs, *C*ardiac defects, *T*racheo*E*sophageal anomalies, and *R*enal and radial *L*imb defects. Diagnosis of an ARM should therefore prompt a search for any of these other anomalies. Down's syndrome is known to be associated with ARM, occurring in 2–5%. A karyotype should be obtained in children with ARMs to evaluate for any chromosomal abnormality.

As already mentioned, initial evaluation of a newborn with imperforate anus includes careful perineal examination, thorough physical examination, and appropriate imaging. No decision should be made regarding the presence or location of the anorectal fistula until 24 h of life. This allows time for meconium to appear at the perineum in cases of rectoperineal fistula, or in the urine in cases of rectourethral or rectovesical fistula. If a stenotic perineal fistula is present, then an anoplasty can be performed within the first few days of life. If there is a perineal fistula and the anal opening is not stenotic, allowing passage of

meconium, then the neonate can be discharged with anal dilations and the procedure performed at around 1 month of age. If no evidence of a perineal fistula exists, then the safest course of action is to proceed with a colostomy at 24–48 h of life. Some authors advocate in these cases a prone cross-table lateral radiograph with the pelvis elevated in order to determine the distance from the rectum to the anal skin. Cases in which that distance is less than 1 cm may be amenable to repair without a colostomy. However, this technique can be imprecise and may lead to misinterpretation of the level of the fistula, especially when done in less experienced centers. A divided colostomy with mucous fistula is the safest approach in equivocal cases. This allows later performance of a distal colostogram, which is done by injecting contrast into the mucous fistula in order to identify accurately where the rectum empties. Precisely defining this anatomy preoperatively reduces the risk of injury, especially to the urinary tract, during the definitive repair, which is usually performed at several months of age. A vestibular fistula can be managed either by primary repair or after a diverting colostomy. Either approach is reasonable, but needs to be based on the experience of the operating surgeon. Definitive repair of ARMs is performed using a posterior sagittal approach through the midline of the gluteal cleft with the patient in the prone position. Laparoscopy or laparotomy is added as needed, particularly in cases of high fistulas. The initial management of cloacas is complex, often requiring decompression not only of the colon, but also of the urinary tract and vagina. Definitive repair requires significant experience and therefore appropriate surgical expertise is essential in the proper management of these very complex cases.

Functional intestinal disorders are the most common complication of ARMs and their repair. Constipation is very common, especially among patients with low fistulas, such as perineal or vestibular fistulas. The cause of the constipation is unknown, but may be due to chronic rectal dilatation, abnormal rectal motility, or increased rectal compliance. Constipation typically presents at around the age of toilet training and can often be managed with laxatives. Fecal soiling is a common and challenging problem following repair of ARMs and is reported in about two-thirds of patients. The higher the anomaly, the more likely incontinence will occur. The incontinence is often associated with poor neuromuscular development of the continence mechanism. Surgical injury to those structures during repair or encopresis due to overflow in patients with severe constipation are other reasons for soiling in these children. Patients with fecal incontinence can be managed with laxatives and enemas to clean out the colon daily and thereby minimize the incidence of soiling. Refractory cases may respond well to an appendicostomy or cecostomy for administration of antegrade colonic enemas (ACE). Severe and unrelenting cases benefit from a diverting ileostomy or colostomy. ARMs are also associated with significant psychosocial morbidity, a high rate of behavioral problems, and an increased risk for suicidal ideation. These risks should be assessed proactively in order to provide support for these young patients early in their course.

Pyloric Stenosis

Introduction

The first complete description of hypertrophic pyloric stenosis was presented more than a century ago by Harald Hirschsprung, who is also credited with the first patient series of esophageal atresia, the treatment of intussusceptions by hydrostatic enema reduction, and the description of and congenital megacolon (Hirschsprung's disease). The disease course is well known and its surgical treatment, as devised by Fredet and Ramstedt in the early 1900s, is straightforward. The etiology of pyloric stenosis, however, remains unknown.

Hypertrophic pyloric stenosis is one of the most common surgical conditions in infancy, occurring in 1 in 250 children. It is usually not present at birth, but develops in the first few weeks of life. There appears to be a slight familial incidence without a clear pattern of inheritance. Sporadic cases are much more common than familial ones. There is a strong male preponderance; first-born infants tend to be more often affected. If pyloric stenosis occurs in a girl, her children are at a significantly increased risk of contracting stenosis also. Pyloric stenosis is more common in full-term infants. When preterm infants are affected, they are typically several weeks older than their term counterparts.

Clinical Presentation

Pyloric stenosis appears to be a progressive process of pyloric muscular hypertrophy, often preceded by a period of intermittent pyloric spasm. The infant first vomits formula but not water or Pedialyte, which can be interpreted as intolerance to a particular type of formula. Not uncommonly, formula changes will have been tried before pyloric stenosis is suspected. Nevertheless, there appears to be an increased awareness among pediatricians and primary care physicians so that pyloric stenosis is often suspected earlier in the disease course.

The hallmark of pyloric stenosis is projectile, nonbilious vomiting. The absence of bile helps rule out more distal causes of intestinal obstruction, such as midgut volvulus or Hirschsprung's disease. The appearance of coffee ground vomiting suggests associated gastritis and is often associated with a delay in diagnosis. The child with pyloric stenosis appears otherwise well and extremely hungry, and does not present with associated signs such as diarrhea or abdominal tenderness. Mild jaundice is not uncommon and is believed to be secondary to glucuronyl transferase deficiency.

If allowed to progress untreated, the infant will become dehydrated and lethargic. In severe cases, there may be signs of malnutrition, constipation, oliguria, and profound alkalosis. The latter is a pathognomonic, sign of pyloric obstruction. As the child vomits chloride- and hydrogen-rich gastric contents, hypochloremic alkalosis sets in. Hypokalemia is a result of intracellular shift of potassium ions (in exchange for hydrogen ions) and renal loss as the body attempts to conserve sodium. As potassium is depleted, sodium is exchanged for hydrogen ions in the proximal tubules, giving rise to paradoxical aciduria. The latter hastens systemic alkalosis and, ultimately, cardiovascular collapse.

Today, the full syndrome is very seldom seen. However, most large pediatric surgical centers treat at least one or two patients each year with profound electrolyte imbalance due to longstanding pyloric stenosis.

Clinical Examination

It is often said that pyloric stenosis can be diagnosed clinically in the vast majority of cases. However, palpation of the hypertrophic pylorus, referred to as the "olive" or "tumor," is sometimes difficult and it requires patience. It is important to have the infant in a parent's lap and in a quiet environment, calmed with either a pacifier or a few sips of clear fluid (5% dextrose in water or Pedialyte). If the stomach is full, one-time nasogastric aspiration facilitates the examination. Prior to aspiration, strong gastric peristaltic waves can be visible in the left upper quadrant. The examiner gently palpates the abdomen from the right to the left upper quadrants in a crosswise and up and down fashion. It is useful to first recognize the contour

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_419,

of structures most likely to be confused with an enlarged pylorus: the right kidney, the spine, and the right and left rectus muscles. The pylorus is then gently teased from under the liver edge and rolled between the examining fingers and the infant's spine.

If pyloric stenosis is suspected, very few laboratory tests need to be obtained. A simple urinalysis may confirm mild or moderate dehydration and, less commonly, aciduria. The most important test, however, is a serum electrolyte panel. Hypokalemia, hypochloremia, alkalosis, and dehydration can all be confirmed and quantified to guide to fluid and electrolyte replacement before surgical correction is entertained. Blood should be drawn carefully (no heel stick) to avoid hemolysis and an erroneously elevated serum potassium value. In general, no other laboratory tests are needed unless other diagnoses are entertained. Imaging studies are theoretically superfluous if a clinical diagnosis was made. In reality, contrast radiographs or an ultrasound will often have been obtained before the child is referred to a surgeon. In cases where the clinical diagnosis is uncertain, these tests are very helpful. Until the late 1980s, an upper gastrointestinal series was the radiographic examination of choice. Typical radiographic signs are the "mushroom" impression of the antrum and protruding pyloric mucosa, the "track" sign caused by an elongated pyloric channel with straight, parallel mucosal folds, and the "number 3" or "umbrella" sign formed by contrast in the first portion of the duodenum. A contrast radiograph helps to rule out gastroesophageal reflux, which is the most common differential diagnosis.

Ultrasonographic examination of the pylorus has become the most accepted imaging test, supplanting the upper GI. The ultrasound signs of hypertrophic pyloric stenosis are well established. The pyloric channel should be less than 16 mm in length, the total thickness of the pylorus should be less than 14 mm, and the muscular thickness should be less than 4 mm. With pyloric stenosis, any or all of the above values are increased. In addition, an experienced ultrasonographer will be able to see propulsive peristaltic waves of the antrum, pyloric spasm and, if present, gastroesophageal reflux secondary to the obstruction.

Management

Surgical correction of pyloric stenosis is the only sensible form of treatment. The operation for pyloric stenosis is not considered an emergency. Rather, the infant should be well hydrated and the electrolyte anomalies should be completely corrected. In severe cases, this may take 1–2 days, although today, less than 10% of all infants with pyloric stenosis present with any electrolyte abnormality resulting in a delay of surgical intervention. A nasogastric tube is not routinely used unless the child continues to vomit after feedings have been withheld. Intravenous hydration should take into account the source of fluid and electrolyte losses: 0.45 N saline or, in severe cases, 0.9 N saline solution should be used, supplemented with potassium chloride (10–30 mEq/L) after urine output has been documented. If electrolyte anomalies are present, they should be corrected gradually.

At the time of operation, any infant with pyloric obstruction is considered to have a full stomach. Studies have demonstrated that the risk of aspiration on induction is not reduced by nasogastric suctioning, even if performed immediately before anesthesia. Therefore, rapid sequence or awake intubation, with cricoid pressure, is the preferred methods of induction.

The technique of pyloromyotomy has not changed since its initial description. However, many approaches and incisions have been tried. Today, the vertical midline and Robertson incisions (a right upper quadrant muscle-splitting incision, in an attempt to prevent dehiscence in severely malnourished infants) are rarely used. A laparoscopic approach has been well described and is now widely embraced by pediatric surgeons, offering cosmetic and functional advantages to the open technique. For those surgeons who prefer the palpable control over visual superiority, the umbilical approach has become popular. It is a cosmetically gratifying, but anatomically awkward incision, and delivering the pylorus is more difficult.

A nasogastric tube is not necessary and is dangerous postoperatively. Feeding are usually resumed within 6 h and advanced gradually from 15 to 30 mL of an electrolyte solution (Pedialyte) to full formula or breast milk. This will typically take five to six feedings, each 3 h part. Many different feeding regimens exist, and differences may not be relevant. A few principles should be observed: some vomiting is still expected postoperatively, either from gastric spasms if the child has been ill for a prolonged period of time or, more commonly, because of coexisting gastroesophageal reflux. If this happens, feedings can be held, but should be resumed 3 h later. As feedings are advanced, it is important to introduce formula or breast milk (full- or half-strength) early on, before increasing the volume. Clear fluids alone are not enough to keep the pylorus open, and recurrent pyloric stenosis may occur if curds are not allowed to stimulate the pyloric channel. The infant is discharged home once a full feeding schedule is attained, usually within 24 of 36 h.

Complications and Outcome

Major complications are very rare unless the infant was severely malnourished preoperatively. Wound infection may occur and appears to be slightly more common than with comparable, clean operations (e.g., inguinal herniorrhaphy). The incidence of wound complications may be as high as 4–5%, according to some series. Skin or fascial dehiscence may occur as well with those that perform an open technique. Treatment is conservative unless fascial dehiscence or evisceration is present. Antibiotic prophylaxis has been advocated by some, but has not been shown to alter the risk of infectious complications.

Recurrent pyloric stenosis is well described and requires a repeat pyloromyotomy. However, it is a very unusual event today, and most instances of postoperative vomiting are due to reflux. Unrecognized mucosal perforation (usually on the duodenal side) and peritonitis are serious complications that can be avoided by meticulous technique and vigilance. The success rate of pyloromyotomy for infantile pyloric stenosis should approach 100%, and late recurrence does not occur.

Intussusception

Introduction

Intussusception is the most common abdominal emergency seen in the early childhood years (3 months to 6 years), exceeding appendicitis in this age group. Under the age of 3 years, 80–90% of patients experience idiopathic ileocolic intussusception for which, in the absence of peritonitis, nonsurgical management is the mainstay of therapy.

The mechanism of intussusception is clearly understood and occurs when one segment of intestine (intussusceptum) is circumferentially invaginated and propelled into an adjacent distal segment (intussuscepiens). This results in luminal obstruction with progressive venous, lymphatic, and eventually arterial compromise. The most widely held theory is that the submucosal lymphoid aggregates (Peyer's patches) enlarge in response to antigenic stimulation from newly introduced food substances or viral infections as suggested by seasonal variation coincident with viral gastroenteritis and respiratory infections. Additional evidence for this mechanism follows the observations of a spike in the number of intussusceptions after a series of former Rotavirus vaccinations. Stimulated Peyer's patches project into the lumen of the intestine, presenting a transient and pseudopolypoid lead point. Alternative theories include the differential size and motility of adjacent segments of intestine. This theory may be most relevant to postoperative intussusception, which usually involves the proximal jejunum and is devoid of Peyer's patches.

The progress in the management of intussusception has covered centuries. Successful operative management was first reported in the mid-nineteenth century when infants and children continued to have a high rate of mortality related to sepsis and dehydration. In 1878, Harold Hirschsprung, in another of his seminal contributions to the care of infants and children, first proposed hydrostatic reduction. The survival rates of 50% with hydrostatic reduction were superior to those achieved with operative reduction. In the United States, William Ladd of Boston was a proponent for the use of the contrast enema for diagnosis in 1913, but only in 1948 was it accepted for therapeutic intervention. Air reduction techniques were first reported from China, where there is an inordinate incidence of intussusceptions. This technique was slowly introduced to the United States in the 1990s. Sonographic evaluation of the abdomen is a less invasive tool for the diagnosis of intussusception. Doppler imaging with ultrasound provides the advantage of being able to assess intestinal blood flow using and thus identifying those patients that would not benefit from attempts at hydrostatic reduction.

Clinical Presentation

Boys and girls, and various ethnic and racial groups appear to be equally affected. The typical history is that of a child, 6 months to 2 years of age (two thirds occur before age 1 year), with the abrupt onset of abdominal pain causing the child to double over and draw their legs to the abdomen. This episode resolves with the child either returning to sleep or resuming normal activity, only to be interrupted again by a wave of colicky abdominal pain. Occasionally, the pain is accompanied by emesis and passage of a normal stool. The child frequently is diaphoretic and pale during these episodes and with time becomes progressively more apathetic and lethargic. As the bowel obstruction persists, emesis progresses to bilious emesis and the child may pass a bloody, mucus stool (currant jelly stool). Depending on the duration of symptoms, the physical signs may vary. By the time a surgeon is typically asked to see the patient, the child may be quite lethargic and apathetic from dehydration. Between episodes of pain, it is possible to palpate the abdomen and identify the essentially pathognomonic features of an empty RLQ

(sign of Dance) accompanied by a sausage-like mass in the RUQ. Gross or occult blood is often detected at this stage. During acute episodes of colic, no reliable abdominal exam can be elicited and may lead to the false conclusion of an acute abdomen, prompting potentially unnecessary laparotomy. Consideration of this diagnosis and patience with the examination are thus necessary.

Management

In the patient with a high index of suspicion for intussusception, intravenous access should be promptly established and fluids administered in the form of isotonic fluid to correct any deficit. This assessment relies on the adequacy of peripheral perfusion, the presence of lethargy, electrolyte derangements, or metabolic acidosis. The use of antibiotics (i.e., ampicillin and gentamicin), although routine in the past, has now been reserved for those patients requiring operative intervention.

Radiographic studies useful in establishing the diagnosis of intussusception include supine and left lateral views of the abdomen, which may delineate a paucity of gas in the RLQ with a density in the RUQ. In advanced cases, a small bowel obstruction will be apparent. The abdominal film can, however, be completely unremarkable and this should not exclude the diagnosis in a patient with a strong clinical history.

If expert sonographic evaluation is available, it is often used for diagnosis. The intussusception appears as a target shaped lesion. When confirmed by sonogram or suspected by radiograph or exam, the next intervention is the contrast or pneumatic enema. This intervention is performed only after ascertaining that there are no peritoneal signs or other severe compromise from bowel obstruction. Although not essential, some radiologists request that the child be sedated to facilitate the reduction. General anesthesia is not warranted. The method of choice for hydrostatic or pneumatic reduction varies with institutions and includes barium, iso-osmolar water-soluble agents, and air reduction. A catheter inserted into the rectum must be secured to assure an airtight seal. Most radiologists use a catheter with a bulb tip and tape the buttocks together. Guidelines for the height of the contrast column or pressure generated by air insufflation are followed to minimize the risk of perforation. When present, in ileocolic intussusception the intussusceptum can be seen outlined as it moves retrograde toward the ileocecal valve. It is critical to visualize the complete reduction of the intussusception demonstrated by free reflux of contrast or air into the distal small intestine. Multiple attempts at reduction may be required before complete reduction is achieved. Hydrostatic reduction should involve the most experienced personnel before a decision is made that it has failed to achieve a complete reduction. Once the intussusception is reduced, the child often immediately acts as if he/she feels better and typically falls into a sound sleep. A fever may follow directly after a reduction as well. Patients are admitted for continued hydration and are observed for any recurrence of the intussusception, which has been found in 5–8% of patients within 24 h of reduction. If asymptomatic the following morning the child is offered liquids and a diet is advanced to diet for age prior to discharge. Recurrent symptoms are treated with repeat hydrostatic reduction, again ensuring that a complete reduction is achieved. Older children with recurrences at greater intervals must be suspected to have a pathologic lead point.

Surgical intervention becomes necessary when a patient presents with unequivocal peritonitis that usually follows a history of abdominal pain in excess of 48 h. Other indices of severe ischemia or gangrene include sonographic findings documenting an absence of mural blood flow or inability to reduce the intussusception with optimal technique. In the latter circumstance, it is acceptable in some institutions with the appropriate personnel to proceed with one final attempt at hydrostatic reduction in the operating room under general anesthesia. Inability to reduce the intussusception may also indicate a pathologic lead point such as with a Meckel's diverticulum or lymphoma of the small bowel.

Special Considerations in Pediatric Intussusception

Only 2–8% of children under age 2 with intussusception will have a pathologic lead point. This most commonly consists of a Meckel's diverticulum. The prevalence of pathologic lead points may be as high as 57% after age 4 years, but markedly less than found in adults (97%). These atypical causes often lead to ileal–ileal rather than ileocolic intussusceptions which are not as easily diagnosed or amenable to hydrostatic reduction. Ultrasound plays a major role in these diagnoses. Other lead points may be provided by hamartomas associated with Peutz Jegher's syndrome or mural lesions such as heterotopic pancreatic nodules, enteric cysts, adenoma, acute lymphoblastic leukemia, neurofibroma, or hemangioma. Conditions resulting in mucosal and submucosal hemorrhage such as in Henoch–Schonlein purpura, disseminated intravascular coagulation, hemophilia, and even trauma

have been associated with intussusception. Although cystic fibrosis may present with intestinal pseudo-obstruction in the later childhood years, one must consider the possibility of intussusception, which in these cases is most often associated with an enlarged, congested appendix.

Idiopathic intussusception occasionally occurs after unrelated upper abdominal or even thoracic procedures. The main feature of an early postoperative bowel obstruction from an intussusception is a high nasogastric tube output despite a decompressed appearing distal intestine by plain radiograph. The diagnosis is established by either ultrasound or upper intestinal series.

The primary complications related to intussusception result from a delayed diagnosis. The consequent dehydration acidosis and potential sepsis account for a fatality rate of about 1%. The most serious complications related to the hydrostatic reduction are intestinal perforations either in the rectum related to the catheter or more proximally related to intraluminal distension against a fixed obstruction. The rates of perforation are reported to be 0.18% with hydrostatic reduction in contrast to between 1% and 2% with pneumatic reduction with successful hydrostatic reduction parents must be warned of the potential for recurrence, which is suspected on the basis of recurrent abdominal pain and is again treated with hydrostatic reduction.

The vast majority of children that experience idiopathic intussusception are managed with hydrostatic or pneumatic reduction. Successful reduction by barium enema is approximately 85% within 12 h of onset of symptoms and decreases to 70% after 24 h, with an overall success rate of 80%. This rate of success despite prolonged symptoms supports an attempt at hydrostatic or pneumatic reduction, in the absence of peritoneal signs or definite evidence of a small bowel obstruction. The rate of successful reduction was found to be improved with repeated attempts at either barium enema or air reduction after a rest period of variable duration (30 min to several hours) only if there was some retrograde movement of the intussusception with consecutive attempts. Of those patients requiring surgery, approximately 60–80% can be managed without requiring resection.

Meckel's Diverticulum

Introduction

Meckel's diverticulum derives its name from Johann Friedrich Meckel, professor of anatomy at Halle, whose 1809 account of the origin of this diverticular structure was so clear that his name has been eponymously attached to it ever since. Meckel's diverticulum is a vestigial structure, which results from failure of the omphalomesenteric (vitelline) duct to involute. The yolk sac is connected by the omphalomesenteric duct to the primitive gut. This duct attenuates, involutes, and separates from the intestine between the fifth and seventh weeks of gestation. Failure of the yolk sac to involute results in a persistent omphalomesenteric duct remnant whose anatomy is determined by the stage at which the arrest occurs. In a small proportion of diverticula, an omphalomesenteric duct remnant extends from the apex of the diverticulum to the undersurface of the umbilicus. This may be a patent mucosal lined fistula, cystic mass, or fibrous band. Most often there is no connection between the diverticulum and the undersurface of the umbilicus.

A Meckel's diverticulum is a true diverticulum arising from the antimesenteric border of the ileum. As such it contains all layers of the intestinal wall. The mucosa of the diverticulum can contain heterotopic gastric or pancreatic mucosa. Grossly, the diverticulum is usually several centimeters long, although occasional cases of giant Meckel's diverticulum have been described. The diverticulum may have either a broad or a narrow base. The blood supply of the Meckel's diverticulum is usually the same as that of the ileum. Occasionally, the blood supply can arise from the abdominal wall. Meckel's diverticulum is usually located within 100 cm of the ileocecal valve. The Meckel's diverticulum is the most common congenital anomaly of the GI tract. Meckel's diverticulum occurs in between 1.3% and 2.2% of the population based on autopsy studies. The ratio of males to females in asymptomatic patients is nearly equal while the incidence in symptomatic patients is three to one. They are associated with several other congenital and acquired disorders. The incidence of Meckel's diverticulum is increased sixfold in patients with esophageal atresia and fivefold in patients with imperforate anus. Some studies point to an increase in Meckel's diverticulum in patients with cardiac or neurologic abnormalities. Exomphalos also increases the likelihood of having a Meckel's diverticulum. Interestingly, Crohn's disease is associated with a higher incidence of Meckel's diverticulum with a threefold increase noted in patients who required surgery for Crohn's disease.

Clinical Presentation

Most Meckel's diverticula are clinically silent and only 40% become symptomatic presenting in a variety of ways depending on the pathophysiology involved.

Complications of Meckel's diverticulum include obstruction, inflammation, or bleeding. The original descriptions of Meckel's diverticulum assumed a complication rate of 25%, however; a review of a baseline population of over one million people over a 15-year period determined the chance of a Meckel's diverticulum being a cause of disease to be 6% over one's lifetime. Symptomatic lesions are age dependent accounting for 85% of the cases in children less than 1 month of age and 77% between 1 month and 2 years of age. In contrast, symptomatic lesions were found in only 15% of cases of children over 4 years of age. More than 50% of patients with symptoms referable to Meckel's diverticulum will be identified before 2 years of life.

Hemorrhagic causes of pathophysiology in Meckel's diverticulum arise from heterotopic gastric mucosa which results in peptic ulceration of adjacent mucosa causing lower gastrointestinal bleeding. Inflammatory consequences may result from perforation secondary to either peptic ulceration or penetration by a foreign body, which cause Meckel's diverticulitis. Obstruction as a result of the diverticulum can follow events that include: intussusception in which the Meckel's diverticulum acts as a lead point, volvulus around a persistent omphalomesenteric remnant, internal herniation through a mesodermal band (vitelline artery remnant), incarceration of a Littre's hernia, external compression by a omphalomesenteric cyst, or segmental intestinal fibrosis from peptic stricture. Congenital abnormalities leading to pathophysiology include umbilical fistula secondary to patent omphalomesenteric duct or paraumbilical cysts or cords caused by omphalomesenteric duct remnants.

Bleeding is the most common clinical presentation of Meckel's diverticulum. Bleeding accounts for between 25% and 56% of patients who present with symptomatic lesions. Usually the patient presents with painless gastrointestinal bleeding before 5 years of age. The lower gastrointestinal bleeding can produce either melena or hematochezia. The bleeding varies considerably in quantity and character but is usually episodic and often causes anemia requiring transfusion. Occult bleeding with anemia is an infrequent presentation of Meckel's diverticulum.

Management

When bleeding is the presenting symptom for a Meckel's diverticulum gastric mucosa is nearly always present. Scintigraphy can be used to detect gastric mucosa based on the uptake and excretion of pertechnetate isotope by gastric mucosa. Normally the stomach and urinary bladder demonstrate a dense uptake of the radionucleotide while the duodenal loop and proximal jejunum demonstrate accumulation. A positive study shows an abnormal accumulation of radionucleotide usually in the right lower quadrant. The sensitivity of this study is 85%, the specificity is 95%, and the accuracy is 90%. Pentagastrin, histamine blockers, and glucagon can be used to increase the accuracy of scanning.

Because the bleeding from a Meckel's diverticulum tends to be episodic and frequently stops spontaneously, elective surgery can usually be deferred until the diagnosis is confirmed and the patient is stabilized. Blood transfusion and rehydration are usually necessary. Emergent exploratory surgery is usually not required. Appropriate treatment is resection of all heterotopic gastric mucosa through either diverticulectomy or segmental ileal resection. Areas of bleeding or ulceration should be sought and resected or oversewn. Incidental appendectomy is usually also performed. The bleeding should not recur after surgery, if it does a retained portion of gastric mucosa should be ruled out. Overall results for diverticulectomy or segmental ileal resection are excellent.

Obstruction: Clinical Presentation

Meckel's diverticulum may cause intestinal obstruction through many mechanisms. Intussusception and volvulus are the most frequent causes of obstruction secondary to Meckel's diverticulum. In a combined series of over 1,000 patients, intussusception accounted for 46% of the obstructions and volvulus 24%. Typically intestinal obstructions present with crampy abdominal pain and vomiting that can become bilious. If an obstruction persists and progresses from a partial to a complete blockage, the intestine will become ischemic and can eventually become gangrenous and perforate. At this point peritoneal signs will develop and the pain will become constant. Associated symptoms can include fever, dehydration, lethargy, diarrhea, or hematochezia. The diagnosis of intestinal obstruction is a clinical diagnosis. Plain abdominal radiographs including a flat and upright or a decubitus view are also essential to making the correct diagnosis. Meckel's diverticulum is rarely diagnosed preoperatively as the cause of the bowel obstruction. If intussusception is suspected the diagnosis can be confirmed using ultrasound or the patient can proceed directly to fluoroscopy where a barium enema or air contrast enema is performed for diagnosis and to reduce the intussusception. If a Meckel's diverticulum is the lead point of the

intussusception the chance of reducing the intussusception nonoperatively is unlikely.

Inflammation: Clinical Presentation

Meckel's diverticulitis is a common cause of a complication of a Meckel's diverticulum but it is unusual in children. Typically, patients present with vague abdominal pain which localizes to the right lower quadrant. Associated symptoms include anorexia, nausea, vomiting, and fever. Meckel's diverticulitis is usually misdiagnosed as acute suppurative appendicitis and should be suspected in all operations for suspected appendicitis in which the appendix is normal. The diagnosis is therefore usually made during laparotomy. The indications for surgery are the same as those of appendicitis and are typically based on clinical findings. If considered within the diagnostic workup for appendicitis, computed tomography and ultrasound can be valuable adjuncts to making the diagnosis.

Fistula: Clinical Presentation

A fistula connecting the ileum to the umbilicus is the result of a persistent omphalomesenteric duct usually present only during the newborn period. A patent duct should be suspected in all infants with umbilical polyps or granulation tissue especially if there is an associated sinus tract. A history of discharge of ileal contents or passage of flatus through the fistula is pathognomonic for a patent omphalomesenteric duct. In the case of a complete omphalomesenteric duct, there can be varying degrees of mucosal prolapse based on the diameter of the fistula. When the fistula is short and broad, the ileum may intussuscept onto the surface of the umbilicus producing a double horned segment of bowel, inside out, with the lumen evident on each horn. When the fistula is incomplete there is either an associated cyst which typically presents after the newborn period due to secondary infection or a cord which may act as the source of intestinal obstruction. The diagnosis of a fistula can be confirmed by performing a sinogram to demonstrate the communication between the umbilicus and ileum in the case of a complete fistula. Ultrasound is another useful tool for diagnosing incomplete, cystic omphalomesenteric duct remnants.

Resection by open or laparoscopic methods is the treatment for all symptomatic cases. This is accomplished with or without small bowel resection and the outcome for all children is universally good.

Appendicitis

For most pediatricians and pediatric surgeons, appendicitis continues to be one of the major emergency evaluations performed either in office or hospital settings. The history and nuances of the evolution of the workup of right lower quadrant pain has occupied numerous texts and articles. Our fascination with the deviations in the course of appendicitis and its outcome has formed the basis of many pediatric and surgical investigations. Just as the diagnostic evaluation of appendicitis has marched forward to utilize imaging techniques of ultrasound, CT, and most recently MRI, so to have positive technical innovations progressed from open appendectomy to the almost universal laparoscopic appendectomy. Although no etiologies have been determined for appendicitis, it still remains open to investigation with evidence of increasing western obesity coinciding with an increasing incidence of appendicitis. These observations point to diet as a main contributory factor.

Clinical Presentation

It is well known that acute appendicitis can mimic any intra-abdominal process; however, the majority of cases of appendicitis appears straightforward and is easily determined by a careful history and physical examination. Most children between the ages of 6 and 18 years old experience epigastric and periumbilical pain followed by nausea, some vomiting, and anorexia. Subsequently, there is localization of the pain to the right lower quadrant. Physical signs indicate right lower quadrant abdominal rigidity and over the course of time there is rebound tenderness indicating peritoneal irritation.

The real diagnostic dilemmas come in the absence of a classic history of appendicitis or a delay in treatment. For those patients with a history of recurrent episodes of abdominal pain or a recent viral or streptococcal illness, the apparent cause of acute appendicitis may not be clear. Many patients lack anorexia as a symptom and similarly many may have diarrhea as a result of peritoneal irritation. It is essential that pediatricians and pediatric surgeons should not abandon the diagnosis of appendicitis or jump to the diagnosis of gastroenteritis as these may be late signs of advanced peritoneal irritation or a pelvic abscess. The anatomic position and the appendix may lead to different symptoms especially irritative urinary symptoms of frequency and urgency which may accompany findings of pelvic appendicitis. Findings on urinalysis of blood or white cells may prompt one to consider

infection or calculus in association with the abdominal pain. Retrocecal acute appendicitis may have no anterior abdominal findings; however, it would present with flank pain as the chief complaint. Finally, abnormalities in the bowel rotation may lead to peritoneal findings in the upper abdominal quadrants.

Fever and anorexia may or may not be present as symptoms and a high fever may indicate advanced appendicitis and perforation. The history obtained from each child allows the physician to generate a differential diagnosis. It is important to note the age, sex, and previous medical history are all important for primary consideration for appendicitis. The physical findings with right lower quadrant tenderness or other signs of peritoneal irritation will lead to the next steps in the diagnostic workup. In older children, it is important to perform rectal and occasionally pelvic examinations to determine whether any other pelvic pathology as the cause of pain and inflammation. Pelvic inflammatory disease must be considered in the differential diagnosis.

Once the diagnosis suspected acute appendicitis and majority of cases should be confirmed by appropriate laboratory studies to include a complete blood count with differential and urinalysis.

Over the past decade, there has been significant controversy over the best examination that will determine appendicitis with uniform high sensitivity and specificity. In centers with outstanding ultrasonagraphy, the sensitivity and specificity can be greater than 85%. CT scanning with contrast has a similar high sensitivity and specificity; however, it comes with the concerns for significant radiation exposure. It is beyond the scope of this chapter to discuss the merits of each as most centers will have a clear understanding of the protocols and clinical pathways that have led to the highest rates of accurate diagnosis to achieve treatment with the lowest rates of complications.

The treatment for acute appendicitis still remains as appendectomy. Whether it is performed through a right lower quadrant incision or performed laparoscopically, patients are usually prepared for surgery with fluid resuscitation and perioperative antibiotics. There are many institutional variations on the types and duration of antibiotic coverage; however, for acute appendicitis a single dose of preoperative antibiotics has been found to be the most effective at reducing wound infection. For those patients who present with advanced appendicitis or are found to have intra-abdominal abscess by imaging, antibiotics are started to reduce the incidence of associated sepsis.

Minimally invasive drainage of intra-abdominal abscess by catheter techniques has reduced significant morbidity from laparotomy in cases where enterotomies and hemorrhage may be significant complications. Many patients with limited symptoms presenting with an abdominal mass in the right lower quadrant have been treated with courses of antibiotics alone followed by interval appendectomy. If the mass fails to respond after between 2 and 5 days of conservative management, an abscess is almost always certainly present and should be drained either by either percutaneous means or by an open operative intervention.

Infants and children under 5 years old have notoriously variable presentations and frequently present with perforation. They often are suspected of having advanced gastroenteritis which further complicates their course and leads to a delay in diagnosis. These patients clearly are most in need of advanced pediatric surgical and often critical care expertise. First and foremost they should be aggressively resuscitated and undergo expert evaluation. Often surgical suspicion and judgment lead to an exploratory laparotomy as the only diagnostic and therapeutic option.

Pediatricians often face complications from appendicitis following appendectomy for acute suppurative, gangrenous, or perforated appendicitis with or without abscess formation. The most common complication is a wound infection. This may occur in the right lower quadrant McBurney incisions in approximately 30% of patients with perforated appendicitis. Alternatively, surgeons may have chosen to leave these wounds open. In the face of a local wound infection, the skin should be opened and dressings utilized to clear any subcutaneous abscess. Wound healing by secondary intention usually follows over 2 weeks.

More rarely, wound infections can occur at the sites of trocar placement for laparoscopic appendectomy. The treatment is the same. Following appendectomy patients may present with diarrhea due to long courses of antibiotic use for intra-abdominal abscess. The most serious complication comes from Clostridium difficile-associated diarrhea. Stool cultures are essential and treatment must be rapid.

A more complicated postoperative presentation may occur in patients with recurrent intra-abdominal abscess. On these occasions, these patients may present with intermittent high fever, nausea and vomiting, diarrhea, and even bowel obstruction due to ileus or mechanical factors. Upper abdominal abscesses may present with shoulder pain or pleural effusions and lower abdominal abscesses may present with diarrhea or urinary symptoms. In these cases, imaging by CT scan is essential to rule out abscess and to define bowel obstruction. Percutaneous abscess

drainage is necessary for most cases. Occasionally, an intra-abdominal phlegmon is determined and a secondary course of antibiotics will be sufficient.

Long-term complications include small bowel obstruction secondary to adhesions along with theoretic implications for fertility due to pelvic inflammation. In all cases of appendicitis, it is essential that there be a continuum of care beginning with the patient's pediatrician that extends to pediatric emergency physicians, pediatric surgery, and back again to the patient's general pediatrician. This allows for the best outcome for these patients and their families.

420 Thoracic Surgical Procedures

Erica R. Gross · Robert A. Cowles

Thoracic surgery in children is indicated for the treatment of both congenital and acquired diseases. Congenital disorders include pulmonary and gastrointestinal (GI) malformations. The most common congenital pulmonary abnormalities result from anomalous development of the lung parenchyma or distal airways, resulting in congenital pulmonary airway malformations (CPAM), bronchopulmonary sequestration (BPS), congenital lobar emphysema (CLE), or bronchogenic cysts (BC). The esophagus is the gastrointestinal organ located in the thorax, and esophageal atresia (EA) is the most common congenital malformation of this organ requiring surgical intervention. Parapneumonic effusion, with or without empyema, is the most commonly acquired thoracic disease that warrants surgical consultation. This chapter will review these most common thoracic surgical conditions affecting infants and children, focusing on presentation, evaluation, and surgical therapy.

Esophageal Atresia

Definition/Classification

Esophageal atresia (EA) is a congenital defect of esophageal development, resulting in a blind-ending upper esophageal pouch and a lower esophageal remnant. There are four anatomic forms of esophageal atresia, three of which are associated with an anomalous communication between the esophagus and the trachea, known as a tracheoesophageal fistula (TEF) (*Fig. 420.1*, types B–D). The fistula may connect the proximal or distal esophagus, or both remnants, to the trachea. EA with a distal TEF is the most common anomaly accounting for approximately 85% of cases. A fifth anatomic variant exists in which only a TEF exists without EA (*Fig. 420.1*, type E).

Etiology/Epidemiology

The trachea and esophagus derive from the foregut during the fourth week of embryogenesis. At this time, the foregut divides into a ventral respiratory tract and a dorsal gastrointestinal (GI) tract, consisting of the esophagus proximally. This separation is not complete in patients with EA, which occurs in approximately 1 in 3,500 live births. Environmental or genetic factors have been speculated to play a role in the pathogenesis of EA, but no definitive etiology has been identified.

No single gene has been found responsible for the development of EA, and the inheritance pattern is multifactorial. The increased risk of having a second child with EA is only 1%. Associated anomalies occur in 50% of patients with EA. Only 6–10% of patients with EA, however, have a defined genetic syndrome. The following genetic syndromes associated with EA have been identified: anophthalmia-esophageal-genital syndrome (SOX2), CHARGE syndrome (CHD7), Feingold syndrome (MYCN), Pallister-Hall syndrome (GLN13), and VACTERL (FANCB).

Clinical Manifestations

Increased utilization of screening ultrasound (U/S) during pregnancy has allowed for identification of EA prenatally in the fetus. Since ultrasonographic findings are not specific for EA, however, it is not uncommon for EA to be diagnosed after birth. Neonates with EA are classically described as having copious oral secretions and respiratory distress, often with initial feeding attempts. Inability to successfully pass an orogastric tube is a common clinical finding. Physical examination may reveal associated anomalies, such as vertebral or limb abnormalities, but in isolated cases of EA with or without TEF, the rest of the physical will be normal.

Diagnosis

Prenatal diagnosis of EA is possible and is based on the findings of polyhydramnios, a small stomach, and decreased fetal weight on fetal U/S or magnetic resonance imaging (MRI). Sometimes, a fluid-filled upper esophageal pouch can be seen, suggesting the diagnosis.

Postnatally, EA is commonly diagnosed clinically by the failure to pass an orogastric tube at birth in a child with

(C) Esophageal atresia with distal tracheoesophageal fistula. (D) Esophageal atresia with both proximal and distal tracheoesophageal fistulae. (E) Tracheoesophageal fistula without esophageal atresia

excessive drooling or after vomiting the initial feed. Chest radiography (CXR) shows coiling of the tube in the upper esophagus. If a TEF connecting the airway to the lower esophageal remnant is present, a normal bowel gas pattern will also be seen. When no connection is present as is seen in pure esophageal atresia, the CXR will show a gasless abdomen (type A). Bronchoscopy can identify the specific location of an upper TEF. A careful esophagogram with contrast administered via the nasoesophageal tube under fluoroscopy can be used to confirm the diagnosis in unclear cases and to evaluate the presence of upper esophageal fistulas.

It is important to assess all patients with EA for the presence of associated anomalies. Epidemiologic studies indicate that 60% of patients with EA have congenital anomalies that may or may not be part of a defined association, such as VACTERL or VATER. Limb and anorectal abnormalities can be appreciated on physical exam, while vertebral, renal, and cardiac malformations require additional imaging. Spinal radiography, renal ultrasound, and echocardiogram are recommended. An echocardiogram also aides in surgical planning by determining the side of the aortic arch.

Differential Diagnosis

It is important to keep in mind that any obstruction of the esophagus in utero will cause polyhydramnios. Therefore, other esophageal, gastric, and duodenal pathology should be considered. Another condition that can mimic EA is iatrogenic perforation of the esophagus at the level of the pharynx. Bloody output from the esophageal tube should alert the surgeon and the neonatologist to this possibility.

Treatment

Initial management of EA focuses on control of oral secretions to minimize aspiration pneumonitis. The infant

should not be fed by mouth, a Replogle tube should be placed and maintained on low continuous wall suction, and the head of bed should be elevated to minimize reflux.

Surgical management consists of separation of the airway and GI tract, esophageal reconstruction, and access for enteral feeding. A distal TEF allows reflux of gastric acid into the respiratory tract, and semi-urgent surgery is necessary to divide this fistula and prevent respiratory complications. Closure of a distal TEF also allows the neonate to be ventilated safely, without distention of the GI tract. A TEF of the upper pouch may be managed acutely with a Replogle, and urgent surgery may be planned for fistula closure. Timing and approach to esophageal reconstruction depends on the size of the gap between the two esophageal pouches and the presence or absence of a TEF. Ideally, primary anastomosis of the proximal and distal esophageal remnants would be performed at the time of fistula division. Primary repair of the esophagus may be delayed in low birth weight infants or neonates with significant cardiac or respiratory comorbidities. Pure esophageal atresia suggests that a long gap exists between the two portions of the esophagus. Therefore, in these cases a gastrostomy tube is placed for enteral feeding while the infant is permitted to grow. Surgery for EA is accomplished via a right thoracotomy unless the TEF is in the cervical region or when the aortic arch is right-sided.

Prognosis

Historically, Waterston et al. determined that prognosis was very closely related to birth weight, as an index of prematurity, associated anomalies and pneumonia. At the time of Waterston's report, overall survival was only 50%, while patients that did not have any of the aforementioned risk factors had a survival of 95%. Today, overall survival approaches 90% and Waterston's criteria have been re-evaluated. Birth weight under 1,500 g and the presence of major congenital cardiac disease have been reported as the remaining significant risk factors contributing to mortality of patients with EA. Advances in neonatal intensive care and surgical and anesthetic techniques have improved the prognosis of infants with EA, but these patients still have significant short- and long-term morbidity.

Anastomotic leak is the most concerning perioperative complication, occurring in 13–20% of cases. Significant leaks can lead to sepsis and may require surgical reintervention. Minor leaks, which are more common, typically present on imaging as extravasation of contrast during post-op esophagogram prior to feeding. When this occurs, management is usually conservative, consisting of prolonged drainage of the retropleural space and postponement of enteral feeding. The majority of these minor leaks close without further intervention.

With improved overall survival, long-term morbidity after EA repair is a major concern. Poor feeding, esophageal stricture, and gastroesophageal reflux (GER) are postoperative sequelae that require active management. Poor feeding is usually secondary to impaired esophageal motility, but stricture must be ruled out. Stricture is a common, early complication and occurrence has been reported as high as 80%. Symptomatic patients with evidence of stricture on imaging studies should undergo dilation. Dilation may be required in approximately 70% of these patients. Stricture may be a complication of the original surgery (anastomosis under tension and/or poor vascularization of anastomosis) or as a result of ongoing GER. Stricture has been reported in >50% of patients with GER versus >20% without GER. Patients with pure esophageal atresia are at the highest risk for stricture.

GER occurs early, and lifelong management is essential in EA patients. Engrum et al. reported 40% of infants had GER after EA repair. Many patients have GER despite not having symptoms and therefore require empiric acid suppression therapy. Extended endoscopic surveillance of patients after repair of EA has shown that 15% of patients have evidence of esophageal metaplasia only 10 years after surgery. Some of these patients had no evidence of reflux on investigation with pH probes. EA is a risk factor for metaplasia and all patients regardless of symptomatology or evidence of GER should have endoscopic surveillance for mucosal changes. Six cases of esophageal cancer have been reported in patients with repaired EA, ranging from 22 to 46 years of age at presentation, with both squamous and adeno-carcinomas having been documented.

Recurrence of TEF is a possible short- or long-term complication. This can occur in the early postoperative period, but may not be recognized or become symptomatic for months, typically presenting as recurrent pulmonary infections. Incidence has been reported as 5–10%, and patients present between 2 and 18 months after EA repair.

Prevention

There is no known prevention.

Congenital Lung Malformations

Screening prenatal U/S has increased in accuracy and this has led to earlier identification of congenital lung

malformations that may otherwise have been asymptomatic after birth. While they can be seen prenatally, these lesions are best differentiated postnatally and fall into several different categories. Congenital pulmonary airway malformations (CPAM), bronchopulmonary sequestration (BPS) or hybrid lesions are most common, and congenital lobar emphysema (CLE) or bronchogenic cysts (BC) occur less frequently. All four lesions require surgical management, but may present differently.

Definition/Classification/Etiology/Epidemiology

Congenital Pulmonary Airway Malformation (CPAM). Previously referred to as congenital cystic adenomatoid malformation (CCAM), CPAM is characterized by an overgrowth of terminal bronchioles, forming various sized cysts. CPAM probably results from a cessation of bronchomaturation and concomitant overgrowth of mesenchymal elements during the fifth to sixth week of gestation. CPAMs are intrapulmonary masses. They are hypovascular and show signs of hyperproliferation. Histologically, cartilage is absent and smooth muscle and elastic tissue are increased in cyst walls. These lesions do not participate in gas exchange, although often there is a small bronchial communication allowing for infection and overinflation of the cyst. CPAMs can rapidly proliferate causing mediastinal shift and hydrops in utero or respiratory distress secondary to restrictive ventilation after birth. U/S studies have shown evidence of regression in antenatal lesions; however, postnatal CT scans are highly sensitive in identifying these lesions. Stocker et al. designed a classification system based on pathological features and cyst size, describing three types of CPAMs. Adzick et al. simplified this classification based on gross anatomy and ultrasound findings.

Bronchopulmonary Sequestration (BPS). BPS is a mass of nonfunctional lung tissue that receives blood supply from an anomalous systemic artery and lacks bronchial connections. The arterial supply can arise from the supradiaphragmatic or infradiaphragmatic aorta. Either the pulmonary or the systemic veins are responsible for venous drainage. Incidence in the general population is estimated at 0.15–1.7%. There are two types of pulmonary sequestration, intralobar (IPS) and extralobar (EPS). Intralobar sequestrations are more common, incorporated and surrounded by normal lung tissue, and commonly located in the lower lobes, left more common than right. Blood supply to an IPS originates from the descending aorta and is typically found within the inferior pulmonary ligament. EPS is isolated from normal lung by a separate visceral pleura. EPS can be found in the thorax or in the abdomen, in a subdiaphragmatic position. These lesions predominate in males and are more commonly identified in the left hemi-thorax. Approximately 4% of cases of EPS are associated with congenital diaphragmatic hernia (CDH), eventration, or tracheoesophageal fistula. Some lesions demonstrate pathology of both CPAM and BPS and are characterized as a hybrid lesion. This shared pathology suggests a shared embryologic origin.

Congenital Lobar Empysema (CLE). CLE results from an abnormality of cartilage formation within the bronchial tree. The flexible cartilage allows for air trapping and overdistention of alveoli, simultaneously compressing adjacent lung tissue and further decreasing surface area available for oxygenation and ventilation. These lesions can become so distended that they cause mediastinal shift. The etiology of CLE is unknown, and the incidence is 1 in 20,000–30,000. CLE is usually unilateral and most often affects the left upper lobe. Upper lobe disease is generally more symptomatic than middle or lower lobe disease.

Bronchogenic Cyst (BC). BCs can be located in the lung parenchyma or more commonly in the mediastinum near the carina. They result from the anomalous budding of the tracheobronchial tree and are part of the spectrum of foregut duplication cysts. They are lined with ciliated epithelium and contain mucoid material. These cysts can communicate with the bronchial airway and are at high risk for infection. If they occur in the mediastinum, they can present with dysphagia rather than respiratory distress.

Clinical Manifestations

Presentation of pulmonary malformations depends less on the specific diagnosis and more on the size of the lesion or the rate of its growth. CLE, CPAM, and IPS are the most likely lesions to become symptomatic in the antenatal or neonatal period. BCs are usually asymptomatic, but may cause recurrent pulmonary infection in childhood. EPS is the least likely lesion to be symptomatic because of the lack of communication with the airway, and typically presents as an incidental finding.

Antenatal. The majority of these lesions are identified on screening prenatal U/S as early as 18–20 weeks gestation. According to a recent meta-analysis, 79% of pulmonary malformations are diagnosed by antenatal screening U/S. Typically, these lesions are asymptomatic in utero and can show regression in the third trimester. A large thoracic mass in utero can lead to mediastinal shift, lung hypoplasia, polyhydramnios, and cardiovascular

compromise resulting in hydrops and even fetal demise. One prospective study showed a 30% rate of hydrops in a cohort of 120 fetuses prenatally diagnosed with CPAM. A similar rate of hydrops was seen in a cohort of 39 cases of extralobar sequestration.

Postnatal. Patients can present in the neonatal period, with respiratory distress, tachypnea, wheezing, grunting, and/or cyanosis secondary to a space occupying lesion and/or mediastinal shift. In a meta-analysis, 17% of live births diagnosed antenatally with CPAM became symptomatic, requiring surgery, in the neonatal period. The majority of patients with CLE present in the first 6 months of life.

Childhood. In childhood, symptomatic patients present with chronic cough, recurrent upper respiratory or pulmonary abscess.

Diagnosis

Antenatal. Prenatal U/S and MRI are sensitive, but not specific in differentiating between congenital pulmonary anomalies. Macrocystic CPAMs are composed of single or multiple cysts $\geq$5.0 mm in diameter on prenatal U/S, whereas microcystic lesions are solid, echogenic masses on sonography. Serial prenatal U/S can show regression of CPAM lesions. BC appears as unilocular well-defined echodense, fluid-filled, homogeneous mass on prenatal ultrasonography. Color-flow Doppler may identify a systemic arterial supply to these lesions. If no arterial artery supply is identified, a microcystic CPAM and BPS are difficult to differentiate on U/S. Intralobar and extralobar sequestrations cannot be differentiated on prenatal ultrasound.

Postnatal. If a mass has been identified antenatally, and the neonate is asymptomatic at birth, a CXR should be the initial imaging study. Normal chest radiography (CXR) does not exclude congenital lung pathology. Computed tomography is 100% sensitive and necessary to evaluate the size and nature of the lesion and should be performed in the first 3 months of life for operative planning.

If the child is symptomatic, immediate CXR will rule out pneumothorax or show mediastinal shift. If the neonate is stable after medical management, a CT can be performed to aide surgical resection. If a child presents with recurrent upper respiratory infection and there is concern for underlying congenital lung pathology, a CT should be performed despite a negative CXR.

In CLE, CXR shows a hyperinflated lobe, often with mediastinal shift. This finding can be misinterpreted as a pneumothorax and mistreated with tube thoracostomy. If this occurs, CT scan is more sensitive than CXR to confirm the diagnosis of CLE. Extralobar pulmonary sequestions are echodense and have a systemic arterial blood supply arising from the aorta. This "feeding vessel" can be seen on CT and less often seen on fetal ultrasound. Significant discrepancy exists between diagnosis of cystic lung lesions made by imaging and histopathological diagnosis.

Differential Diagnosis

The differential diagnosis for a fetal thoracic mass can include CPAM, BPS, CLE, BC, or congenital diaphragmatic hernia (CDH). Prenatal MRI can aide with differentiation, but results will not change in utero management. With a delayed diagnosis of CPAM or BPS in the second and third decades, malignant transformation needs to be ruled out.

Treatment

Surgical excision is the mainstay of treatment for all four entities. Timing of surgery depends on presentation and comorbidities of the child.

Symptomatic. When identified in utero with morbid complications, such as hydrops or polyhydraminos, fetal intervention should be considered. Thoracoamniotic shunting, laser ablation, and fetal lobectomy (intrauterine surgery) are available at a few, highly specialized centers.

For patients that present in the neonatal period in respiratory distress, after medical stabilization, lobectomy is indicated. The surgeon should be present at induction of anesthesia to perform an emergent thoracotomy if needed to relieve intrathoracic pressure, which can cause vascular collapse if sustained. This is especially true for CLE.

Complete surgical resection with lobectomy is also recommended in patients that present outside of the neonatal period with chronic cough and/or recurrent pulmonary infection.

Asymptomatic. For infants that are diagnosed antenatally, and remain asymptomatic through the first month of life, thoracoscopic lobectomy of the affected lobe is recommended to prevent infection and possible malignant degeneration. The average time of onset of symptoms is 7–10 months. Elective lobectomy is typically performed between 3 and 6 months of age to reduce postoperative ventilation days, maximize intrathoracic space to utilize laparoscopic equipment, and decrease the likelihood of infection.

Surgical Approach. Lobectomy, rather than segmentectomy of the affected lobe is recommended because recurrence of infection in incompletely resected lesions (segmentectomy) has been reported. Thoracoscopic lobectomy is an attractive alternative to thoracotomy, which may result in fewer ventilator days and shorter hospitalizations. Thoracoscopy, however, may not be tolerated by all patients, especially in an emergent setting. Extralobar BPS and BC can be treated with segmental resection alone; however, intralobar BPS, CLE, and CPAMs require lobectomy to prevent postoperative complication such as prolonged air leak or recurrence of infection, which requires reoperation.

Prognosis

Overall prognosis depends primarily on the size of the lesion, rather than the type. Presentation with hydrops during pregnancy is an indicator of poor outcome. In fetuses with prenatal diagnosis of CPAM, Adzick et al. reported 100% mortality after expectant management of hydropic fetuses (n = 25). All nonhydropic fetuses (n = 76), that were expectantly managed, survived to discharge, with or without (13%) surgical management. Eight of 13 (62%) hydropic fetuses that underwent intrauterine lobectomy, survived to follow-up of 1–7 years.

Complete resection results in cure. Asymptomatic antenatal diagnosis is very favorable. In a meta-analysis, of all antenatally diagnosed CPAM, 4% died in utero and only 1% of live-born infants died in the neonatal period prior to surgery. The same study reported a 7.5% perioperative mortality rate and a 28% morbidity rate after resection in symptomatic neonates. Elective neonatal cases had a lower rate of perioperative complication (9%) and 0% mortality. After the neonatal period, complications were reported in 17% of patients that were symptomatic prior to surgery, with a mortality rate of 3%. The complication rate in elective surgery was 5%, with one reported mortality (0.3%). Residual disease was reported in 15% of patients after segmentectomy, while no recurrence was reported after lobectomy.

Approximately, 30 cases have been reported with malignant degeneration of CPAMs and BCs. Pathology has been identified as bronchoalveolar carcinoma, embryonal rhabdomyosarcoma, and mucinous adenocarcinoma. The age at diagnosis of malignant degeneration has been reported as 20–40 years old; however, embryonal rhabdosarcoma arising in a CPAM has been documented as early as 22 months old. Few pulmonary function tests have been performed and reported in these patients, however, new alveoli and acini are forming until approximately 5 years of age, followed by enlargement of existing alveoli.

Prevention

There is no known prevention. However, because of documented cases of malignant degeneration of these lesions, resection is strongly recommended, even when asymptomatic.

Parapneumonic Effusions and Empyema

Definition/Classification/Etiology

Pneumonia is an infection of the lung parenchyma. If not quickly or effectively treated with antibiotics, a transudative (parapneumonic) effusion can develop. When a parapneumonic effusion becomes consolidated, purulent and fibrinous, it is classified as an empyema. This evolution has been separated into three stages. The initial stage, or exudative stage, is characterized by increased permeability secondary to inflammation resulting in a collection of fluid in the pleural space. When sampled, the fluid is thin, is typically serous, contains neutrophils, has a normal pH and glucose, and is often sterile. The fibrinopurulent stage occurs after translocation of bacteria into the pleural space, increasing the inflammatory reaction, neutrophil activation, and fibrin deposition. Glucose and pH levels decrease and protein and LDH levels increase. Finally, in the organizing stage a pleural peel develops secondary to fibroblast proliferation, and restrictive lung disease develops.

Epidemiology

Complicated parapneumonic effusions are increasing in incidence in the United States and Europe. In the United States, the incidence is approximately 10 per 10,000 cases of pneumonia or 1 in every 150 children that are hospitalized with pneumonia.

Pathogenesis

The pleural inflammatory response activates the coagulation cascade, favoring increased procoagulant activity and depressing fibrinolysis. This new balance favors fibrin deposition. Fibrin strands act as a framework for

fibroblasts to deposit basement membrane proteins, creating loculations and the pleural "peel" that are seen on imaging studies and at surgery.

Pathology

Patient age or immune state typically defines the bacteriology of the infection. The most common organisms in the pediatric population are *Streptococcus pneumonia* and *Staphalococcus aureus*. Group A strep can be seen as a complication of an infectious skin disorder, such as varicella or impetigo. *Haemophilus influenzae* is seen in patients who have not been adequately vaccinated. Methicillin-resistant *Staph aureus* is growing in incidence in the older pediatric and adolescent age groups.

Clinical Manifestations

In general, patients with parapneumonic effusions present with the same clinical manifestations of bacterial pneumonia, such as fever, cough, pleuritic chest pain, and dyspnea. These symptoms may be suppressed in the immunocompromised population. Patients with empyema may have worsening respiratory distress secondary to lung restriction. The course of empyema is different between children and adults. Children commonly develop empyema after community acquired pneumonia, whereas adults more commonly have risk factors, such as diabetes, neurologic impairment, or underlying respiratory disease that put them at higher risk for developing empyema after pneumonia.

Diagnosis

Radiographic evaluation and fluid analysis are the mainstay for diagnosis of parapneumonic effusion. CXR is the first step in assessment, including an upright view and a lateral decubitus to evaluate for mobility of the pleural fluid. Ultrasound is helpful in evaluating loculations. CT scan aids in identification of consolidated lung or fibrinous tissue, as well as necrotic lung parenchyma. Fluid should be sampled for culture, cell count, glucose, pH, and LDH.

Differential Diagnosis

Differential diagnoses of parapneumonic effusions include: pleural effusion, hemothorax, congestive heart failure, pulmonary infarction, pulmonary sequestration, or nephritic syndrome.

Treatment

Treatment of parapneumonic effusions depends on the stage. If imaging and fluid analysis indicates a transudative stage, simple thoracostomy tube insertion for drainage of the fluid and expansion of the lung is recommended. Deep breathing exercises and pain control are also important management strategies to decrease atelectasis and consolidation. The tube can be removed when the lung reexpands and drainage stops. Antibiotic treatment should continue as indicated for pneumonia, usually 10–14 days. If fevers continue, drainage does not decrease, or if the patient remains hypoxic, the thorax should be reimaged to evaluate for loculations, missed collections, or necrotizing pneumonia. Cross-sectional imaging, such as CT scan with intravenous contrast, is often the best test.

If imaging suggests a more complicated stage, treatment may range from tube insertion and fibrinolysis to thoracotomy. Patients with loculated effusions require debridement, which can be achieved with fibrinolysis or mechanically with surgery. After the advent of thoracoscopy, the mainstay of surgical management is now video-assisted thoracoscopic surgery (VATS) rather than formal thoracotomy. Fibrinolysis or VATS has been shown to result in earlier and more complete resolution of empyema than tube drainage alone.

Two randomized controlled trials have been performed, comparing fibrinolysis to VATS for treatment of emypema in children. Both studies found no difference in days of hospitalization after intervention, days of oxygen therapy, days until afebrile, or analgesic requirements between patients that received tube thoracostomy and fibrinolysis (urokinase or tPA) or VATS. Both groups also showed a 16% failure rate. St. Peter et al. did report higher costs in the VATS treatment group.

Fibrinolysis should be continued until drainage is 1 cc/kg/12 h period and symptoms (fever, oxygen requirement) have resolved. Fibrinolytic treatment should not be continued based on radiologic images alone. Patients may still have evidence of disease in the pleural space for up to 6 months after symptoms resolve. Also, Stefanutti et al. found that the efficacy of intrapleural fibrinolysis was not influenced by the duration of symptoms or hospital stay before the initiation of treatment. Therefore, all patients with loculated parapneumonic effusions can undergo a trial of fibrinolytic treatment (without contraindications, like drug

allergy or other coagulopathy) prior to evaluation for surgical intervention.

Prognosis

Tube thoracostomy drainage is an effective therapy in greater than 50% of patients. Pulmonary function testing in children (≥6 years old) 6 weeks after resolution of symptoms (treated with antibiotics alone or closed thoracostomy tube) showed no evidence of restrictive lung disease. However, 50% of those examined had evidence of mild obstructive airway disease.

Prevention

The best prevention is early diagnosis of pneumonia and prompt treatment with antibiotics with surveillance for development of a simple parapneumonic effusion. Early diagnosis and treatment with tube thoracostomy and directed antibiotic therapy is essential for preventing evolution of a parapneumonic effusion into empyema.

421 Head and Neck

Christopher S. Muratore

Overview of Pediatric Head and Neck Masses

Head and neck masses are a common clinical concern in infants, children, and adolescents. The differential diagnosis for a head or neck mass across these age groups is broad and includes congenital, inflammatory, and neoplastic lesions (Table 421.1). An orderly and thorough examination of the head and neck with an appropriate directed workup will facilitate the diagnosis. The most common entities occur repeatedly within the various age groups and can be differentiated with a clear understanding of embryology and anatomy of the region, and an understanding of the natural history of a specific lesion.

Congenital lesions most commonly found in the pediatric population include the thyroglossal duct cyst and the branchial cleft and arch anomalies. Hemangiomas, lymphatic malformations, dermoid cysts, bronchogenic cysts, teratomas, and thymic cysts are other common congenital lesions. The *inflammatory masses* are secondary to local or systemic infections. The most common etiology for cervical adenopathy in children is reactive lymphadenopathy following a viral or bacterial illness. Persistent unilateral adenopathy over several months observation is concerning and can include acquired etiologies such as mycobacterium tuberculosis, the atypical mycobacterium spectrums such as mycobacterium avium intracellulare, and mycobacterium scrofulaceum, granulomatous processes, or cat scratch disease.

The midline lesions most commonly are represented by thyroglossal duct sinus and cyst conditions and dermoid cyst are usually easily distinguished from the more lateral lesions represented by branchial cleft sinus and arch anomalies. Acute bilateral or diffuse cervical adenopathy is often the result of a recent viral infection and is usually a self-limited process. Acute unilateral adenopathy, particularly in infants and young children, may be associated with pyogenic sources such as Staphylococcus aureus or group B Streptococcal infections. Persistent adenopathy raises more concerns but is usually still secondary to an infectious etiology. Enlarged lymph nodes within the posterior triangle or supraclavicular space, nodes that are painless, firm, and not mobile, or a single dominant node that persists for more than 8–10 weeks should all heighten concern for malignancy. *Malignant lesions* such as non-Hodgkin's and Hodgkin's lymphoma, neuroblastoma, salivary, parathyroid, and thyroid gland carcinoma need to be differentiated from benign lesions. In the pediatric population, 80–90% of all head and neck masses represent benign conditions. Hemangioma is one of the most common benign tumors of infancy and childhood and is found in the head and neck region approximately 60% of the time. Cystic lymphatic malformations (cystic hygromas, lymphangiomas) are benign vascular lesions that arise from an embryological disturbance in lymphatic development most commonly found in the head and neck region. They can be detected antenatally on a prenatal ultrasound or may be noted at birth; most present before the age of 2 years.

Finally, the ex utero intrapartum treatment (EXIT) procedure, initially developed for reversal of fetal tracheal occlusion in fetuses with severe congenital diaphragmatic hernia, has evolved and can be employed by a multidisciplinary team to treat peripartum airway obstruction. The indications for the EXIT procedure have expanded to include management of giant fetal neck masses, lung or mediastinal tumors, and congenital high airway obstruction. It is important, therefore, for surgeons to appreciate the relevant embryology, anatomy, and natural history of head and neck lesions and to be familiar with their appropriate evaluation and management.

Evaluation: History and Physical Examination

A detailed history and physical examination is the usual starting point. Historical information including the patient's age, onset and duration of symptoms, as well as any systemic signs of disease such as fever, night sweats, fatigue, or weight loss should be taken into consideration. Although some congenital neck lesions, particularly cysts, may not present until later in childhood after the accumulation of secretions or becoming secondarily infected, many congenital lesions present at birth or are noted shortly thereafter.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_421,

Table 421.1
Differential diagnosis of pediatric head and neck masses

Congenital masses	Inflammatory masses	Neoplastic disease
Thyroglossal duct cyst	Reactive lymphadenopathy	Benign
Brancial cleft cyst/sinus	Bacterial	Lipoma
Vascular anomalies	Viral	Fibroma
Hemangioma	Granulomatous	Neurofibroma
Lymphatic	Mycobacterium tuberculosis	Thyroid nodule
Capillary	Atypical mycobacterium	Malignant
Venous	Toxoplasmosis	Hodgkin' lymphoma
Arterial	Histoplasmosis	Non-Hodgkin's
Mixed	Sarcoid	Rhabdomyosarcoma
Dermoid cyst	Cat scratch disease	Neuroblastoma
Bronchogenic cyst		Thyroid carcinoma
Teratoma		Metastasis

Modified from Dickson PV, Davidoff AM (2006) Malignant neoplasms of the head and neck. Semin Pediatr Surg 15(2):92–98. Reprinted with permission

Features from the history and examination should help to elicit and narrow the etiology. Specific questions to ask include whether the adenopathy is an acute or chronic process; whether the adenopathy was associated with a recent upper respiratory illness or following contact with an individual with a recent illness; whether the neck masses were associated with a systemic infection; if there had been any known animal bites or scratches; and whether there had been any recent changes in the character of the lesion. The physical examination should be directed at a systematic evaluation of each cervical lymph node region. The size, laterality, tenderness, overlying skin changes, and mobility should be noted. Finally, an examination of the chest, abdomen, groin, genitalia, and extremities must not be forgotten. A firm painless mass with fixation to underlying structures or overlying skin is always concerning for malignancy. Although most pediatric cervical adenopathy is of benign etiology, rapidly enlarging, nontender, or long-standing, persistent adenopathy particularly within the supraclavicular space or posterior cervical triangle are concerning for malignant disease.

The experienced clinician will seldom require laboratory evaluation for the classic midline or lateral congenital lesions associated with branchial arch anomalies; however, the workup for persistent adenopathy is more extensive and should include a complete blood count with differential, a chest X-ray, PPD skin test, and serological studies to investigate Epstein-Barr virus, cytomegalovirus, HIV, toxoplasmosis, or to establish a background of Bartonella. Radiographic studies are usually unnecessary for evaluation of these lesions. However, persistent adenopathy suspicious for malignant disease warrants a chest X-ray. A plain chest X-ray might detect pulmonary or mediastinal lesions as a source for cervical or supraclavicular adenopathy. Ultrasonography has advantages, particularly in the pediatric population, because it does not involve ionizing radiation and is readily available. It can easily distinguish solid from cystic masses. It is helpful in evaluating the thyroid and parotid lesion and may be useful in diagnosing confusing congenital lesions. Ultrasound is also helpful in evaluating and characterizing the long-standing solitary lymph node (*Figs. 421.1* and *421.2*).

Congenital Cystic Lesions

Thyroglossal Duct Cyst

Thyroglossal duct cysts are the most common congenital midline cervical anomalies in children. The thyroid gland originates in early gestation from a diverticulum between the anterior and posterior muscle complex of the tongue. This region represents the proximal remnant of the foramen cecum. As the embryo elongates and the thyroid gland descends, it does so in the vicinity of the eventual location of the hyoid bone. As this occurs, the median thyroid anlage elongates with the descending gland forming the thyroglossal duct. The thyroglossal duct generally obliterates by the fifth week of gestation leaving behind a proximal remnant as the foramen cecum. A thyroglossal duct sinus persists when the thyroglossal duct fails to obliterate before the formation of the hyoid bone.

Based on this embryological descent, a thyroglossal duct cyst and sinus tract remnant can occur anywhere from the base of the tongue to the lower midline neck. The most frequent presentation is a midline painless cystic mass in the region of the hyoid bone. Most thyroglossal duct cysts present during the first 5 years of life. Clinically, the uncomplicated cyst typically moves cranially with swallowing and protrusion of the tongue because of its close relationship with the hyoid bone and the foramen cecum. Dermoid cysts, the most likely item in the

differential diagnosis, typically do not move with this maneuver. Infection is a complication seen in thyroglossal cysts because of the close anatomic association with the oral cavity. Many patients will present with a concurrent or recent history of an upper respiratory tract infection. The infected thyroglossal duct cyst usually resembles other abscesses, with intense erythema and fluctuance (*Fig. 421.3*). The most common pathogens are Haemophilus influenza, Staphylococcus aureus, and Staphylococcus epidermidis. It is unusual for a thyroglossal duct cyst to present as a communicating sinus tract to the skin, since the thyroglossal duct does not communicate with the ectoderm during the development. However, up to 25% of these lesions may present as a draining sinus tract in the midline, thought to represent a spontaneous rupture.

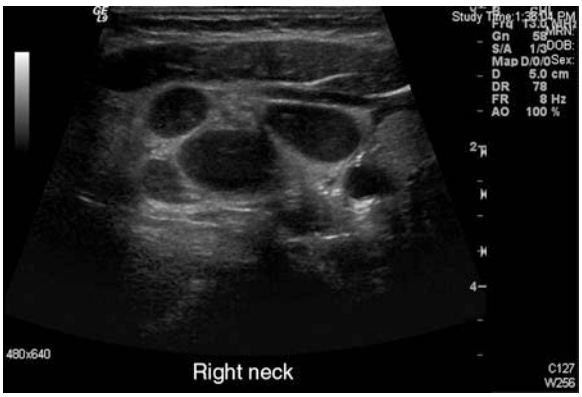

Figure 421.1
Ultrasonography of a large, bulky mass at the base of the neck. Differential diagnosis included lymphoma, cystic lymphatic malformation, or combined vascular malformation. Ultrasound demonstrated cystic structures surrounded by stroma

Thyroglossal duct remnants can contain functional thyroid tissue and may have a solid component since they are lined by ductal epithelium. A patient who presents with symptoms of hypothyroidism should be worked up for the possibility of median ectopic thyroid. In approximately 1% of patients with a thyroglossal duct cyst, the only functional thyroid tissue is located within the cystic mass. These patients are frequently hypothyroid with elevated thyroid stimulating hormone (TSH) levels. The incidence of thyroid carcinoma in a thyroglossal duct cyst remnant is reported to be less than 1%. However, since the majority of thyroglossal duct cysts are removed in childhood, the absolute risk is unknown. With the exception of medullary carcinoma of thyroid, all types of thyroid malignancy have been reported, with the majority being papillary. Approximately 90% of cases of presumed thyroglossal duct carcinoma have presented in adulthood.

The diagnosis of thyroglossal duct cyst is usually straightforward and almost never requires an extensive evaluation. The literature does, however, contain controversial claims regarding the need for preoperative thyroid scanning to identify those patients that have a median

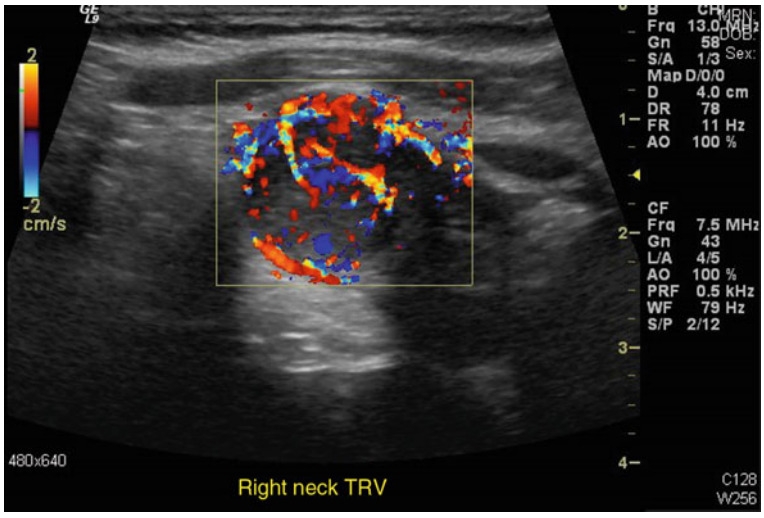

Figure 421.2

ectopic thyroid. Others argue that the cost of routine scanning is excessive given the overall incidence of 1–2%, and exposes many patients to unnecessary radiation. A safe approach is to perform a thorough history looking for signs and symptoms consistent with hypothyroidism. If hypothyroidism is suggested then TSH screening and preoperative ultrasound of the midline neck should provide the necessary information to select patients for preoperative thyroid scanning.

Surgical Management

In the uncomplicated thyroglossal duct cyst, an elective procedure described by Sistrunk is the operation of choice. The patient is positioned supine, with the head of the table slightly elevated and the neck extended, and a transverse incision is used. Careful dissection is performed to identify the distal tract. Dissection around the cyst proceeds cranially toward the hyoid bone, which is facilitated by elevating the cyst out of the wound. Once the hyoid bone is reached, its central portion associated with the tract is resected. En bloc resection of the proximal tract is important to ensure complete removal of the lesion. The anesthesiologist or another surgeon may, if necessary, insert a finger into the mouth and press against the base of the tongue to ensure proximal dissection is complete. The tract is suture ligated at the most proximal end and the block is removed (*Fig. 421.4*).

Occasionally patients will present with an infected thyroglossal duct cyst unresponsive to initial antibiotic therapy. Intense erythema and fluctuance suggest an abscess, and formal incision and drainage may be necessary to control the infection. There is some concern that drainage procedures can "seed" the surrounding tissues, predisposing to recurrence. Occasionally the thyroglossal duct cyst or abscess will spontaneously erupt. A Sistrunk procedure is performed once the infection has cleared (after incision and drainage or spontaneous drainage). A clinically palpable mass usually remains. It is important to excise an ellipse of skin including the area of the drainage in order to prevent recurrence. The infection usually makes the otherwise elegant Sistrunk procedure more challenging secondary to the inflamed surrounding tissues. Although the presence of a preoperative or concurrent infection has historically been associated with increased recurrence rates, a recent review of 100 patients from a major pediatric hospital found no association between preoperative infection and increased recurrence rates.

Branchial Cleft Cyst and Sinus

Branchial cleft anomalies are the second most common congenital head and neck lesion found in children, after thyroglossal duct cysts. These anomalies are composed of a heterogeneous group of congenital malformations that arise from incomplete obliteration of the pharyngeal clefts and pouches during embryogenesis. Most branchial cleft anomalies involve the first and second cleft and pouch complexes. Normally the first branchial arch forms the mandible and a portion of the maxillary process of the upper jaw. This arch is also involved in development of portions of the inner ear, whereas the cleft and pouch

become part of the external auditory canal and mastoid ear cells. The second arch contributes to the hyoid bone and the adjacent area of the neck. This pouch becomes the palatine tonsil and supratonsillar fossa. Understanding this developmental process clarifies the clinical presentation of branchial anomalies. First branchial cleft and pouch anomalies enter the external auditory canal and occasionally the middle ear, while second arch anomalies enter the supratonsillar fossa. Third and fourth sinuses and fistula may appear similarly to the second cleft sinus externally. However, as a rule it is the internal opening of the sinus that is crucial in defining the cleft or pouch origin and the exceedingly rare third and fourth derivatives enter the pharynx through the pyriform sinus.

Presentation and Diagnosis

First cleft remnants typically present as a cyst sinus or fistula somewhere between the external auditory canal and the submandibular area. These lesions have an intimate relationship with the parotid gland and the branches of the facial nerve. Second branchial cleft anomalies account for the vast majority of all branchial cleft disorders and usually present as a fistula or cyst found in the lower anterior lateral region of the neck. Fistulas are usually diagnosed in infancy in childhood and typically have intermittent and chronic drainage from the opening along the anterior border of the sternocleidomastoid muscle. Cysts are more often diagnosed in adults as a nontender mass in the neck. The second branchial arch anomalies can be intimately associated with the glossopharyngeal and hypoglossal nerves, and enter the pharynx at the level of tonsillar fossa. Third and fourth arch anomalies are uncommon. Branchial cleft cysts are lined by squamous epithelium but can contain respiratory epithelium as well.

Surgical Management

The definitive treatment for all branchial cleft remnants is complete surgical excision. If incompletely resected, there is a high incidence of recurrence. Second branchial arch remnants are usually approached through a cosmetic transverse surgical incision. This cyst is meticulously dissected from the superficial tissue at fascia and dissected proximally keeping the fistulous tract intact. It is possible to cannulate the tract with a small probe to aide in its dissection. Some surgeons prefer to inject the tract with a small amount of methylene blue. It is occasionally necessary to use a step-ladder incision to gain better visualization of the upper portion of the tract as the dissection moves superiorly. Once the proximal opening near the pharynx has been identified, the tract is ligated and divided.

Preauricular Cysts

Preauricular cysts do not represent true cysts or sinuses of the neck but need to be distinguished from first branchial cleft cysts. Unlike branchial cleft cysts, preauricular cysts are common, often bilateral, tend to be inherited and are rarely complicated by infection. Furthermore, they neither are involved with the facial nerve nor do they enter the external auditory canal. They are thought to arise from abnormal formation of the external ear from the developing hillocks and are successfully excised by removing all the ductal epithelium through an inverted "L-shaped" incision.

Inflammatory and Infectious Adenopathy

Clinically palpable cervical lymphadenopathy occurs with a reported prevalence of 28–55% in otherwise normal infants and children. Acute bilateral cervical lymphadenopathy is most commonly caused by viral respiratory tract infections or streptococcal pharyngitis, whereas unilateral cervical lymphadenitis is usually caused by streptococcal or staphylococcal infection in 40–80% of cases. Acute suppurative lymphadenitis is typically caused by bacterial infections from penicillin-resistant Staphylococcal, group A Streptococcal infections, or both. Infants commonly have Staphylococcal lymphadenitis; anaerobic bacteria, group B streptococcal, and haemophilus influenza type B are less frequent. Local signs of inflammation, suppuration, erythema, fever, and malaise should preclude a search for primary infection around the oropharynx, head, and neck. Initial empiric treatment includes 5–10 days of an oral beta lactamase-resistant antibiotic directed at the most likely organism. Failure to note improvement indicates the need for further diagnostic testing, including the use of serology, ultrasonography, fine needle aspiration with or without sedation, with a gram stain evaluation of the collected material, and aerobic and anaerobic cultures. Bacterial infections, usually Staphylococcal aureus or Streptococcal pyogenes cause 40–80% of acute unilateral cervical lymphadenopathy in the 1–4 years old age group. Group B strep may cause unilateral facial or submandibular swelling, erythema, tenderness, and fever associated with poor feeding and irritability in the infant. Anaerobic bacteria can occur in the older child with dental caries or periodontal disease. Community acquired methicillin-resistant staphylococcus

aureus (MRSA) has become more prevalent as the etiology for pediatric suppurative adenitis. If MRSA is identified then clindamycin or Bactrim should be started. Bactrim is effective for simple skin and soft tissue infections but is generally ineffective against group A and B Streptococcal infections. Clindamycin is highly effective treatment for pediatric MRSA, covers group A and B Streptococci and clindamycin-resistant strains of MRSA remain uncommon. Since the spectrum of antibiotic resistance and the most common types of MRSA infections vary from one location to another, it is imperative to have a working knowledge of the local prevalence of clindamycin resistance to combat MRSA effectively.

Many cases of bilateral cervical adenitis are caused by upper respiratory tract infections of viral etiology including rhinovirus, parainfluenza virus, respiratory syncytial virus, cytomegalovirus and Epstein-Barr virus. Less frequent etiologies include mumps, measles, rubella, herpes simplex, and human herpes simplex 6 (roseola) and coxsackie viruses. Virally induced adenopathy rarely suppurates and generally resolves spontaneously.

Surgeons generally do not see children at the time of initial presentation for isolated cervical adenopathy. Most physicians would administer therapy for 10 days, and cover for 5 days beyond the resolution of acute signs and symptoms. In most cases, symptomatic improvement should be noted after 2–3 days of therapy, although complete resolution may require several weeks. Failure to improve usually brings a patient to a pediatric surgeon. The question of surgical intervention becomes more controversial with respect to persistent lymphadenopathy of greater than 2 weeks duration on antibiotic therapy, or unilateral adenopathy in the supraclavicular or posterior triangle. Fluctuance develops in 25% of patients with acute bacterial adenitis, and may be managed by additional antibiotics and or multiple needle aspirations. However, adequate drainage may not be obtained, particularly in the young and uncooperative child. These patients are best managed with a formal operative incision and drainage under general anesthesia. This allows for proper drainage of all associated loculations and cavities not amenable to single needle aspiration attempts. The abscess cavity is usually packed with gauze to facilitate continued drainage and to prevent early premature closure. The gauze pack is removed over a period of several days, either as an inpatient completing an intravenous antibiotic course or as an outpatient. Surgical intervention is indicated for atypical mycobacterial adenitis, suppurative inflammatory or fistulous lymphadenopathy.

Atypical mycobacterial infections usually present in a subacute pattern, with relatively nontender, indurated, and suppurative nodes. PPD positivity is variable, and pulmonary involvement is absent. Although complete resection is the definitive therapy, macrolide antibiotics (such as clarithromycin) may have some utility. In one recent series, 30/45 (67%) of children treated with cervicofacial atypical mycobacterial infections resolved with antibiotic therapy. A trial of medical therapy may be worthwhile in these children.

Fungal Disease

Histoplasma capsulatum, Blastomyces dermatitidis, and Coccidioides immitis are soil saprophytes endemic to certain geographic regions of the United States that cause fungal infections in humans. Most patients present with pulmonary or mediastinal involvement, with cervical lymphadenopathy secondary to the primary infection. Fungal disease must therefore be considered in the diagnosis in the child or adolescent with a mediastinal mass and cervical adenopathy, particularly in an endemic area or in an immunocompromised patient. Serological or skin testing is usually diagnostic and most infections resolve spontaneously.

Neoplastic Adenopathy

By far the most common head and neck malignancy in children is lymphoma. However, cervical rhabdomyosarcoma, neuroblastoma, and teratoma account for many pediatric neck lesions. Half of malignant neoplasms in the head and neck region are made up of lymphomas: 60% are non-Hodgkin's lymphoma, and Hodgkin's lymphoma makes up the remaining 40%. Commonly, the origin of lymphoma is from the lymph node. However, lymphomas of the head and neck may also arise from extra nodal sites and often are associated with extensive lesions within the mediastinum. Neck lesions associated with mediastinal findings might represent nonmalignant disease such as fungal or systemic inflammatory conditions and must be distinguished from neoplastic lesions (*Figs. 421.5* and *421.6*).

Hodgkin's Disease

Hodgkin's disease has a bimodal age distribution, with adolescents accounting for 15% of cases. Hodgkin's disease is rare in children under 10 years of age, and is responsible for approximately 5% of all pediatric malignancies. The etiology is likely multifactorial, with a known

Figure 421.5
MRI evaluation of extensive Hodgkin's lymphoma presenting as a complex neck mass. Note the nodular appearance and surrounding fibrosis characteristic of nodular sclerosing Hodgkin's disease involving the mediastinum surrounding the airway and great vessels

Figure 421.6
MRI evaluation of extensive Hodgkin's lymphoma presenting as a complex neck mass. Note the nodular appearance and surrounding fibrosis characteristic of nodular sclerosing Hodgkin's disease involving the mediastinum surrounding the airway and great vessels

association to Epstein-Barr viral (EBV) exposure. The precise role of EBV in the pathogenesis and biology in Hodgkin's lymphoma is not entirely clear. However, clinical studies indicate EBV infection precedes expansion of the tumor cell population. Hodgkin's lymphoma is characterized by a small number of clonal tumor cells surrounded by a pleomorphic inflammatory cell population that constitutes the bulk of the tumor tissue. Only a small percentage of the cells (usually less than 10%) are represented by the malignant monoclonal expansion. It is therefore imperative that Hodgkin's lymphoma be differentiated from the subtypes of non-Hodgkin's lymphoma that present with similar morphologic characteristics, and from other benign reactive lymphoid hyperplasias. The WHO classifications recognize two major classes of Hodgkin's lymphoma: classic Hodgkin's lymphoma has four subtypes: nodular sclerosing, mixed cellularity, lymphocyte rich, and lymphocyte depleted. Nodular lymphocytic predominate Hodgkin's lymphoma (NLPHL) contains only rare Reed–Sternberg cells (in contrast to the classic Hodgkin's lymphoma). "Popcorn cells" are seen histologically. NLPHL is seen in 10–15% of all Hodgkin's lymphoma patients, is more common among males under 10 years of age, presenting often as localized disease in an otherwise asymptomatic patient.

Clinical Management

Patients usually present with painless persistent supraclavicular or cervical lymphadenopathy. The affected lymph nodes are firmer than inflammatory lymph nodes and are usually characterized as firm, rubbery, and nontender. Importantly, more than two thirds of patients with cervical Hodgkin's lymphoma will have mediastinal involvement at the time of presentation. When a mediastinal mass is confirmed by plain radiographs it is advisable to evaluate the mediastinum more completely with a CT scan. In this setting, it is best to start with the assumption that airway compression exists in planning the approach to cervical Hodgkin's lymphoma.

All patients with Hodgkin's disease require a biopsy of the involved lymph node to establish the diagnosis and confirm and histological subtype. Needle aspirations and frozen sections are inadequate: permanent hematoxylin/eosin sections must always be obtained and tissue procured for more detailed studies including immunohistochemistry and cytogenetics. Excisional lymph node biopsy or incisional biopsy of an enlarged or matted group of lymph nodes is essential to make an accurate diagnosis. The contemporary therapy uses a risk-adapted approach that considers disease-related factors such as the

presence of constitutional symptoms, stage, number of involved nodal regions, and the presence of tumor bulk.

Non-Hodgkin's Lymphoma

Non-Hodgkin's lymphomas in children and adolescents are a diverse group of neoplasms with 10% of these tumors arising in the head and neck region. The etiology of non-Hodgkin's lymphoma (NHL) is unknown. There is a marked male predominance in all age groups, particularly in children younger than 15 years of age. Compared to Hodgkin's disease (which is mostly of nodal origin), NHL often arises as a mass in extra nodal tissues. NHLs are classically divided into Burkett's and non-Burkett's lymphomas, lymphoblastic lymphomas, diffuse large B cell lymphomas, and anaplastic large cell lymphomas. The pathogenesis of NHL appears to relate to a malignant transformation of a single B or T-cell of origin along its path of terminal differentiation.

Clinical Management

A contrast enhanced CT scan or MRI of the head and neck is helpful to define the tumor in relation to other anatomic structures. Complete metastatic scanning is an important part of the staging process, because NHLs are often diffuse at diagnosis and the treatment involves multi-agent chemotherapy based on stage. It is important to remember that childhood lymphoma is a systemic disease: The operative procedure should not delay institution of chemotherapy. Initial surgical management should include an incisional biopsy, followed by intense multi-agent chemotherapy once the diagnosis is confirmed, except in the cases of small and easily resectable isolated lesions. Cervical primary tumors should undergo initial diagnostic biopsies with procurement of enough tissue to determine the histological subtype.

Mediastinal Masses Associated with Neck Masses

Because non-Hodgkin's and Hodgkin's lymphoma are often associated with lesions in the mediastinum, it is imperative for the pediatric surgeon to determine from the history and physical examination whether the possibility of airway compromise exists, particularly when contemplating a biopsy and the potential need for general anesthesia. Respiratory collapse under general anesthesia is a recognized complication associated with anterior mediastinal masses. Identification of patients at risk has been a major challenge because the presence of specific respiratory symptoms has not been shown to correlate with the severity of airway compression. Preoperative measures for identifying patients at risk for respiratory collapse upon induction of general anesthesia have centered on measurement of the tracheal cross-sectional area by CT scans, in combination with pulmonary function tests. Shamberger et al.'s prospective study of the risk assessment in 31 children with mediastinal masses, using the combination of cross-sectional area of the trachea and peak expiratory flow rate, demonstrated that all patients with values greater than 50% for both predicted peak expiratory flow rate and tracheal area underwent administration of general anesthesia without respiratory complications. Conversely, all children with peak expiratory flow rate and tracheal areas that were less than 50% of predicted received local anesthetic for their biopsy without sequelae.

All patients with cervical adenopathy and a significant mediastinal mass discovered by plain films should therefore be evaluated by a CT scan of the chest to determine the cross-sectional area of the trachea, the burden of mediastinal disease, and also the possibility of pleural effusion. The peak expiratory flow rate has been determined to be the best predictor for evaluating the magnitude of an extra thoracic obstruction.

Cervical Neuroblastoma

Cervical neuroblastoma may occur as a primary tumor but is more commonly a site of metastatic disease from and abdominal or thoracic primary tumor. Primary cervical disease may occur as a mass in the lateral neck or retropharyngeal space. Metastatic disease may cause proptosis, periorbital swelling, ecchymoses, acute cerebellar ataxia characterized by opsoclonus-myoclonus and chaotic nystagmus. Primary cervical neuroblastoma has a favorable outcome. Localized lesions or low stage disease has an excellent prognosis with complete surgical resection. Radiation therapy and or chemotherapy and secondary surgeries are strategies to eradicate residual disease.

Cervical Teratomas

Teratomas are tumors with elements derived from all three germ-cell lineages in various degrees of differentiation. Teratomas arise in a variety of locations throughout the body. Most are sacrococcygeal, with cervical teratomas

Figure 421.7
Antenatal diagnosis of a threatened airway by a cervical teratoma mandated the EXIT procedure. Neonatal tracheostomy was performed on placental support after bronchoscopy failed to secure the airway

representing less than 10%. Most cervical teratomas in infants and children are benign lesions. The diagnosis is usually obvious at birth but due to the widespread use of prenatal ultrasound, there has been an increase in the diagnosis of fetal neck masses, particularly airway threatening lesions. The vast majority of cases of fetal airway obstruction are due to cervical teratomas or lymphatic malformations. Fetal MRI provides better detail about the size and position of the mass and its anatomic relationship to the airway. A compromised airway secondary to cervical teratoma is an indication for the EXIT (ex utero intrapartum treatment) procedure (*Fig. 421.7*).

Vascular Anomalies

Introduction

Vascular anomalies are best classified as vascular tumors or vascular malformations. The biological classification based on cellular kinetics and clinical behavior distinguishes vascular tumors as lesions that arise by endothelial hyperplasia. In contrast, vascular malformations are congenital lesions derived from capillaries, veins, lymphatic vessels, arteries, or a combination of these. They are lesions that arise by dysmorphogenesis but exhibit normal endothelial turnover.

Vascular Tumors of the Head and Neck: Hemangioma

Hemangioma is one of the most common tumors of infancy and childhood and is found in the head and neck region approximately 60% of the time. Most cutaneous hemangiomas appear approximately 2–4 weeks after birth. Hemangiomas of infancy follow a predetermined course of proliferation followed by involution. The proliferative phase is characterized by rapid growth in the first 6–8 months of infancy. There is a variable period of quiescence followed by the involution phase. Maximum involution occurs in approximately 50% of children by age 5 years, and 90% of children by age 9 years. Based on the anatomic depth, hemangiomas are characterized as superficial, deep, or combined. Superficial lesions tend to be soft, red, raised, and occasionally telangiectatic. Deep lesions may show a spectrum of appearances and consistency ranging from soft and subtle to raised and more firm with a bluish color. Combined lesions appear as red dermal tumors with epidermal and dermal components along with subcutaneous masses.

A variation of hemangioma is the congenital hemangioma; unlike the hemangiomas of infancy, these lesions are fully developed at birth and do not undergo additional postnatal proliferative growth. These congenital hemangiomas fall into two distinct subgroups: rapidly involuting congenital hemangiomas (RICHs) and non-involuting congenital hemangiomas (NICHs). Both are high flow lesions that can be misdiagnosed as arterial-venous malformations. The RICHs rapidly regress over the first year of life, while NICH does not.

Sixty-five percent of patients with hemangiomas have cervicofacial involvement and hemangiomas account for 60% of all pediatric salivary gland neoplasms. Of the salivary gland hemangiomas, 80% arise in the parotid glands (*Fig. 421.8*), 18% arise in the submandibular glands, and 2% arise in the minor salivary glands. Lesions that cover a beard distribution including the chin, jaw line, and preauricular areas may have associated airway involvement. Infants with hemangiomas in the beard distribution area should be inspected for glottic and subglottic hemangiomas, the two most common locations in the airway. Treatment should be initiated if airway involvement is confirmed. Localized lesions are managed

Figure 421.8
Infantile parotid hemangioma. Photographs depict bulky parotid glandular involvement, superficial cutaneous stigmata, and encroachment on external auditory meatus. Treatment options included ±prednisone and hearing exams

with laser therapy, intralesional steroids, or surgical resection. These lesions can proliferate for up to 12–16 months and require systemic treatment if the airway is compromised; tracheostomy should be reserved for patients who fail medical therapy.

Treatment

Since many hemangiomas spontaneously involute, with little or no functional disability or cosmetic defect, reassurance and observation is usually all that is required. It is important to periodically see these patients so the lesions can be monitored for signs of ulceration, growth, and complications that may indicate additional therapy. The decision to intervene with a cervical facial hemangioma is based on the size and location of the lesion, presence of complications such as ulceration or bleeding, age of the patient, and the phase of growth at the time of the evaluation. Larger lesions that interfere with the function of vital structures (such as the eye or eyelid, mouth, or nares), are likely to require some form of treatment. Additional therapies include corticosteroids (either systemically or via intralesional injection), propranolol, laser therapy, and surgical excision. Intralesional cortical steroid injection should be considered for small localized cutaneous hemangiomas located on the nasal tip, cheek, or eyelid. Triamcinolone (25 mg per ml) is injected slowly at low pressure with a 3 ml syringe and a 25-gauge needle. A dosage of 3–5 mg/kg per injection is administered every 6–8 weeks for three to five injections. Oral corticosteroids historically have been the first-line treatment for problematic, endangering, or life-threatening hemangiomas. Prednisone or prednisolone is administered at 2–4 mg/kg/day for 2 weeks. The use of systemic corticosteroids accelerates the involutional phase. Propranolol, a nonselective beta-blocker, is emerging as a first-line therapy for complicated lesions. Clinical results are superior to agents previously used and propranolol appears to have an excellent risk-to-benefit ratio. Various clinical protocols exist however; it is generally dosed at 2–3 mg/kg/day, divided three times per day. Some incorporate cardiac clearance, ECG, echocardiography or Holter monitoring, however, most frequently, vital signs and glucose measurements are used especially with initiation of therapy. The mechanism of action of propranolol for hemangioma remains unclear. Hypotheses include decreased expression of angiogenic factors such as basic fibroblastic

growth factor (bFGF) and vascular endothelial growth factor (VEGF). Interferon alpha 2A or 2B should be considered as a second-line drug for endangering or life-threatening hemangiomas. Laser treatment for cervicofacial hemangioma remains controversial. Surgical excision is usually reserved for cervicofacial hemangiomas that present a threat to vital structures associated with complications such as ulceration, hemorrhage, or infection unresponsive to pharmacological therapy. Surgical excision may be indicated for the residual scar after complete involution, or when the emotional burden to the child or family is significant and potential for cosmetic deformity is quite low. The timing of surgery remains controversial, particularly in regard to the growth phase of the lesion and the age of the patient. Although lenticular excision has traditionally been commonplace, a useful approach with circular hemangioma is the technique of circular excision followed by a purse string closure. This technique has been widely used with excellent results.

Vascular Malformations

The classifications of these anomalies is based on the clinical and histological appearance of the abnormal channels as resembling either capillaries, lymphatics, veins, arteries, or combinations thereof. Cystic lymphatic malformations (formerly referred to as cystic hygromas, lymphangiomas) are benign vascular lesions that arise from an embryological disturbance in lymphatic development. They are most commonly found in the head and neck region. They can be detected antenatally on a prenatal ultrasound or may be noted at birth; most present before the age of 2 years. Lymphatic malformations can be characterized as microcystic, macrocytic, or combined. The prenatal diagnosis of anterior or posterior cervical lymphatic malformations may have significant clinical implications with potential neonatal airway obstruction. Prenatal consultation is usually obtained and observation over the remainder of pregnancy occurs with follow-up level II ultrasounds and fetal MRI scans to judge the size and development of the lymphatic malformation and potential for airway obstruction. The EXIT procedure is a technique that occasionally needs to be employed by a multidisciplinary team in order to deliver the child and obtain control of the airway in a timely fashion (Fig. 421.9).

Postnatally, most cervicofacial lymphatic malformations are easily diagnosed by physical examination. All patients should have a chest X-ray to identify cervical extension into the mediastinum, which is common. Ultrasound is helpful to determine the macrocystic

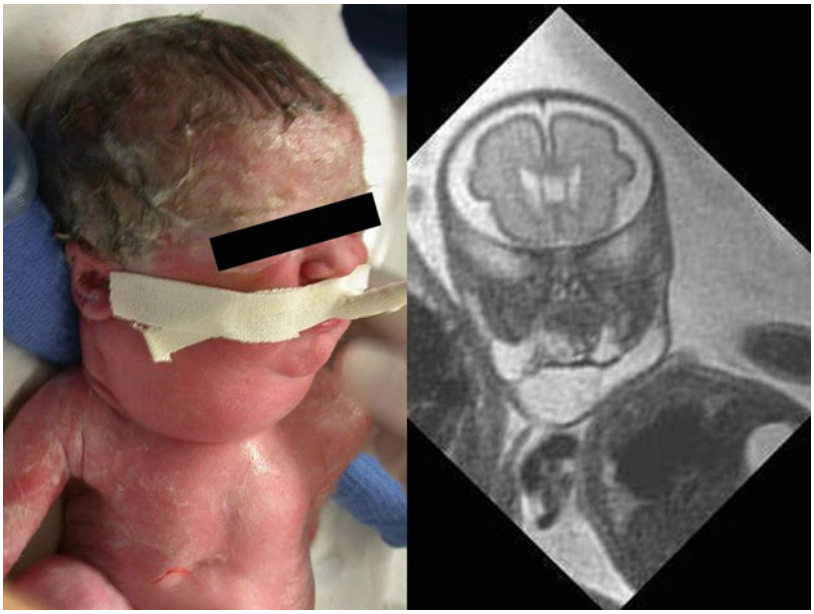

Figure 421.9
Cervical macrocystic lymphatic malformation. Airway was secured with bronchoscopy and intubation via EXIT procedure as the fetal MRI demonstrated cervical macrocysts and potential airway catastrophe

and microcystic features. However, it is less valuable in showing deep extension into the structures of the neck and mediastinum. CT and or MRI are superior modes to demonstrate the anatomical relationships.

Treatment depends on the clinical presentation, size, and complications of the lymphatic malformation. Small lesions may be amenable to complete surgical excision with excellent results, whereas other macrocytic lesions might be better served with intralesional sclerotherapy. The microcystic or combined macro- and microcystic lymphatic malformations, particularly ones that traverse different tissue planes of both the neck and mediastinum require a careful and deliberate approach, usually in a staged fashion. Cervical cystic lymphatic malformations may become infected. General enlargement or swelling of the lymphatic malformation may be associated with cellulitis, and can occur following an upper respiratory tract infection. Asymptomatic patients may develop respiratory distress secondary to the concurrent infection. Expectant management of the patient's airway is prudent in these cases, with administration of intravenous antibiotics. Another cause of rapid enlargement is hemorrhage into cyst. Other complications include lymphatic leakage, and chylothorax. Since surgical excision is a large undertaking for complex and combined micro- and macrocytic lesions of the head and neck, sclerotherapy has frequently become an alternative initial approach, particularly for patients with macrocystic disease. A number of sclerosing agents have been used (Bleomycin, OK-432, fibrin glue, and others). However, ethanol is most commonly utilized in this country because of its efficacy and availability. The lymph is aspirated under ultrasound guidance and ethanol is injected into the cyst. The procedure is usually done under general anesthesia. Fever, erythema, tenderness, and leakage are not uncommonly noted. As mentioned previously, swelling in the malformation is a dangerous side effect following sclerotherapy, potentially causing airway compromise when the lesion involves the cervicofacial and mediastinal locations. Good results (partial or complete regression) are obtained slightly more than 50% of patients in the literature, dependent on the nature of the lesion, patient selection, and other variables.

Summary

Head and neck lesions are some of the most common entities encountered in the pediatric population and can be distinguished as congenital, inflammatory, or neoplastic. The majority of these lesions are benign conditions that are readily diagnosed and have a predictable natural history. The role of the pediatric surgeon is to facilitate the diagnosis and provide definitive care for these lesions.

422 Vascular and Lymphatic malformations

Arlet G. Kurkchubasche

Hemangiomas are the most common soft tissue lesion encountered in infancy. The pediatric practitioner must recognize and distinguish them from other soft tissue lesions and lymphatic or vascular malformations, in order to correctly predict the natural course of these lesions, which are often of great concern to parents. The ability to provide up-to-date and accurate information on diagnosis and potential treatment is critical. Much of the nomenclature of the past has contributed to the ongoing confusion in diagnosis and consequent poor correlation with predictions for growth and resolution. This fundamentally changed with the classification system proposed by Drs. Mullikan and Glowacki in 1982, which was based on pathologic characteristics, rather than macroscopic descriptive features. With revisions, this was ultimately the basis for the staging system adopted by the International Society for the Study of Vascular anomalies in the 1990s. This system is based on the observation that there are two classes of vascular anomalies – (1) those that exhibit increased endothelial activity which correspond to periods of proliferation and (2) those lesions that exhibit normal endothelial activity. The former group corresponds to the behavior expected of a neoplasm, and thus these lesions correctly carry the terminal "oma" (as in hemangioma). The second set of lesions, the vascular malformations, is best described as a constellation of lymphatic and vascular anomalies, which are the consequence of embryonic errors in vasculogenesis. They have no proliferative features, but as with other congenital anomalies, may expand and change with time. *Table 422.1* depicts the major lesions in each of these categories.

Vascular lesions are differentiated by a number of features, including the timing of their appearance (at birth, in first few months of life vs adolescence), physical characteristics (color, texture, size location, involvement of subcutaneous or deeper tissues, presence of pulse, thrill or bruit), and the association with other disorders. When clinical findings are insufficient, adjunctive studies, which can include handheld Doppler flow examinations, ultrasound with flow assessment, MRI, and angiography will generally establish the diagnosis. Although biopsy is rarely necessary, pathologic analysis will describe the endothelial characteristics and further analysis can evaluate gene and protein expressions, which often is characteristic to specific lesions and syndromes.

Unfortunately, while some consistency has been developed in establishing the clinical diagnosis, based on the development of multidisciplinary clinics in which dermatologists, surgeons (plastic and pediatric), and interventional radiologists simultaneously see the patient and come to a consensus diagnosis, pathologic terminology has not adjusted, leading to potential confusion unless the microscopic findings are clearly described. Since treatments can range from simple observation to interventions both in radiology and surgery, a clear understanding of the nature of the lesion needs to be appreciated before making treatment recommendations.

General Characteristics of Hemangioma Lesions

Infantile Hemangioma

This common lesion is often mistaken for other complex vascular malformations. It is estimated that 4–5% of Caucasian children are diagnosed with infantile hemangioma (IH) and that it is more frequent in premature (<1,200 g) infants and particularly in females (up to 5×). Typically, a single site is involved (80%) and 60% involve the head and neck (H and N). The trunk and extremities are involved in 25% and 15% respectively. They are typically small lesions that become protuberant from the surrounding skin, although much larger lesions involving a dermatomal region, referred to as segmental hemangiomas, can also be encountered. The initial appearance of these lesions depends on how superficial their origin is, with those involving the superficial tissues often being bright red, while deeper lesions having a bluish hue through the overlying skin. While most IH become clinically apparent after the second week of life, this can be further delayed when the lesion arises from deeper tissues.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_422,

Table 422.1
Categories of vascular lesions based on endothelial activity

Hemangiomas	Vascular malformations
Increased endothelial activity	Normal endothelial turnover
Juvenile/infantile hemangioma (IH)	*High flow lesions*
	Arteriovenous malformation (AVM)
Rapidly involuting congenital hemangioma (RICH)	*Low flow lesions*
	Venous Malformation (VM)
Non-involuting congenital hemangioma (NICH)	Lymphatic malformation (LM) (aka cystic hygroma, lymphedema)
Kaposiform hemangioendothelioma (KHE)/tufted angioma	Capillary malformation (CM) (aka portwine stain, stork bite)
Capillary hemangioma (pyogenic granuloma)	Combined lymphatic – venous malformation (CLVM)

The hallmark of the IH is that it grows faster than the child for a period of time (typically the first 9 month) and reaches 80% of size by 3–4 months of age, then plateaus and flattens and starts to fade after age 12 months, ultimately resolving by 5 years of age. With involution, the color fades and the mass effect recedes, often leaving some lax skin and fibro-fatty tissue at the site of the original lesion.

Evaluation with ultrasound demonstrates a homogenous lesion, which is generally well circumscribed and has high flow characteristics on Doppler interrogation, indicating a significant arterial inflow. These features are also evident on magnetic resonance imaging, which shows a generally uniform, well-circumscribed lesion with high signal intensity on T2. The pathologic features depend on the phase of the hemangioma, but proliferation of endothelial cells is the hallmark finding. The cellular regulation of these proliferative lesions is associated with Glut-1, which is an erythrocyte type glucose transporter protein. Testing for glut-1 is commercially available to pathology laboratories and allows for definitive diagnosis of IH. While biopsy is rarely necessary, there are instances when concern for soft tissue tumor, such as infantile fibrosarcoma, leads to pathologic evaluation.

Congenital Hemangioma (CH)

This lesion is present at birth, has a ruddy-red violaceous coarse surface with central pallor and pale halo surrounding it base, and generally measures up to 5 cm in diameter. In contrast to the infantile lesion, it does not show postnatal growth and it is more likely to occur on the extremities. The gender incidence is equal. There are two types of CH that are distinguished by their behavior: the rapidly involuting and the non-involuting congenital hemangioma (RICH and NICH). RICH commences involution after birth and 50% will have completed regression by 7 months of age, while the remainder will resolve within 14 months. These are highly vascular lesions, and with increased size and flow, they can be associated with heart failure. In the process of involution, there can be superficial ulceration and necrosis, which places the infant at risk for significant hemorrhage. NICH does not involute and rarely ulcerates. In contrast to the infantile form, neither RICH nor NICH stains with glut-1, helping discriminate them from IH. *Table 422.2* illustrates some of the radiographic features associated with this lesion.

Kaposiform Hemangioendothelioma (KHE)

In contrast to the first two forms of hemangioma, this lesion is considered a vascular neoplasm that is locally aggressive, but does not metastasize. Fifty percent of KHE are present at birth. There is an equal gender distribution, and these solitary lesions can occur at any site (cutaneous and visceral) and will often achieve sizes of >5 cm. The clinical feature, which often sets this lesion apart, is the association with pain. While there may be some regression starting at age 2 years, this is often incomplete. Importantly, this lesion is associated with the *Kasabach–Merritt phenomenon* in 50% of patients. This is a diffuse consumptive coagulopathy associated with thrombocytopenia, which is associated with enlargement of the underlying KHE or tufted angioma, a related lesion. Pathology reveals sheets or nodules of endothelial cells lining capillaries. Treatment response to vincristine has been reported, but unlike IH, these do not respond to steroids (see "Treatment Strategies for Vascular Anomalies"). Acceleration of growth has been noted with heparin.

Table 422.2
Radiographic features of hemangiomas and vascular malformations

Lesion	General/clinical findings	U/S characteristics	MRI/MRA characteristics
Infantile hemangioma	Well-circumscribed mass	Very homogenous parenchymal component, lobulated when proliferating. Variable echogenicity	(+) parenchymal component. Iso-intense to muscle on T1 weighted images (T1)/ hyper-intense on T2 weighted images (T2)
		High flow lesion, generous vascularity with low resistance arterial waveforms	High flow vessels manifest as flow voids on T2
			Contrast enhances intensely and diffusely in proliferative stages, becomes less homogenous with involution
RICH/NICH	Difficult to separate from IH on basis of radiology	Greater number of discernable vessels, intravascular thrombi, calcifications, aneurysms	Indistinguishable from IH on MRI
			MRI and angiography may help distinguish these from infantile fibrosarcoma
KHE	Painful cutaneous lesions	High flow vascular lesion with soft tissue edema	Ill-defined soft tissue mass, contrast intense, but heterogeneous. Prominent fat stranding. Flow voids correspond to high flow vessels
			Usually infiltrative, crosses tissue planes, and may exhibit osseous destruction
Lymphatic	Macrocystic	Uni- or multilocular cysts (>1 cm) with thin septations, which may have vascular channels	Cysts hypo-intense on T1, hyper-intense on T2
		No color flow within cysts	Fluid-fluid levels in cysts, no flow voids, no phleboliths
			Contrast enhancement only of septae
	Microcystic	Ill-defined hyper-echoic mass which may appear to be solid	Solid, minimal enhancement with contrast, difficult to distinguish from soft tissue mass.
Venous malformation	Cavitary type	Spongy mass w/venous channels containing stagnant blood which is evacuated with compression	Multi-locular, lobulated septated masses that infiltrate into adjacent structures especially muscle. Anomalous venous drainage system. Phleboliths correspond to signal voids
	Ectasia/dysplastic	Multiple irregular varicose veins. Color flow seen in both cysts and septae	Delayed post contrast images with central enhancement, phleboliths
AVM	Vascular lesion without parenchymal component	Poorly defined hypervascular lesion w/o soft tissue mass	No soft tissue mass but edema and abnormal enhancement in surrounding tissues, overlying skin thickening, underlying osteolytic changes
		Tortuous feeding arteries with increased diastolic flow. Draining veins large with pulsatile high velocity flow	Contrast fills feeding branches with early enhancement of draining veins. Feeding and draining vessels visible connected by dilated central channels = AV shunts

Capillary Hemangioma (Pyogenic Granuloma)

The capillary hemangioma is a lesion which is clinically similar to infantile hemangioma except that it presents later in childhood. These are rapidly growing, shiny red protuberances emerging from the skin on head and neck, trunk and extremities and can also involve mucosal surfaces. They are often described as starting as a "mosquito-bite" lesion and expanding into a lesion 5–10 mm in

diameter. They rarely present in infancy, with the mean age at presentation being approximately 6 years, but extending well into adulthood. These lesions are extremely friable and will bleed vigorously with minimal trauma, but quickly respond to the application of gentle pressure. Superficial cautery (i.e., silver nitrate) is often inadequate, and excision is advised for complete eradication.

Specific Considerations for Hemangiomas Based on Site, Multifocality, and Associated Syndromes

Hemangiomas can occur as focal lesions (small or segmental), multifocal lesions, and diffuse lesions. While the above sections have focused on the cutaneous presentation of hemangiomas, these can also occur within other tissues and regions of the body. Among the more concerning are hemangiomas involving the aerodigestive tract and specifically subglottic lesions. One of the hallmarks for possible airway involvement is a large segmental hemangioma of the face, which is often associated with one or more of the following congenital anomalies: posterior fossa brain malformation, cardiac anomalies, coarctation of the aorta, eye abnormalities, and sternal clefts. This constellation of associated findings is known as the *PHACES syndrome* or complex. This is a sporadic disorder affecting female infants most often.

Subglottic hemangiomas may also present as symptomatic lesions with biphasic stridor, retractions, and recurrent croup symptoms. Although one of the more rare causes of airway compromise, they should be suspected in the presence of cutaneous hemangiomas. Plain airway films may suggest the presence of a mass, and this may need to be augmented with CT or MRI evaluation; however, endoscopic evaluation will be the best diagnostic modality. Whereas even in the recent past, these were primarily treated with endoscopic laser therapy, they have now been shown to be responsive to beta-blocker therapy (i.e., propranolol), which may obviate neonatal airway interventions.

Hemangiomas may also involve the digestive tract and most frequently the liver, although multifocal involvement of the small intestine has been reported as presenting with intestinal bleeding and with perforation. Other forms of presentation can include obstruction and intussusception, which become less frequent as these lesions spontaneously involute. Hepatic involvement has been reported sporadically, but tends to be impressive. With the variability in presentation, there has been much ambiguity as to the optimal method for intervention, especially when the treatment recommendations are as extensive as consideration of hepatic transplantation.

An attempt to categorize these lesions and establish an international registry for future reference has been proposed. In this schema, focal lesions are generally diagnosed by screening studies pre- or postnatally. They tend to resemble the RICH lesions in that they are larger, glut-1-negative, and may spontaneously regress over time. Multifocal lesions, also referred to as hemangiomatosis, are frequently identified when screening liver ultrasound is obtained due to the presence of three or more cutaneous hemangiomas. These lesions behave like their infantile hemangioma counterparts in that they are glut-1-positive and resolve. The most significant hepatic lesions present as diffuse involvement of the liver resulting in cardiac failure, fulminant hepatic failure, or abdominal compartment syndrome. Severe hypothyroidism due to overproduction of type III iodothyronine deiodinase has been reported and can also contribute to cardiac failure and lead to mental retardation. These lesions do not respond favorably to either pharmacologic management or embolic therapies and may be the only instance in which liver transplantation may become a lifesaving intervention for hemangioma. These behave akin to the kaposiform hemangioendothelioma in that they may be associated with platelet consumption as part of the Kasabach–Merritt phenomenon. This condition must be differentiated from epithelioid hemangioendothelioma, which is a malignant condition with metastatic potential.

General Characteristics of Vascular and Lymphatic Malformations

AV Malformations

The arteriovenous malformations (AVM's) are the consequence of errors in embryonic development, resulting in the absence of developed capillary bed. Direct communications between the arterial and venous circulation persist with complete transduction of arterial pressures on the thin-walled venous structures. This is thought to be the result of failure of apoptosis of the primitive arteriovenous shunts. This is probably of most consequence in the cerebral circulation where AVMs are believed to occur in up to 1% of the population and may cause fatal hemorrhage especially during the adolescent years and young adulthood. There is 20-fold higher incidence of intracranial vs extracranial AVM's, which is believed to be related to the milieu of the developing brain.

The extracranial sites for these lesions are not confined to the superficial tissues of the head and neck; they may also arise on the limbs and trunk and involve the deeper structures. Because they initially tend to be flat lesions, they may not be as easily apparent as the hemangiomas, especially during infancy. These may start as innocuous, ill-defined, homogenous pink areas, which progress over time and become more complex and most apparent in later childhood. Hormones may contribute to expansion during adolescence. This natural history is utilized in the Schobinger staging system which considers the progressive potential for ulceration, bleeding, and CHF. With decreased oxygen delivery through shunting, the higher pressures lead to hemorrhage through venous structures or rupture of arterial aneurysms. Generally, these lesions progress over time and recur after treatment. The choice and timing of interventions should receive considerable thought, and parents should be cognizant that these are not lesions to be "cured."

While hemangiomas and AV malformations share Doppler characteristics of high flow, they are radiographically dissimilar. Most distinguishing is the fact that AVM's do not have significant parenchymal mass and MRI, which is the study of choice, will show the nidus and vascular channels. The use of angiography is limited to diagnostic dilemmas and mostly for the purpose of intervention. (See *Table 422.2*)

Venous Malformations

These anomalies also arise from an error in vascular morphogenesis which results in venous structures that are relatively deficient in smooth musculature or have abnormal smooth musculature. Although present at birth, they may not become apparent until later childhood. The natural history is that of slow progressive enlargement as these veins dilate. Blood flow stagnates, and thrombosis occurs. There is the potential for pulmonary emboli and chronic pulmonary hypertension on the basis of recurrent small emboli. These anomalies can occur in skin, mucous membranes, and internal organs including the intestine. In the skin and subcutaneous tissues, these present as isolated soft, blue lesions that are generally >5 cm. When in dependent positions, engorgement occurs and drainage results with elevation. Superficial color changes are also noted with compression.

Five to ten percent of patients with venous malformations will have multiple lesions and a family history. *Glomu-venous lesions* (previously, glomangiomas) are cutaneous bluish purple lesions that are extremely sensitive to touch. These lesions can be focal or widespread and often are in multiple locations. They tend to be flat and cannot be compressed. This characteristic and the painful response to touch make them ineligible for compression therapy, and resection is often advocated. Pathology reveals the glomus cells which are likely improperly differentiated vascular smooth muscle cells.

Another specific variant of venous malformations is the *blue rubber bleb nevus* syndrome: rare variant with involvement of skin, soft tissue, and GI tract – associated with recurrent GI bleeds. These are usually not massive life-threatening events, but result in chronic anemia with the need for iron supplementation or chronic transfusion. The optimal mode for management is not evident, and given the multifocal nature, operative resections may not be feasible.

Lymphatic Malformations

These common lesions were previously referred to as lymphangiomas or cystic hygromas. Their origin is an error in embryonic development of the lymphatic system, resulting in budding off of sprouting lymphatics from lymphatic sacs or the development of lymphatic channels in abnormal locations. Lymphatic malformations comprise 6% of benign lesions of infancy and childhood, and 75% are cervicofacial. They are clinically apparent by 2 years of life in 80–90% of patients with only 50–60% apparent at birth. The resultant anomalies are classified based on the size of the lymphatic cysts: micro (<1 cm), macro (>1 cm), and mixed. The macroscopic variants (previously known as cystic hygromas) are most commonly encountered in the head and neck, axilla, chest, and perineum. Although there is some tendency toward regression (in up to 16% cases), they often necessitate interventions. The advances in sclerotherapy have benefited these lesions greatly, since surgical resection was always compromised by their infiltrative nature. Involvement of vital neurovascular structures required leaving residual LM and was frequently associated with development of seromas or prolonged lymphatic drainage from the surgical wound. Infection, while at times a complication of surgical therapy, was also often therapeutic in establishing a milieu of inflammation and fibrosis which supported resolution of the lymphatic leak. The use of various sclerosants, including a streptococcal wall derivative developed in Japan (OK432), had variable results. Absolute alcohol and 5% ethanolamine oleate have become the favored agents, but the potential for side effects remains, particularly with concern for necrosis

of the overlying skin and adjacent nerves, hemoglobinuria, and cardiovascular events.

Mixed lesions (CLVM) are often encountered recognizing that the origin of the lymphatic system is closely related to that of the venous system. For this constellation of slow flow lesions, sclerotherapy and surgical therapy are the primary modes of treatment. Timing and sequence are determined based on symptoms, and location and size of the lesion.

Capillary Stains and Malformations

The most common region of discoloration seen immediately at the time of birth is the capillary stain. It affects 40% of infants. They are not associated with pathologic entities and probable result from dysregulation of the autonomic nervous system, resulting in vasodilation of the capillaries in the papillary dermis. They are most often seen on the glabella, nose, eyelid, nape of neck (stork bite mark) and generally lighten with time.

Capillary Malformations

True capillary malformations are congenital lesions, which rather than fading will persist with time and often become more complex with the development of telangiectasias and vascular ectasias. They have been referred to as portwine stain and nevus flammeus and are a deeper red color than the transient pink capillary stains. The can occur over any portion of the body, but when they occur in a dermatomal distribution particularly in the face, they must be considered in the context of associated syndromes (discussed in the following separate section on vascular anomalies and associated syndromes)

Associated Syndromes, Musculoskeletal Disorders, and Tumors

While most vascular malformations occur in isolation and are not associated with hereditary/genetic syndromes, there are some important conditions to consider when a congenital vascular malformation is evident.

While capillary stains are the most common and often transient, the occurrence of a butterfly pattern over the sacrum can be an indicator for an underlying spinal disorder and screening ultrasound/MRI may be recommended. Other considerations related to skeletal problems include the potential effect of the vascular lesion on limb growth. While some lesions exist within the bone and result in expansion of the bone itself, other lesions have an effect by virtue of the increased blood flow to the extremity and result in musculoskeletal overgrowth with consequent limb length discrepancies. When assessing infants born with enlarged extremities, considerations should include the hemihypertrophy syndromes, the presence of an extremity soft tissue lesion which can be a lymphovascular malformation or potentially a soft tissue tumor. This differential diagnosis must be considered and appropriate radiographic imaging and/or biopsy instituted to assure a correct diagnosis.

One of the most confounding diagnostic dilemmas in early infancy is the *infantile fibrosarcoma*, which enlarges during the first few weeks of life and by virtue of the associated telangiectatic skin changes, and even deeper vascular changes appear to be a benign infantile hemangioma or potentially a congenital hemangioma (RICH or NICH). Physical characteristics which may be useful in distinguishing the lesions include the consistency of the lesion. While both have significant parenchymal components, the hemangioma should have greater compressibility. Ultrasound for both will delineate a highly vascularized lesion which may have high flow components. In contrast to the infantile hemangioma, the tumor will have less of a consistent internal structure on MRI and MRA. In particular, the MRA may show larger feeding vessels and neovascularization to suggest the need for biopsy.

Sturge Weber syndrome consists of a facial capillary malformation in the distribution of the facial nerve (V1), an ipsilateral leptomeningeal vascular malformation, and choroidal malformation of the eye. Clinical features include seizures, hemiparesis, migraines, and developmental delay (50%).

Macrocephaly – CM denotes a sporadic association, for which no genetic basis has been identified, of a blotchy, poorly demarcated facial capillary malformation with macrocephaly, hypotonia, and developmental delay

Cutis marmorata telangiectasia congenita (*CMTC*) presents on the extremities as a region of discoloration that may resemble the reticular pattern seen with poor perfusion in infants. It, however, does not respond to local warming measures. Even when not associated with extremity hyper- or hypoplasia at birth, it is necessary to follow these patients long term, as there may be associated leg length discrepancies that develop. Overall this has a better prognosis that when associated with the venous and lymphatic components seen in *Klippel–Trenaunay Syndrome* (*KTS*). It has no known genetic basis.

Syndromes Associated with Combinations of Vascular Anomalies and Overgrowth

Capillary malformation – arteriovenous malformation syndrome is the consequence of an autosomal dominant mutation of the RASA1 gene, which is an inhibitor in the Ras – Map kinase pathway. Clinically, these present as small multifocal CM's with underlying AVM's when evaluated with Doppler probe. They may be components of the Parkes Weber syndrome.

Although *Klippel–Trenaunay Syndrome* was traditionally described as a CM (port wine stain) with visible venous varicosities particularly over the lateral aspect of the leg and bony and soft tissue overgrowth, the actual vascular anomaly is best described as a CLVM. These patients develop progressive venous stasis and lymphedema with resultant thrombosis and ulceration.

Parkes Weber syndrome is clinically very similar to KTS in that there is significant skeletal hypertrophy of the affected limb. The capillary malformation is accompanied by multiple AV fistulas which alter the constellation of problems presented to the patient.

PTEN-associated vascular anomaly affects a subset of patients with PTEN gene mutations. They have altered function of a tumor suppressor gene and are at risk for PTEN hamartoma tumor syndrome (Cowden's syndrome) which is an autosomal dominant condition. In addition to surveillance for endocrine and GI malignancies, these patients may have arteriovenous malformations particularly involving the musculature in 50% with resultant overgrowth of bone and soft tissue.

Treatment Strategies for Vascular Anomalies

The options for treatment vary with the type of lesion (hemangioma vs vascular malformation), location (skin/soft tissue vs cranial, orbital or airway) and involvement of deeper tissues (superficial CM vs intramuscular AVM).

Since hemangiomas are proliferative lesions, pharmacologic options are available which would be expected to play a lesser, or no, role in the vascular anomalies. The decision to intervene on an infantile hemangioma or congenital hemangioma is generally driven by its location and inherent complications. Lesions that threaten eyesight and or airway (life) as well as large segmental hemangiomas have been the traditional candidates for treatment. Parental reassurance is the primary treatment for the isolated hemangioma that can be predicted to involute without adverse consequences. As the therapies offered become safer, there may be less reluctance to provide an intervention for nontraditional indications.

Corticosteroid therapy has remained the first-line therapy at initial doses of 2–4 mg/kg/day, extended over a period of 9 months to cover the period of proliferation. While effective in >80% of cases, the associated side effects (behavioral disturbances including sleeplessness, cushingoid features, growth delay, and hypertension) often limit tolerance. Intralesional injections separated by 6–8 weeks are instituted to avoid the systemic effects, but do not eliminate them. Topical therapy using steroid creams and another immune-modulating agent imiquinod has very limited effectiveness.

When corticosteroid therapy was ineffective or not tolerated, the next line agent was *interferon alpha*, which was initially developed as an antiviral agent but was recognized to have potent antiangiogenic properties. Although it had clinical efficacy, unfortunately, the incidence of neurologic complications, which included irreversible spastic diplegia, limited the use of this agent. *Vincristine* became a second-line agent when its effect on KHE was appreciated and the use as a mitotic inhibitor during the proliferative phase of hemangiomas was supported clinically. Both agents have since been replaced with *beta-adrenergic antagonists* such as propranolol which serendipitously was noted to have a dramatic regression effect on a steroid recalcitrant hemangioma in a child who required a beta-blocker for a cardiomyopathy. Although standardized protocols have not been developed, there are a multitude of reports of its efficacy. The potential side effects include hypoglycemia, bradycardia, and hypotension, but this agent has been well tolerated to date.

Nonpharmacologic Interventions

Therapies in this category are employed for both hemangiomas and vascular malformations. It is imperative that the indications are delineated clearly to parents and caretakers and that an understanding exists that these are intended to either: (1) resolve a cosmetic issue, (2) address a eyesight or life-threatening lesion, (3) address superficial ulceration and necrosis associated with aneurysmal dilation of either arteries or veins in complex malformations (*Table 422.3*).

Beyond their proliferative phase, when pharmacologic therapy is optimal, or when this is inadequate, hemangiomas may require interventions using laser therapy, angiographic interventions, or surgical excision. Laser therapies are based on thermal-induced coagulation initiated by the absorption of a specific wavelength of light by a target, such as oxyhemoglobin, which results in elevation

Table 422.3

Physical findings and their clinical context

Lesion	Physical findings	Clinical context
Infantile hemangioma (IH)		(a) Four-month-old infant with expanding vascular lesion with irregular surface c/w hemangioma in proliferative phase (b) Infant with multiple cutaneous hemangiomas
RICH/NICH		(a) Two month old with highly vascular lesion on thigh and knee present from birth with superficial ulceration and consequent hemorrhage (b) Arteriogram pre-embolization (Photograph courtesy of C. Muratore, MD)
Lymphatic (LM)		(a) Lymphatic malformation that suddenly became apparent in 3 month old as consequence of infection. No soft tissue mass was appreciated prior to infection (b) Two year old with microcystic LM
		(a) Subaxillary lymphatic malformation diagnosed prenatally (b) Note macro- and microcystic components on MRI (Photographs courtesy of C. Muratore, MD)
Venous malformation (VM)		Ten-year-old male who presented at age 4 years with recurrent GI bleeding, ultimately determined to arise from venous malformation in distal ileum. Note prominent veins in submucosa

Table 422.3 (Continued)

Lesion	Physical findings	Clinical context
Combined lesion (CLVM)		Combined venous and lymphatic malformation in posterior axillary fold. Note bluish hue
Capillary malformation (CM)		Preadolescent female with capillary malformation involving lower extremity and perineum
Arteriovenous malformation (AVM)		Six-year-old girl with limb hypertrophy and heat radiating from right chest and arm as consequence of high flow vascular malformation c/w AVM

of local tissue temperature. Effectiveness is primarily limited by the depth of energy penetration, and therefore, this modality is most frequently used for superficial dermal lesions. There are many forms of laser therapy, and a discussion of specifics is beyond the scope of this text. Airway lesions have traditionally been treated with the carbon dioxide laser.

Ultrasound-guided and angiographic techniques are principally used for the vascular and lymphatic malformations. The principle of these therapies is either to occlude inflow to a lesion reducing its size, cause necrosis, or reduce the shunting that led to congestive heart failure. Angiographic interventions are limited by the complications associated with access to the arterial system. While appropriate size catheters and embolic devices have been developed, particularly for cerebrovascular interventions, access via the small caliber femoral vessels has been associated with thrombosis and limb length discrepancies on the basis of arterial insufficiency. These risks have to be balanced with the indications for considering an intervention. In extensive AVMs, the occlusion of one source of inflow is often accompanied by an increased flow via other channels. Furthermore, the actual induction of hypoxemia as a consequence of embolic therapy is a potent stimulator of vascular neogenesis.

To offset the risks of femoral access, direct puncture into lesional vessels can be another effective technique. Agents instilled for thrombosis include dehydrated alcohol which acts as a sclerosant. This injection of vessels is often guided by ultrasound. These interventions require sedation and/or general anesthesia with considerations for good pain management in the postprocedure phase. Sclerosis can be used as an independent intervention or as a preliminary step to facilitate resection.

Surgical resection has generally been limited to the residual skin and soft tissue anomalies after regression of a hemangioma. Intervention in a well-vascularized lesion for resection is naturally associated with the potential for significant bleeding. Adjuncts such as use of an extremity tourniquet, hemostatic topical agents, and even systemic

therapies such as Novo7 have allowed for higher risk surgical interventions to be performed with acceptable morbidity and mortality.

Summary

Vascular lesions in the infant and child should be categorized into hemangiomas or vascular malformations based on their clinical and radiographic features. With an understanding of the natural history of the lesions, appropriate discussions can be held regarding the indications for and timing of interventions. The multidisciplinary approach to the patient with a vascular lesion will allow for a multimodality treatment approach.

Drug Dosing in Pediatrics

Kristine A. Parbuoni

423 Drug Dosages: Pediatric Pharmacokinetics and Pharmacodynamics

Donna Huynh · Kristine A. Parbuoni

In order for drugs to exert their therapeutic and toxic effects, they need to reach their site of action. Pharmacokinetics describes the process by which drugs are absorbed, distributed, metabolized, and eliminated by the body. With the exception of the intravenous route of administration, drugs need to be absorbed into the systemic circulation in order to reach their site of action. Once absorbed into the systemic circulation, drugs are distributed to the various tissues. To eliminate the drug from the body, drugs may undergo a series of enzymatic reactions which can lead to an active form of the drug, a toxic metabolite, or a molecule that can be more easily excreted by the kidneys. Some drugs can be eliminated by the kidneys without undergoing any metabolism by the body. Important pharmacokinetic differences exist between children and adults which can have significant implications on drug dosing in pediatric patients.

Oral Drug Absorption

Drug absorption using the enteral route can be affected by gastric pH, gastric emptying time, and enzymes and efflux transporters that are found in the gastrointestinal tract. Neonates and infants have a higher gastric pH in comparison to adults due to a reduction in acid production and secretion by the stomach. The higher gastric pH leads to the decreased absorption of drugs that are weak acids, such as phenobarbital, and therefore higher oral doses are required in comparison to adults. In contrast, there is an increased absorption of basic or acid-labile drugs such as penicillin G in neonates compared to adults. The gastric pH reaches adult values by 2 years of age. Gastric emptying time is also delayed in neonates and infants due to decreased peristalsis and motility in the gastrointestinal tract. The delayed gastric emptying time prolongs the time it takes to reach peak concentration in neonates and young infants when compared to adults. In addition to gastric emptying time, the lack of mature efflux transporters and enzymes in the gastrointestinal tract of neonates and young infants can also reduce the absorption of specific medications such as gabapentin.

Other Routes of Administrations

There is decreased muscle mass and erratic blood flow to the muscles in neonates compared to adults. This may result in slower and reduced absorption of some drugs using the intramuscular route in neonates in comparison to adults. Intramuscular injections should be avoided if possible in neonates due to pain and questionable absorption. If given to neonates and infants, intramuscular injections should be given to the anterolateral aspect of thigh.

Neonates and infants have increased absorption of topical medications compared to older children and adults. Percutaneous drug absorption occurs more readily in neonates and infants due to larger body surface area to body mass ratio, thinner stratum corneum, and increased hydration and perfusion to skin. Neonates and infants are at an increased risk for toxicities from drugs applied to the skin, and certain topical medications such as povidone-iodine should be avoided in neonates.

Drug Distribution

In neonates and infants, there is a greater total body water and less fat content when compared to adults. The volume of distribution for hydrophilic drugs is increased and for lipophilic drugs is decreased in neonates and infants. In order to reach the same therapeutic drug levels as in adults, a larger dose needs to be given to neonates and infants for hydrophilic drugs such as gentamicin.

Protein binding can also affect drug distribution since only unbound drug is active and is able to exert its therapeutic effect. Neonates and infants have decreased concentrations of albumin and α_1-acid glycoprotein which are

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_423,

the primary proteins that bind drugs. In addition, they have a high concentration of fetal albumin which has a decreased binding affinity for drugs compared to albumin. This means that there is an increased fraction of unbound drugs in neonates and infants for highly protein bound drugs such as phenytoin. There are also higher concentrations of endogenous substances such as bilirubin that can compete with drugs for binding sites. It is important to avoid drugs that can displace bilirubin from albumin binding sites which can lead to kernicterus. Ceftriaxone and sulfonamides should be avoided in infants less than 2 months of age.

Drug Metabolism

Drugs are metabolized in the body via two different categories of reactions. Phase I reactions are responsible for oxidation and reduction type reactions. Phase II reactions are responsible for conjugation reactions such as sulfation and glucuronidation. The isoenzymes of the CYP450 system mature at different rates and are responsible for the majority of the Phase I reactions in the body. For example, CYP1A2 is responsible for the metabolism of caffeine and is only at 50% adult capacity by 0.9 years of age. The sulfation pathway is fully developed at birth which makes infants and young infants more tolerant to acute ingestion of acetaminophen. The glucuronidation pathway is only at 10% adult capacity at birth but reaches adult values by 2 years of age. As a result of this, chloramphenicol should be avoided in neonates and infants due to increased risk of grey baby syndrome.

Drug Elimination

The elimination of drugs by the kidney is dependent on renal blood flow, glomerular filtration rate, and tubular secretion. Renal blood flow is decreased in neonates and young infants in comparison to adults with only 5% of cardiac output at birth in comparison to 15% of cardiac output in adults. Both glomerular filtration and tubular secretion are decreased at birth and reaches adult values by 1 year of age. Therefore, for drugs that are eliminated by the kidneys, they have a slower clearance and a longer half-life. This means that drugs are often dosed less frequently in neonates and infants in comparison to adults. To estimate creatinine clearance in neonates and children, the Schwartz equation should be used.

424 Drug Dosages: Administration of Medications

Jill A. Morgan · Kristine A. Parbuoni

Patients should be educated about their medications. For recommended pharmacologic treatments, providers should explain the dosing frequency, common adverse events that should be expected, and what to do if they occur or the condition worsens. The patient and caregiver should also be counseled on how to administer the medication.

Children can generally swallow pills around 7 years of age. Therefore, most oral medications for children are in the liquid form. Administration errors with liquid medications are frequent with 50–60% of parents incorrectly measuring the dose of a medication. In 1975, the American Academy of Pediatrics (AAP) published a statement on the inaccuracies of administering liquid medications to children. It is well known that household teaspoons measure anywhere from 2.5 to 7.8 mL; therefore, the AAP has recommended using oral syringes to measure liquid medication doses.

Yin and colleagues described errors related to medication dosing cups including confusing the teaspoon measure with the tablespoon measure and assuming the whole dosing cup was the prescribed dose. Medication cups were associated with a statistically significant increased number of errors compared to oral syringes. Researchers also noted the lack of eye level dose verification with plastic dosing cups.

In another study, McMahon (1997) demonstrated that parents are able to correctly measure liquid doses if given a demonstration, verbal instructions, and a marked, oral syringe with a line. For parents given verbal instructions, 37% measured a correct dose. When given verbal instructions and a marked syringe, 83% were able to measure the correct dose. For parents who received verbal instructions, a demonstration, and a marked syringe, 100% measured the correct dose.

Sobhani looked at the ability of adults to measure 5 mL using an oral syringe and the provided dose cup from the manufacturer. In a survey completed at the beginning of the study, participants were asked about measuring devices they had previously used. The survey revealed that 68% of participants had used droppers, 67% of participants had used dose cups, and only 49% of participants had used oral syringes previously at home. In this study, 66.7% measured a dose correctly using the oral syringe versus 14.6% with the dose cup. It is interesting to note that more people thought the dose cup was easier to manipulate than the oral syringe (87% vs. 63%). Also, about 30% of participants were not able to correctly measure a dose using the oral syringe.

Each prescription should be dispensed with an oral syringe that is marked for that medication. Color-coded syringes can help to decrease confusion if there is more than one medication or child at home on medications. Parents and caregivers must be taught how to measure the dose in an oral syringe with verbal instructions and a demonstration. The pharmacist should also consider recommending the use of bottle adaptors to make the manipulations of the oral syringe easier for parents and to decrease medication loss.

For oral medications, infants and toddlers may need to be restrained before giving a dose. Have the parents hold the child in their lap. Cradle the child's head in the crook of their arm. Reach the same arm around the child and hold their free arm. The child's other arm should be pressed against the parent's body. Place the child's legs between the parent's legs. Administer the liquid in 1 mL increments to the inside of the cheek. Gently blowing on an infant's face will elicit the swallowing reflex. Older children can sit or stand for the administration of oral medications.

For ophthalmic medications, tell the patient or caregiver to wash their hands and remove contact lenses before applying eye drops. Most ophthalmic agents contain the preservative benzalkonium chloride, which is known to permeate contact lenses; therefore, remove contact lenses prior to instilling the ophthalmic preparation and wait 10–15 min before placing the contact back in the eye. Check the expiration date, clarity, and color of the ophthalmic solution to ensure there is no change from the original formulation. Discard the product if it has expired, changed color, or is cloudy. Instruct the patient to tilt their head back, look up and pull down the eyelid to make

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_424,

a pouch, instill a drop into the pouch, then close the eyes while applying light pressure with a finger to the lacrimal sac for 1–2 min after instillation. This prevents the medication from draining away from the eye. For young children that may resist the instillation of the ophthalmic preparation, there are a couple of useful techniques that will help to ensure safe administration of the medication. Have the child lay down on a couch or bed. If two caregivers are available have one caregiver hold the child in place by stabilizing the head while the second caregiver pulls down the eyelid to make a pouch and instills the ophthalmic drop. If only one caregiver is available do the following: if the child is an infant, swaddle the baby to stabilize or while the child is lying down with their arms folded in their lap, use one arm to stabilize the child's body. The hand on the arm that is used to stabilize the body is used to form a pouch in the lower eyelid. With the other arm, hold the forehead still and use the hand on this arm to instill the ophthalmic preparation. The purpose of using the hand on the arm holding the forehead for instillation is that the ophthalmic bottle will move with the child and should not cause injury to the eye with undesired movement(s) of the child. In order to avoid contamination of the eye dropper, do not touch the top of the dropper bottle to the eyes, fingers, or any other surface.

For rectal medications, have the parent wash their hands and possibly put on gloves. An infant can lie across an adult's lap on their belly or on a bed on their belly. An older child should lie on their left side with the right leg bent toward the chest. Remove the suppository from the wrapper and put some petrolatum on the end of it. With one hand, separate the child's buttocks and gently insert the suppository into the anal opening. With the pinky finger, gently push the suppository into the rectum until there is no resistance (about ½ in. in infants <6 months of age and 1 in. in older children). Hold the child's buttocks together until the urge to go to the bathroom is gone. Have the child remain in the prone position for 20 min.

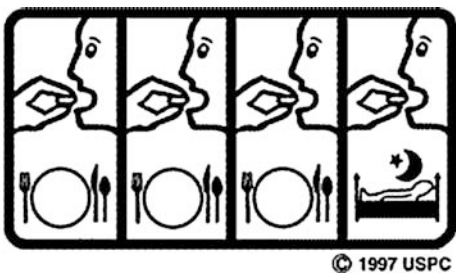
For otic medications, have the parents warm the medication in their hands to prevent nausea and dizziness. The child can lie down or sit up and tilt their head to the side. If the child is <3 years, straighten the ear canal by pulling the ear lobe down and back. If the child is ≥3 years, straighten the ear canal by holding the upper part of the ear and pulling up and back. Instill the drops into the ear canal on the side, not directly in the canal and do not touch the dropper to the ear. Have the child continue to lie on their side or tilt their head for 5 min.

When administering medication to children, parents and caregivers should be able to explain what they are going to do to the pharmacist or medical practitioner. Medication administration should follow a routine. Parents and caregivers should not refer to medications as candy. It is important to praise their child for good behavior and cooperation during medication administration.

Education

Pharmacists and providers should counsel parents and children on their medications. Counseling needs to be directed to the child even if the child might not understand all of the information shared. The education materials should be tailored to the developmental stage of the child. Materials for young children should not contain medical jargon and should explain terms using a child's language. They should consist of mainly pictures. Young children will only remember 2–3 messages per session. Older children and adolescents can have more complex information in their education materials. The material should contain pictures and text.

A variety of methods are available to help improve understanding of medical information. Pictograms have been shown to improve medication knowledge in patients with 7 years of schooling and English as a second language. The HELPix project developed medication instruction sheets that are patient-specific with plain language and pictograms for medication preparation, route, frequency, storage, and duration. This program was developed to help patients with low literacy. Yin (2008) and colleagues evaluated this program and found that the pictogram-based medication information sheets used in conjunction with a counseling program decreased medication errors and increased adherence in children treated at an urban ED. Samples of medication information sheets can be located at the HELPix website: http://helpix.med.nyu.edu/the-helpix-intervention/overview-helpix. Another patient-friendly site for patient education handouts is www.safemedication.com. Also, pictograms can be downloaded for free from www.usp.org. Below is a sample pictogram from USP:



Take 4 times a day, with meals and at bedtime (http://www.usp.org/audiences/consumers/pictograms/)

Schillinger (2003) introduced the concept of assessing knowledge taught in counseling sessions by having the patients repeat back what information was shared. This process may be very helpful in gauging the parent's and child's understanding of the information delivered in the counseling session.

The following information should be conveyed in each counseling session: the indication for use, directions on how to administer (including taking with or without food) and how often, patient-specific drug interactions, special storage instructions, and side effect information. Explain common adverse reactions as well as rare serious adverse reactions. It is important for parents to know how to handle an adverse event and when to involve the physician. Also, for prescription products, it is important to highlight to parents and caregivers that if any adverse drug event occurs they can call the toll-free phone number listed on the product labeling. Lastly, explain when the medication should take effect or when a child should see improvement and what to do if this does not happen.

Counseling sessions should also reinforce the importance of adherence. Encourage and give children charts to track adherence. A child can color or place stickers on the chart after administration of a dose. For complicated tapers or patients on chronic medications, calendars can be developed that can be marked off as doses are administered. Pharmacists should recommend that parents keep the charts near the medications (e.g., on the refrigerator door).

Adherence can be linked to the palatability of the medication. This can be increased using products that flavor medications. Also, a child can numb their taste buds with a popsicle or a piece of ice before taking a medication. The metallic aftertaste from some medications such as metronidazole and clarithromycin can be reduced with orange juice or chocolate. After the administration of a poor tasting medication, encourage the child to eat some peanut butter (check for allergies first), drink a carbonated beverage, or have chocolate sauce to remove the taste from the tongue. In general, bitter medications can be masked with chocolate flavors, citrus can be used for sour medications, and salty can be masked with peanut butter, cinnamon, or butterscotch.

425 Drug Dosages

Donna Huynh · Jill A. Morgan · Kristine A. Parbuoni

Table 425.1
PALS resuscitation medications

Medication	Indication	Dose	Comments
Adenosine	Supraventricular tachycardia	0.1 mg/kg (max dose: 6 mg)	Rapid IV/IO bolus
		Repeat dose: 0.2 mg/kg (max dose: 12 mg)	May repeat after 2 min
Amiodarone (Cordarone®, Pacerone®)	Ventricular tachycardia	5 mg/kg IV/IO (max dose: 300 mg)	Push if no pulse
	Ventricular arrhythmia	May repeat up to max total daily dose: 15 mg/kg (2.2 g/day)	Administer over 20 min if pulse present
			Monitor for hypotension
			Use caution with other QT prolonging agents
Atropine	Bradycardia	IV/IO: 0.02 mg/kg	Repeat once if needed
	Primary AV block	ETT: 0.04–0.06 mg/kg	
		Minimum dose: 0.1 mg	
		Maximum dose: 0.5 mg (child), 1 mg (adolescent)	
Calcium chloride (10%)	Hypocalcemia	20 mg/kg IV/IO (0.2 ml/kg)	Slow push
	Hyperkalemia		Repeat as needed
	Hypermagnesemia		
	Calcium channel blocker overdose		
Dextrose (glucose)	Hypoglycemia	0.5–1 g/kg IV/IO	D10W: 5–10 ml/kg
			D25W: 2–4 ml/kg
			D50W: 1–2 ml/kg
Epinephrine	Bradycardia	0.01 mg/kg IV/IO (0.1 ml/kg, 1:10,000)	May repeat every 3–5 min
	Asystole	Maximum dose: 1 mg	
	Pulseless arrest	0.1 mg/kg ETT (0.1 ml/kg 1:1,000)	
		Maximum dose: 2.5 mg	
Insulin	Hyperkalemia	0.1 units/kg IV/IO with 0.5 g/kg dextrose	
Lidocaine (Xylocaine®)	VF	1 mg/kg IV/IO	
	Pulseless VT	2–3 mg/kg ETT	
Magnesium sulfate	Torsades de Pointes	25–50 mg/kg IV/IO	Push if no pulse
	Hypomagnesemia	Maximum dose: 2 g	Administer over 10–20 min if pulse present

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_425,

Table 425.1 (Continued)

Medication	Indication	Dose	Comments
Naloxone (Narcan®)	Opioid overdose	Total reversal: 0.1 mg/kg IV/IO/IM/SQ	May repeat as needed
		Maximum dose: 2 mg	
		Respiratory depression with therapeutic opioid use: 1–15 mcg/kg IV/IO/IM/SQ	
Sodium bicarbonate	Metabolic acidosis	1 mEq/kg IV/IO	Administer slowly
	Hyperkalemia		Dilute 1:1 with sterile water for patients <10 kg
	Tricyclic antidepressant overdose		

Table 425.2
Respiratory medications

Medication	Indication	Dose	Comments
Beta-agonists			
Albuterol (ProAir®HFA, Proventil®HFA, Ventolin®HFA)	Asthma quick relief of bronchospasm	Acute attack: 2.5–5 mg via nebulizer every 20 min then every 1–4 h as needed	Tolerance can develop.
			Use >2/week indicates poor control of asthma
		Can increase to 10–15 mg/h	Use spacer with MDI. Shake MDI well before use
			Wait 1 min between inhalations
		MDI: Four to eight puffs every 20 min then every 1–4 h as needed	May cause hyperactivity, insomnia, coughing, hoarseness, tachycardia, palpitations, chest pain, and hypokalemia (with continuous use)
		Non-acute attack: 2.5 mg via nebulizer every 4–6 h as needed	Remove canister and wash plastic inhaler once a week and air dry to prevent clogging of medication
		MDI: One to two puffs every 4–6 h as needed	Inhaler requires priming
Terbutaline	Asthma quick relief of bronchospasm	Loading dose: 2–10 mcg/kg IV followed by 0.1–10 mcg/kg/min continuous infusion	Titrate drip up 0.1 mcg/kg/min every 30 min
			Can administer undiluted (1 mg/ml)
			May cause hyperactivity, insomnia, coughing, hoarseness, tachycardia, palpitations, chest pain, hyperglycemia, and hypokalemia, QT prolongation, CPK isoenzyme elevation

Table 425.2 (Continued)

Medication	Indication	Dose	Comments
Corticosteroids			
Budesonide (Pulmicort Respules®, Pulmicort Flexhaler™, Rhinocort® Aqua®)	Asthma controller	Oral inhalations: ≤4 years:	Not first line therapy for asthma attack
	Seasonal and perennial rhinitis	Low dose: 0.25–0.5 mg	Increase dose every 2 weeks until achieve control
		Medium dose: >0.5 to 1 mg	Nebulization: Administer nebulized doses once or twice a day. Shake before use. Administer with a compressed air jet nebulizer. Avoid exposure to eyes
		High dose: >1 mg	
		5–11 years:	For the flexhaler: Divide dosing twice daily. Remove cap. Hold inhaler with mouthpiece up to load dose. Turn bottom to right and back until clicks. Do not shake or prime. Put mouthpiece between lips and inhale fast and deep. Do not exhale or blow into inhaler. Replace inhaler when dose counter reads "0." Contains lactose. Avoid in allergic patients
		Low dose: 0.5 mg neb or 180–400 mcg/day (90 mcg 2–4 inhalations/day)	
		Medium dose: 1 mg neb or 400–800 mcg/day (180 mcg 2–4 inhalations/day)	
			Wait 1 min between inhalations
		High dose: 2 mg neb or >800 mcg/day (180 mcg >4 inhalations/day)	Rinse mouth and spit or brush teeth after each administration to decrease risk of thrush
		≥12 years	May cause HPA suppression and growth suppression
		Low dose: 180–600 mcg/day (90 mcg 2–6 inhalations/day)	For nasal spray: Shake well. Blow nose before use. Insert applicator into nostril, keep bottle upright, and close off the other nostril; breathe in through nose; press pump to release dose. Avoid spraying into eyes. May cause nose bleeds, nasal burning or irritation, and nasal ulcers
		Medium dose: 600–1,200 mcg/day (180 mcg 3–6 inhalations/day)	
		High dose: >1,200 mcg/day (180 mcg >6 inhalations/day)	Max effect for nasal use seen in 2 weeks, for oral use seen in 2–6 weeks
		Nasal: ≥6 years: 1–2 sprays each nostril once a day	Bioavailability 11%

Table 425.2 (Continued)

Medication	Indication	Dose	Comments
Fluticasone (Flovent®, Flonase®)	Asthma controller	Oral inhalations	Not first line therapy for asthma attack
	Seasonal and perennial rhinitis	Low dose: 88–176 mcg (44 mcg 2–4 puffs/day)	Increase dose every 2 weeks until achieve control
		Medium dose: 177–352 mcg (110 mcg 2–3 puffs/day)	Administer inhaler twice daily
			Use spacer with MDI. Shake MDI well before use
		High dose: >352 mcg (220 mcg ≥2 puffs/day)	Wait 1 min between inhalations
			Rinse mouth and spit or brush teeth after each administration to decrease risk of thrush
		Nasal: ≥4 years: 1–2 sprays in each nostril once a day	May cause HPA suppression and growth suppression
			For nasal spray: Shake well. Blow nose before use. Insert applicator into nostril, keep bottle upright, and close off the other nostril; breathe in through nose; press pump to release dose. Avoid spraying into eyes. May cause nose bleeds, nasal burning or irritation, and nasal ulcers
			Inhalers and nasal sprays require priming
			Max effect seen in 2 weeks
			Bioavailability 1%
Mometasone (Asmanex® Twisthaler®, Nasonex®)	Asthma controller	4–11 years: 110 mcg one inhalation every evening	Not first line therapy for asthma attack
			Increase dose every 2 weeks until control is achieved
		≥12 years:	For the twisthaler: Remove twisthaler from foil pouch and write date on cap. Discard inhaler 45 days later. Hold inhaler with mouthpiece up and colored base on bottom. Hold base and turn cap in counterclockwise fashion to remove and load dose. Do not shake or prime. Put mouthpiece between lips and inhale fast and deep. Do not cover ventilation holes. Do not exhale or blow into inhaler. Replace cap and turn clockwise until hear click. Wait 1 min between inhalations
		Low dose: 200 mcg one inhalation every evening	
		Medium dose: 400 mcg (200 mcg two inhalations every evening)	
		High dose: >400 mcg (200 mcg >2 inhalations)	
			Rinse mouth and spit or brush teeth after each administration to decrease risk of thrush
			May cause HPA suppression and growth suppression
			Contains lactose. Avoid in allergic patients
			Do not wash inhaler. Wipe with dry cloth if needed
			Max effect seen in 2 weeks
			Bioavailability <1%

Table 425.2 (Continued)

Medication	Indication	Dose	Comments
Antihistamines and Others			
Cetirizine (Zyrtec®)	Allergic Rhinitis	6 months–5 years: 2.5 mg once a day, can increase to 5 mg/day	May cause drowsiness and photosensitivity reactions.
	Urticaria	≥6 years: 5–10 mg once a day	Caution in children <2 years
Diphenhydramine (Benadryl®)	Treatment of allergy symptoms	5 mg/kg/day divided every 6 h (Max dose = 300 mg/day)	May cause drowsiness, dizziness, hypotension, wheezing, dry mouth, constipation, and urinary retention. May cause paradoxical excitation, hallucinations in children
	Mild sedation	Adolescents: 25–50 mg every 4–6 h	
	Relief of pain and itching from insect bites		Avoid in asthmatics (due to thickening of mucous in lungs and wheezing)
	Treatment of dystonic reactions		Do not apply topical preparations to large portion of body or open skin due to risk of psychosis and seizures
	Prevents motion sickness		Caution use in closed-angle glaucoma, peptic ulcer disease, and hyperthyroidism
Loratadine (Claritin®)	Allergic Rhinitis	2–5 years: 5 mg once a day	May cause drowsiness, dry mouth, discolor urine, and photosensitivity reactions
	Urticaria	≥6 years: 10 mg once a day	Food increases bioavailability by 40%.
			Check for drug interactions that may impair Loratadine's hepatic metabolism
Caffeine citrate (Cafcit®)	Apnea of prematurity	Loading dose: 10–20 mg/kg as caffeine citrate (5–10 mg/kg as caffeine base)	If received theophylline in last 3 days, decrease loading dose by half
		Maintenance dose: 5 mg/kg/day as caffeine citrate (2.5 mg/kg/day as caffeine base)	Start maintenance dose 24 h after loading dose
			Monitor heart rate, caffeine levels once a week, and number of apnea episodes
			Therapeutic level: 8–20 mcg/ml
			Each 1 mg/kg dose will increase level by 1 mcg/ml
			May cause cardiac arrhythmias, agitation, hyperactivity, muscle tremors, and hyper- or hypoglycemia
			Can administer IV form orally
			Avoid use of caffeine sodium benzoate to prevent gasping syndrome in neonates
Ipratropium Bromide (Atrovent®)	Status asthmaticus to prevent hospital admission	0.5 mg via nebulizer every 20 min then every 6 h for 24 h	Not first line therapy for asthma attack
			May cause dry mouth
		MDI: Four to eight puffs every 20 min then every 6 h for 24 h	Avoid spraying aerosol in eyes due to risk of blurred vision
			Caution some generic inhalers contain soy and should be avoided in peanut and soybean allergic patients
			No evidence to use routinely in asthma patients

Table 425.2 (Continued)

Medication	Indication	Dose	Comments
Montelukast (Singulair®)	Asthma controller	6 months–5 years: 4 mg once a day	Not first line therapy for asthma attack
	Seasonal and perennial rhinitis	6–14 years: 5 mg once a day	Administer at bedtime
	Prevent exercise bronchospasm	>14 years: 10 mg once a day	Administer 2 h before exercise as needed to prevent bronchospasm
			Administer granules within 15 min of opening package by placing directly into mouth or can mix in applesauce, mashed carrots, rice, or ice cream. Do not dissolve granules into liquid
			May cause headaches, insomnia, nightmares, agitation, aggression, depression (rare)

Table 425.3
Opioid analgesics

Drug	Onset (min)	Duration (h)	Equianalgesic dose (mg/kg/dose)	Route	Comments
Codeine	30–60	4–6	0.5–1	PO	Not for children <6 months old
					Converted in liver to morphine. 10% of US population cannot convert codeine to morphine therefore will not experience analgesia
Fentanyl	1–2	0.5–1	0.001	IV	Chest wall rigidity can occur with rapid infusion; treat with naloxone or neuromuscular blockers
Hydrocodone	10–20	3–6	0.1	PO	Formulated with acetaminophen; consider acetaminophen dose limits
Hydromorphone (Dilaudid®)	5–10	3–4	0.015	IV	Less pruritis than morphine
	30–60	4–5	0.03–0.08	PO	
Meperidine (Demerol®)	5–10	2–3	0.75–1	IV	Not recommended for routine use due to potential for accumulation of a neurotoxic metabolite; interacts with MAO inhibitors; use low dose (0.1–0.25 mg/kg) for shivering
	15–60	2–4	1.5–2	PO	
Methadone	10–20	Acute: 4–6	0.1	IV	Consider a pain/palliative care specialist consult. Prolonged elimination half-life that increases with repeat doses and drug accumulation. Wide variations in response to methadone. May prolong QT interval
	30–60	Chronic: >8	0.1	PO	
Morphine (MS Contin®, Oramorph® SR)	5–10	3–4	0.1	IV	Can cause significant histamine release
	15–60	3–5	0.3	PO–IR	
	90–120	8–12	0.3	PO–SR	
Oxycodone IR (Roxicodone®, Oxycontin®)	15–30	3–4	0.1–0.2	PO	Controlled-release tablets should be swallowed whole; Caution in severe renal impairment
	60	12	0.1–0.2	PO–CR	

Table 425.4
Non-opioid analgesic medications

Drug	Dose	Route	Comments
Acetaminophen (Tylenol®)	10–15 mg/kg every 4–6 h Max: 90 mg/kg/day or 4,000 mg/day	PO, PR	Acetaminophen does not have antirheumatic or systemic anti-inflammatory effects; may cause severe hepatotoxicity with overdose
Aspirin	Analgesic, antipyretic, antiinflammatory 10–15 mg/kg every 4–8 h Max: 100 mg/kg/day or 4,000 mg/day Antiplatelet effects: 5 mg/kg/day once daily	PO, PR	Do not use aspirin in children and teenagers who have or who are recovering from chickenpox or flu symptoms (due to the association with Reye's syndrome)
Choline Magnesium Trisalicylate	10–15 mg/kg every 6–8 h Max: 4,500 mg/day	PO	No antiplatelet effect; Do not use in children and teenagers who have or who are recovering from chickenpox or flu symptoms (due to the association with Reye's syndrome)
Ibuprofen (Motrin®, Advil®)	5–10 mg/kg every 6 h Max: 40 mg/kg/day or 3,200 mg/day	PO	To reduce the risk of adverse cardiovascular and GI effects, use the lowest effective dose for the shortest period of time
Ketorlac (Toradol®)	0.5 mg/kg every 6–8 h Max: 30 mg/dose	IV IM	Use caution in renal impairment; do not exceed 48–72 h in children <2 years of age; do not exceed 5 days of therapy in patients 2–16 years of age
Naproxen (Naprosyn®)	5–7 mg/kg every 8–12 h Max: 20 mg/kg/day or 1,000 mg/day	PO	To reduce the risk of adverse cardiovascular and GI effects, use the lowest effective dose for the shortest period of time

Table 425.5
Sedation agents

Drug	Onset (min)	Duration (h)	Dose	Route	Comments
Chloral hydrate	10–20	4–8	Procedural sedation: 25–75 mg/kg/dose 30–60 min prior to procedure; may repeat in 30 min to total max of 120 mg/kg or 1,000 mg infants, 2,000 mg children	PO	Avoid use in renal impairment
Diazepam (Valium®)	1–3	0.25–1	0.1 mg/kg	IV	Poor choice for procedural sedation; ideal for prolonged sedation or muscle relaxation; painful IV injection
	7–15	2–3	0.2–0.3 mg/kg	PR	
	30–60	2–3	0.2–0.3 mg/kg	PO	
Lorazepam (Ativan®)	1–5	3–4	0.03–0.1 mg/kg	IV	Ideal for prolonged anxiolysis
	10–20	3–6	0.05 mg/kg	IM	
	30–60	3–6	0.05–0.1 mg/kg	PO	
Midazolam (Versed®)	1–3	1–2	0.05–0.1 mg/kg	IV	Rapid onset; use IV form for intranasal and rectal
	5–10	1–2	0.1–0.2 mg/kg	IM	
	5–10	1–2	0.2–0.3 mg/kg	INH	
	10–30	1–2	0.3–1 mg/kg	PO/PR	

Table 425.5 (Continued)

Drug	Onset (min)	Duration (h)	Dose	Route	Comments
Ketamine (Ketalar®)	0.5–2	0.25–2	0.25–0.5 mg/kg	IV	Induces general anesthesia; dissociative agent, may cause hallucinations; increases heart rate and blood pressure; causes bronchodilation and increased secretions
	10–15	0.5–4	1.5–3 mg/kg	IM	
Pentobarbital (Nembutal®)	1–10	1–4	0.5–1 mg/kg	IV	Associated with slow wake up and agitation
	5–15	2–4	2–6 mg/kg	IM	
	15–60	2–4	2–6 mg/kg	PO	
			Max: 100 mg		

Table 425.6
Medications used for attention-deficit hyperactivity disorder

Medication	Type of agent	Initial dosing	Formulations and duration of action	Comments
Dextroamphetamine and Amphetamine (Adderall®, Adderall XR®)	Stimulant	IR: 2.5–5 mg 1–2 times/day. Max: 40 mg/day	Immediate release tablet (IR): 4–6 h	Use with caution in patients with pre-existing cardiac abnormalities. Monitor for weight loss, insomnia, hypertension, tachycardia, and increased irritability
		ER: 10 mg daily. Max: 30 mg/day	Extended release capsule (ER): 12 h	
Methylphenidate (Concerta®, Daytrana™, Metadate CD®, Metadate® ER, Methylin®, Methylin® ER, Ritalin®, Ritalin LA®, Ritalin-SR®)	Stimulant	IR: 0.3 mg/kg/dose twice daily. Max: 2 mg/kg/day or 60 mg/day	Immediate release (IR) tablet: 2–4 h	Use with caution in patients with pre-existing cardiac abnormalities. Monitor for weight loss, insomnia, hypertension, and tachycardia
		Osmotic: 18 mg daily. Max: 2 mg/kg/day or 72 mg/day	Sustained/extended release tablet and capsules: 6–8 h	
			Osmotic released oral delivery tablet: 12 h	
			Transdermal patch: 9–12 h	
Atomoxetine (Strattera®)	Non-stimulant	0.5 mg/kg/day. Max: 1.4 mg/kg/day or 100 mg/day	Capsule: 6–8 h	Monitor for increased irritability, suicidal thinking, or changes in behaviors. Requires dosage adjustments in patients with hepatic insufficiency. Extensively metabolized by CYP 2D6 system therefore dosage adjustment required in patients who are poor metabolizers
Clonidine (Catapres®)	Non-stimulant	0.05 mg divided 3–4 times/day. Max: 0.3–0.4 mg/day	Tablets: 6–10 h	Rebound hypertension may occur with abrupt withdrawal of medication. Taper gradually over greater than 1 week
			Transdermal patch: 24 h	

Table 425.7

Properties of antiepileptic medications

Drug name	Indications	Dosing	Comments	Target drug levels
Levetiracetam (Keppra®)	Generalized and partial seizures	Initial: 10 mg/kg/dose twice daily; Max: 30 mg/kg/dose twice daily	Avoid abrupt withdrawal of medication due to increase risk of seizures. Requires dose adjustments in patients with renal insufficiency. IV to PO conversion is one-to-one	Therapeutic range has not been established
Oxcarbazepine (Trileptal®)	Partial seizures	Initial: 8–10 mg/kg/day divided 2 times/day; Max: 900 mg–2,100 mg/day (based on weight)	Monitor for hyponatremia and severe dermatological adverse drug reactions. Requires dose adjustments in patients with renal insufficiency	Therapeutic trough levels for epilepsy (Carbamazepine): 4–12 mcg/ml
Phenobarbital	Generalized and partial seizures	Status epilepticus	Potent inducer of the CYP450 system leading to drug–drug interactions. Requires dose adjustments in patients with renal and hepatic insufficiency	Therapeutic trough levels for epilepsy: 15–40 mcg/ml
		Loading dose: 15–20 mg/kg/dose (Max: 40 mg/kg/dose or 1,000 mg/dose)		
		Anticonvulsant		
		Maintenance dose		
		Neonates: 3–4 mg/kg/day daily		
		Infants: 5–6 mg/kg/day divided 1–2 times/day		
		Children:		
		1–5 years: 6–8 mg/kg/day divided 1–2 times/day		
		5–12 years: 4–6 mg/kg/day divided 1–2 times/day		
		>12 years and adults: 1–3 mg/kg/day divided 1–2 times/day		
Phenytoin (Dilantin®, Phenytek®)	Generalized and partial seizures	Status epilepticus: I.V	Potent inducer of the CYP450 system leading to drug–drug interactions. Requires dose adjustments in patients with renal and hepatic insufficiency	Therapeutic trough levels for epilepsy: Total: 10–20 mcg/ml
		Loading dose		
		All ages: 15–20 mg/kg/dose		
		Maintenance dose		Free: 1–2 mcg/ml
		Neonates: Initial: 5 mg/kg/day in two divided doses; usual: 5–8 mg/kg/day in two divided doses		
		Infants and Children: Initial: 5 mg/kg/day in two to three divided doses; usual doses		
		0.5–3 years: 8–10 mg/kg/day		
		4–6 years: 7.5–9 mg/kg/day		
		7–9 years: 7–8 mg/kg/day		
		10–16 years: 6–7 mg/kg/day		
Topiramate (Topamax®)	Generalized and partial seizures	Initial: 1–3 mg/kg/day (max: 25 mg) daily. Maintenance: 5–9 mg/kg/day given in two divided doses (max: 1,600 mg/day)	Requires dose adjustments in patients with renal and hepatic insufficiency. Use caution in patients with sulfa hypersensitivity	Therapeutic levels: 2–20 mg/dl

Table 425.7 (Continued)

Drug name	Indications	Dosing	Comments	Target drug levels
Valproic Acid Derivatives (Depacon®, Depakene®, Depakote®, Stavzor®)	Generalized and partial seizures	Initial: 10–15 mg/kg/day in one to three divided doses; maintenance: 30–60 mg/kg/day in two to three divided doses	Brands are not bioequivalent. Avoid use in children <2 years old due to increased risk of hepatotoxicity.	Therapeutic trough levels for epilepsy: 50–100 mcg/ml
Zonisamide (Zonegran®)	Generalized and partial seizures	Initial: 2–4 mg/kg/day given in two divided doses/day; maintenance dose: 4–8 mg/kg/day divided twice a day; max: 12 mg/kg/day or 400 mg/day	Requires dose adjustments in patients with renal and hepatic insufficiency. Avoid use in patients with sulfonamide hypersensitivity	Proposed therapeutic trough range: 10–30 mcg/ml

Table 425.8
Immunosuppressant medications

Drug name	Dosing	Comments	Supportive care measures
Cyclophosphamide	Systemic lupus erythematosus: I.V.: 500–750 mg/m^2 every month; max: 1 g/m^2	Requires dose adjustments in patients with renal insufficiency. Monitor for hemorrhagic cystitis, nephrotoxicity, SIADH, and pulmonary fibrosis	Use mesna and hydration to prevent hemorrhagic cystitis
	Juvenile rheumatoid arthritis: I.V.: 10 mg/kg every 2 weeks		
	Nephrotic syndrome: Oral: 2–3 mg/kg/day every day		
Cyclosporine (Gengraf®, Neoral®, Sandimmune®)	Transplantations	Requires dose adjustments in patients with hepatic insufficiency. Brands are not bioequivalent. Therapeutic trough levels varies with type of organ transplant and type of assay	
	Renal: 9 mg/kg/day (range: 6–12 mg/kg/day) divided every 12 h		
	Liver: 8 mg/kg/day (range: 4–12 mg/kg/day) divided every 12 h		
	Heart: 7 mg/kg/day (range: 4–10 mg/kg/day) divided every 12 h		
	Focal segmental glomerulosclerosis: Oral: Initial: 3 mg/kg/day divided every 12 h		
	Autoimmune diseases: Oral: 1–3 mg/kg/day		
Methotrexate (Rheumatrex®, Trexall™)	Juvenile rheumatoid arthritis: Oral, I.M., SubQ: Initial: 10 mg/m^2 once weekly	Requires dose adjustments in patients with renal insufficiency. Monitor for hepatotoxicity, nephrotoxicity, and neurotoxicity	High dose treatment will require leucovorin rescue. Add sodium bicarbonate to intravenous fluids to help clear methotrexate

Table 425.8 (Continued)

Drug name	Dosing	Comments	Supportive care measures
Tacrolimus (Prograf®)	Children:	Requires dose adjustments in patients with hepatic insufficiency. Many drug–drug interactions. Therapeutic trough levels varies with type of organ transplant and type of assay	
	Oral:		
	Liver transplant: Initial: 0.15–0.2 mg/kg/day divided every 12 h		
	Heart transplant: Initial: 0.1–0.3 mg/kg/day divided every 12 h		
	Kidney transplant: Initial: 0.2–0.3 mg/kg/day divided every 12 h		
	I.V.:		
	Liver transplant: 0.03–0.05 mg/kg/day as a continuous infusion		
	Heart transplant: 0.01–0.03 mg/kg/day as a continuous infusion		
	Kidney transplant: 0.06 mg/kg/day as a continuous infusion		

Table 425.9
Properties of corticosteroids

Drug name	Formulations	Relative mineralocorticoid/glucocorticoid potency	Conversions
Dexamethasone (Decadron®)	IV, PO	0/25–30	0.75 mg of dexamethasone is equivalent to 5 mg of prednisone
Hydrocortisone (Solu-cortef®)	IV, PO	1/1	20 mg of hydrocortisone is equivalent to 5 mg of prednisone
Methylprednisolone (Solu-medrol®)	IV, PO	0/5	4 mg of methylprednisolone is equivalent to 5 mg of prednisone
Prednisolone (Orapred®, Pediapred®, Prelone®)	PO	0.8/4	1 mg of prednisolone is equivalent to 1 mg of prednisone
Prednisone	PO	0.8/4	1 mg of prednisolone is equivalent to 1 mg of prednisone

Table 425.10
Antibiotic medications

Medication	Indication	Dose	Comments
Penicillins			
Amoxicillin	Acute otitis media (AOM)	Oral:	May cause rash, anaphylaxis, GI upset, diarrhea, anemia, thrombocytopenia, acute interstitial nephritis with large doses of PCN and nafcillin, hepatotoxicity, and phlebitis with nafcillin therapy; and seizures with decreased renal function or increased levels
	Sinusitis	Neonates: 20–30 mg/kg/day divided every 12 h	
	Skin and skin structure infections		
	Urinary tract infections	Infants >3 months and children <40 kg: 25–45 mg/kg/day divided every 8–12 h	
	Community acquired pneumonia (CAP)	AOM: 80–90 mg/kg/day divided every 12 h	
	Lyme disease	CAP: 80–100 mg/kg/day divided every 6–8 h	Take on empty stomach except amoxicillin and amoxicillin/clavulanate
	Endocarditis prophylaxis	Endocarditis prophylaxis: 50 mg/kg 1 h prior to procedure, max 2 g	Adjust doses in renal dysfunction except nafcillin
	H. pylori eradication		
	Postexposure inhalation anthrax prophylaxis	Postexposure inhalation anthrax prophylaxis	
		<40 kg: 45 mg/kg/day divided every 8 h	
		>40 kg: 500 mg every 8 h	
Amoxicillin/ Clavulanic Acid (Augmentin®)	Acute otitis media (AOM)	Oral	
	Sinusitis	Neonates: 30 mg of amoxicillin/kg/day divided every 12 h	
	Skin and skin structure infections	Infants and children <40 kg: 25–45 mg of amoxicillin/kg/day divided every 12 h	
	Urinary tract infections		
	Community acquired pneumonia (CAP)	AOM: 80–90 mg of amoxicillin/kg/day divided every 12 h	
		CAP: 80–100 mg of amoxicillin/kg/day divided every 8 h	
		Children >40 kg: 500 mg every 12 h	
		More severe infection: 500 mg every 8 h	
		Sinusitis and CAP: 2,000 mg every 12 h	

Table 425.10 (Continued)

Medication	Indication	Dose	Comments
Ampicillin	Neonatal sepsis and meningitis	Children PO: 50–100 mg/kg/day divided every 6 h	
	Endocarditis prophylaxis	IV, IM	
	Susceptible bacterial infections caused by streptococci, pneumococci, enterococci, nonpenicillinase-producing staphylococci, *Listeria*, meningococci	Neonates: 100 mg/kg/dose every 6–12 h depending on postnatal age and birth weight	
		Children: 100–200 mg/kg/day divided every 6 h	
	Some strains of *H. influenzae*, *P. mirabilis*, *Salmonella*, *Shigella*, *E. coli*, *Enterobacter*, and *Klebsiella*	Meningitis: 200–400 mg/kg/day divided every 6 h	
		Endocarditis prophylaxis: 50 mg/kg 30 min before procedure, max 2 g	
Ampicillin/ Sulbactam (Unasyn®)	Skin and skin structure infections	IV, IM	
	Aspiration pneumonia	Infants: 100–150 mg/kg/day of ampicillin divided every 6 h	
	Abdominal infections	Meningitis: 200–300 mg/kg/day of ampicillin divided every 6 h	
	Pelvic inflammatory disease (PID)		
		Children: 100–200 mg/kg/day of ampicillin divided every 6 h	
		Meningitis: 200–400 mg/kg/day of ampicillin divided every 6 h	
		Max 8 g of ampicillin/day	
Nafcillin	Osteomyelitis	Mild: 100 mg/kg/day divided every 6 h IV	
	CNS infections	Severe: 100–200 mg/kg/day divided every 4–6 h IV, max 12 g/day	
	Endocarditis		
	Sepsis	Endocarditis: 200 mg/kg/day divided every 4–6 h IV for 6 weeks or longer (if prosthetic valve add gentamicin and rifampin for first 2 weeks)	

Table 425.10 (Continued)

Medication	Indication	Dose	Comments
Penicillin G (Parenteral/ Aqueous) (Pfizerpen®)	Sepsis	IV, IM	Aminoglycosides can inactivate penicillins. Do not mix and separate administration by 30–60 min
	Meningitis	Neonates: 50,000 units/kg/dose every 6–12 h depending on postnatal age and birth weight	
	Pericarditis		
	Endocarditis	Group B Strep meningitis: 250,000–450,000 units/kg/day divided every 6–8 h	
	Pneumonia		
		Infants and children: 100,000–250,000 units/kg/day divided every 4–6 h	
		Severe infections: 250,000–400,000 units/kg/day divided every 4–6 h	
		Max 24 million units/day	
Penicillin V Potassium	Skin and skin structure infections	Children <12 years: 25–50 mg/kg/day PO divided every 6–8 h, max 3 g/day	
	Urinary tract infections		
	Upper respiratory tract infections	≥12 years: 125–500 mg PO every 6–8 h	
	Prophylaxis for rheumatic fever and pneumococcal infections		
Piperacillin/ Tazobactam (Zosyn®)	Sepsis, empiric	IV	
	Skin and skin structure infections	Infants <6 months: 150–300 mg/kg of piperacillin/day divided every 6–8 h	
	Abdominal infections	Children >6 months: 240–400 mg/kg of piperacillin/day divided every 6–8 h (use higher doses divided every 6 h for severe or pseudomonas infections), max 16 g of piperacillin/day	
	Appendicitis		
	Peritonitis		
	PID	Abdominal infections, appendicitis, peritonitis	
	Post-partum endometriosis	Infants <9 months: 240 mg/kg of piperacillin/day divided every 8 h	
	Lower respiratory tract infections		
	Urinary tract infections	Infants and children >9 months and <40 kg: 300 mg/kg of piperacillin/day divided every 8 h	
		Children >40 kg: 3 g of piperacillin (3.375 g of Zosyn) every 6 h	

Table 425.10 (Continued)

Medication	Indication	Dose	Comments
Carbapenems			
Meropenem (Merrem®)	Multi-drug resistant infections	IV	Meropenum can decrease valproic acid levels
	Meningitis	Children ≥3 months:	
	Neutropenic fever	Skin infections: 10 mg/kg/dose every 8 h up to 500 mg per dose	
	Sepsis, empiric		
	Skin and skin structure infections	Abdominal infections and neutropenic fever: 20 mg/kg/dose every 8 h up to 1,000 mg per dose	
	Abdominal infections		
	Lower respiratory tract infections	Meningitis and CF: 40 mg/kg/dose every 8 h up to 2,000 mg per dose	
	CF exacerbations		
	Urinary tract infections		
Cephalosporins			
Cefazolin (Ancef®)	IV first generation cephalosporin	IV, IM	May cause rash, anaphylaxis, GI upset, diarrhea, pseudo-membranous colitis, headaches, dizziness, neutropenia, anemia, eosinophilia, aplastic anemia, thrombocytopenia, and reversible interstitial nephritis. In children <3 years see increase in BUN without increase in creatinine
	Skin and skin structure infections	Neonates: 20 mg/kg every 8–12 h depending on postnatal age and birth weight	
	Lower respiratory tract infections		
	Urinary tract infections	Infants and Children: 25–100 mg/kg/day divided every 6–8 h, max 6 g/day (use 100 mg/kg/day for severe infections)	
	Biliary tract infections		
	Bone and joint infections		
	Genital infections		
	Septicemia		
Cefdinir (Omnicef®)	Oral third generation cephalosporin	PO	Cefdinir may discolor stools and needs to be separated from antacids
	AOM	≥6 months	
	Pharyngitis/tonsillitis	AOM and sinusitis: 14 mg/kg/day divided every 12 h for 5–10 days or 14 mg/kg/day once daily for 10 days, max 600 mg/day	
	Sinusitis		
	Skin and skin structure infections		There is a 10–15% chance of cross reactivity with hypersensitivity reactions from penicillins
	CAP	Skin: 14 mg/kg/day divided every 12 h for 10 days, max 600 mg/day	
	Acute bronchitis		Adjust doses in renal dysfunction except ceftriaxone
	CF exacerbations		

Table 425.10 (Continued)

Medication	Indication	Dose	Comments
Cefepime (Maxipime®)	IV fourth generation cephalosporin	IV, IM	
	Neutropenic fever	Neonates: 30 mg/kg/dose every 12 h	
	Skin and skin structure infections	Children 2 months–16 years: 50 mg/kg/dose IV every 8 h, max 2 g/dose	
	Abdominal infections (with metronidazole)		
	Pneumonia	>16 years: 1–2 g every 12 h (may need dosing every 8 h for pseudomonal infections)	
	Urinary tract infections		
	Pyelonephritis		
Cefixime (Suprax®)	Oral second generation cephalosporin	PO	
	Respiratory tract infections	Infants and children: 16 mg/kg/day divided every 12 h × 1 day, then 8 mg/kg/day once daily, max 400 mg/dose	
	Urinary tract infections	Prophylaxis after sexual attack: 8 mg/kg/dose once daily plus azithromycin, max 400 mg/dose	
	Uncomplicated gonorrhea	Adolescents and adults: Uncomplicated gonorrhea: 400 mg PO × 1 dose plus azithromycin or doxycycline	
Cefotaxime (Claforan®)	IV third generation cephalosporin	IV, IM:	
	Skin and skin structure infections	Neonates: 50 mg/kg/dose every 8–12 h depending on postnatal age and birth weight	
	Lower respiratory tract infections		
	Intra-abdominal infections	Infants and children:	
		<50 kg: 100–200 mg/kg/day divided every 6–8 h	
	Genitourinary tract infections	Meningitis: 200–300 mg/kg/day divided every 6 h	
	Bone and joint infections	>50 kg: Moderate infection: 1–2 g every 6–8 h	
	Meningitis	Severe: 2 g every 4 h, max 12 g/day	

Table 425.10 (Continued)

Medication	Indication	Dose	Comments
Ceftriaxone (Rocephin®)	IV third generation cephalosporin	IV, IM	Ceftriaxone can cause gallbladder sludge. Avoid use in neonates since ceftriaxone will displace bilirubin from albumin and increase risk of kernicterus. Also, do not administer ceftriaxone with calcium containing fluids. Precipitates have occurred in the lungs and kidneys of neonatal patients
	Skin and skin structure infections	Neonates: Gonococcal prophylaxis: 25–50 mg/kg × 1 dose, max 125 mg	
	Lower respiratory tract infections	Infants and children: 50–75 mg/kg/day divided every 12–24 h	
	Intra-abdominal infections	Meningitis: 100 mg/kg/day divided every 12 h, max 4 g/day	
	Urinary tract infections		
	Bone and joint infections	AOM: 50 mg/kg/dose × 1 dose, max 1 g	
	Meningitis	May repeat once daily × 3 doses for persistent AOM	
	Sepsis	Uncomplicated Gonococcal infection:	
	AOM	Children ≤45 kg: 125 mg IM × 1 dose	
	Gonococcal or chancroid infections	Children >45 kg: 250 mg IM × 1 dose	
		Chancroid: 50 mg/kg IM × 1 dose, max 250 mg	
Cefoxitin (Mefoxin®)	IV second generation cephalosporin	IV, IM	
	Respiratory tract infections	Neonates: 90–100 mg/kg/day divided every 8 h	
	Skin and skin structure infections	Infants ≥3 months and children: 80–100 mg/kg/day divided every 6–8 h	
	Bone and joint infections		
	Urinary tract infections	Severe infections: 100–160 mg/kg/day divided every 4–6 h, max 12 g/day	
	Gynecologic infections		
	Septicemia	Perioperative prophylaxis: 30–40 mg/kg 30–60 min prior to surgery and repeated every 6 h for no more than 24 h following surgery	
	Surgical prophylaxis		
	Intra-abdominal infections		

Table 425.10 (Continued)

Medication	Indication	Dose	Comments
Cephalexin (Keflex®)	Oral first generation cephalosporin	PO	Cholestatic jaundice with cephalexin
	Skin and skin structure infections	Children: 25–100 mg/kg/day divided every 6 h, max 4 g/day	
	Respiratory tract infections		
	Genitourinary tract infections	Pharyngitis: 25–50 mg/kg/day divided every 12 h	
	Bone infections		
Macrolides			
Azithromycin (Zithromax®)	AOM	PO	May cause rash, anaphylaxis, GI upset, epigastric pain, diarrhea, chest pain, heart palpitations, jaundice, and photosensitivity reactions. The erythromycin stearate can cause cholestatic hepatits. The IV formulations can cause phlebitis, more common with erythromycin
	Sinusitis	Infants <6 months: Pertussis: 10 mg/kg/dose once daily × 5 days	
	Skin and skin structure infections		
	Urinary tract infections	Children >6 months: 10 mg/kg (max 500 mg) on day 1, then 5 mg/kg (max 250 mg) days 2–5	
	CAP		
	Upper and lower respiratory tract infections	CAP and Sinusitis alternate dosing: 10 mg/kg daily × 3 days, max 500 mg/dose	
	PID	AOM: 30 mg/kg × 1 dose, max 1,500 mg OR 10 mg/kg daily × 3 days, max 500 mg/dose	Stevens-Johnson syndrome and toxic epidermal necrolysis has been seen with azithromycin
	Chancroid and Chlamydia	OR 10 mg/kg (max 500 mg) on day 1, then 5 mg/kg (max 250 mg) days 2–5	
	Pertussis	Pharyngitis: 12 mg/kg/day (max 500 mg) once daily × 5 days	
	CF (to decrease inflammation in chronic pseudomonal infections)		
		Chanroid and Chlamydia: 20 mg/kg × 1 dose, max 1 g	
		CF: 25–40 kg: 250 mg on Monday, Wednesday, and Friday	
		≥40 kg: 500 mg on Monday, Wednesday, and Friday	
		IV	
		Children 6 months–16 years: 10 mg/kg once daily	

Table 425.10 (Continued)

Medication	Indication	Dose	Comments
Erythomycin (Erythrocin®, E.E.S. ®, EryPed®)	Skin infection	Neonates: 25–40 mg/kg/day IV divided every 6 h for Ureaplasma	Erythromycin can cause hypertrophic pyloric stenosis in infants. Generally avoid in infants <1 month
	Upper and lower respiratory tract infections	PO	Erythromycin and clindamyin are antagonistic
	Chancroid and Chlamydia	Infants and children: Base and ethylsuccinate: 30–50 mg/kg/day divided every 6–8 h, max 2 g/day for base and 3.2 g/day for ethylsuccinate	Erythromycin has many drug interactions. Caution use with theophylline, digoxin, carbamazepine, and warfarin
	Pertussis		
	Lyme disease	Chlamydia: 50 mg/kg/day divided every 6 h × 14 days, max 2 g/day	
	Increase motility		
	Ureaplasma in neonates	Pertussis: 40–50 mg/kg/day divided every 6 h × 14 days, max 2 g/day	
		Motility	
		Infants: 3–10 mg/kg/dose every 6–8 h	
		Children: 10–20 mg/kg/day divided every 6–8 h (with meals and at bedtime)	
		IV	
		Lactobionate: 15–50 mg/kg/day divided every 6 h, max 4 g/day	
Miscellaneous			
Ciprofloxacin (Cipro®)	Fluoroquinolone	Children:	Has caused arthropathy of cartilage in weight bearing joints of animals, green discoloration of teeth in newborns, Achilles tendonitis, and rupture. Monitor for CNS stimulation, dizziness, increased ICP, toxic psychosis, tendon pain or swelling, and photosensitivity reactions. Check for drug interactions with ciprofloxacin. Modify dose in renal dysfunction. Administer extended release tablets 2 h after a meal. Do not administer oral suspension into a feeding tube (will adhere to the tube). Separate ciprofloxacin from dairy products, antacids, mineral supplements, iron, zinc, calcium by at least 2 h before and after the dose
	Respiratory or UTI infection with pseudomonas	PO: 20–30 mg/kg/day divided every 12 h, max 1,500 mg/day	
	Skin infections	IV: 20–30 mg/kg/day divided every 12 h, max 800 mg/day	
	Bone and joint infections	Complicated UTI or pyelonephritis:	
	Complicated UTI or pyleonephritis	PO: 20–40 mg/kg/day divided every 12 h, max 1,500 mg/day	
	Infectious diarrhea		
	Cystic fibrosis pulmonary exacerbations	IV: 18–30 mg/kg/day divided every 8 h, max 1,200 mg/day	
	Otitis externa	CF	
	Osteomyelitis	PO: 40 mg/kg/day divided every 12 h, max 2,000 mg/day	
	Gram negative bacterial infections	IV: 30 mg/kg/day divided every 8 h, max 1,200 mg/day	

Table 425.10 (Continued)

Medication	Indication	Dose	Comments
Clindamycin (Cleocin®)	Respiratory infections	Neonates: 5 mg/kg/dose IV every 6–12 h depending on postnatal age and birth weight	Shake solution well before each dose. Take capsules with water to prevent esophageal irritation. Decrease dose in severe renal or hepatic dysfunction. Monitor for severe diarrhea or pseudomembranous colitis
	Skin infections		
	Pelvic inflammatory disease	Infants and children	
	Sepsis	PO: 10–30 mg/kg/day divided every 6–8 h, max 1.8 g/day	
	Intra-abdominal infections	IV: 25–40 mg/kg/day divided every 6–8 h max 4.8 g/day	
	Endocarditis prophylaxis in penicillin allergic patient	Bacterial endocarditis prophylaxis for dental procedures in penicillin allergic patients: 20 mg/kg IV/PO 1 h before procedure	
	Babesiosis		
	Acne	Babesiosis: 20–40 mg/kg/day PO divided every 8 h for 7 days plus quinine	
Doxycycline (Adoxa®, Doryx®, Vibramycin®)	Rickettsia	Children <8 years	Take capsule and tablets with plenty of water to prevent esophageal ulceration. Separate doxycycline from dairy products, antacids, iron by at least 1 h before and 2 h after the dose. Can give with food to decrease stomach upset. Can see some staining of the teeth in children <8 years; may discolor fingernails. Monitor for photosensitivity reactions, GI pain, and IV extravasations
	Ehrlichiosis	Ehrlichiosis: 2 mg/kg PO/IV every 12 h, max 200 mg/day	
	Chlamydia	Tickborne rickettsial disease: 2.2 mg/kg PO/IV every 12 h, max 200 mg/day	
	Mycoplasma		
	Listeria	Children ≥8 years: 2–4 mg/kg/day PO/IV divided every 12 h, max 200 mg/day	
	Clostridium		
	Anthrax		
	Ureaplasma urealyticum		
	Lyme disease		
	Acne		
Linezolid (Zyvox®)	Pneumonia	PO, IV	Avoid pseudoephedrine, SSRIs, and high tyramine foods due to risk of serotonin syndrome. Monitor for vision changes, diarrhea, and vomiting. If on therapy >14 days, monitor for thrombocytopenia. Suspension contains phenylalanine
	Skin infections	Neonates, infants and children:	
	Bacteremia with vancomycin-resistant *Enterococcus faecium* (VREF)	Complicated skin infections, pneumonia, VREF	
		10 mg/kg/dose every 8 h, max 600 mg/dose for children less than 12 years old	
		Uncomplicated skin and skin structure infections	
		Children <5 years: 10 mg/kg every 8 h	
		Children 5–11 years: 10 mg/kg every 12 h	

Table 425.10 (Continued)

Medication	Indication	Dose	Comments
Metronidazole (Flagyl®)	Anaerobic antibacterial agent	Neonates: PO, IV: 7.5 mg/kg every 12–48 h depending on postnatal age and birth weight	Avoid alcohol for 48 h after last dose. Monitor for GI upset, diarrhea, black furry tongue, and red-brown urine. Caution use in patients with seizures and aseptic meningitis. Can decrease metallic taste with acidic liquids
	Trichomoniasis		
	Amebiasis	Anaerobic infections, AAPC:	
	Giardiasis	Infants and children: PO, IV: 30 mg/kg/day divided every 6 h, max dose 4 g/day	
	Antibiotic-associated pseudomembranous colitis (AAPC)	Amebiasis: 35–50 mg/kg/day PO divided every 8 h	
	Skin and skin structure infections	*Helicobacter pylori* infections (in combination with amoxicillin and bismuth subsalicylate): 15–20 mg/kg/day PO divided every 12 h	
	Bone and joint infections		
	CNS infections		
	Intra-abdominal infections		
	Gynecological infections		
Sulfamethoxazole/Trimethoprim (Bactrim™, Septra®, Sulfatrim®)	UTI	Mild infections: 6–12 mg/kg/day of trimethoprim PO/IV divided every 12 h	Do not use in children <2 months of age due to risk of kernicterus. Avoid use in sulfa allergic patients
	Chronic bronchitis		
	Shigella	Severe infections/PCP treatment: 15–20 mg/kg/day of trimethoprim PO/IV divided every 6 h	Adjust dose for renal impairment. Rare cases of Stevens-Johnsons Syndrome reported. Discontinue medication if rash appears
	Nocardia		
	Pneumocystis jiroveci pneumonitis (PCP)		
		PCP prophylaxis: 150 mg trimethoprim/m^2/day PO divided every 12 h 3 days/week on consecutive or alternate days	Administer oral formulations with plenty of fluids
		UTI prophylaxis: 2 mg/kg/day of trimethoprim PO given once daily	
Vancomycin (Vancocin®)	MRSA	IV	Administer IV over 60 min. If rash or redness appears on face or neck, slow infusion to 90–120 min
	Coagulase negative *Staphylococcus*	Neonates: 10–15 mg/kg/dose every 8–24 h depending on postnatal age and birth weight	
	Endocarditis		
	Meningitis	Infants and children: 10–15 mg/kg/dose every 6 h	Monitor for hearing loss and renal dysfunction. Monitor serum troughs around third to fourth dose. Goal trough is 10–20 mcg/ml
	Osteomylitis	Serious infections (meningitis, MRSA): 15–20 mg/kg/dose every 6–8 h	
	Line infections		
	VP shunt infections	PO (Antibiotic-associated pseudomembranous colitis, AAPC)	
	Graft infections		
	Prosthetic valve infections	Children: 10 mg/kg/dose every 6 h, max 2 g/day (metronidazole is initial drug of choice)	

Table 425.11
Antifungal medications

Medication	Indication	Dose	Comments
Amphotericin B	Severe infections or meningitis caused by *Candida*, *Histoplasma*, *Cryptococcus neoformans*, *Aspergillus*, *Mucor*, *Blastomyces*, *Torulopsis glabrata*	IV	Administer over 4 to 6 h. Rapid infusions cause hypotension, hypokalemia, and arrhythmias
		Initial dose: 0.25–1 mg/kg/day once daily	
		Severe infections: 1 mg/kg/day once daily	Monitor for anaphylaxis with first dose. Infusion related reactions include chills, rigors, and fever. This can be prevented with administration of acetaminophen and diphenhydramine. Meperidine can be used if rigors occur. Other adverse reactions include renal failure, hypokalemia, hypomagnesemia, hyperglycemia, phlebitis, increase in LFTs
			Sodium loading before each dose can help to prevent renal failure. Administer 10–20 ml/kg of NSS or 0.45% NSS before the dose
Amphotericin B Liposome (AmBisome®), Amphotericin B Lipid Complex (Abelcet®)	Febrile, neutropenic patients	AmBisome, IV	Administer over 1 to 2 h
	Severe infections or meningitis caused by *Candida*, *Histoplasma*, *Cryptococcus neoformans*, *Aspergillus*, *Mucor*, *Blastomyces*, refractory to conventional amphotericin	Empiric therapy: 3 mg/kg/day once daily	
		Systemic fungal infections: 3–5 mg/kg/day once daily, up to 10 mg/kg/day in documented *Aspergillus* infections	Monitor for anaphylaxis with first dose. Infusion related reactions include chills, rigors, and fever. This can be prevented with administration of acetaminophen and diphenhydramine. Meperidine can be used if rigors occur. Other adverse reactions include renal failure (incidence less common than with conventional amphotericin), hypokalemia, hypomagnesemia, hyperglycemia, phlebitis, increase in LFTs
		Cryptococcal meningitis: 6 mg/kg/day once daily	
	Fungal infections in patients with renal impairment	Abelcet, IV	
		2.5–5 mg/kg/day once daily	
Caspofungin Acetate (Cancidas®)	Febrile, neutropenic patients	IV	Administer over 1–2 h
	Severe infections caused by *Candida*, or *Aspergillus*	Preterm neonates to infants <3 months: 25 mg/m^2/dose once daily	Use caution in patients with hepatic dysfunction
		3 months–17 years: 70 mg/m^2/dose on day 1, then 50 mg/m^2/dose once daily	Monitor for anaphylaxis, phlebitis, vomiting, diarrhea, abdominal pain, cough, edema in extremities, and chest pain
		Can increase dose to 70 mg/m^2/dose if no clinical response, max dose 70 mg	
		Patients receiving enzyme inducers should receive 70 mg/m^2/dose once daily	

Table 425.11 (Continued)

Medication	Indication	Dose	Comments
Fluconazole (Diflucan®)	Susceptible *Candida* infections	Neonates >2 weeks, infants, and children: 6–12 mg/kg/day IV/PO once daily	Better activity against *C. albicans*
			Shake oral suspension well before each dose. Suspension is stable for 14 days at room temperature
	Prophylaxis in bone marrow transplant patients		Monitor for bleeding, bruising, skin rash, nausea, vomiting, headache, yellowing of skin, or eyes and anaphylaxis with first dose
			Check for drug interactions with other therapies
Voriconazole (VFEND®)	Treatment of invasive *Candida*, or *Aspergillus*	IV	Administer oral medication on empty stomach
	Treatment of serious fungal infections caused by *Scedosporium apiospermum* or *Fusarium*	Children >2 years to Adults: 6 mg/kg every 12 h × 2 doses, then 4 mg/kg every 12 h	Monitor for vision changes (blurry), photophobia, rash, increased LFTs, hepatitis, cholestasis, acute renal failure, hypokalemia, photosensitivity, cardiac arrhythmias, and QT prolongation
		Invasive aspergillosis: 5–7 mg/kg/dose every 12 h	
		PO	
		<40 kg: 100 mg every 12 h; if response inadequate, may increase to 150 mg every 12 h	Check for drug interactions with other therapies
		>40 kg: 200 mg every 12 h; if response inadequate, may increase to 300 mg every 12 h	IV formulation should not be used in patients with renal dysfunction (CrCl <50 ml/min)
Griseofulvin (Grifulvin V®, Gris-PEG®)	Tinea on skin or hair	>2 years: 20–25 mg/kg/day once daily PO for 6–8 weeks	Shake oral suspension well before each dose. Administer with fatty meal to increase absorption
			Monitor for photosensitivity reactions, nausea, vomiting, diarrhea, and increases in LFTs (generally not seen in first 6–8 weeks of therapy)
Nystatin	Oral *Candida*	Neonates: 50,000 units to each side of mouth four times daily	Shake oral suspension well before each dose
		Infants and Children: 100,000 units to each side of mouth four times daily	Monitor for local irritation, diarrhea, vomiting. Rare cases of Stevens-Johnsons Syndrome reported

Table 425.12
Antiviral medications

Medication	Indication	Dose	Comments
Acyclovir (Zovirax®)	Initial and prophylactic treatment of herpes simplex virus (HSV1) and (HSV2) infections	HSV encephalitis:	Shake suspension well before each dose
		Neonates – 12 years: 20 mg/kg/dose IV every 8 h	Administer IV slowly over 1 h to avoid crystalluria
	HSV encephalitis	Children >12 years–Adults: 10–15 mg/kg/dose IV every 8 h	Adjust dose in renal dysfunction
	Herpes zoster (shingles) infection	HSV infection, first infection: Children: 40–80 mg/kg/day PO divided three to four times daily, max 1,000 mg/day	With IV monitor for phlebitis, renal dysfunction, bone marrow suppression, increases in LFTs, and hyperbilirubinemia
	Varicella–zoster (VZV) infection	Recurrent HSV infection: Children: 40–80 mg/kg/day PO divided three times daily, max 1,000 mg/day	
		Herpes zoster (shingles) in immunocompetent patient	
		PO: ≥12 years: 800 mg five times a day	
		IV: Infants <1 year: 10 mg/kg/dose every 8 h	
		Children ≥1 year: 10 mg/kg/dose or 500 mg/m^2/dose every 8 h	
		Herpes zoster (shingles) in immunocompromised patient	
		Infants to adults (all ages): 10 mg/kg/dose IV every 8 h	
		Varicella zoster in immunocompetent patient	
		PO: Children ≥2 years and ≤40 kg: 20 mg/kg/dose four times daily, max 3,200 mg/day	
		Children ≥40 kg to Adults: 800 mg four times daily	
		IV: Children ≥2 years: 10 mg/kg/dose or 500 mg/m^2/dose every 8 h	
		Varicella zoster in immunocompromised patient	
		Infants <1 year: 10 mg/kg/dose IV every 8 h	
		Children 1–12 years: 10–20 mg/kg/dose or 500 mg/m^2/dose IV every 8 h	
		Children >12 years–adult: 10–15 mg/kg/dose IV every 8 h	

Table 425.12 (Continued)

Medication	Indication	Dose	Comments
Ganciclovir (Cytovene®)	Treatment or prophylaxis of CMV	IV	Administer oral medication with food. Do not open or crush oral capsules. Administer IV slowly over 1 h. Handle as cytotoxic medication
		Congenital CMV infection: Neonates and Infants: 12 mg/kg/day divided every 12 h	
			Adjust dose in renal dysfunction
		Prophylaxis of CMV: 10 mg/kg/day divided every 12 h for 1–2 weeks, then 5 mg/kg/day once daily or 30 mg/kg/dose PO every 8 h, max 1,000 mg/dose for maintenance	Monitor for phlebitis, renal dysfunction, nausea, vomiting, pancreatitis, vision changes, neutropenia, thrombocytopenia, and increases in LFTs
Lamivudine (Epivir®)	Treatment of HIV infection	PO	Adjust dose in renal dysfunction.
	Prophylaxis of HIV exposure	HIV infection	Use with extreme caution in pediatric patients with a history of pancreatitis
	Treatment of chronic hepatitis B infections	Neonates <30 days: 2 mg/kg/dose twice daily	
		Infants 1 month of age to adults: 4 mg/kg/dose every 12 h, max 150 mg every 12 h	Monitor for pancreatitis, lactic acidosis, hepatomegaly, persistent severe abdominal pain, nausea, vomiting, numbness, or tingling. Avoid alcohol
		Chronic hepatitis B infection	
		Children 2–17 years: 3 mg/kg/dose once daily, max 100 mg/day	
		HIV postexposure prophylaxis: Children ≥16 years to adults: 150 mg twice daily or 300 mg once daily (in combination with zidovudine, tenofovir, stavudine, or didanosine, with or without a protease inhibitor)	
Oseltamiviz (Tamiflu®)	Treatment of influenza A or B infection	PO	Treatment should be initiated within 48 h of symptoms
		Treatment: Children ≥1 year to adults	
			Adjust dose in renal dysfunction
	Prophylaxis of influenza A or B infection	≤15 kg: 30 mg twice daily for 5 days	Monitor for hallucinations, confusion, unusual behavior, and self-injury
		>15 kg to 23 kg: 45 mg/dose twice daily for 5 days	
		>23 kg to 40 kg: 60 mg/dose twice daily for 5 days	Other adverse reactions include diarrhea, abdominal pain, vomiting, and anaphylaxis
		>40 kg: 75 mg/dose twice daily for 5 days	
		Prophylaxis: Children ≥1 year to adults:	
		≤15 kg: 30 mg once daily	
		>15 kg to ≤23 kg: 45 mg once daily	
		>23 kg to ≤40 kg: 60 mg once daily	
		>40 kg: 75 mg once daily	

Table 425.12 (Continued)

Medication	Indication	Dose	Comments
Palivizumab (Synagis®)	Prevention of serious lower respiratory infections due to respiratory syncytial virus (RSV) in infants and children at high risk for RSV disease	Infants <24 months of age: 15 mg/kg IM once a month during RSV season	Monitor for rare anaphylaxis
		The American Academy of Pediatrics recommends RSV prophylaxis with palivizumab during RSV season for:	
		Infants <3 months of age who were born between 32 and $34^{6}/_{7}$ weeks gestational age and have one of the following: Daycare attendance; ≥1 sibling who is <5 years of age living in the same household	
		Infants <6 months of age who were born between 29 and $31^{6}/_{7}$ weeks gestational age	
		Infants <12 months of age who were born ≤28 weeks gestational age	
		Infants <12 months of age with congenital airway abnormality or neuromuscular disorder that decreases the ability to manage airway secretions	
		Infants and children <24 months of age with chronic lung disease (CLD) necessitating medical therapy within 6 months of age prior to the beginning of RSV season	
		Infants and children <24 months with congenital heart disease and one of the following: Receiving medication to treat congestive heart failure; Moderate to severe pulmonary hypertension; Cyanotic heart disease	
Valacyclovir (Valtrex®)	Varicella zoster (chickenpox) infection	PO	Adjust dose in renal dysfunction
	HSV and VZV prophylaxis in immunocompromised children	Varicella zoster: 2 years–18 years: 20 mg/kg/dose three times daily, max 1,000 mg/dose	Monitor for thrombotic thrombocytopenic purpura/hemolytic uremic syndrome, headache, nausea, vomiting, vision changes, behavioral changes, bleeding or bruising, neutropenia, thrombocytopenia, and increases in LFTs
	Herpes labialis	HSV or VZV prophylaxis: 15–30 mg/kg/dose three times daily, max 2,000 mg/dose	
		Herpes labialis: Children >12 years: 2 g every 12 h for 1 day	
Valganciclovir (Valcyte®)	Treatment or prophylaxis of CMV	PO	Do not substitute these capsules for ganciclovir. They are not equivalent
		Congenital CMV infection: >7 days to 3 months: 16 mg/kg/dose every 12 h	Administer oral medication with food. Do not open or crush oral capsules. Handle as cytotoxic medication
		Prophylaxis of CMV: 4 months to 16 years	

Table 425.12 (Continued)

Medication	Indication	Dose	Comments
		7 × BSA × creatinine clearance = dose once daily, max 900 mg/day	Monitor for renal dysfunction, nausea, vomiting, pancreatitis, vision changes, hallucinations, peripheral neuropathy, psychosis, seizures, dehydration, hyperglycemia, hypocalcemia, hypomagnesemia, hypophosphatemia, neutropenia, thrombocytopenia, and increases in LFTs
Zidovudine (Retrovir®)	Treatment of HIV infection	Prophylaxis of perinatal HIV transmission	May be administered without regard to meals. Administer IV over 1 h. Hazardous agent; use appropriate precautions for handling and disposing
	Prophylaxis to reduce perinatal transmission	Neonates <35 weeks gestational age (GA) at birth	
		IV: 1.5 mg/kg/dose every 12 h	Check for drug interactions with other therapies
	Prophylaxis of HIV exposure	PO: 2 mg/kg/dose every 12 h	Monitor for muscle weakness, shortness of breath, headache, insomnia, signs of infection, unusual bleeding, rash, lactic acidosis, hepatotoxicity, anemia, and bone marrow suppression
		Increase to every 8 h dosing	
		GA at birth <30 weeks: Increase above dose to every 8 h at 4 weeks of age	
		GA at birth ≥30 weeks: Increase above dose to every 8 h at 2 weeks of age	
		Neonates >35 weeks gestational age at birth	
		IV: 1.5 mg/kg/dose every 6 h	
		PO: 2 mg/kg/dose every 6 h	
		Treat for first 6 weeks of life. Use IV route only until oral route can be given	
		HIV infection	
		Dosing based on body surface area	
		Infants ≥4 weeks old to <18 years	
		240 mg/m^2/dose every 12 h, max 300 mg every 12 h or 160 mg/m^2/dose every 8 h, max 200 mg every 8 h	
		Dosing based on weight	
		4 to <9 kg: 12 mg/kg/dose twice daily or 8 mg/kg/dose 3 times/day	
		≥9 to <30 kg: 9 mg/kg/dose twice daily or 6 mg/kg/dose 3 times/day	
		≥30 kg: 300 mg twice daily or 200 mg 3 times/day	
		HIV postexposure prophylaxis: Children ≥12 years to Adults: 300 mg twice daily or 200 mg 3 times/day (in combination with lamivudine or emtricitabine, with or without a protease inhibitor)	
		Begin therapy within 2 h of exposure if possible	

Table 425.13
Hematologic medications

Drug	Indications	Dosing	Comment	Monitoring and administration instructions
Deferasirox (Exjade®)	Treatment of chronic iron overload due to blood transfusions	Initial: 20 mg/kg daily Maintenance: 20–30 mg/kg/day; Max: 40 mg/kg/day	Monitor for renal and hepatic impairments and gastric bleeds	Disperse tablets in water, orange juice, or apple juice
Enoxaparin (Lovenox®)	Prophylaxis and treatment of thromboembolic disorders	Infants <2 months Prophylaxis: 0.75 mg/kg/dose every 12 h	Requires dose adjustments in patients with renal insufficiency	Therapeutic antifactor Xa levels for treatment: 0.5–1 units/ml
		Treatment: 1.5 mg/kg/dose every 12 h	Higher doses may be needed in neonates and infants	Therapeutic antifactor Xa levels for prophylaxis: 0.2–0.45 units/ml
		Infants ≥2 months and Children ≤18 years Prophylaxis: 0.5 mg/kg/dose every 12 h Treatment: 1 mg/kg/dose every 12 h		
Epoetin Alfa (Epogen®, Procrit®)	Treatment of anemia associated with chronic diseases	Anemia of prematurity: Neonates: 25–100 units/kg/dose 3 times/week or 100 units/kg/dose 5 times/week or 200 units/kg/dose every other day for ten doses Anemia in cancer patients Children 6 months to 18 years: 25–300 units/kg 3–7 times/week	Patients need to have adequate iron stores	Goal is hemoglobin between 10–12 g/dl
Ferrous Sulfate (Fer-In-Sol®)	Prevention and treatment of iron deficiency anemia	Severe iron deficiency anemia: 4–6 mg elemental iron/kg/day in 3 divided doses Mild to moderate iron deficiency anemia: 3 mg elemental iron/kg/day in one to two divided doses Prophylaxis: 1–2 mg elemental iron/kg/day iron/day	Oral is the preferred route of administration. Should be dosed in mg of elemental iron	May interfere with the absorption of tetracyclines and fluoroquinolones. Do not take with milk or antacids
Filgrastim (Neupogen®)	Reduction of the duration of neutropenia	Neonates: 5–10 mcg/kg/day Children and adults: 5–10 mcg/kg/day	May be given subcutaneous or intravenous	Monitor absolute neutrophil counts to determine duration of therapy
Heparin	Prophylaxis and treatment of thromboembolic disorders	Neonates and Infants <1 year: I.V. infusion: Initial loading dose: 75 units/kg given over 10 min; then initial maintenance dose: 28 units/kg/h; adjust dose to maintain antifactor Xa level of 0.35–0.7 units/ml Children >1 year I.V. infusion: Initial loading dose: 75 units/kg given over 10 min, then initial maintenance dose: 20 units/kg/h; adjust dose to maintain antifactor Xa level of 0.35–0.7 units/ml	High alert medication. Many different concentrations exist	Goal is antifactor Xa level of 0.35–0.7 units/ml or PTT 1.5–2.5 times control value

Table 425.13 (Continued)

Drug	Indications	Dosing	Comment	Monitoring and administration instructions
Phytonadione	Prevention and treatment of hypoprothrombinemia caused by vitamin K deficiency	Hemorrhagic disease of the newborn: Neonates: SubQ, I.M. Prophylaxis: 0.5–1 mg within 1 h of birth Treatment: 1–2 mg/day	Oral route preferred due to increased risk of hypersensitivity reaction with IV administration	Maximum IV rate is 1 mg/min
Rasburicase (Elitek™)	Management of hyperuricemia in patients at risk for tumor lysis syndrome	0.2 mg/kg/dose once daily, duration based on uric acid levels	Avoid use in patient with G6PD deficiency	Can interact with uric acid measurements in the laboratory
Warfarin (Coumadin®)	Prophylaxis and treatment of thromboembolic disorders	Initial loading dose on day 1: 0.1–0.2 mg/kg (max dose: 10 mg) Usual maintenance range: 0.05–0.34 mg/kg/day	Maintain consistent Vitamin K intake. Many drug–drug interactions	Goal INR is two to three for deep vein thrombosis

Table 425.14
Gastrointestinal medications

Drug	Drug class	Indication	Dosing	Comments and special administration instructions
Lansoprazole (Prevacid®)	Proton-pump inhibitor	Gastroesophageal reflux disease, Zollinger-Ellison syndrome, and ulcers associated with *Helicobacter pylori*	Oral Infants ≥3 months: 1–2 mg/kg/day or 7.5 mg twice daily or 15 mg once daily Children 1–11 years ≤30 kg: 15 mg daily >30 kg: 30 mg daily Max: 30 mg twice daily	Administer dose 30 min before meals
Pantoprazole (Protonix®)	Proton-pump inhibitor	Gastroesophageal reflux disease, Zollinger-Ellison syndrome, ulcers associated with *Helicobacter pylori*	Children: Oral/IV: 0.5–1 mg/kg/day Max: 40 mg twice daily	Administer dose 30 min before meals
Ranitidine (Zantac®)	Histamine 2 receptor antagonist	Ulcers, gastroesophageal reflux disease (GERD)	Premature and Term Infants <2 weeks Oral: 2 mg/kg/day divided every 12 h I.V.: 1.5–2 mg/kg/day divided every 12 h Children ≥1 month to 16 years Oral: 4–8 mg/kg/day divided twice daily; max: 300 mg/day I.V.: 2–4 mg/kg/day divided every 6–8 h; maximum: 200 mg/day	Requires dose adjustments in patients with renal insufficiency. Administer with meals and at bedtime

Table 425.14 (Continued)

Drug	Drug class	Indication	Dosing	Comments and special administration instructions
Sucralfate (Carafate®)		Gastrointestinal ulcers; prevention of stress ulcers	Oral: 40–80 mg/kg/day divided every 6 h; Max: 1 g/dose	Avoid use in patients with renal insufficiency due to potential accumulation of aluminum. May interfere with the absorption of other medications. Recommend administering other medications 2 h before or after sucralfate administration
Metoclopramide (Reglan®)	Dopamine antagonist	Gastroesophageal reflux and prevention of nausea and vomiting	Oral/IV: 0.4–0.8 mg/kg/day in four divided doses	Requires dose adjustments in patients with renal insufficiency. Monitor for extrapyramidal symptoms. IV to PO conversion is one-to-one
Ondansetron (Zofran®)	5-HT3 receptor antagonist	Prevention of nausea and vomiting associated with chemotherapy or radiotherapy	Oral	Requires dose adjustments in patients with hepatic insufficiency
			<0.3 m^2: 1 mg 3 times/day	
			0.3–0.6 m^2: 2 mg 3 times/day	
			0.6–1 m^2: 3 mg 3 times/day	
			>1 m^2: 4 mg 3 times/day	
			or	
			Children 4–11 years: 4 mg 3 times/day	
			Children >11 years and Adults: 8 mg 3 times/day or 24 mg once daily	
			IV: 0.15 mg/kg 30 min prior to chemotherapy	
Ursodiol (Actigall®)		Prevention and treatment of gallstone. Primary biliary cirrhosis and treatment of cholestasis	10–15 mg/kg/day (Max: 30 mg/kg/day in two to three divided doses)	Monitor for hepatotoxicity
Pancrelipase (Creon®, Pancreaze™, Pancrelipase™, Zenpep™)	Pancreatic enzymes	Treatment of exocrince pancreatic insufficiency	≤ 1 year: Lipase 2,000–4,000 units per 120 ml of formula, breast milk, or per breast-feeding	Brands are not bioequivalent. Do not chew or crush capsules
			>1 to <4 years: Initial dose: Lipase 1,000 units/kg/meal. Dosage range: Lipase 1,000–2,500 units/kg/meal. Max: Lipase 10,000 units/kg/day or lipase 4,000 units/g of fat/day	
			≥ 4 years: Lipase 500 units/kg/meal. Dosage range: Lipase 500–2,500 units/kg/meal. Max: Lipase 10,000 units/kg/day or lipase 4,000 units/g of fat/day	
Polyethylene Glycol 3350 (Miralax®)	Osmotic laxative	Treatment of constipation	Children >6 months: 0.5–1.5 g/kg daily (Max: 100 g/day)	Mix 17 g in 120–240 ml of water, juice, or other beverages

Table 425.15

Properties of insulin preparations

Type of insulin	Insulin	Onset of action	Time to reach peak (h)	Duration of action (h)	Total daily insulin dose
Long-acting	Detemir (Levemir®)	1–2 h	6–8	10–20	0.5–1 units/kg/day
	Glargine (Lantus®)	1–1.5 h	No peak	20–24	
	NPH (Humulin N®, Novolin N®)	1–2 h	4–12	18–20	
Short-acting	Regular (Humulin R®, Novolin R®)	30–60 min	2–5	5–8	
Rapid-acting	Aspart (Novolog®)	5–15 min	0.5–2	3–5	
	Glulisine (Apidra®)	20 min	0.75–1	5	
	Lispro (Humalog®)	5–1	0.5–2	3–5

Disclaimer

Care has been taken to confirm the accuracy of the information presented and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of this information in a particular situation remains the professional responsibility of the practitioner.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in this publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the health care provider to ascertain the FDA status of each drug or device planned for use in their clinical practice.
