Supplementation with vitamin K is recommended for newborn infants to increase levels of the vitamin K–dependent proteins and prevent bleeding in the neonatal period. A great deal of debate has occurred regarding the relative merits of IM versus oral vitamin K, particularly due to the concern for an increased risk of leukemia which had been reported in an earlier British study. Subsequent studies, however, have failed to show a link between IM vitamin K and cancer. Some countries, however, recommend the use of oral vitamin K preferentially. If vitamin K is administered orally, it is important to recognize that multiple doses are required to prevent late VKDB. IM vitamin K at a dose of 0.5–1 mg is recommended for all neonates. In the event that an oral regimen is chosen, typical dosing is 1–2 mg on day of life 1, then again around 1 week and around 4 weeks of age. Alternate regimens prescribe 2 mg of oral vitamin K weekly until the infant is 3 months of age.

Diagnosis of VKDB is made on the basis of a prolonged PT and prolonged PTT, with a greater prolongation in the PT as compared to the PTT. Vitamin K–dependent clotting factors will be low, with normal levels of nonvitamin K–dependent clotting factors such as factor V and factor VIII. Treatment should not wait for confirmation of the diagnosis, but rather vitamin K should be administered as soon as the diagnosis is suspected. If severe bleeding, such as intracranial hemorrhage or GI bleeding, is present, emergent treatment may be required. Fresh frozen plasma is usually readily available, but other treatment options include prothrombin complex concentrates or rFVIIa.

Neonatal Thrombocytopenia and Other Platelet Defects

Quantitative platelet disorders in neonates may be due to decreased production or increased destruction (*Table 334.4*). Decreased production is typically secondary to inherited platelet disorders. Congenital amegakaryocytic thrombocytopenia, a disorder where megakaryocytes are absent or significantly reduced, presents with petechiae or bruising. Thrombocytopenia-absent radii (TAR) syndrome is, as the name implies,

Table 334.4
Differential diagnosis of neonatal thrombocytopenia

Immune-mediated	Inherited quantitative defects	Qualitative defects	Acquired thrombocytopenias
Neonatal alloimmune thrombocytopenia	Congenital amegakaryocytic thrombocytopenia	Drugs: aspirin, indomethacin	Sepsis
Maternal ITP	TAR syndrome	Diet	DIC
Neonatal ITP	Wiskott–Aldrich syndrome	Maternal alcohol use	Necrotizing enterocolitis
Drug-dependent antibodies	Jacobsen syndrome	Maternal tobacco use	Kasabach–Merritt syndrome
	X-linked macrothrombocytopenia	Maternal diabetes	Perinatal asphyxiation
	Bernard–Soulier syndrome	Nitric oxide	
	Velocardiofacial syndrome	ECMO	
	MYH-9 disorders		

ITP immune-mediated thrombocytopenic purpura, *ECMO* extracorporeal membrane oxygenation

a syndrome where thrombocytopenia is associated with skeletal abnormalities including radial hypoplasia. The diagnosis is generally not difficult due to the characteristic limb appearance. Wiskott–Aldrich syndrome is an X-linked thrombocytopenia which also manifests with eczema and immune deficiency. Platelets are characteristically small. Neonates may present with bloody diarrhea, but infection due to the immune deficiency is also a serious risk.

There are several disorders that lead to decreased platelet production and large platelets. Jacobsen syndrome, otherwise known as Paris–Trousseau syndrome, involves macrothrombocytopenia as well as mental retardation, facial dysmorphogenesis, and cardiac abnormalities. The defect has been localized to a deletion of part of chromosome 11. X-linked macrothrombocytopenia is due to mutations in GATA-1 and may also present with anemia. Bernard–Soulier syndrome is a defect in glycoprotein (GP) Ib or associated proteins GPIX or GPV. Platelets are large and characterized by defective aggregation in response to ristocetin, which induces VWF binding to platelet GPIb. Platelet aggregation with other agonists, however, is normal in Bernard–Soulier syndrome. Velocardiofacial syndrome, a gene deletion syndrome involving chromosome 22q11.2, may manifest with macrothrombocytopenia similar to that seen in Bernard–Soulier syndrome due to deletion of the GPIbα gene in this region. Macrothrombocytopenia may also be caused by a defect in MYH-9, the myosin heavy chain, which has now been found to be the underlying problem in a number of platelet disorders, including Epstein syndrome, Fechtner syndrome, May–Hegglin anomaly, and Sebastian syndrome.

Qualitative platelet disorders are generally due to medications or other treatments the neonate is receiving. Maternal medications, diet, alcohol, or tobacco use may also induce temporary platelet dysfunction. Maternal diabetes may actually lead to platelet hyperreactivity with increased platelet aggregation, although the clinical significance of this finding is unclear. Aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) lead to platelet dysfunction, either permanently with the use of aspirin or temporarily with the use of other NSAIDs. Indomethacin is frequently used to induce closure of a patent ductus arteriosus in premature infants, and may contribute to qualitative platelet dysfunction in newborns. Nitric oxide also interferes with platelet adhesion by inhibition of platelet aggregation in response to ADP. Extracorporeal membrane oxygenation (ECMO) is associated with bleeding complications, primarily due to the need for anticoagulation and depletion of clotting factors, but is also associated with platelet dysfunction due to chronic activation.

Neonatal Alloimmune Thrombocytopenia

Platelet destruction may occur through immune-mediated or nonimmune mechanisms. The most common cause of immune-mediated thrombocytopenia in neonates is neonatal alloimmune thrombocytopenia (NAIT). NAIT is quite common, with an incidence of around 1:1,000. In NAIT, the father's platelets have an antigen not present on maternal platelets. When the infant inherits this antigen, the mother recognizes it as foreign and makes antibodies, which cross the placenta and lead to thrombocytopenia in the fetus. Thrombocytopenia may be severe. NAIT carries a high risk of intracranial hemorrhage, up to 20% of affected neonates. Diagnosis is made by testing the reactivity of maternal serum against the father's platelets. The most frequent antigen responsible for NAIT is HPA-1a, or PI^{A1}, although other antigens may also cause NAIT. Treatment involves infusion of platelets lacking the causative antigen. Until a suitable donor is found, washed maternal platelets may be used, as these are typically the most readily available. Some blood banks stock HPA-1a negative platelets for use in such cases. While waiting for suitable platelets to become available, random donor platelets may be used, as infants may still respond. In addition, IVIG may be used for NAIT, typically at a dose of 1 g/kg. Head ultrasound is recommended to evaluate any infant at risk of intracranial hemorrhage.

Maternal autoimmune thrombocytopenia may lead to temporary thrombocytopenia in the neonate due to IgG antibodies crossing the placenta in mothers affected with immune-mediated thrombocytopenic purpura (ITP) or systemic lupus erythematosus (SLE). Passive antibodies are more common with true ITP in neonates due to an endogenous antibody, a rare occurrence except in the setting of immune dysfunction. Drug-dependent antibodies may also cause immune-mediated thrombocytopenia less commonly in this age group. Thrombocytopenia due to acquired antibodies will resolve within the first several months of life.

Nonimmune Thrombocytopenia

Destruction may also be nonimmune-mediated. Thrombocytopenia is common in the NICU setting, present in anywhere from 6% to 22% of infants. The most common

cause in sick neonates is sepsis, which commonly presents with thrombocytopenia and may also present with DIC. Both bacterial and viral infections may be the cause. Some infections may also lead to decreased production. Premature infants may also experience thrombocytopenia related to necrotizing enterocolitis, respiratory distress syndrome, and persistent pulmonary hypertension. Perinatal asphyxiation has been associated with thrombocytopenia. Vascular malformations such as Kasabach–Merritt syndrome lead to consumption of platelets (and coagulation factors). Affected infants may present with systemic bleeding due to the severe thrombocytopenia.

Treatment of decreased platelet function or decreased platelet number due to a production defect consists of administration of platelets, generally at a dose of 10–15 mL/kg. Unless there is a treatable underlying cause, platelet support may need to be continued for some time. The precise threshold for transfusion is not entirely clear. Most physicians consider a platelet count less than 50,000 to signify an increased risk of bleeding. A survey of neonatologists showed that most transfused a bleeding neonate with a platelet count of <50,000, but most used a platelet count of <20,000 as the threshold for prophylactic transfusions. Transfusion thresholds of 30,000 as compared to 50,000 in one study did not demonstrate a difference in risk of hemorrhage.

Thrombotic Disorders in the Neonate

Like the neonate, the study of thrombosis in infants and children is rapidly evolving. During childhood, the greatest risk of thromboembolism is in the neonatal period. The greatest incidence reported, from the Canadian childhood thrombosis registry, is 2.4 per 1,000 admissions to the neonatal intensive care unit. As in hemostasis, the delicate balance between coagulation and anticoagulation proteins may be disturbed by a number of acquired conditions, which then can predispose to thromboembolism. Most infants who develop abnormal clots have comorbid conditions that predispose to thrombosis. However, given that not all sick neonates develop clots and that thrombosis sometimes occur in newborns who are otherwise healthy, genetic factors may also play a role. Virchow's triad, the intersection between the vasculature, blood flow, and blood clotting proteins, applies to neonatal thrombosis as well (*Table 334.5*).

Thrombophilia is the term used to describe a range of defects in coagulation, fibrinolysis, endothelial cells, and primary hemostasis that can predispose to thrombosis. Most of these conditions are inherited, but some, like antiphospholipid syndrome, may be acquired (*Table 334.6*). In the neonate, antiphospholipid antibodies are most likely maternal.

Table 334.5
Virchow's triad in the neonate

Abnormal vessel wall	Inflammation
	Intravascular catheters damage endothelium
	Thrombosed chorionic vessels embolize to fetal vessels
	Local thrombi from patent ductus arteriosus
Stasis of blood flow	Large catheters in small veins
	Increased blood viscosity, polycythemia
	Poor deformability of newborn red cells
Altered constituents of blood	Shock/consumption
	Sepsis/inflammation
	Extracorporeal membrane oxygenation (ECMO)
	Congenital disorders

Deficiency of Anticoagulant Proteins

Of the congenital anticoagulant factor deficiencies, homozygous protein C and protein S deficiency are the most clinically significant. Purpura fulminans is characterized by acute onset of microvascular thrombosis followed by perivascular hemorrhage. Although purpura fulminans can be associated with acquired factors (like DIC and meningococcal infections), if it occurs in the newborn period, inherited protein C (and less commonly protein S) deficiency needs to be ruled out. Protein C concentrate (nonactivated) may be used for the management of both acquired and congenital protein C deficiency. A plasma transfusion would be needed to replace protein S.

Also, aside from the physiologically low anticoagulant protein levels in neonates, many acquired conditions can affect these levels. Congenital heart disease, hepatic dysfunction, and nephrotic syndrome have all been associated with decreased anticoagulant protein levels in the plasma. Antithrombin deficiency in the newborn is most commonly acquired, in association with cardiopulmonary bypass or ECMO, which can cause activation of the coagulation system and consumption of coagulant and anticoagulant proteins because of the interaction with the

Table 334.6
Prothrombotic risk factors

Inherited thrombophilia	Acquired conditions
Factor V Leiden mutation	Central venous line
Prothrombin G20210A mutation	Cancer
Hyperhomocysteinemia	Congenital heart disease
Increased lipoprotein (a) levels	Hyperalimentation
Protein C deficiency	Infection
Protein S deficiency	Nephrotic syndrome
Antithrombin deficiency	Liver failure
Dysfibrinogenemia	Antiphospholipid syndrome
Increased fibrinogen, factor VIII (probably inherited)	ECMO
	Polycythemia
	Perinatal complications
	Sepsis

biomaterials in the circuit, as well as a systemic inflammatory reaction; this deficiency is usually manifested by difficulty in obtaining therapeutic heparin effect. A purified antithrombin concentrate is available. However, because thrombosis in neonates is likely multifactorial, in the absence of an actual thrombus, it is unclear whether factor replacement would be of benefit in these situations.

Thrombotic Manifestations in the Neonate

Thrombotic manifestations in neonates include ischemic perinatal stroke (IPS), cerebral sinus venous thrombosis (CSVT), venous systemic thrombosis, renal vein thrombosis, portal vein thrombosis, and arterial systemic thrombosis.

The clinical presentation of IPS is often subtle and nonspecific, including seizures, poor feeding, and lethargy. Often diagnosis is delayed until hemiparesis is evident, sometimes months later. The etiology of IPS remains unclear. In a recent meta-analysis, it was found that genetic prothrombotic risk factors significantly contributed to the risk of stroke in children; as other risk factors were also present in many instances, the significance of this is unclear. IPS does not seem to independently increase the risk of recurrent thromboembolic disease. Given that the diagnosis of IPS is frequently delayed, the prognosis generally better than in older children and adults, and the risk of bleeding is high, anticoagulation or aspirin therapy is not generally recommended for neonates with initial IPS unless there is an embolic source.

In the Canadian pediatric stroke registry, the incidence of CSVT was 0.67 per 100,000 children per year, and neonates were the most commonly affected group. Risk factors include head and neck disorders, dehydration, perinatal complications, and bacterial sepsis; of note, prothrombotic disorders were found in 20% of neonates with CSVT. In pediatric CSVT, in contrast to adults, non-anticoagulation resulted in increased thrombus propagation, while anticoagulation (with heparin, low-molecular-weight heparin, or warfarin) did not increase the risk of fatal bleeding or bad outcome, with neonates having the best outcome. Evidence-based practice guidelines for anticoagulation in children recommend, but not strongly, anticoagulation for neonatal CSVT for 6 weeks to 3 months.

The incidence of venous thromboembolism in children varies among registries, but the association with acquired risk factors is consistent with the presence of a central venous line (CVL), the most common association. These thrombi are often asymptomatic or associated only with CVL dysfunction. Other risk factors in neonates include congenital heart disease, sepsis, and hyperalimentation. Despite the risk of thrombosis associated with CVL in children, prophylactic anticoagulation has not been proven effective at prevention.

Renal vein thrombosis (RVT) comprises up to 33–58% of neonatal thrombotic events according to registry data. In a recent meta-analysis, 7% occurred in utero and 67% occurred in the first day of life; most children were born >36 weeks age of gestation (73%). Features at presentation included macroscopic hematuria (55%), thrombocytopenia (47%), and a palpable mass (42%). Associated conditions included perinatal asphyxia (29%), maternal diabetes (8%), and dehydration (1.5%). The thrombus extended into the inferior vena cava in 44%, and there was adrenal hemorrhage in 14%. Fifty-three percent of those tested had at least one thrombophilia. Anticoagulation or thrombolytic therapy does not seem to change the long-term outcome in children with RVT. Evidence-based guidelines recommend observation for unilateral RVT and anticoagulation or fibrinolytic therapy for bilateral RVT, depending on the renal dysfunction.

Portal vein thrombosis (PVT) can be associated with umbilical vein catheterization and omphalitis. Diagnosis is by ultrasound, and it is often found incidentally. Treatment with anticoagulation and catheter removal is usually indicated as portal hypertension can develop over time.

Arterial systemic thrombosis in neonates is usually iatrogenic, associated with catheterization. Spontaneous arterial thrombosis is uncommon in neonates, usually involves the aorta, and can have a mortality rate of up to 33%. For extensive arterial thrombosis, thrombolysis or surgical thrombectomy should be performed; for less extensive thrombosis, anticoagulation may be considered.

Testing for Thrombophilia

Although older guidelines recommend testing for genetic thrombophilia for all neonates with thrombosis, more recent studies have questioned the utility of such testing given that the ability of such testing to improve clinical outcome even in adults is unclear. This lack of evidence is even more apparent in children, such that the effect of thrombophilia on duration of anticoagulation is not addressed in the most recent evidence-based practice guidelines. Clearly, neonates with purpura fulminans and, possibly, those with very extensive unexplained thrombi, should be tested, as replacement therapy may be necessary.

Treatment of Neonatal Thrombosis

Although heparin and low-molecular-weight heparin have been used safely in neonates with thrombosis, efficacy has not been clearly established, except possibly in CSVT. There are no randomized control trials, and current evidence supports anticoagulation for neonates with thrombi only weakly. Consultation with a hematologist is recommended. When needed, low-molecular-weight heparin and heparin are given at higher doses per kilogram body weight than those in adults because of the increased volume of distribution in infants. Initial check of the low-molecular-weight heparin level and periodic monitoring of aPTT and heparin level are recommended.

335 Bleeding Disorders

Hassan M. Yaish · Eugenia Chang

Familial bleeding disorders affecting males have been described in religious and historical texts for thousands of years. Hemophilia A (classic hemophilia) and B (Christmas Disease) are clinically indistinguishable and discussed together in this chapter. Some of most famous individuals affected with hemophilia have been the descendents of Queen Victoria of England and the Empress of the Indies, including Czar Alexis. The downfall of the Russian aristocracy is partially attributed to the poor health of Czar Alexis and the royal family's dependence upon their physician, Rasputin, for advice. Analysis of Czar Alexis' DNA revealed a substitution in exon 4 of the factor IX gene. Schonlein termed the disease hemophilia in the 1820s. In the early twentieth century, experiments by several investigators determined that the plasma and, more specifically, the "globulin fraction" of blood plasma could correct the clotting defect of the blood of affected patients in vivo and in vitro, leading to identification of coagulation factors VIII and IX in the 1940s and eventually to the characterization and sequencing of factor VIII and IX in the 1980s. Since the 1980s, rapid progress has been made in high purity factor replacement and prophylactic therapy for these populations and has opened the door to the potential for gene therapy.

Classification

The incidence of hemophilia is 1:6,000 live male births with no racial predilection. Eighty to eighty-five percent of patients have factor VIII deficiency (hemophilia A) and 10–15% of patients with factor IX deficiency (hemophilia B), 2–3% with factor XI deficiency (hemophilia C). Severity is determined by the patient's baseline level of factor VIII or IX. factor levels are expressed as % activity, with 1 ml of normal plasma containing 100% activity and expressed as units/dL. In both hemophilia A and B, severe patients have levels of $<1\%$, moderate with levels of 1–5% and mild with levels of $>5\%$. Plasma factor levels correlate with frequency and severity of bleeding episodes.

Diagnosis

Hemophilia is suspected in a bleeding male patient with a prolonged aPTT on screening tests. However, some patients with mild factor VIII and IX deficiencies may have a normal aPTT. A hemophilia patient typically has a normal PT, platelet count, and bleeding time/PFA testing. Mixing studies exclude inhibitors and confirm the presence of a factor deficiency. Definitive diagnosis is based in direct assays of plasma factor VIII and IX activity levels.

The diagnosis of hemophilia is suspected based upon family history in two third of patients. One third of patients have a new mutation. Although severe patients tend to present within the first year of life, mild or moderate patients may not present until after injury or surgery in adulthood. Because inheritance is X-linked, almost all patients are male, with very rare homozygous female patients. Female carriers are variably affected and are more commonly detected by screening and treated as necessary.

Factor IX is a vitamin K-dependent factor, with low, normal neonatal levels, reaching the level of adult normals at 4–6 months of age. Factor VIII levels in newborns are similar to adult normals. Patients with mild factor VIII deficiency should also have von Willebrand factor (VWF) levels measured to differentiate mild von Willebrand disease from mild hemophilia A. The normal range of activity is 50–150%, with a typical ratio of factor VIII:VWF of 1:1. Overall, hemophilia A affected individuals and carriers have decreased levels of factor VIII, but normal plasma levels of the carrier, VWF, thus resulting in a factor VIII:VWF ratio of less than 1:1. On the other hand, patient with von Willebrands disease have decreased levels of both with a relative decrease in VWF. In the case of factor IX deficiency, carriers may have decreased levels of Factor IX activity as well. There are rare families with mutations in hormone-dependent promoters (factor IX Leyden) that have bleeding symptoms that improve with age.

Prenatal Diagnosis and Carrier Detection

Since description and sequencing of the Factor VIII and IX molecules, more than 2,000 different mutations of factor VIII and factor IX have been described. Utilizing this data has allowed earlier and more accurate detection of affected patients and carriers. The genes for factor VIII and factor IX are both located on the X chromosome at q28 and q27.1, respectively. The factor VIII gene is 186 kb with 26 exons. The factor IX gene is considerably smaller at 34 kb and 8 exons. Both genes have a number of normal allelic variants that can be associated with ethnicity.

In the case of hemophilia A, 45% of severe cases are due to "inversions" of the factor VIII gene at intron 22, which result from intrachromosomal recombination. Nearly all spontaneous mutations are due to an inversion of intron 22. Point or small mutations resulting in truncated proteins and inversions of intron 1 and the inverted repeat 5′ end of the factor VIII gene cause the remaining cases of severe factor VIII deficiency. Missense mutations comprise of nearly all patients with moderate or mild hemophilia A.

In the case of Hemophilia B, there is also a high spontaneous rate of mutation, but there is no single common mutation. While most patients with mild or moderate disease have missense point mutations, patients with severe disease have a variety of large mutations, frame shift splice junction, nonsense or missense mutations. This heterogeneity makes the screening of carriers of factor IX deficiency more complex than that of factor VIII deficiency.

Carriers for Hemophilia A and B can be detected by direct gene mutation analysis, linkage studies, or by measurement of reduced plasma factor VIII or IX activity. Only two third of carriers are detected by reduced plasma factor activity, with the remainder having normal plasma levels.

Prenatal and antenatal screening is available to those families in whom the mutation is known or linkage analysis has been performed. While helpful for the expectant families, the infant's factor levels are not essential to make delivery room recommendations, discussed later in this chapter. Genetic counseling is recommended for all known carriers to discuss testing options and optimal delivery room management of potentially affected males.

Preimplantation diagnosis can be performed using molecular techniques or preimplantation sex screening by biopsying the embryo at the cleavage stage or biopsy of the polar body of the oocyte. Prenatal diagnosis can be performed as early as 10–12 weeks gestation using chorionic villus sampling or at 15 weeks' gestation using amniocentesis. If DNA markers are not known, fetal blood sampling for the purpose of measuring factor VIII activity can be done at 20 weeks gestation. Unfortunately, measuring fetal factor IX levels are not helpful in detecting factor IX deficiency because of the physiologically low factor IX levels in the normal fetus and newborn.

Presentation and Clinical Manifestation

Patients with both hemophilia A and B present in a similar manner. These patients have decreased thrombin formation resulting in friable and delayed clot formation. They commonly present with bleeding following minor or no trauma. Bleeding is frequently prolonged or recurrent. Thirty percent of patients present with bleeding with circumcision, 1–2% present with intracranial hemorrhage. Other bleeding manifestations include deep muscle and joint hemorrhage, bruising, hematomas, posttraumatic bleeding, postsurgical bleeding, oozing after dental procedures or oral injury, epistaxis, gastrointestinal, renal, and retroperitoneal bleeding. The most disabling long-term sequellae are related to repeated joint and muscular hemorrhages. Many patients treated prior to 1985 also have acquired HIV and/or slowly progressive liver disease from hepatitis C. These associated diseases and the cost of hemophilia treatment add social and economic difficulties to the psychological and physical challenges that this population faces.

In the severe patient (70% of A and 50% of B), bleeding in the neonatal period and muscular bleeding associated with immunization is common. Once the child begins to walk, both spontaneous and posttraumatic joint and muscle bleeds are seen. Moderate hemophiliacs (15% of hemophilia A and 30% of B) more commonly present with posttraumatic bleeding. Mild patients (15% of hemophilia A and 20% of B) frequently are not diagnosed until they have prolonged or severe posttraumatic or postsurgical bleeding.

Hemarthrosis is the hallmark of hemophilia, accounting for 90% of serious bleeding episodes. Knees, elbows, and other large joints are involved in 80% of the bleeding episodes. Bleeds can be spontaneous or following minimal trauma. Patients describe an "aura" of warmth or tingling sensation hours before the joint bleed is evident. While mild bleeds can resolve in several hours, severe bleeds can cause significant joint swelling, lasting for weeks. Once several bleeds occur in a joint, the synovium, which normally makes lubricating fluid for the joint, begins to proliferate and becomes hypertrophied, friable, leading

to increased risk of repeated bleeding, cartilaginous damage, and eventual severe arthropathy. There are validated radiologic and joint examination scoring systems to assist in quantification and follow-up of joint outcomes in hemophilia (*Tables 335.1* and *335.2*).

Repeated bleeding episodes eventually cause loss of joint space, bone cysts, crippling arthritis, and eventual fusion of the joint. Chronic synovitis can be treated with surgical or radiosynovectomy, while end-stage arthropathy is frequently treated with joint fusion or replacement.

Deep muscle bleeding is another common manifestation of hemophilia. Of particular interest is bleeding within the retroperitoneal muscles. Large bleeds can occur in the iliopsoas muscles, causing lower quadrant abdominal pain that can mimic appedicitis or referred pain to the groin or hip, easily confused with hip

Table 335.1
Orthopedic joint scoring system (Gilbert score)

	Score[a]			
	0	1	2	3
Chronic Pain	No pain	Mild pain	Moderate pain partial or occasional interference with occupation or ADL	Severe pain
	No functional deficit	Does not interfere with occupation or activities of daily living (ADL)	Use of non-narcotic medications	Interferes with occupation or ADL
	No analgesic use (except with acute hemarthrosis)	May require non-narcotic analgesic	May require occasional narcotic medications	Requires frequent use of non-narcotic and narcotic medications
Axial deformity				
Elbow	None	$\leq$10° varus or valgus	>10° varus or valgus	–
Knee	No deformity (0–7°valgus)	8–15° valgus or 0–5° varus	>15° valgus or >5° varus	–
Ankle	No deformity	$\leq$10° valgus or$\leq$5° varus	>10° valgus or >5° varus	–

hemarthrosis. The patient with an iliopsoas bleed will hold his leg flexed and inwardly rotated. Non-contrast CT scan of the abdomen and pelvis or ultrasound can confirm the diagnosis. Large muscle bleeds of the extremities can lead to a compartment syndrome, where the hematoma can compromise the neurovascular integrity of the limb, requiring surgical fasciotomy to save the limb.

Gross hematuria is another characteristic manifestation of hemophilia. These episodes are typically spontaneous and painless. Severe pain should raise the suspicion of urinary tract obstruction due to blood clot. Treatment is controversial, but most practitioners treat with hydration, corticosteroids, and factor replacement. Antifibrinolytics are contraindicated.

Intracranial hemorrhages and bleeds around the airway are among the most life-threatening complications of hemophilia and account for 25% of hemorrhagic deaths in hemophilia.

Treatment for Hemophilia

Treatment is focused on prevention of injury, local control of bleeding, and replacement therapy. The surroundings of the infant should be cleared of objects that may cause injury. Once the child starts walking, close supervision and guidance are essential to prevent trauma. As the child becomes older, sports, such as swimming, should be encouraged and contact sports should be avoided. Participation in physical activity and physiotherapy improves strength and mobility, decreases bleeding, and prevents the development of hemophilic muscle atrophy.

Local control of a bleeding episode is a helpful adjunct to replacement therapy. RICE is a frequently used mnemonic by the National Hemophilia Foundation to teach essentials of local control: Rest, Ice, Compression, and Elevation. Topical therapies to stop an active bleeding can also be useful to reduce usage of factor replacement therapy.

Replacement Therapy

The earliest attempts to treat hemophiliacs by providing them with blood obtained from normal individuals were undertaken by a British physician 100 years before the relationship between effective blood transfusion and the temporary replacement of a missing blood coagulation factor was understood and appreciated. For many years, blood transfusion was the only effective mode of therapy until fresh frozen plasma (FFP) was developed. FFP was more practical to administer and provided more factor per volume than whole blood. Cryoprecipitate was introduced later and became the treatment of choice until lyophilized factor concentrates were available in the 1970s. Development of factor concentrates has enabled patients with hemophilia to undergo orthopedic and dental treatment, followed by home infusion therapy with factor concentrates. Life expectancy for patients with hemophilia without inhibitor increased from 11 years in 1921 to 71.2 years after 2000, now approaching the life expectancy of a normal male.

One of the great tragedies of the hemophilia population was the HIV epidemic. Between 1979 and 1985, 55% of treated hemophiliacs were infected with HIV-1 virus and 60–95% with hepatitis C, due to exposure to factor replacement products. Each lot of these factor concentrates is manufactured from more than 2,000 blood donors. In response to the HIV epidemic, the 1980s brought numerous methods of factor purification including monoclonal antibody purification of factors, viral inactivation with heat and solvent detergent treatment methods, as well as recombinant factor VIII and factor IX products.

Several types of purified factor VIII concentrates are currently available. Lower-purity, plasma-derived, VIII concentrate products containing VWF and VIII can be used to treat hemophilia A, but this has been largely replaced by high purity factor concentrates. Since the late 1980s, monoclonal antibody purified products that are virally inactivated with a combination of pasteurization, dry heat treatment, and solvent detergent methods have been available (Monarc-P(no longer available)®, Hemophil M®). Over the last 20 years, recombinant factor VIII products have been widely used. Purity in these products has progressively improved over the three generations of recombinant factor products. First-generation products include human albumin in the final product (Recombinate®), second-generation products (Helixate FS®, Kogenate FS®) only contain human or animal albumen in the cell culture medium, and third-generation products contain no human or animal albumin in their production (Advate®). Since deleting the B domain of the factor VIII molecule does not alter its activity but increases yields of the recombinant protein, several B domain–deleted second- and third-generation products have also been used (Refacto(no longer available), Xyntha®).

Much of the emphasis of newer factor VIII products has been on purity and safety, but currently commercially available products contain essentially the same factor VIII molecule. Future factor VIII products may have more favorable properties that improve its ease of use.

For patients with factor IX deficiency, previously, only low purity prothrombin complex concentrates (PCC) were available. These products contain factors II, variably activated VII, IX, and X. These products have been largely replaced by plasma-derived, monoclonal antibody–purified factor IX concentrates (Mononine®, AlphaNine SD®) and third-generation recombinant factor IX products (Benefix®).

Despite the number of factor concentrate products available, the fundamentals of factor replacement therapy have remained the same: prompt and adequate therapy to achieve a hemostatic level for the type of bleeding being treated. One milliliter of normal plasma contains 1u of clotting activity of all coagulation factors, including factor VIII and IX (*Table 335.3*). Since plasma volume is 45 mL/kg of body weight and has 100% activity for both factor VIII

Table 335.3
Guidelines for factor replacement therapy for hemophilia A and B

Type of bleed	Goal hemostatic level	Factor VIII dose	Factor IX dose
Soft tissue, muscle, joint	40–80%	20–40 u/kg daily	40–80 u/kg
Oral mucosa	50%	25 u/kg	50 u/kg
Epistaxis, GI, GU	100% initially then 30% until healing	50 u/kg initially then 15 u/kg	100 u/kg initially then 30 u/kg
CNS, trauma, surgery or life threatening	100% initially then 50–100% until wound healing	50 u/kg initially then 25–50 u/kg until wound healing	100 u/kg initially then 50–100 u/kg until wound healing

and IX, in a normal individual, infusion of 45 u/kg would be expected to raise the factor level from 0–100% of normal. In the case of factor VIII, 1 U factor VIII/kg will raise the level 2%, with a half-life of 8–12 h. Because of the increased rate of diffusion of the smaller factor IX molecule to the extravascular space, 1U factor IX/kg will raise the factor level by 1%, with a half-life of 18–24 h.

Home Infusion/Self Therapy Program

Virtually, all patients with reliable family support and adequate vascular access are candidates for home infusion therapy. Most families can be trained when the patient is 3–8 years of age to perform home infusion therapy. Families with even younger patients can be trained, if a permanent indwelling vascular access device (portacath) or arteriovenous fistula is placed. Refer to Sangostino for a review of vascular access issues in patients with hemophilia.

This has opened the door to routine prophylactic treatment that permits these patients to participate in most physical activities.

Infusion Schedules

Many older and mild/moderate hemophilia patients treat themselves "on demand" (episodic factor replacement for bleeding episodes or trauma). Mild or moderate hemophiliacs will frequently infuse prior to higher risk physical activity, such as downhill skiing. However, the mainstay of treatment for a severe hemophiliac is routine scheduled prophylactic infusion therapy. Joint outcomes in severe hemophiliacs that are treated "on demand" are poor, prompting clinical trials that have demonstrated improved long-term joint outcomes in patients that receive routine prophylactic infusions. Many patients that are treated on demand will begin secondary prophylaxis after repeated bleeding episodes in order to decrease symptoms in a target joint (a joint with recurrent bleeding).

In essence, severe hemophiliacs can be converted to a moderate phenotype with routine infusions of factor VIII (25–40 units/kg) one to four times per week or factor IX (50 units/kg) one to two times per week. A study by Collins et al., elegantly demonstrated that decreasing the time with factor VIII levels of $<1\%$ in patients with hemophilia A by infusing with factor VIII replacement therapy at least three times per week correlated with decreased total bleeding episodes and hemarthrosis. Studies performed in patients with factor IX deficiency also demonstrated the efficacy of prophylactic infusions (15–50 units/kg) in preventing bleeding episodes. With the advent of routine prophylaxis, many severe hemophiliacs lead a life full of activities much like their healthy peers without daily fear of life-threatening hemorrhage.

Ancillary Pharmacologic Therapies

Desmopressin: Desmopressin or 1-deamino-8-D-argnine vasopressin (DDAVP) stimulates a transient, fourfold increase in factor VIII levels by releasing factor VIII stored in endothelial cells and platelets. This is an effective alternative therapy for patients with mild hemophilia A. Administration of 0.3 mcg/kg of DDAVP in 30–50 mL of saline IV over 15–30 min results in peak factor VIII level at 30–60 min. A concentrated nasal spray (Stimate®) administers 150 mcg/spray and can be self-administered in the home. 150 mcg is sufficient for a child <50 kg, 300 mcg is indicated for a >50 kg person, with the nasal spray peak levels are attained at 60–90 min. Fluids should be restricted in patients receiving DDAVP because of the risk of hyponatremia. Tachyphylaxis (temporary cessation of response) can occur with repeated doses of DDAVP, even if given no more frequently than daily. Transient facial flushing, hyponatremia, hypertension, and headache can occur after administration.

Antifibrinolytic therapy: Another effective method of controlling bleeding in the hemophilia patient is the use of antifibrinolytics to stabilize and protect the friable clot. Clots in the oropharynx are particularly sensitive to degradation due to the high levels of fibrinolytic enzymes in saliva. Two agents are available, ϵ-aminocaproic acid (EACA, Amicar®) and tranexamic acid (Cyclokapron®). Both can be administered intravenously or orally. Generally these agents are administered in patients with oronasopharyngeal bleeding, for 2–5 days to permit healing of the mucosa. The greatest risk with these agents is thrombosis. Administration with prothrombin complex concentrates or with urinary tract bleeding is relatively contraindicated due to the risk of thrombosis and urinary tract obstruction, respectively.

Topical therapy: There are three categories of topical treatments: sealants, matrix dressings, and other topical therapies. Sealants include Tisseel VH®, topical thrombin, and cyanoacrylate. The matrix dressings promote fibrin formation. Finally, other materials such as zeolite and hydrophilic polymers that form artificial scabs can be used to assist with hemostasis.

Future therapeutic strategies: Due to improved understanding of the factor VIIa, VIII, and IX molecules, one future avenue of treatment would be to improve the stability, potency, and half-life of the molecules and facilitate alternative delivery systems such as oral and intrapulmonary routes. Current clinical trials include agents with extended half-lives, improving the convenience of prophylactic factor infusion. Even more attractive is the potential to cure disease using gene therapy or hepatocyte transfer. While a number of these approaches utilizing adenoviral, adeno-associated viral, and retroviral vectors have been tried in clinical trials, thus far these approaches have not resulted in sufficient long-term factor VIII or IX protein levels and have been limited by immunologic response.

Delivery Room Management of Potential Hemophilia Patients

The risk of intracranial hemorrhage in hemophilia patients delivered vaginally is 4% compared to 0.5% in patients delivered by cesarean section. The risk is tripled in deliveries assisted by forceps or vacuum extraction which is contraindicated when delivering a potential hemophilia patient. Fetal scalp electrodes also increase the risk of bleeding in affected infants and should be avoided. After delivery, umbilical cord blood specimens can be sent to determine if the infant is affected and requires additional care or observation. Ideally, a 4.5 mL specimen should be drawn from a double clamped 10 in. section of cord, drawn from the umbilical vein, and placed into a citrated syringe or tube after discarding the initial 1–2 mL. This method decreases the risk of hemorrhage in the affected infant due to difficult venopuncture. Routine factor infusion after delivery is not indicated, but a high index of suspicion for bleeding and low threshold for prompt intervention with factor replacement therapy for bleeding episodes is essential.

Management of Carriers

There is great variability to symptomatology of carriers for factor VIII and IX deficiency. Ten percent of carriers of factor VIII and IX deficiency are symptomatic with levels of less than 35% and 30%, respectively. Patients with depressed factor VIII and IX levels of <50% (50 IU/dL) may require factor replacement therapy for severe bleeding episodes, delivery, or surgery. Factor VIII levels increase during pregnancy and should be evaluated in the event of unusual bleeding and during the last trimester to determine if intervention is necessary. Factor VIII levels also rise in response to inflammation, estrogen therapy, and aerobic exercise. Carriers with blood type O also have factor VIII levels that are 25% lower than those with blood group A, B, or AB. Factor IX levels do not increase during pregnancy, so a postpubertal baseline level should be adequate to determine the necessity of treatment for delivery.

Management of Hemophiliac Patients with Inhibitors to Factor VIII or IX

Ten to fifteen percent of patients with severe hemophilia A, 3% of patients with severe hemophilia B, and 2.7–13% of mild/moderate hemophilia A eventually become refractory to factor replacement therapy due to the development of immunoglobulin G (IgG) antibodies to factor VIII or IX. The risk factors for inhibitor development include genotype, major histocompatibility class II alleles, polymorphisms in immune response genes (IL10, TNFa, CTLA4), reason for first treatment (surgery vs routine infusion), >5 days of initial exposure, and some suggestion that initial continuous infusion may increase the risk. There are two preferred methods of evaluating inhibitors: the Nijmegen assay and the Bethesda assay. The Nijmegen assay is a modification of the Bethesda assay that has improved specificity and inter-laboratory reliability, but the Bethesda assay continues to be more widely used. Both assays quantify inhibitors to the A2 domain better than for inhibitors to the C2 domain. The unit utilized to measure the titer of inhibitor is the Bethesda unit (BU). This is defined as the amount of inhibitor present in 1 ml of the patient's plasma that neutralizes 50% of the factor VIII or IX in 1 ml of normal plasma. Patients with inhibitors to factor VIII and IX are divided into low titer (<5 BU), high titer (5–30 BU), and very high titer patients (>30 BU) for purposes of treatment recommendations. Patients with low-titer inhibitors that do not increase in response to factor replacement therapy are known as low responders (25% of hemophilia A inhibitor patients), whereas those that have rapidly increasing titers with repeated exposure to factor replacement are high responders (75% of hemophilia A inhibitor patients). Typically, the inhibitor titer begins to rise 2–3 days after reexposure to replacement therapy and reaches a peak at 7–21 days, decreasing slowly if there are no further exposures to factor replacement. The highest risk of development of inhibitors is in the first 50 days of exposure to factor replacement therapy, with only rare patients developing inhibitors after 150 exposure days. Once formed, high-titer inhibitors in high responders tend

to persist and low-titer inhibitors in low responders tend to disappear without recurrence.

Treatment of these patients is challenging and complex. Low-titer, low-responder patients can generally be treated with higher and more frequent doses of factor replacement therapy. Some treating physicians will change from a recombinant factor to a plasma-derived factor in inhibitor patients. For patients with high titer inhibitors or high responders, plasmapheresis can reduce titers temporarily to permit emergent treatment of a life-threatening hemorrhage with factor replacement.

There are other options for the treatment of hemophilia A in the presence of inhibitors. Porcine factor VIII (Hyate:C) at a dose of 100–150 u/kg can be used to treat acute bleeds, but is associated with allergic reactions and hematologic side effects. It may cause an amnestic response to both human and porcine factor VIII. Once anti-porcine inhibitor titers rise to 15–20 BU, the product becomes less effective.

Bypass therapy with prothrombin complex concentrates (PCC, Proplex® at 100 u/kg) and activated prothrombin complex concentrates (aPCC, FEIBA® at 50–75 u/kg) is effective for treatment of acute bleeds in inhibitor patients with both hemophilia A and B, but is not used for prophylaxis because of the risks of thrombosis and amnesis associated with their use. Both of these products contain Vitamin K–dependent factors, including activated factor II, VII, IX, X, explaining their ability to bypass factor VIII and IX with the activated factor X and VII.

There is now 20 years of experience administering recombinant activated factor VII (NovoSeven®). It is highly effective in hemophilia A and B patients with inhibitors. Dosing is variable and can range from (35–300 mcg/kg). Its use is limited by its short half-life (2.7 h in adults and 1.3 h in children) and its cost. In the subset of hemophilia B patients with inhibitors and anaphylaxis associated with factor IX administration, it is currently the only treatment option for acute bleeds, as they can develop proteinuria due to immune complex formation with repeated factor IX exposure. There is in vitro evidence that demonstrates a synergistic effect between the use of aPCC with recombinant VIIa, but clinical trials are needed, given the potential risk of thrombosis with concurrent use.

The best solution for hemophilia patients with inhibitors is to eradicate them with immune tolerance therapy. When successful, this permits the use of factor replacement products, frequently at normal dosing. Induction of immune tolerance is possible in 60–80% of hemophilia A patients. The success rate in hemophilia B patients with inhibitors appears to be significantly lower. The process of immune tolerance is time consuming and expensive. There are several methods currently being utilized including high dose factor replacement therapy (frequently by continuous infusion), cyclophosphamide, corticosteroids, and intravenous immunoglobulins. There are promising preliminary findings with the use of cyclosporin, mycophenylate mofetil, and rituximab therapy.

Comprehensive Hemophilia Clinic

Because of the complexity of the ongoing care of these patients, most patients in the USA are managed in a federally funded network of comprehensive hemophilia clinics. These clinics have a staff experienced in the complex medical and psychosocial needs of this population. Comprehensive clinics usually include hemophilia physicians, nurses, orthopedists, infectious disease specialists, dentists, social workers, genetic counselors, nutritionists, and physical therapists.

Factor XI Deficiency (Hemophilia C)

Hemophilia C comprises only 2–3% of hemophilia. The gene is 23 kb and located on the long arm of chromosome 4. It is autosomal recessive and most symptomatic patients have factor XI levels of 1–10% of normal. Symptoms are most typically post surgical, posttraumatic, epistaxis, menorrhagia, and hematuria. Spontaneous bleeding is rare. Bleeding tendency and factor levels do not always correlate, likely due to coinheritance of additional hemostatic defects, VWF levels, reduced thrombin-activatable fibrinolysis inhibitor levels (TAFI), and abnormalities in platelet associated factor XI. Over half of the reported cases are in the Jewish population with a gene frequency of 1:8 of Ashkenazi Jews. The half-life of factor XI is 45–55 h. Treatment is FFP or solvent detergent pooled plasma. In France, a plasma-derived factor XI concentrate (Hemoleven) is available as well. DDAVP and antifibrinolytic therapy can be an effective adjunct. Rare patients with abnormalities in platelet-associated factor XI may require platelet transfusion as well.

Factor Deficiencies Associated with Laboratory Abnormalities but No Bleeding Tendency

Factor XII deficiency, prekallikrein (Fletcher factor), and HMW kininogen (Fitzgerald factor) deficiency can all

result in impressive prolongation of the aPTT but are not associated with bleeding tendency. In patients with a prolonged aPTT and absence of bleeding, this diagnosis is suggested with a mixing study demonstrating factor deficiency but normal factor VIII, IX, and XI levels. The diagnosis can be confirmed with factor assays.

von Willebrand disease

General

von Willebrand disease (VWD) is the most common congenital bleeding disorder, with an incidence of over 1% in the general population. VWD was initially described by Eric A. von Willebrand in 1926 in a family with a bleeding disorder affecting both males and females and distinctive from hemophilia. Many patients have symptoms and laboratory findings that can be confused with hemophilia A (*Table 335.4*). Mucocutaneous bleeding is more common than joint bleeding. The disease is caused by qualitatively abnormal and quantitatively decreased levels of von Willebrand factor (VWF). VWF is a carrier protein for factor VIII, complexed together in a 1:1 ratio. The gene for VWF is located on chromosome 12. Among the three main clinical subtypes of VWD, a significant overlap between normal individuals and patients with type 1 VWD, makes the diagnosis very challenging.

Physiologic Regulation of von WF Synthesis and Release

VWF is a multimeric glycoprotein consisting of dimeric subunits. The multimers are classified as low, intermediate, and high depending upon their molecular weight. The protein is synthesized by both the megakaryocyte and the endothelial cell. VWF produced by the endothelial cell is high molecular weight (HMW) and stored in Weibel–Palade bodies. VWF produced in the megakaryocytes is LMW and stored in the alpha granules of the platelets. Secretion is facilitated by two pathways, constitutive from the platelets and regulated from endothelial cells in response to vascular endothelial damage and other endothelial cell stimulation. Levels vary according to inflammation, exercise, vasopressin, pregnancy, and blood group type, with blood type O individuals having significantly lower levels of VWF.

Function of von Willebrand Factor

VWF serves two key roles in normal hemostatis: it is a cofactor for platelet adhesion and the carrier protein for factor VIII procoagulant. In platelet adhesion, VWF promotes the attachment of platelets to the areas of vessel injury. To optimize the availability of VWF at the site of injury, a highly active form of the protein (HMW multimers) is stored in the α granules of the platelets

Table 335.4
Differences between von Willebrand disease and hemophilia

	von Willebrand disease	Hemophilia A
Symptoms	Mucous membrane bleeds and bruising (epistaxis, menorrhagia)	Joint and muscle bleeds
Sexual distribution	Males and females	Males
Incidence	1/100 or more	1/6,000 males
Abnormal protein	von Willebrand factor	Factor VIII
Function	Platelet adhesion and carrier to factor VIII	Clotting cofactor
Site of synthesis	Endothelial cells and megakaryocytes	Liver
Gene location	Chromosome 12	X chromosome
BT	Often prolonged	Normal
PTT	Prolonged or normal	Prolonged
Factor VIII	Low normal or decreased	Decreased or absent
VWF:Ag	Decreased or absent	Normal or increased
VWF:Rcof	Decreased or abnormal	Normal or increased

BT bleeding time, *PTT* partial thromboplastin time, *VWF:Ag* von Willebrand factor antigen, *VWF:Rcof* von Willebrand factor/ristocetin cofactor activity

and the endothelial cells. When such cells sense tissue injury (e.g., by contact with thrombin), they instantly mobilize the stored protein. Each HMW multimeric unit has a binding site for (a) the receptor glycoprotein (GP) Ib on nonactivated platelets, (b) the integrin-type receptors (GPIIb/IIIa on activated platelets), and (c) fibrillar collagen and heparin-like molecules. Each multimeric unit can also facilitate factor VIII binding onto platelet surface templates to mediate the coagulation process. The result is bridging of the platelets and vascular endothelium (adhesion) to GPIb as well as the platelets with other platelets (aggregation) via GPIIb/IIIa, resulting in the formation of the platelet plug. Adhesive proteins such as fibrinogen also react with the GPIIb/IIIa on the surface of the activated platelets and contribute to platelet aggregation and platelet plug formation in primary hemostasis.

LMW and intermediate-molecular-weight (IMW) multimers have fewer platelet binding sites and serve as carriers for factor VIII, unlike the HMW multimers, which are rich in platelet bridging sites. In secondary hemostasis, which facilitates fibrin clot formation, VWF, a carrier of factor VIII, will deliver this important component to the site of adherent platelets, resulting in clot formation. VWF also stabilizes factor VIII, protecting it from premature activation by activated factor X or inactivation by protein C, and preventing it from binding to phospholipids and activated circulating platelets. Unbound factor VIII is an unstable molecule that decays rapidly in the circulation. This probably explains, at least in part, the low factor VIII activity (factor VIII:C) in some types of VWD, such as type 2N.

Genetics of von Willebrand Disease

Typically, VWD is a heterozygous autosomally inherited disorder with depressed levels of VWF or function. Patients with severe disease are usually homozygotes or double heterozygotes, with an autosomal recessive pattern of inheritance (◉ *Table 335.5*).

Classification of VWD

There are three types of von Willebrand Disease and a group of individuals that are classified as "low von Willebrand factor" (◉ *Table 335.6*).

Type I: The most common subtype of VWD is type I, accounting for 80% of affected individuals. These patients have a heterozygous or partial deficiency of structurally normal VWF. There is an overrepresentation of individuals with the blood group O due to the lower levels in this population. Ten percent of patients have the Y1584C missense mutation. Most other known mutations are also missense mutations. A distinct variant of type I VWD is type 1 Vicenza, characterized by a markedly decreased half-life. Adding to the mystery of VWD, there are affected patients that do not have detectable mutations in the VWF gene and do not demonstrate linkage, suggesting that there may be other genetic interactions that modify level of VWF:Rcof. These patients range from those with mild bleeding disorder to those who are asymptomatic. The diagnosis can be challenging because of the many factors affecting circulating VWF levels. Because these patients have present but reduced levels of VWF and factor VIII in the platelets and endothelial cells, they respond to DDAVP.

Low VWF: There is considerable controversy in the diagnosis of individuals with VWF 30–50IU/dL. 2.5% of the general population has a VWF level in this range. Many of the individuals with levels in this range do not demonstrate typical inheritance for VWD or abnormalities in the VWF gene. Linkage to VWF gene abnormalities was only present in 51% of these individuals. These individuals have a mild bleeding tendency, occasionally can require treatment for bleeding, and may have some protective effect against thrombosis. This group of individuals is currently classified as having low von Willebrand factor, a risk factor for bleeding.

Type 2: 15–20% of patients belong to this type. These patients have both qualitative and quantitative abnormalities in VWF. These variants can have decreased numbers of HMW and IMW VWF multimers with variable bleeding tendency. Inheritance is can be dominant or recessive. There are a number of subgroups of this type. All of these subtypes have missense mutations that impair functional domains of the VWF molecule responsible for binding to GP1b, factor VIII, or multimerization.

Type 2a: This is the most common type 2 variant. This subtype has a lack or relative decrease of high and intermediate weight multimers of VWF. Mutations are in the A2 domain. Sixty percent of cases are either R1597W or Q or Y, or S1506L. These mutations affect the multimerization of VWF. There are two groups of these patients: group I that have impaired secretion of HMW multimers due to abnormal transport and group II that have mutations with a greater susceptibility to in vivo proteolysis.

Type 2b: This subtype also has a lack of high molecular weight multimers, with the exception of the New York/Malmo variant. Mutations are in the A1 domain. Ninety percent of cases are due to R1306W, R1308C, V1316M,

Table 335.5

Main characteristics of von Willebrand disease types

Type of VWD	Laboratory	Multimers	Mutations associated	Comments
Type 1	Concurrent reduction of FVIII:C and VWF in plasma; VWF:RCo/VWF:Ag $\geq$ 0.6	All multimers present; some minor abnormalities may be evident using sensitive methods	Missense mutations scattered over the entire gene. Possible dominant-negative effect. Y1584C in about 10%. Single null allele not associated with bleeding.	Usually co-dominant or dominant-negative. Ideal candidates for desmopressin. Short VWF half-life in VWD Vicenza (R1205H) and other rare mutations.
Type 2A	Usually VWF:RCo/VWF:Ag $<$ 0.6	Lack or relative decrease of the high molecular weight (HMW) and of intermediate multimers	Mutations in A2 domain; R1597W or Q or Y and S1506L represent about 60% of cases.	Usually co-dominant. Two mechanisms demonstrated by expression experiments. Group I: impaired secretion of HMW multimers, due to defective intracellular transport. Group II: normal synthesis and secretion of a VWF with greater susceptibility to in vivo proteolysis. Patients of the latter group may respond to desmopressin.[27]
Type 2B	Usually VWF:RCo/VWF:Ag $<$ 0.6; RIPA occurs at low ristocetin concentration	Lack of HMW multimers; a normal pattern is present in New York/Malmö variant	Mutations in A1 domain; 90% of cases are due to R1306W, R1308C, V1316M, and R1341Q.[51] P1266L associated with gene conversion and New York/Malmö phenotype.[12]	Usually co-dominant. Enhanced affinity of abnormal VWF for platelet GpIb receptor. Thrombocytopenia after desmopressin and sometimes during pregnancy or stress situations; thrombocytopenia may aggravate bleeding risk conferred by the abnormal VWF.
Type 2M	Usually VWF:RCo/VWF:Ag $<$ 0.6;	Large multimers present; inner abnormalities may be evident (e.g., ''smeary pattern'')	A few heterogeneous mutations recurrent (e.g., R1315C, G1324S/A, R1374C/H).	Usually co-dominant. Some overlap with Type 2A may occur. Desmopressin may be useful in selected cases.
Type 2N	VWF may be normal or only slightly reduced; FVIII:C/VWF:Ag $<$ 0.5; defective FVIII-VWF binding	All multimers present	Mutations in NH2-terminus; R854Q largely the most frequent mutation.	Usually recessive. Bleeding only for homozygosity or compound heterozygosity. Heterozygosity for R854Q in up to 2% of population in Northern Europe. Desmopressin may be useful for the majority of minor bleedings
Type 3	Virtual absence of VWF; markedly reduced FVIII:C ($<$5 IU/dL)	Lack of multimers	Mutations scattered over the entire gene, but some (e.g., 2,430delC exon 18[a] or Arg2535stop) are particularly recurrent in North Europe. High prevalence of null mutations (stop codons, frameshift, gene deletions).	Recessive. Desmopressin does not work since cellular storage is devoid of VWF

and R1341Q. The New York/Malmo phenotype has the P1266L mutation. These mutations are associated with an increased affinity for the platelet Gp1b receptor leading to increased thrombocytopenia after desmopressin, pregnancy, or stress.

Type 2M: This subtype is characterized by the presence of large multimers, but have decreased function of the VWF, resulting in a VWF:Rcof/VWF:Ag of <0.6. Mutations are heterogeneous and there is some overlap with type 2a.

Type 2N (Normandy): This subtype is characterized by mutations in the NH2 terminus leading to impaired binding and subsequent rapid decay of factor VIII. The most frequent mutation is R854Q. Up to 2% of the Northern European population is heterozygous for this mutation. Bleeding is only seen in individuals that are homozygous or double heterozygotes. These patients mimic hemophilia A patients.

Type 3: These patients inherit disease in an autosomal recessive manner. They are severely affected with virtual absence of VWF and markedly reduced FVIII:C. The mutations associated with this subtype are scattered over the entire gene, many of which are null mutations. This subtype has an increased risk of inhibitor development with exposure to VWF. DDAVP does not work in this population.

Platelet-type Pseudo VWD: This disorder is actually a mutation in the platelet GP1b gene resulting in increased affinity for the VWF. This disease clinically resembles type 2B. There are reduced levels of HMW multimers in these individuals because of the adsorption of VWF by the platelets.

Acquired VWD: Some autoimmune and lymphoproliferative diseases and less frequently solid tumors, such as Wilms tumor, congenital heart disease, hypothyroidism, or liver diseases are occasionally associated with a hemorrhagic diathesis resembling congenital VWD, but characterized by the presence of antibodies to VWF. Some pharmacologic agents have also been implicated in the development of acquired VWD, such as dextran, valproate, and ciprofloxacin. A prolonged infusion of factor VIII preparations devoid of VWF (recombinant preparations) has resulted in a similar syndrome due to binding of all available VWF by the excessive factor VIII, resulting in complete consumption of VWF, leaving behind a large amount of unbound factor VIII that is then rapidly cleared from the circulation.

Clinical Presentation and Diagnosis

The clinical manifestations of VWD are frequently mild and might go unnoticed until the patient is subjected to physical or surgical trauma. Many patients do not recognize their symptoms as abnormal and go undiagnosed. The most frequent symptoms are easy bruising and mucous membrane bleeding, such as epistaxis, menorrhagia, dental, and gastrointestinal bleeding. Deep muscle bleeds and hemarthrosis are uncommon, with the exception of individuals with type 3 VWD. Differentiating between normal individuals and those with mild VWD requires a combination of family history, characterization of bleeding symptoms, and careful laboratory evaluation.

Given the variation of VWF levels within a single individual, diagnosis may require repeating assays numerous times. In the adult literature bleeding scores distinguish between affected individuals and normal with low levels. Unfortunately, bleeding scores have not proven to be consistent in children, given their limited past bleeding history.

Laboratory Diagnosis of VWD

Laboratory diagnosis of VWD can be difficult because of the overlap between normal and affected individuals. In the most characteristic cases, aPTT is prolonged, bleeding time is prolonged, but PT, platelet counts, and platelet morphology is normal. Unfortunately normal screening tests are relatively insensitive and a number of patients will require specific testing for VWD. In patients with suspected VWD, it is important to exclude bleeding disorders that present with similar symptoms such as primary disorders of platelet function and number.

The bleeding time is abnormal in the presence of qualitative or quantitative platelet abnormalities, or abnormalities of connective tissues. It is variably prolonged in VWD and is occasionally normal in mild forms of disease. Ingestion of medications such as aspirin and nonsteroidal anti-inflammatory drugs can inhibit platelet function, resulting in a prolonged bleeding time, so it is not sufficient for diagnosis of VWD. Because of inherent variability in the Ivy bleeding time, many centers have replaced its use with automated platelet functional analyzers such as PFA-100™. The analyzers use either collagen/epinephrine or collagen/ADP to stimulate platelet adherence to block a small aperture, and this appears to be more reproducible than the Ivy bleeding time.

Initial evaluation includes measurement of VWF antigen (VWF:Ag), VWF activity by evaluating the ability to bind to platelet GP1b in the presence of ristocetin (VWF:Rco), factor VIII activity (VWF:VIIIc) and ABO blood type. The diagnosis of VWD is complex and may require serial evaluations of suspected patients and/or performing platelet aggregations. It is particularly difficult to diagnose individuals on hormone replacement therapy or during acute infections, as both of these factors increase the circulating VWF. Menstruating female patients have variation in their VWF levels during the menstrual cycle, with lowest levels day 1–4 and highest levels on day 9–10 of the menstrual cycle. Diagnosis of VWD is confirmed with a VWF:Rcof of <30%. Depending upon the subtype, the individuals may have a normal or decreased VWF:Ag. When the VWF:Rcof is 30–50%, individuals with a family history, abnormal multimeric analysis, or detectable VWF mutation have VWD. Other individuals are classified as low VWF and have a bleeding tendency, likely due to factors outside of the VWF gene that modulate activity or levels of VWF. Additional tests are performed in patients with confirmed VWD to classify their disease and determine therapeutic options (*Table 335.7*).

Table 335.7
Phenotypic analysis of VWD

Test	Type	Measurement
VWF:Ag[a]	Initial	Antigen; quantity of protein
VWF:Rco[a]	Initial	Ristocetin cofactor activity; ability to bind platelet GpIb in the presence of ristocetin
FVIII:C[a]	Initial	FVIII coagulant activity
VWF:A[c]	Initial	Monoclonal antibody binding to a functional epitope of the A1 loop: immunoassay of GpIb binding
RIPA	Subtyping	Ability to aggregate platelets at varying doses of ristocetin. Aggregation at low doses of ~0.5 mg/ml indicates 2B VWD
VWF:FVIIIB[a]	Subtyping	FVIII binding capacity. Reduced values indicate 2N VWD
VWF:CB[a]	Subtyping	Collagen binding capacity. Reduced values correlate with reduction in HMW multimers
VWFpp[b]	Subtyping	Quantity of propeptide. Elevated VWFpp/VWF:Ag ratio indicates enhanced clearance rate from plasma
Multimer profile	Subtyping	Aberrant profiles can indicate reduction in dimerisation/multimerisation HMW multimer loss enhanced or reduced ADAMTS13 cleavage enhanced clearance and mutations that replace/introduce cysteine residues affecting disulphide bonding

Treatment of VWD

The goals of treatment of VWD are to prevent spontaneous bleeding, hasten hemostasis, or prevent postoperative bleeding. This can be achieved by administration of several different treatments. The first is DDAVP, to stimulate the release of VWF and factor VIII from tissue storage sites. The next is plasma-derived factor VIII concentrates rich in VWF. Currently not available in the USA are purified VWF and recombinant VWF.

Desmopressin: This agent is the first line of therapy for individuals with low von Willebrand, VWD types 1, 2a. Some patients with 2B, 2M, and 2N can also be treated with DDAVP. Pretesting is indicated for patients to determine response and to evaluate for degree of resultant thrombocytopenia in type 2b patients. Desmopressin is available for intravenous and intranasal administration. Dosing is identical to that for mild hemophilia. The intravenous dosing is 0.3 mcg/kg over 20–30 min in normal saline. The intranasal dosing is one puff (150 mcg) for patients <50 kg and two puffs (300 mcg) for those over 50 kg, similar to that of hemophilia A.

Plasma-derived products: Intermediate purity factor VIII/VWF virally inactivated factor VIII products are the treatment of choice for individuals with type 3 and most type 2B patients. Dosing is dependent upon the product and can be dosed in VWF:Rcof or factor VIII units. Products currently licensed in the USA for the treatment of VWD include Alphanate®, Humate-P®, and Wilate®. Koate-DVI is not currently licensed for use in VWD, but contains both factor VIII and VWF. Each of these products contains a different ratio of VWF:factor VIII. Dosing and products are not interchangeable. Only in emergent, life-threatening bleeding should cryoprecipitate (1 unit/5kg) be administered.

Purified VWF products: There are purified VWF products that are currently in clinical development. Initial studies of purified, plasma-derived products were limited by the need to either coinfuse factor VIII or allow 24 h for native factor VIII to bind to the VWF. A recombinant VWF product coexpressed with recombinant factor VIII is currently under development as well.

Recombinant factor VIII products: Most types of VWD cannot be treated with recombinant factor VIII products. The exception to this is severe type 3 patients. These patients are at increased risk for development of VWF inhibitors and are occasionally treated with recombinant factor VIII products.

Ancillary therapy: The antifibrinolytic agents described for the treatment of mucous membrane bleed in hemophilia, namely, EACA (Amicar®) or Tranexamic acid (Cyklocapron®), are also recommended in the management of mucous membrane bleeding in VWD.

336 Introduction to Hemostasis and Bleeding Disorders Other Than Hemophilia

Hassan M. Yaish · Eugenia Chang

► *Gone are the days of simply saying, "Pass the fresh frozen plasma; if something is missing, it is bound to be there."*

Hemostasis is defined as arrest of blood flow within or outside blood vessel. Thrombosis, on the other hand, indicates "the formation and propagation of blood clot in a vessel."

Thrombotic events were described by Virchow in 1856; he believed at the time that elements leading to the formation of thromboembolism in the veins are related to alterations in blood flow, blood vessels, and constitution of the blood. Even though such facts were individually known and have been described by others earlier, they were put together and came to be known as "Virchow's Triad."

What is currently known about the pathophysiology of thrombus formation is very similar to the description provided by Virchow. Slowing of blood flow by any means, damaging the endothelium of the blood vessels, or alteration in procoagulants or inhibitors component of the blood are the main activities leading to thrombotic events.

In the physiologic state, hemostasis is a balance between closely coordinated groups of plasma factors designed to keep the blood in a fluid state and yet capable of forming efficient clotting when blood vessels are damaged. These factors are categorized as *procoagulants* (clot promoting) *anticoagulant* proteins (clotting inhibitors), and *fibrinolytic* proteins (clot lysing). They interact with physiologic surfaces such as the platelets, vascular endothelium, and subendothelial matrix, all of which are known to promote the function of the various clotting factors.

The physiology of the hemostatic system in infancy and childhood is profoundly different from that in adults. It is a dynamic and constantly maturing system with multiple reference ranges that reflect both gestational and postnatal age. After the age of 6 months, however, adult reference ranges are usually used in children, with the exception of Protein C (PC), which remains lower until adolescence.

Physiology of Hemostasis

As a result of injury to the blood vessel endothelium, several events take place simultaneously, as the affected vessel constricts (vascular phase) and the homostatic process proceeds through four well-coordinated functional phases:

1. The *initiation* phase of "platelets plug formation," or the primary hemostatic phase
2. The *propagation* phase by the activated clotting factors leading to fibrin clot formation (the secondary or plasma phase)
3. The *termination* phase by the coagulation inhibitors
4. The *fibrinolytic* phase leading to clot lyses by the fibrinolytic system

Initiation Phase

In the *initiation* phase, the functional response of activated platelets at the site of injury includes four different phases:

1. *Adhesion* which involves the deposition of platelets on the damaged endothelium with the exposed collagen acting as strong platelets activator and the Von Willebrand's factor as adhesive to bridge the platelets to the endothelium
2. *Aggregation* which is the formation of platelets clump by platelet–platelet interaction utilizing fibrinogen as another adhesive protein in the plasma
3. *Release reaction* which is the secretion of various platelets chemicals and proteins (ADP, Thromboxane A2) from storage sites to aid in the process of plug formation (Fig. 336.1)
4. *Procoagulant activity* (PF3) which contributes to thrombin generation

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_336,

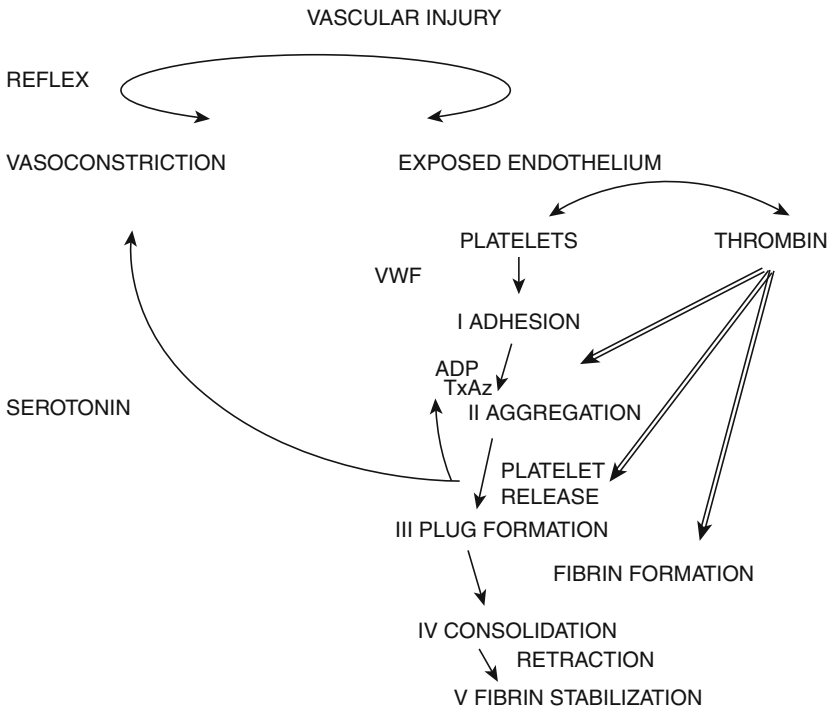

Figure 336.1
The formation of platelet plug (primary hemostatic mechanism)

Propagation Phase

Propagation phase results from a sequential activation of a series of zymogens (proenzymes) to active enzymes resulting in significant stepwise response amplification. This process represents the coagulation cascade which proceeds in three phases through one of two pathways, the *intrinsic* and the *extrinsic* pathways which were initially thought to be distinct and independent pathways. At the present time, however, it is known that they are closely interrelated and the extrinsic pathway is not actually intrinsic, since the tissue factor itself is now known to be present in the circulation and is the main element in the initiation of coagulation and not the intrinsic system as it was believed earlier. The formation of *multiple component macromolecular complexes* such as the intrinsic and extrinsic Tenases (X-ase) and the prothrombinase (*Fig. 336.2*), the first to activate FX and the second to activate FII in the process of thrombin generation), support the function of the various enzymes involved in the process of coagulation. Such complexes amplify the response in the various reactions significantly. For example, thrombin is generated from prothrombin through the prothrombinase complex 300,000 times more efficient than when produced from Prothrombin and Xa alone. The role of the platelets in providing surfaces for the various reactions and the role of its procoagulant function are very essential in the coagulation process. Patients with thrombocytopenia however do not exhibit the major bleeding manifestations that patients with clotting factors deficiencies show, unless the platelets counts are profoundly low. This suggests that small numbers of normal platelets is adequate for the clotting process.

The two traditional coagulation pathways are capable of producing *thromboplastin* in the initial phase, for the purpose of activating FX which activates FII into thrombin, which in turn carries out the last step of the coagulation cascade converting fibrinogen into fibrin to enforce and strengthen the platelet plug.

In the *intrinsic pathway* is activated by the exposure of the blood to the negatively charged surfaces (such as the Kaolin in vitro for measuring the aPTT). The *extrinsic pathway* on the other hand is activated by the Tissue factor (TF) exposure, or tissue factor–like material such as thromboplastin used in the in vitro process of measuring prothrombin time (PT). Activation of FX is the end result of both pathways that activates FII to FIIa or thrombin which in turn activates the soluble plasma fibrinogen to insoluble fibrin clot by splitting it into four small peptides

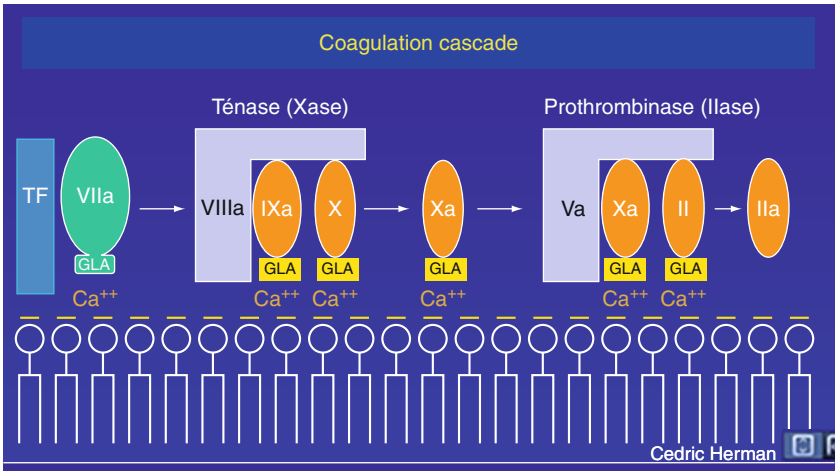

Figure 336.2
Macromolecular complexes for activation of FX (Tenase) and FII (II ase)

(two fibrinopeptide A and two fibrinopeptide B molecules). These fibrin monomers then polymerize spontaneously to form fibrin. Another one of the many functions of thrombin is activation of FXIII (fibrin stabilizing agent) to FXIIIa which in turn causes covalent bonding of the fibrin strands resulting in stable clot (*Fig. 336.3*).

It is now known that the exposure of TF at the wound site and its interaction with FVIIa is the primary physiologic event in initiating the clotting process. Only a small amount of thrombin is generated in this reaction which is capable of priming the clotting cascade, activating platelets and components of the intrinsic pathway (FVIII, FIX, FXI) which will be responsible for the amplification and the bulk generation of thrombin in the propagation phase. This interpretation of the clotting process is supported by the fact that deficiencies in FXII, HK, and PK (members of the contact factors) do not cause any bleeding disorder. Deficiency of FXI (contact factor), however, may be associated with mild bleeding symptoms. It is clear now that the classical classification of the clotting pathways into intrinsic and extrinsic (even though useful for interpretation of the clotting tests) is not physiologically accurate as was indicated earlier. The term "extrinsic" was initially introduced to indicate that TF is present only in tissues extrinsic to circulation. It is known now that TF is present in the circulation. Furthermore, the separation of the two pathways is also theoretical, since they clearly interact together. Finally, the major role of thrombin in sustaining the clotting process through a feedback mechanism is recognized (*Fig. 336.3*).

Termination Phase

The two main circulating enzymatic inhibitors are involved in this process, the antithrombin (AT), (previously antithrombin III), and the tissue factor pathway inhibitor (TFPI). In addition a clotting-initiated inhibitory process, the protein C pathway (PC), and other platelets and vascular modulators such as prostacyclin, thromboxane A2, and nitric oxide (NO) are also involved in the termination phase (*Fig. 336.4*). In the newborn and young infants, AT, PC, and PS are deficient which explain in part the high incidence of thrombotic events in this age group. Thrombin which is known to be a major procoagulant now plays a different role in the termination phase. Once it is bound to thrombomodulin and AT, it creates a conformational change which activates PC, forming another multiple macromolecular complex, of inhibitory nature, and no longer activates platelets or cleaves fibrinogen (*Fig. 336.5*). FVa and FVIIIa are cleaved by this complex, thus Tenase and Prothrombinase are inhibited. TFPI, an enzymatic inhibitor which circulates in the plasma (20%) and on endothelial surfaces (80%), inhibits FXa, directly and could form complex with such factor to inhibit TF/FVIIa. The level of this inhibitor increases significantly in plasma after parenteral administration of heparin, a phenomena that explains the effective anticoagulation effect of LMW heparin despite its weak antithrombin activity. The role of prostacyclin and thromboxane A2 in the termination phase is mainly by blocking platelet activation which is discussed under the topic of Platelets.

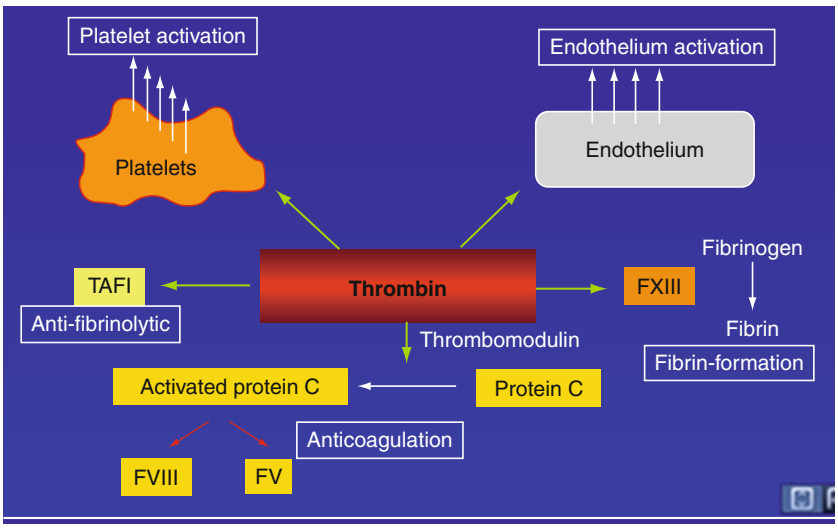

Figure 336.4

Thrombin multiple thrombotic and antithrombotic functions

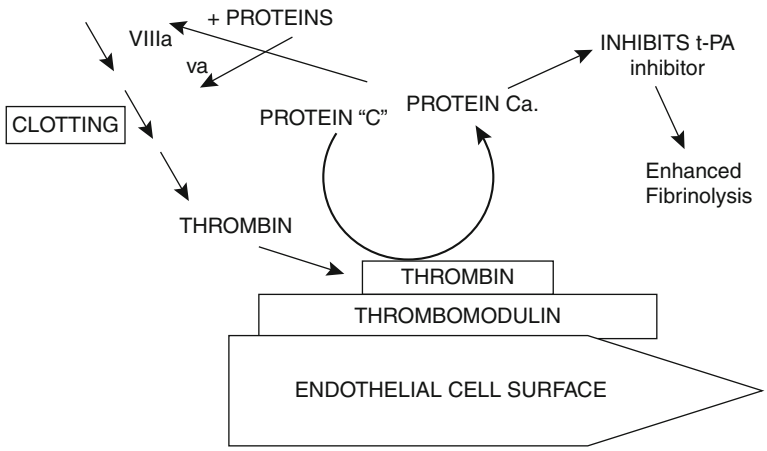

Figure 336.5
Protein C/protein S pathway

Clot Termination and Fibrinolysis

The residual clot in this stage lyses by the activation of plasminogen to plasmin, a process mediated by the intravascular activator tPA. Urokinase on the other hand is the major activator of plasminogen in the extravascular compartment. Plasmin cleaves fibrin, fibrinogen, and other proteins and clotting factors. It cleaves the polymerized fibrin strands at multiple sites resulting in the production of fibrin degradation products (FDP), one of such products is the D-Dimers which represent monomers that have been cross-linked by FXIIIa. Plasmin activator inhibitor (PAI) and alpha-2 anti-plasmin are inhibitors of the fibrinolytic process, the first is an anti-tPA and the second inhibits plasmin. They prevent the process of over fibrinolysis and if deficient, some thrombotic disorders may develop.

Evaluation of the Patient with a Suspected Hemostatic Defect

History and Physical Examination

It is said that the medical history in the patient with suspected bleeding or thrombotic disorder, when done effectively, is the most sensitive "test" for such disorders. The history and the physical examination should focus on (a) whether the suspected defect is hereditary or acquired, and (b) whether it is related to a primary or secondary hemostatic mechanism defect. The first is usually determined by the finding of documented bleeding disorders in family members or manifestations highly suggestive of such disorders. The second requires determination of the site and the nature of the bleeding manifestations. Mucous membrane bleeds (epistaxis, menorrhagia, hematuria, or gastrointestinal bleeds), petechiae of the skin, and multiple small ecchymoses are all characteristic of the defect in the primary hemostatic mechanism in patients with quantitative or qualitative platelet disorders or blood vessel abnormalities. Patients with a defective secondary hemostatic mechanism (coagulation system) usually present with joint and deep muscle bleeds, hematomas, and large spreading ecchymotic lesions. A combination of both manifestations may be encountered in the occasional patient with severe von Willebrand disease (VWD). It is also important to evaluate the severity and duration of the bleed, whether it was spontaneous or induced, and what was required to control it.

Previous surgical procedures should be reviewed. Tooth extraction, tonsillectomy, and circumcision are of particular value, even though the absence of bleed after this last procedure does not exclude a coagulation defect. The age of onset of the bleeding or thrombotic episode may give a clue to the diagnosis. A history of poor wound healing or delayed umbilical cord stump separation may suggest factor XIII deficiency. Epistaxis, a frequent manifestation of coagulation defect in the child, should be evaluated carefully. Several other conditions are known to cause epistaxis and should be considered. Epistaxis in the teenager has more significance than in the younger child. Epistaxis episodes occurring in clusters during a respiratory infection or in certain seasons are less likely to represent a coagulation problem, unlike epistaxis that causes anemia or requires cautery. Drug history is also significant in both determining the cause of the bleed and interpreting an abnormal coagulation test (e.g., bleeding time (BT) or platelet function tests after NSAID drugs

ingestion). Evaluation of the adolescent with menorrhagia also requires certain skills in determining the significance of the symptom. Young women going into menarche may not know what is normal. It is important in such cases to quantitate the amount of bleeding (pads per day), length of bleeding in days, and timing of cycle. Chronic anemia in such patients may indicate a clotting defect. Strokes and thrombosis are most common at the extremes of life, with preterm infants and elderly adults each having a natural predisposition to thrombosis. The occurrence of stroke in a child beyond the neonatal period is often an indication of inherited thrombophilia such as AT, protein C, or protein S deficiency.

In addition to the previously mentioned elements, physical examination should include looking for loose skin (hyperelasticity) and hyperflexibility of the joints. Telangiectasia should also be sought on skin and mucous membranes. Both conditions may give clues to the presence of a systemic disease known to be associated with a hemostatic defect.

Laboratory Evaluation

The laboratory evaluation of children of all ages presenting with bleeding complications should include a prothrombin time (PT), activated partial thromboplastin time (aPTT), BT (or PFA if indicated), thrombin time (TT), and fibrinogen level. One should remember, however, that the laboratory evaluation is not conclusive in many hemorrhagic conditions and may even be in the normal range in the presence of a bleeding disorder that requires a completely different set of tests. For this reason, the importance of a careful history and good physical examination in directing the clinician to an appropriate laboratory evaluation cannot be overemphasized. It is also important to know the normal values for each of the tests performed in relation to the patient's age, since many of the coagulation factors do not reach adult values until the child is 6 months of age or older.

Prothrombin Time

This test measures phase II of coagulation or, more precisely, the function of the extrinsic pathway. The test is performed by adding exogenous thromboplastin (tissue factor) and calcium to the patient's plasma. Thromboplastin complexes with factor VIIa to activate the extrinsic pathway clotting system. The test is most sensitive to deficiencies of factors at the initiation of the extrinsic pathway, such as factor VII and factor X. It is less sensitive to deficiencies of prothrombin itself. The normal values range from 11.5 to 14 S. This test does not measure the activities of factors XII, XI, IX, VIII, or XIII. Since the thrombopalstin reagent differs by the lab and the manufacturer, and so the instruments used in different laboratories to measure the PT, one expects the sensitivity of the test to the effect of Wafarin (for which the test is usually used) to vary as well. For this reason, the INR (International Normalized Ratio), a derivative of the PT was introduced to correct this deficiency and to standardize the test. The INR is calculated by dividing the patient's PT by the control PT (the midpoint of the normal range for that lab) multiplied by the ISI (International Sensitivity Index); this value is provided by the manufacturer based on the sensitivity of their reagent to the effect of Warfarin. If the reagent is less sensitive, the ISI will have a greater value. The INR should not be utilized for evaluation of liver functions, since it is calibrated with plasma from individuals on Warfarin and thus its sensitivity to factor deficiencies related to liver disease cannot be predicted.

Activated Partial Thromboplastin Time

This test measures the time required for the clotting of plasma that has been activated by incubation with an inert activator (kaolin, celite, etc.) when calcium and platelets (or lipid substitute for platelets) are added. In this process, thromboplastin is formed internally (intrinsic system) by activation of the clotting factors. Unlike in the PT testing procedure, thromboplastin is not added in this test, therefore, it is described as "partial." The test therefore measures the function of the intrinsic pathway, and it is most sensitive to deficiencies of factors at the initiation of the intrinsic pathway, such as factor XII, Fletcher factor (prekallikrein), and Fitzgerald factor (HMW kininogen). These three factors, when deficient, give the longest partial thromboplastin times (PTTs), despite the fact that they are not associated with any bleeding disorder. The sensitivity of the PTT reagents is variable, and the normal value should be established for each of the PTT reagents in each laboratory. The variation of sensitivity can be appreciated when a PTT is found to be normal with factor IX as low as 10–13% or prolonged in patients with a factor VIII level of 60% (normal range). The optimal PTT, however, should be prolonged when factor VIII or factor IX is below 30–40% of normal (*Table 336.1*).

The PTT measures factors XII, XI, IX, and VIII. It does not measure factors VII or XIII. In both the PT and the PTT, a prolonged value may indicate a relevant factor

Table 336.1
The clotting factors

Factors	Common name	Biologic half-life(h)	Plasma level
I	Fibrinogen	90	200–400
II	Prothrombin	60	50–150
III	Total thromboplastin	?	0
IV	Calcium		
V	Labile factor	12–36	50–150
VI	Activated labile factor	Part of V	
VII	Stable factor	6–8	50–150
VIII	Antihemophilic factor	8–12	50–150
IX	Christmas factor	12–24	50–150
VWF	Von Willebrand factor	8–12	50–150
X	Stuart factor	32–58	50–150
XI	Plasma thromboplastin antecedent	48–72	50–150
XII	Hageman factor	48–52	50–150
XIII	Fibrin-stabilizing factor	72–120	50–150
High-molecular-weight kininogen	Fitzgerald factor	136	
Prekallikrein	Fletcher factor		

deficiency or the presence of an inhibitor. To determine which condition is present, an inhibitor mix is performed where equal amounts of the patient's and normal plasmas are mixed and a PTT is performed. A normal PTT indicates a factor deficiency, while lack of correction indicates the presence of inhibitor; a low inhibitor titer could be misdiagnosed as deficiency since the mixing study could correct a weak titer, which usually neutralizes the factor activity present in the normal plasma. Should a bleeding tendency exist in addition to the prolonged PTT, then the inhibitor is probably directed against factor VIII, IX, or XI. If no bleeding manifestations are present, the inhibitor is probably of the "lupus anticoagulant" type.

Heparin Anti-Xa

The heparin anti-Xa test is listed here not as a diagnostic test for patients with bleeding disorders, but for the sake of comparison with aPTT test when used for monitoring of anticoagulation therapy with heparin. This test is becoming available in almost all centers, and has gained grounds in replacing aPTT for monitoring UH therapy, in addition to monitoring the treatment with LMW heparin. The many shortcomings of aPTT for monitoring UH treatment make this test a very attractive alternative. It is basically the same test used to derive the therapeutic range for aPTT each time a new reagent is used. It is an ideal test for patients with heparin resistance, and for monitoring UH therapy in the newborn whose base line aPTT is already prolonged. The test is not affected by tube under fill, elevated FVIII or FI due to inflammation, or factors deficiency except for AT.

Bleeding Time

The bleeding time is currently underutilized or unavailable in many laboratories for various reasons, even though a quick, relatively not expensive, and noninvasive test to replace it is not available. The most commonly used method for measuring the BT is the modified Ivy method. An incision is made on the volar surface of the forearm using a standardized template that controls the depth and the length of the incision while a blood pressure cuff is applied to the arm and inflated to 20–40 mmHg. At 30-s intervals, drops of blood are blotted from the margin of the incision. Normally, blood flow stops at 4–8 min. Despite all efforts to standardize this test, a high degree of variability continues to exist. Therefore, it is usually advantageous, whenever possible, to have a technologist in the laboratory to perform this test at all times. This test is not perfect, and it has a high degree of variability and poor sensitivity, yet for lack of alternative tests, it continues to be the best screening test available for assessing the vascular and platelet phases of hemostasis. Bleeding times are prolonged in the presence of thrombocytopenia, thrombocytopathy, connective tissue diseases (Ehlers-Danlos syndrome), and some cases of VWD.

Thrombin Time

This test evaluates phase III of the coagulation cascade. It measures the time required for plasma to clot after the addition of thrombin (factor IIa), which converts fibrinogen to fibrin. The normal TT is 15–20 s. It is prolonged by heparin, fibrin split products, uremia, decreased fibrinogen, or dysfibrinogenemia. In the presence of heparin, the TT can be performed by adding snake venom (reptilase)

instead of thrombin, since this agent is not usually affected by heparin. Other coagulation tests are more specific for certain hemostatic processes. Euglobulin clot lysis time (ELT), for instance, is a crude test designed to measure the fibrinolytic activity. It is performed by using acetic acid to precipitate a euglobulin fraction of the plasma. This fraction is then clotted with thrombin or calcium. The time required for the clot to lyse is then measured (usually 2–4 h). A long ELT may be related to a low plasminogen level, reduced activator, or an extremely increased level of fibrinogen. A short ELT, however, indicates increased activators and/or reduced fibrinogen. Plasminogen, plasminogen activators, and inhibitor assays, as well as assays for fibrin degradation products (FDPs) are other tests for the assessment of the fibrinolytic system.

The marked differences in the various clotting factor levels between newborns and older children and adults make it necessary to discuss the neonatal coagulation system separately. *Table 336.2* shows reference values for coagulation tests in the healthy full-term infant during the first 6 months of life compared to adult values. The striking differences at this stage in life include a prolonged PT, mostly related to the low level of vitamin K–dependent factors; a prolonged PTT, attributed to low levels of the four contact factors (XI, XII, prekallikrein, and HMW kininogen); a BT that is slightly short; and a prolonged TT, which is probably related to the presence of the "fetal" type of fibrinogen at this age. Factors V and VIII, Von Willebrand Factor (VWF), and fibrinogen are not decreased at birth and might actually be elevated. The inhibitors levels are either elevated or low; AT, protein C, and protein S are all low at birth; and other inhibitors are usually higher than adult levels. As for fibrinolysis in the newborn, plasminogen and α_2-antiplasmin are decreased while tissue plasminogen activator (tPA) and PAI are twice the adult values (*Table 336.3*).

Platelet Counts

The platelet component of hemostasis is less difficult to evaluate. Both its quantitative and qualitative aspects can be measured. Thrombocytopenia in infants and children, including premature babies, is defined as it is in adults: a platelet count of less than 150×10^9/L. There is a linear relationship between platelet counts and the BT – the

Table 336.2
Normal coagulation values in the healthy full-term infant during the first 6 months of life[a]

Test	Day 1	Day 5	Day 30	Day 90	Day 180	Adult
PT (s)	13.0(10.1–15.9)[b]	12.4(10.0–15.3)[b]	11.8(10.0–14.3)[b]	11.9(10.0–14.2)[b]	12.3(10.7–13.9)[b]	12.4(10.8–13.9)

Table 336.3
Hemostatic mechanisms of the newborn compared to older children and adults

Hemostatic mechanism	Typical values versus adults
Coagulation Factors	
Fibrinogen	Normal limit
Factors II, VII, IX, X	Very low
Factors VIII, VWF	Normal to increased
Factors XI, XII, high-molecular-weight kininogen	Slightly low–low normal
Prekallikrein	
Factors V and XIII	Low normal
Inhibitors	
Antithrombin III	Low
Proteins C and S	Low
Heparin cofactor II	Low
α_2-Macroglobulin	High
α_1-Antitrypsin	Normal
Fibrinolytic components	
Plasminogen	Low
Plasminogen activators	High
Plasminogen activator inhibitors	Normal/high
Plasmin inhibitors	Low

lower the platelet count, the more prolonged the BT. The etiology of thrombocytopenia, however, plays a role in this relation. Patients whose thrombocytopenia is due to lack of marrow production of platelets, as in aplastic anemia or leukemia, may reveal prolonged BTs at a platelet count of 80,000/μL or lower. In consumptive thrombocytopenias (e.g., idiopathic thrombocytopenic purpura), however, the BT will remain normal until the platelet count drops below 30,000–40,000/μL. If the BT is disproportionate to the platelet count, a qualitative platelet defect, VWD, or a vascular defect should be suspected. Ingestion of anti-inflammatory agents, including aspirin, may prolong the BT; therefore, such testing should be delayed for a minimum of 1 week after the drug ingestion.

Platelet Function Tests

These studies delineate the functional abnormalities of the platelet. One test is based on the increase in light transmittance of a platelet suspension when a platelet activator is added to the suspension. This increase in light transmittance is recorded on a chart for interpretation. Various disorders of platelet function have specific aggregation pattern. Release of platelet-specific proteins (platelet factor 4 and platelet factor 3) is one of the other studies that may be performed to delineate platelet participation in the secondary hemostatic mechanism.

Platelet Function Analyzer-100

(PFA-100) is a relatively new, rapid, and simple in vitro test for the evaluation of platelet function. Some clinicians hoped that the test will be able to replace the vanishing bleeding time (BT), and decrease the need for the traditional, more complicated, and demanding platelet aggregation testing with various agonists. The test is based on simulating the in vivo hemostatic plug formation and is initiated by aspiration of a citrated whole blood sample at high shear rate through a 150 μm aperture in a membrane coated with collagen and epinephrine (CEPI) or collagen and ADP (CADP). Mediated by VWF, platelets adhere to the collagen on the membrane causing them to aggregate in and around the aperture which results in closure of the aperture and arrest of blood flow. The time in seconds needed to reach this point is called "the closure time." Several pre-analytic variables were found to interfere with the test results including: a low level of VWF in the plasma, the high concentration of the citrate in the specimen, an O blood group, low platelet counts or low hematocrit, as well as ingestion of drugs which may affect platelet function such as NSAIDs. All could prolong the closure time giving the impression of a platelet function defect. PFA-100 is now commonly used in clinical practice for the purpose of screening for platelet defects. In our experience, the test is frequently abnormal in many patients with VWD especially those with significantly low VWF.

Congenital Coagulation Disorders

Phase I Disorders: The Hemophilias

The hemophilias are the most common severe inherited bleeding disorders of children and adults. Probably originally named hemorrhaphilia, the disorder was referred to as hemophilia by Schönlein in the early 1800s. Its sex-linked inheritance was recognized 50 years before the Mendelian principles of genetics were introduced. Legg further distinguished hemophilia from other known bleeding disorders on the basis of clinical symptoms, i.e., a congenital tendency to bleed into joints and muscles. It

was not until 1920 that the etiology of hemophilia was attributed to a defect in blood clotting rather than gout or tuberculosis. In the 1940s and 1950s, coagulation factors VIII and IX were identified: the first as the deficient factor in hemophilia A (classic hemophilia) and the second as the deficient protein in hemophilia B (Christmas disease). In the 1970s, factor VIII was isolated from its carrier protein in the plasma, VWF, which has helped to distinguish two previously confused bleeding disorders, hemophilia A and VWD. Since both hemophilia A and B are indistinguishable clinically, they are discussed together in the chapter on bleeding disorders in hemophilia. VWD will also be discussed in that chapter. Hemophilia C, a significantly less common type of hemophilia resulting from deficiency of factor XI, is discussed separately.

Disorders of the Second Phase of Coagulation

The factors that might be involved in this phase are factor II (prothrombin), factor V, factor VII, and factor X. All are produced in the liver, and, with the exception of factor V, they all require vitamin K for their synthesis. Together with factor IX (which is also vitamin K dependent), they are called the "prothrombin complex factors." Vitamin K is needed for the Y-carboxylation of glutamic acid residues, which converts the inactive precursors into active forms. These precursors are described as protein induced by vitamin K absence (PIVKA). The precursor protein for factor II, for instance, is called PIVKA-II.

Factor II (Prothrombin) Deficiency

Quick reported the first case of prothrombin deficiency and, fewer than 100 cases were reported so far. The condition is of autosomal recessive inheritance and could be homozygous, heterozygous, or compound heterozygous. In the first and the third conditions, the activity level may range from <1% to 20% based on the variants reported. This level is about 50% in the heterozygous. The antigen however is usually normal in almost all cases, suggesting a dysprothrombinemia. Heterozygous are usually asymptomatic while homozygous patients present with easy bruising, epistaxis, menorrhagia, and, rarely, joint bleeds. The PT is usually prolonged in the presence of normal TT, and the diagnosis is confirmed by measuring the functional level of the factor. FFP was the treatment of choice for significant bleed (half-life of FII is 3 days). Prothrombin complex concentrates (PCCs) could be used in severe cases after the prothrombin content of that particular brand is checked.

Factor V Deficiency: Owren's Disease

This is a very rare condition with an incidence of one in a million. It is inherited as autosomal recessive and in the severe form (<1% level) is associated with umbilical stump bleed, easy bruising, epistaxis, and menorrhagia. Facor V was previously known as the labile factor since it is not stable in the plasma. Unlike FVIII and IX deficiency, spontaneous Joint bleeds are very unusual. The severity is frequently attributed to the deficient FV in the platelets. Both PT and PTT are prolonged, with normal TCT. FFP (less than 2–3 months old) is the treatment of choice for significant bleed (half-life is 36 h), with local and antifibrinolytic agents for the mild bleed. Platelet transfusion could be considered in the very rare situation of severe nonresponding bleed.

Factor VII Deficiency

The incidence of this deficiency is about 1:500,000. It has a similar mode of inheritance (AR) like the other factors described earlier. The level does not correlate well with the bleeding manifestations in many cases due to the fact that it depends on the reagent used in measuring the factor level. Human tissue factor gives more accurate values which correlate more with the clinical symptoms. This could explain why some patients with <1% level have no bleeding manifestations while others manifest severe disease with hemophilia A and B–like symptoms including hemarthrosis and ICH. The PT is prolonged with normal PTT and TCT. A level of 5–10% is adequate for hemostasis in mild bleed and 15–25% for surgery. Since half-life of FVII is very short (3–4 h), FFP is not practical for treatment. PCCs or recombinant VIIa are usually used.

Factor X Deficiency

This is another rare inherited coagulation factor deficiency with an incidence of 1:500,000. Bleeding manifestations seem to correlate well with the level of the factor. They range from mild to very severe with hemophilia-like symptoms including severe hemarthrosis. Both PT and PTT are prolonged, and so the Russell's viper venum time (measures direct activation of FX). Patients with

amyloidosis may have an associated FX deficiency which is difficult to manage due to the shortened half-life in this disease. FFP and PCCs products are used for treatment of bleeds in FX deficiency. A level of 10–15% is usually adequate. Since half-life is about 40 h, the patients could be managed with FFP.

Factor XI Deficiency (Hemophilia C)

In the individual homozygous for factor XII deficiency, a marked prolongation of the PTT is usually encountered without any evidence of bleeding tendency. Similar findings are encountered with deficiencies of two other contact factors. The prekallikrien (Fletcher) factor and the HMW kininogen (Fitzgerald) factor both result in prolonged PTTs without any bleeding tendency.

Factor XII Deficiency (Hageman Factor)

The deficiency of factor XII is not associated with bleeding and does not require any treatment. The PTT is usually very long in the homozygous (>100 s). Adults with FXII deficiency were reported to have tendency for thrombosis, spontaneous abortion, myocardial infarction, and pulmonary embolism.

Factor XIII Deficiency (Fibrin Stabilizing Factor)

Since this deficiency was first described in 1960, 200 proved cases were reported. The condition is extremely rare and estimated at one in several millions. The protein is present in the plasma as well as the platelets (50% of body total FXIII activity). The condition could be suspected in a bleeder when all coagulation tests are normal. The bleeding manifestations start very early in life with umbilical stump hemorrhage in 80% of the cases. Poor wound healing, bleeding after circumcision, and gum bleed during teething. Females develop recurrent spontaneous abortions, and males develop oligospermia and infertility. ICH could occur in as many as 30% of the cases and is the leading cause of death in this deficiency. The diagnosis is made by clot solubility in urea or by factor level measurement. Only low level of this factor is needed for hemostasis (5%), and since half-life is 9–10 days, prophylactic therapy to prevent intracranial bleed is effective. FFP or cryoprecipitate every 4–6 weeks or, FXIII concentrate by IV infusion every 5–6 weeks will be adequate.

Disorders of the Third Phase of Coagulation

The inherited disorders of fibrinogen (α-fibrinogenemia, hypofibrinogenemia, and dysfibrinogenemia) may present in the homozygous newborn with a clinical picture of delayed umbilical cord bleeds (similar to factor XIII deficiency). Heterozygous newborns are usually asymptomatic except after major challenge. Cryoprecipitate provides effective therapy. Each bag contains 200–250 mg of fibrinogen; 100-mg/kg infusions provide adequate hemostatic levels. Frequent infusions are not necessary since the half-life of fibrinogen is 3–5 days. In dysfibrinogenemia, the fibrinogen level is usually normal despite bleeding manifestations and prolonged TT. This disorder is usually inherited as an autosomal dominant trait.

Aquired Coagulation Disorders

Vitamin K Deficiency

Neonatal vitamin K deficiency (hemorrhagic disease of the newborn) is discussed somewhere else in this text; therefore, only postnatal vitamin K deficiency is presented here. Late manifestations of vitamin K deficiency are reported more frequently in breast-fed infants (low vitamin K in breast milk) and infants with chronic diarrhea, fat malabsorption (celiac disease, systic fibrosis), biliary atresia, hepatitis, and α_1-antitrypsin deficiency. Infants and children on chronic broad-spectrum antibiotics are also susceptible to vitamin K–deficiency hemorrhagic complications. Prophylactic oral administration of water-soluble vitamin K to such infants is indicated (2–3 mg/day for children and 5–10 mg/day for adolescents and adults). In advanced liver disease, the production of the precursor proteins is defective, so vitamin K supplementation is not expected to be of any value. Prolonged PTs and PTTs are the only abnormal coagulation findings. Factor assays may delineate the nature of the problem.

Liver Disease and Liver Transplant

As many as 85% of children with significant liver disease manifest coagulation abnormalities that are directly proportional to the severity of the liver condition. About 15% of such patients manifest significant clinical hemorrhagic disorders. Decreased synthesis of clotting proteins is the major contributing factor, even though other factors, such

as poor clearance of the products of hemostasis, activation of the clotting and fibrinolytic systems, and loss of clotting factors into ascitic fluid, may also be involved. Fulminant liver disease in both newborns and older children may result from viral hepatitis, hypoxia, and shock. Treatment involves replacement therapy. FFP contains all the coagulation factors except fibrinogen, which is provided by cryoprecipitate. Lethal hepatic disorders have been treated with liver transplant since the mid-1980s. Survival rates for such children are on the order of 80%. Two major causes of morbidity and mortality in such patients are intraoperative bleeding and postoperative vascular thrombotic events in the transplanted vessels (portal vein and hepatic artery). This second complication is significantly more common in infants less than 1 year of age (20–25%) than in adults (3–5%).

The incidence is also related to the quality of the graft. Damaged blood vessels for instance increase the rate of thrombotic complications. The clinical features and precipitating factors for coagulopathy in liver transplant vary according to the stage of the procedure. In the preimplant stage for instance, the coagulopathy reflects the underlying liver disease, as well as the effect of clotting factors dilution due to frequent blood product replacement. In the a hepatic stage, the lack of clotting factors synthesis as well as lack of clearance of activated products are the main reasons for the profound coagulopathy, fibrinolysis, and possible DIC encountered in this stage. A very high level of tPA is generated within minutes after the donor liver is placed. In the reimplantation stage, factors and inhibitors of coagulation are gradually restored, fibrinolysis begins to resolve, fibrinogen and plasminogen levels increase while FDPs gradually decrease.

Disseminated Intravascular Coagulation (Consumptive Coagulopathy)

DIC is not a disorder in itself but a process that is secondary to a large variety of underlying conditions. The name indicates the presence of diffuse fibrin deposits scattered in the microvasculature. Both hemorrhagic and thrombotic complications are usually encountered. The first are the result of reduced clotting factors, which were consumed in the circulation, in addition to active fibrinolysis, which also contributes to the bleeding process. The thrombotic complications are the result of increased clotting triggered by various precipitating factors. Underlying disease processes may occur at all ages or be unique to a certain age group. Unique to newborns are adverse events affecting the fetoplacental unit that result in asphyxia and shock, which cause release of tissue thromboplastin that triggers the intravascular clotting process. Other pathologic disorders related to prematurity, such as respiratory distress syndrome, congenital viral infection, hypothermia, and meconium aspiration, may all initiate disseminated intravascular coagulation (DIC). The recent improvements in the care of neonates, together with a better understanding of the DIC process, have significantly changed both the classic clinical picture and the outcome of the affected newborns.

The diagnosis of DIC is based on compatible clinical features in conjunction with abnormal screening tests (PT, aPTT), low levels of certain coagulation factors (fibrinogen, factor V, factor VIII) and inhibitors (AT, heparin cofactor II, protein C), elevated fibrinogen/fibrin split products (FDPs), thrombocytopenia, and fragmented red blood cells (*Table 336.4*). Milder forms of DIC are diagnosed by tests that measure the subtle effects of small amounts of thrombin or plasmin. These include fibrin monomers, thrombin–AT complexes, FDPs, and *D*-dimer. Positive tests alone, however, cannot confirm the process of DIC.

The cornerstone of the management of DIC is the treatment of the underlying disease and its complications. The decision to treat the secondary hemostatic complications has been an issue of debate for some time. Currently, however, the old argument that replacement therapy with plasma products may "fuel the fire" is believed to be theoretical and not true. If the patient is symptomatic

Table 336.4
Laboratory findings in children with three acquired coagulation defects

P prolonged, *L* low, *N* normal, *N/L* normal or low, + increased

due to hemostatic abnormalities, replacement therapy with FFP, exchange transfusion, cryoprecipitate, or platelet transfusion should be initiated. A reasonable therapeutic approach is to maintain a normal PTT, platelets of 50×10^9/L, and fibrinogen of 1.0 g/L. Treatment with anticoagulants such as heparin has also been an issue of controversy. The current recommendation is to restrict heparin therapy to infants with purpura fulminans, usually secondary to meningococcemia. This disorder is characterized by small and large vessel thrombi leading to organ and limb damage. Heparin is probably not indicated in children with skin necrosis only. Heparin is given either as intermittent intravenous administrations in a dose of 75–100 IU/kg every 4 h or as continuous infusion with 50–70 IU/kg as a bolus followed by 1525 IU/kg/h. This therapy should be closely monitored with serial measurements of the anti-Xa or aPTT. In children with evidence of organ or limb necrosis, anticoagulant therapy with heparin may be helpful.

Fibrinolysis

Fibrinolysis is the process responsible for the removal and degradation of the fibrin clot, whether the clot is formed physiologically, as a result of inflammation, tissue repair, or hemostasis, or precipitated by a pathologic process, such as deep vein thrombosis, pulmonary embolism, or DIC. In the first situation, the clot plays a temporary role and must be removed when normal tissue structure and function are restored. In pathologic circumstances, however, the fibrinolytic system, for some reason, fails to dissolve the fibrin clot. Similar to the other coagulation and thrombosis processes, the fibrinolytic system action is coordinated through the interaction of activators, zymogens, enzymes, and inhibitors to provide local activation at sites of fibrin deposition. Activation of the fibrinolytic system can also be achieved by intrinsic or extrinsic pathways. In intrinsic pathway, the activated contact factors (XIIa, XIa, prekallikrein) are known to activate plasminogen to plasmin while the intrinsic coagulation system is being activated. In the extrinsic system (activators are not in the plasma), however, two serine proteases tissue activators have been identified: the first is tPA and the second is urokinase-type plasminogen activator. Both have been produced by recombinant DNA and are available for therapeutic purposes.

Plasminogen is the precursor of the active fibrinolytic enzyme plasmin. It is produced by the liver and present in the plasma as a single-chain molecule. When activated to a two-chain plasmin molecule, a smaller molecule cleaved by plasmin with an amino-terminal lysine is produced (lys-plasminogen). This molecule has higher affinity for binding to fibrin and greater reactivity with plasminogen activators, through sites known as lysine-binding sites. Lysine analogs such as EACA are capable of binding to these sites on plasminogen, thus competing with the lysine-like sites on fibrin, resulting in inhibition of fibrinolysis by rendering the fibrin protected from binding with plasmin or plasminogen. The physiologic fibrinolytic inhibitor α_2-antiplasmin is also mediated in part by binding to the same sites of plasminogen. Plasmin is capable of hydrolyzing proteins other than fibrin and fibrinogen; factor V, factor VIII, complement components, adrenocorticotropic hormone, growth hormone, and glucagon are some examples. Together with other fibrinolytic system inhibitors such as PAI, α_2-antiplasmin plays an important role in the regulation of fibrinolysis.

Once the clot is physiologically formed, fibrinolysis is instantly stimulated. Plasminogen, activated by tPA and single-chain urokinase plasminogen activator (SCU-PA), binds to fibrin while fast-acting inhibitors such as α_2-antiplasmin and PAI-1 go into action. Both are more efficient when their substrates (plasmin for the first and tPA for the second) are free in the plasma rather than bound to other proteins. This allows plasminogen activation on the fibrin while avoiding its effect systemically. When therapeutic quantities of tPA are infused, however, virtually all the plasminogen in the plasma is converted to plasmin, overcoming the neutralizing capacity of antiplasmin and leading eventually to fibrinogenolysis (the lytic state).

337 Pediatric Venous Thromboembolism

Brian R. Branchford · Neil A. Goldenberg

The incidence of pediatric venous thromboembolism (VTE) is increasing and has become a significant cause of morbidity and mortality in infants and children. It is therefore crucial for the primary care pediatrician and subspecialist alike to appreciate the epidemiology, etiologies, presentations, diagnostic evaluation, management, and outcomes of VTE in neonates and older children.

The objectives of this narrative review are to: (1) briefly consider physiologic mechanisms of hemostasis; (2) discuss epidemiology, etiology, and clinical presentation of VTE in children; and (3) present diagnostic measures and treatment options.

Background: Brief review of physiologic mechanisms of hemostasis.

Coagulation is not, in itself, a pathologic condition. Indeed, coagulation and fibrinolysis dynamically interact in the normal physiological state, and it is only when coagulation is insufficiently inhibited or fibrinolysis is excessively inhibited that pathologic thrombosis results. Understanding these processes in normal physiology will facilitate a comprehension of pathologic thrombosis.

Hemostasis is defined as the process by which blood flow from within a vessel is arrested. It is helpful to conceive of hemostasis in two major phases – primary and secondary – that interact in dynamic fashion. Primary hemostasis is triggered when blood vessel damage (i.e., endothelial injury) exposes subendothelial tissue factor (TF) and collagen to flowing blood. Von Willebrand factor and fibrinogen then mediate platelet adhesion and aggregation, resulting in the formation of a platelet plug. Additionally, platelet activation results in surface exposure of phospholipid, forming the scaffold for the plasma clotting reactions of secondary hemostasis. In secondary hemostasis, coagulation activation is initiated as exposed subendothelial TF combines with small amounts of circulating activated factor VII, forming a complex that directly activates factor X (Xa). This is known as the TF pathway (formerly called the extrinsic pathway) of the coagulation cascade. Subsequently, through the common pathway, Xa combines with activated factor V (Va) as the prothrombinase complex, converting prothrombin to thrombin. This process of thrombin generation via the TF pathway is described as thrombin initiation. Thrombin generation is greatly upregulated (described as thrombin propagation) when thrombin activates factor XI, which in turn activates factors VIII (VIIIa) and IX (IXa) through the "contact pathway" (historically known as the "intrinsic pathway") of the coagulation cascade. VIIIa and XIa form a "tenase" complex, converting factor X to Xa, ultimately generating thrombin through the common pathway. The thrombin propagation phase of secondary hemostasis is also mediated by thrombin-induced activation of factors VIII and V. Thrombin is important in the conversion of soluble fibrinogen to insoluble fibrin, forming polymers (fibrils) that are cross-linked by factor XIII to form a hemostatic clot that, in the venous system, is rich in fibrin and interspersed with platelets. Thrombin also serves to activate platelets, thereby fueling further platelet plug and clot formation.

Principal regulators of coagulation activation include the native anticoagulants (antithrombin, protein C, and protein S), thrombomodulin, and tissue factor pathway inhibitor. Antithrombin (formerly known as antithrombin III) is the primary inhibitor of circulating thrombin. Protein C inhibits activation of factors V and VIII. Protein S and thrombomodulin serves as cofactors for protein C.

The coagulation system is in dynamic balance with the fibrinolytic system. In the fibrinolytic system, clot-bound plasminogen is converted by tissue plasminogen activator to plasmin, which cleaves fibrin into monomers and dimers. This process mediates clot lysis, and the fibrin monomers and dimers produced also inhibit further fibrin polymerization.

Further discussion of genetic and acquired thrombophilia traits is beyond the scope of this review, but details can be found in several other texts.

Epidemiology

Historically, the incidence of VTE in children has been perceived to be low. Review of data from multiple recent patient registries revealed an estimated cumulative incidence of 0.07 per 10,000 individuals (5.3 per 10,000 hospitalizations) for extremity deep venous thrombosis (DVT) and/or pulmonary embolism (PE) among non-neonatal Canadian children, and an incidence rate of 0.14

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_337,

per 10,000 Dutch children per year for VTE in general. An evaluation of the National Hospital Discharge Survey and census data for VTE in the United States from 1979 to 2001 disclosed an overall incidence rate of 0.49 per 10,000 individuals per year. During a recent 7-year period of study the annual rate of pediatric VTE increased by 70%, from 34 to 58 cases per 10,000 hospital admissions.

A bimodal age distribution of the incidence rate for childhood VTE is noted, with peak rates in neonates and adolescents. The Dutch registry, for example, indicated a VTE incidence rate of 14.5 per 10,000 per year in the neonatal period, approximately 100 times greater than the overall rate in childhood, while the VTE-specific incidence rate in the United States among adolescents 15–17 years of age was determined to be 1.1 per 10,000 per year, a rate nearly threefold that observed overall in childhood.

Most recently, an analysis of the Pediatric Health Information System (PHIS) database from 2001 to 2007 revealed that approximately 1 in 200 hospitalized children are diagnosed with VTE. This figure likely includes both patients who developed VTE in hospital as well as those children admitted for VTE that developed outside the hospital.

Etiology

Virchow's triad consists of venous stasis, endothelial damage, and the hypercoagulable state. This group of clinical situations encapsulates the primary risk factors responsible for pathogenesis of VTE. In children, greater than 90% of VTE are risk-associated (as compared to approximately 60% in adults), with risk factors in children often disclosed from more than one component of this triad. Of the clinical prothrombotic risk factors, one of the most common is an indwelling central venous catheter. Over 50% of cases of DVT in children and over 80% of cases in newborns occur in association with central venous catheters. The presence of an indwelling central venous catheter, underlying malignancy or disorder for which bone marrow transplantation was undertaken, and congenital cardiac disease and its corrective surgery were all highly prevalent in the Canadian pediatric thrombosis registry, whereas underlying infectious illness and the presence of an indwelling central venous catheter were identified as pervasive clinical risk factors in a recent cohort study analysis from the United States. A recent review of the Pediatric Health Information System revealed that a majority (63%) of children with VTE had >1 coexisting chronic complex medical condition and that pediatric malignancy was the medical comorbid condition associated most strongly with recurrent VTE.

As noted above, thrombophilia may be caused by any alteration in hemostatic balance that increases thrombin production, enhances platelet activation/aggregation, mediates endothelial activation/damage, or inhibits fibrinolysis. Regarding the hypercoagulable state, blood-based risk factors for VTE in children include both inherited and acquired thrombophilic conditions. Potent thrombophilic conditions (e.g., severe anticoagulant deficiencies, antiphospholipid antibodies) in children are frequently acquired, rather than congenital. By contrast, the common congenital thrombophilia traits (e.g., heterozygosity for the factor V Leiden or prothrombin G20210A polymorphisms) tend to be more mild.

Common examples of acquired thrombophilia in children include: increased factor VIII activity with significant infection and inflammatory states; anticoagulant deficiencies due to consumption in bacterial sepsis and disseminated intravascular coagulopathy (DIC) or to the production of inhibitory antibodies in acute viral infection; and para-infectious development of antiphospholipid antibodies (APA). In order to provide an appreciation of the magnitude of VTE risk increase associated with several congenital/genetically influenced thrombophilia traits, population-based VTE risk estimates derived from the adult literature are shown in *Table 337.1*. As seen in the Table, the addition of standard-dose estrogen oral contraceptive pill to an underlying heterozygous factor V Leiden (in large part by virtue of a "double-hit" to the protein C pathway) would be expected to increase the risk for VTE from a baseline risk of 15 per 10,000 US females aged 15–17 years per year to a risk of over 500 per 10,000, or 5%, per year.

Table 337.1
VTE risk estimates for selected thrombophilia traits and conditions

Trait/condition	VTE risk estimate (× baseline)
Hyperhomocysteinemia	2.5
Prothrombin 20210 mutation, heterozygous	2–3
Oral contraceptive pill (OCP; standard-dose estrogen)	4
Factor V Leiden mutation, heterozygous	2–7
OCP+Factor V Leiden mutation, heterozygous	35
Factor V Leiden mutation, homozygous	80

Clinical Presentation

The degree of clinical suspicion for acute VTE in children should be primarily influenced by the following characteristics: (1) clinical signs and symptoms; (2) personal history of VTE; (3) clinical prothrombotic risk factors; (4) family history of early (e.g., before age 50 years) VTE or other vascular events; and (5) known thrombophilia traits/risk factors. In many cases, information from this last category is not available at the time of clinical presentation with possible VTE.

The signs and symptoms of VTE vary based upon anatomic location.

Limb Deep Venous Thrombosis

The classic manifestation of acute limb DVT is painful unilateral extremity swelling. The presence of Homan's sign (pain upon manual calf compression or with forced dorsiflexion of the foot while the knee is flexed) or the presence of a palpable cord in the popliteal fossa may suggest lower extremity DVT; however, these physical findings are both insensitive and nonspecific. In upper extremity DVT with extension into, and occlusion of, the superior vena cava (SVC), signs and symptoms may include swelling and/or erythema of neck and face, visualization of superficial collateral vessels in the chest, bilateral periorbital edema, and headache.

Pulmonary Embolism

Pulmonary embolism usually presents with sudden- or progressive-onset dyspnea and/or pleuritic chest pain, and is occasionally accompanied with hypoxemia (particularly in settings of extensive or proximal PA involvement). Associated right heart failure (cor pulmonale) may manifest with hepatomegaly, visible superficial collateral vessels in the abdomen, and/or peripheral edema. Proximal PE and especially saddle embolus can present with cyanosis or sudden cardiopulmonary collapse. In many cases, however, PE may be asymptomatic or subtle in children, especially when involving limited segmental or subsegmental branches of the pulmonary arteries. At the same time, the most peripheral PE near the pleura frequently causes pleuritic reactions (pleuritis) and/or effusions that are quite symptomatic. In one retrospective series, only 50% of affected children had clinical symptoms attributable to PE.

Cerebral Sinovenous Thrombosis

Signs and symptoms of acute cerebral sinovenous thrombosis (CSVT) may include severe and persistent headache, blurred vision, neurologic signs (e.g., cranial nerve palsy, papilledema), or seizures. Although not signs and symptoms of the CSVT per se, one must also be attentive to the constellation of findings in otitic hydrocephalus and Gradenigo's syndrome (the triad of suppurative otitis media, pain in the distribution of the trigeminal nerve, and abducens nerve palsy), in which otitis media is complicated by mastoiditis and petrositis, with development of thrombus in the adjacent sigmoid or lateral sinus. Mastoid tenderness, fever, and findings (or recent history) of otitis media should therefore prompt suspicion for this disorder.

Renal Vein Thrombosis

Renal vein thrombosis (RVT) is classically associated with hematuria and thrombocytopenia, sometimes accompanied by anemia and hypertension. Bilateral involvement is sometimes associated with uremia and/or oliguria. RVT is most common during the neonatal period and may be noted on physical exam as a flank mass. RVT in older children is often associated with nephrotic syndrome (a risk factor for VTE in general), and may therefore present with peripheral and/or periorbital edema.

Portal Vein Thrombosis and Hepatic Vein Thrombosis

Portal vein thrombosis (PVT) characteristically presents with splenomegaly, and is associated with thrombocytopenia and, often, anemia; gastrointestinal bleeding at presentation typically signals the presence of gastroesophageal varices due to portal hypertension.

Hepatic vein thrombosis without PVT is typically asymptomatic, and usually found incidentally upon abdominal imaging.

Intracardiac Deep Venous Thrombosis

Isolated intracardiac thrombosis in association with cardiac surgery or central venous catheter placement is most often asymptomatic. Thrombocytopenia, described for RVT above, can also be seen with intracardiac (e.g., right atrial) thrombus.

Internal Jugular DVT and Lemierre's Syndrome

Internal jugular vein thrombosis may manifest with neck pain or swelling. Lemierre's syndrome (classically caused by Fusobacterium, but occasionally identified with other potentially causative organisms) is associated with fever, trismus, and a palpable thrombus in the lateral triangle of the neck.

Diagnosis

Radiologic Evaluation

The importance of radiologic imaging lies in its dual ability to confirm the clinical diagnosis of VTE as well as define both the extent and occlusiveness of thrombosis. The gold-standard for diagnosis of venous thrombosis is conventional venography, but the utility of this modality is limited by its invasive nature and the associated risks.

Currently, when DVT of an extremity is suspected, compression ultrasonography with Doppler color flow imaging is typically used for confirmation. When the thrombus may involve or extend into deep pelvic or abdominal veins, computed tomography venography (CTV) or magnetic resonance venography (MRV) is often required.

If involvement of the central thoracic vasculature (e.g., right atrial thrombosis, SVC thrombosis) is suspected, echocardiogram may be used in addition to CT or MRI. In the case of asymptomatic non-occlusive extremity DVT disclosed by ultrasound, CTV, MRV with gadolinium contrast, or conventional venography may be necessary for diagnostic confirmation. To establish a diagnosis of DVT of the jugular venous system (such as in suspected cases of Lemierre's syndrome), compression ultrasound with Doppler imaging is typically used.

PE in children is commonly evaluated with spiral CT angiography or by ventilation-perfusion scan. The latter, however, is generally suboptimal in cases involving other potentially confounding lung pathologies or at centers without sufficient expertice with this modality. CSVT is typically diagnosed by MRV or CTV. This diagnosis occasionally is made in the course of head imaging (e.g., plain CT or MRI) for another cause. RVT is most often diagnosed clinically in neonates and is supported by Doppler ultrasound findings of intrarenal vascular resistive indices; however, in some cases a discrete thrombus may be suggested by Doppler ultrasound (especially when extending into the inferior vena cava) or may be further disclosed via MRV. When RVT occurs in older children, Doppler ultrasound or CTV is often diagnostic. Similarly, portal vein thrombosis is typically visualized by Doppler ultrasound or CTV.

In some cases, new-onset venous thrombosis is being evaluated in patients with anatomic abnormalities of the venous system, including extensive collateral venous circulation due to a prior VTE episode, May-Thurner anomaly (left iliac vein is compressed by right iliac artery, causing increased risk of DVT due to compressive stasis), or atretic IVC with azygous continuation. For these patients, more sensitive methods such as CTV or MRV are often required to define the vascular anatomy as well as the presence, extent, and occlusiveness of thrombosis. Conventional venography may also be required.

Disadvantages of MRV include its expense, and necessity of sedation in young, developmentally delayed, or anxious children. Additionally, its use during acute VTE evaluation requires availability of MR-trained technologists. However, MRV offers a significant advantage over CTV by providing diagnostic sensitivity at least as great as CTV (particularly when gadolinium enhancement is used for scenarios in which non-occlusive thrombus must be distinguished from flow artifact), without significant radiation exposure.

Laboratory Evaluation

A thorough diagnostic laboratory evaluation in the setting of pediatric acute VTE should include a complete blood count, DIC panel, comprehensive thrombophilia evaluation (see Etiology, above), and beta-HCG testing in postmenarchal females. Additional laboratory studies may also be necessary depending upon associated medical conditions and possible VTE involvement of specific organ systems. *Table 337.2* summarizes a panel of thrombophilia traits and markers that each have been identified as risk factors for VTE in pediatric studies, and as such have been recommended by the Scientific and Standardization Committee Subcommittee on Perinatal and Pediatric Haemostasis of the International Society on Thrombosis and Haemostasis for the diagnostic laboratory evaluation of acute VTE in children. This comprehensive panel includes tests of anticoagulant deficiency (e.g., protein C, protein S, antithrombin), procoagulant excess (e.g., factor VIII), mediators of hypercoagulablity and/or endothelial damage (e.g., APA, lipoprotein(a), homocysteine), and markers of coagulation activation (e.g., D-dimer).

Significant debate currently surrounds the issue of comprehensive laboratory testing for thrombophilia traits

Table 337.2
Thrombophilic conditions and markers tested during comprehensive diagnostic laboratory evaluation of acute VTE in children

Condition/marker	Testing method(s)
Genetic	
Factor V Leiden polymorphism	PCR
Prothrombin 20210 polymorphism	PCR
Elevated plasma lipoprotein(a) concentration[a]	ELISA
Acquired or genetic	
Antithrombin deficiency	Chromogenic (functional) assay
Protein C deficiency	Chromogenic (functional) assay
Protein S deficiency	ELISA for free (i.e., functionally active) protein S antigen
Elevated plasma factor VIII activity[b]	One-stage clotting assay (aPTT-based)
Hyperhomocysteinemia	Mass spectroscopy
Antiphospholipid antibodies	ELISA for anticardiolipin and anti-beta-2-glycoprotein-I IgG and IgM; clotting assay (dilute Russell Viper Venom time or aPTT-based phospholipid neutralization method for lupus anticoagulant)
Disseminated intravascular coagulation	Includes platelet count, fibrinogen by clotting method (Clauss), and D-dimer by semiquantitative or quantitative immunoassay (e.g., latex agglutination)
Activated protein C resistance	Clotting assay (aPTT-based)

[a]Although designated here as genetic, lipoprotein(a) may also be elevated as part of the acute phase response
[b]Noted as worthy of consideration in original International Society on Thrombosis and Haemostasis recommendations; this has since been shown to be a prognostic marker in pediatric thrombosis. Additional testing involving the fibrinolytic system and systemic inflammatory response is also noted as worthy of consideration

in children with, or at heightened risk of, VTE. Many of the current guidelines are based upon consensus expert opinion or low-grade clinical evidence. Indeed, given the low incidence of VTE in the general pediatric population, widespread, unselected thrombophilia screening would neither be ethical nor cost-effective.

A comprehensive thrombophilia assessment is likely to have greatest clinical utility among individuals with a personal or close family history of a thrombotic event before the age of 55 years. A recent analysis of comprehensive laboratory evaluation in 56 children with positive family history of early VTE, but negative personal history of the same, advocated a risk-stratified approach to laboratory-based thrombophilia evaluation in these asymptomatic children that would target individuals with familial early VTE. Particularly in children and young adults, populations in which the incidence of VTE is low, efforts to identify individuals with clinical risk factors for VTE who have meaningful underlying thrombophilia may provide a rational approach to VTE prevention by targeting a subpopulation at heightened risk, in which comprehensive laboratory testing would be more beneficial.

Conventional Therapy

Table 337.3 provides a summary of conventional antithrombotic agents and corresponding target anticoagulant levels, based upon recent pediatric recommendations for both initial (i.e., acute phase) and extended (i.e., subacute phase) treatment. Conventional anticoagulants attenuate hypercoagulability, decreasing the risk of thrombus progression and embolism, while relying principally upon intrinsic fibrinolytic mechanisms to dissolve the thrombus. The most commonly employed conventional anticoagulants in children include heparins (either unfractionated [UFH] or low molecular weight heparin [LMWH] varieties) and warfarin. Heparins work by enhancing the activity of antithrombin, as discussed above. Warfarin acts through antagonism of vitamin K, thus interfering with gamma-carboxylation of the vitamin K-dependent procoagulant factors II, VII, IX, and X, as well as intrinsic anticoagulant proteins C and S.

Initial anticoagulant therapy for the acute phase of VTE in children involves UFH or LMWH. Two LMWH agents commonly employed in the United States (based upon labeling for adult VTE) are enoxaparin and

Table 337.3
Recommended intensities and durations of conventional antithrombotic therapies in children, by etiology and treatment agent (adapted from current consensus-based recommendations)

Episode	Agents and target anticoagulant activities				Duration of therapy, by etiology
	Initial treatment		Extended treatment		
First	UFH	03–0.7 anti-Xa U/mL	Warfarin	INR 2.0–3.0	Resolved risk factor: 3–6 months
	LMWH	0.5–1.0 anti-Xa U/mL	LMWH	0.5–1.0 anti-Xa U/mL	No known clinical risk factor: 6–12 months
					Chronic clinical risk factor: for duration of risk factor (often with prophylactic dosing, after initial 3–6 months of therapeutic dosing)
					Potent congenital thrombophilia: indefinite
Recurrent	UFH	0.3–0.7 anti-Xa U/mL	Warfarin	INR 2.0–3.0	Resolved risk factor: 3–6 months
	LMWH	0.5–1.0 anti-Xa U/mL	LMWH	0.5–1.0 anti-Xa U/mL	No known clinical risk factor: indefinite
					Chronic clinical risk factor: for duration of risk factor (often with prophylactic dosing, after initial 3–6 months of therapeutic dosing)
					Potent congenital thrombophilia: indefinite

dalteparin. In recent years, LMWH has become increasingly popular as the first-line agent for initial anticoagulant therapy in children given the relative ease of subcutaneous administration, the decreased need for blood monitoring of anticoagulant efficacy, and a decreased risk of the development of heparin-induced thrombocytopenia (HIT). LMWH is not ideal in all situations, however. UFH has a much shorter half-life than LMWH, and is therefore preferred in circumstances of heightened bleeding risk, upcoming surgery/invasive procedure, or labile acute clinical status, since the anticoagulant effect rapidly dissipates following cessation of the drug. Additionally, because LMWH is partly eliminated through the renal system, UFH (which is largely heptically eliminated) is more appropriate for acute VTE therapy in the setting of significantly impaired renal function.

Common initial dosing for UFH in non-neonatal children begins with an IV loading dose of 50–75 U/kg followed by a continuous IV infusion of 15–20 U/kg/h. Due to lower antithrombin levels in full-term neonates, a maintenance dose of up to 50 U/kg/h may be required for these patients, especially if the clinical condition is complicated by antithrombin consumption. The starting dose for enoxaparin in non-neonatal children commonly ranges between 1.0 and 1.375 mg/kg subcutaneously on an every-12-h schedule and does not require a bolus dose. In full-term neonates, a dose of 1.5 mg/kg is typically necessary. For dalteparin, on the other hand, initial maintenance dosing of 1.0–1.5 mg/kg (100–150 anti-Xa U/kg) appears appropriate based upon available pediatric data.

Anti-factor Xa activity levels can be used to follow either type of heparin therapy, whether UFH or LMWH. Anti-Xa level should be obtained 6–8 h after initiation of UFH infusion or 4 h following any one of the first few doses of LMWH. For UFH, the therapeutic range is 0.3–0.7 anti-Xa activity U/mL, while for LMWH the therapeutic range is 0.5–1.0 U/mL. When the anti-Xa assay is not available, the activated partial thromboplastin time (aPTT) may be used (with a goal aPTT of approximately 1.5–2 times the upper limit of age-appropriate normal values); however, this approach is especially suboptimal in the pediatric age group, in which transient antiphospholipid antibodies are common and may alter the clotting endpoint. Notably, one study of pediatric heparin monitoring demonstrated inaccuracy of aPTT approximately 30% of the time. When dosed by weight in childhood, LMWH does not require frequent monitoring, but anti-Xa activity should be evaluated with changes in renal function, weight shifts $>10\%$ of baseline, or in clinical situations where bleeding side effect is of particular concern. In addition, there are cases of acute VTE in which acquired antithrombin deficiency is related to consumption in acute infection or inflammation. In these instances, the anti-Xa activity may rise as antithrombin levels normalize with resolution of the acute illness, warranting follow-up evaluation of anti-Xa in the subacute period.

Controversy exists regarding length of therapy during both the acute and subacute phases of anticoagulation for VTE in children. Due to lack of pediatric data, the recommended duration of heparinization of 5–10 days during the initial therapy for acute VTE has been extrapolated

from adult data. UFH treatment is rarely maintained beyond the acute period, given the risk of osteoporosis with extended administration and the inconvenience of continuous intravenous administration. Although adult data suggest efficacy of subcutaneous administration of unfractionated heparin for acute VTE, this has only been evaluated for the acute therapy period prior to extended therapy with warfarin, and the appropriateness of such an approach in children has not been established.

Extended anticoagulant therapy (i.e., subacute phase) for VTE in children may employ LMWH or warfarin. For warfarin anticoagulation, warfarin is often started during the acute phase. As above, however, severe congenital PC deficiencies can present as VTE in early childhood and are associated with warfarin skin necrosis. Warfarinization should, therefore, be initiated only after therapeutic anticoagulation is achieved with a heparin agent. Due to the relatively short half-life of PC, warfarin's interference with its activation can result in a transient hypercoagulable state. It is therefore also important to use LMWH or UFH as a "bridge" until warfarin reaches effective levels.

A common starting dose for warfarin in children is 0.1 mg/kg orally once daily. Warfarin is monitored by international normalized ratio (INR), derived from the measured prothrombin time. The therapeutic INR range for warfarin anticoagulation in VTE is 2.0–3.0. Recent adult data do not agree with the historical evidence for maintaining a higher INR (2.5–3.5) in the presence of APA; however, pediatric data are lacking with regard to both optimal dose intensity and duration in children with APA syndrome. The INR is typically checked after the first 5 days of initiation of (or dosing change in) warfarin therapy, and weekly thereafter until stable. As levels become more stable, less frequent monitoring is often feasible. The INR should also be evaluated at the time of any bleeding manifestations or increased bruising. Warfarin must be discontinued at least 5 days prior to invasive procedures, with an INR obtained prior to the procedure to ensure resolution of anticoagulant effect. In some situations, an anticoagulant transition, or "bridge," to LMWH can be performed, to minimize the time off anticoagulation perioperatively.

As mentioned above, clear recommendations for long-term duration of anticoagulant therapy are not available, and depend heavily on clinical situation, as well as provider preference. For initial VTE in children in the absence of potent chronic thrombophilia (e.g., APA syndrome, homozygous anticoagulant deficiency, homozygous factor V Leiden or prothrombin 20210), the recommended duration of anticoagulant therapy is 3–6 months in the presence of an underlying reversible risk factor (e.g., postoperative VTE) and 6–12 months when idiopathic. In the case of chronic risk factors (systemic lupus erythematosus), the initial 3–6 months consist of therapeutic dosing, followed by prophylactic dosing for the duration of the risk factor's presence. Recurrent VTE is treated for 3–6 months in the presence of an underlying reversible risk factor, and indefinitely when idiopathic. As above in the case of chronic risk factors (systemic lupus erythematosus), the initial 3–6 months of therapy for recurrent VTE consist of therapeutic dosing, followed by prophylactic dosing for the duration of the risk factor's presence. In the setting of APA syndrome or potent congenital thrombophilia, the treatment duration for first-episode VTE is often indefinite. Some evidence suggests that children with SLE and persistence of the lupus anticoagulant (LA) have a 16- to 25-fold greater risk of TEs than children with SLE and no LA. However, in children with primary (i.e., idiopathic) or secondary (i.e., associated with SLE or other underlying chronic inflammatory condition) APA syndrome, it is possible that the autoimmune disease will become quiescent in later years, such that the benefit of continued therapeutic anticoagulation as secondary VTE prophylaxis may be reevaluated. Some experts have recommended consideration of low-dose anticoagulation as secondary VTE prophylaxis following a conventional 3- to 6-month course of therapeutic anticoagulation for VTE in children with SLE who have APA syndrome. Such low-dose, or prophylactic, anticoagulation might, for example, consist of enoxaparin 1.0–1.5 mg/kg subcutaneously once daily, enoxaparin 0.5 mg/kg subcutaneously twice daily, or daily warfarin with a goal INR of 1.5. However, further study to optimize the intensity and duration of therapy/secondary prophylaxis for VTE in children with APA syndrome is urgently needed, especially given the recent evidence in adult VTE that secondary prophylaxis with low-dose warfarin not only may offer little risk reduction beyond no anticoagulation, but also is associated with bleeding complications despite a reduced warfarin dose.

A multicenter randomized trial is underway to determine whether a shorter duration of anticoagulant therapy (i.e., 6 weeks) is appropriate for pediatric VTE associated with identifiable reversible risk factors and no potent genetic thrombophilia state.

Novel/Emerging Therapies and New/Alternative Anticoagulants

Direct Thrombin Inhibitors

Direct thrombin inhibitors inhibit thrombin directly via its active site or by binding to its target on fibrin. This class

includes intravenously administered drugs such as bivalirudin and argatroban, as well as oral alternatives such as dabigatran.

The intravenous direct thrombin inhibitors are indicated for the treatment of heparin-induced thrombocytopenia (HIT), particularly when associated with acute thrombosis (HITT), and are also used in patients with a history of HIT.

Dabigatran is an oral direct thrombin inhibitor, which has been approved in Europe and Canada since 2008 for venous thromboembolism (VTE) prophylaxis in the setting of orthopedic surgery, and was recently approved in the US for stroke prevention in adults with atrial fibrillation. A recent meta-analysis of the three phase-3 studies, RE-MODEL, RE-MOBILIZE, and RE-NOVATE, supported the individual trials' conclusions of noninferiority to enoxaparin. Results of the RE-COVER study which compared dabigatran with warfarin for the treatment of acute VTE in 2,539 patients were recently reported and showed equivalent rates of recurrent VTE without significantly different major bleeding episodes in patients treated with dabigatran versus those who received warfarin.

Xa Inhibitors

Factor Xa inhibitors, including fondaparinux, inhibit the activation of factor X, thereby indirectly inhibiting thrombin. Fondaparinux is an entirely synthetic pentasaccharide that is structurally related to the antithrombin-binding site of heparin. In contrast to heparin, which interacts with many plasma components, the pentasaccharide selectively binds to antithrombin, causing it to rapidly inhibit factor Xa, a key enzyme in the coagulation pathway.

Rivaroxaban, an oral factor Xa inhibitor, is already approved for VTE prophylaxis following hip and knee replacement in Europe and Canada, and appears near to approval in the United States. The RECORD series of clinical trials compared rivaroxaban to subcutaneous enoxaparin for the prevention of venous thromboembolism after orthopedic surgery and illustrated both efficacy and safety. Another Factor Xa inhibitor, apixaban, is currently in trials for VTE treatment and post-orthopedic surgery prophylaxis.

Intravenous direct thrombin inhibitors are routinely monitored by aPTT, with the therapeutic goal ranging from a 1.5- to 3.0-fold aPTT prolongation. A variety of factor Xa inhibitors and oral direct thrombin inhibitors are undergoing preclinical development or evaluation in adult clinical trials.

Both the factor Xa inhibitors and the direct thrombin inhibitors are also being evaluated for their efficacy in stroke prevention in the setting of atrial fibrillation. Though these new agents may allow for similar efficacy and safety as warfarin for long-term oral anticoagulation therapy or prevention, significant cost may be prohibitive. Also, despite the inconvenience of frequent lab monitoring of warfarin, it is an effective means of evaluating compliance. An effective antidote or reversal agent for these drugs (such as protamine sulfate might be used for overdose of unfractionated heparin or LMWH) is not currently available. Therefore, optimal safety information regarding dosing regimens is of vital importance. It is hoped that head-to-head trials of these new anticoagulants will provide useful information regarding the challenges that will arise in optimal therapeutic selection.

Thrombolytic Modalities

Systemic TPA

One treatment approach that is becoming more common in children with hemodynamically significant PE or extensive limb-threatening VTE is the use of thrombolysis. The conventional anticoagulants discussed above act by attenuating clot progression while intrinsic fibrinolysis occurs physiologically. Thrombolytics, on the other hand, promote fibrinolysis directly. Tissue-type plasminogen activator (TPA) is an intrinsic activator of the fibrinolytic system, and can be administered in its recombinant form by various routes (e.g., systemic bolus, systemic short-duration infusion, systemic low-dose continuous infusion, local catheter-directed infusion with or without interventional mechanical thrombectomy/thrombolysis). A recent cohort study analysis of children with acute lower extremity DVT, who had an a priori high risk of poor post-thrombotic outcomes by virtue of completely veno-occlusive thrombus and plasma FVIII activity >150 U/dL or D-dimer concentration >500 ng/mL, revealed that a thrombolysis regimen followed by standard anticoagulation may substantially reduce the risk of post-thrombotic syndrome when compared to standard anticoagulation alone. However, bleeding risk must be carefully assessed prior to the use of this approach.

Percutaneous Mechanical/ Pharmacomechanical Thrombolysis (PMT/PPMT)

Percutaneous mechanical/pharmacomechanical thrombolysis (PMT/PPMT), using a combination of

intravenous mechanical clot disruption and local TPA infusion, is a therapeutic option that is gaining popularity. This procedure may be followed by catheter-directed thrombolytic infusion (CDTI), a practice in which TPA is administered locally over a period of 1–2 days following the procedure.

One recent prospective cohort study evaluated 16 children who suffered from completely occlusive proximal limb DVT in association with acute elevation of FVIII and D-dimer who elected to undergo PMT/PPMT within 60 days of symptom onset. PMT/PPMT was successfully conducted in 15 cases and CDTI was employed adjunctively in 11 of these for the purpose of providing local therapy only, thereby reducing the risks of systemic thrombolysis (including systemic bleeding risks involving critical sites such as the central nervous system). There were no peri-procedural major bleeding events, but one symptomatic pulmonary embolism occurred. Clot lysis was achieved in 94% of cases. There were five acute local recurrences within 1 week (all of which were successfully re-lysed). Despite acute local re-thrombosis in 40%, 83% of these were successfully re-lysed, and late recurrent DVT occurred in 31% overall. These data suggest that PMT with/without adjunctive CDTI can be used safely in adolescents with DVT known to be at high a priori risk for PTS. Although signs and/or symptoms of PTS were still observed in some patients even when PMT was performed within 10 days of symptom onset, the rate of functionally significant PTS occurred in only 25% of these high-risk patients.

At the time of this writing, the existing literature contains no randomized control trials of PMT, in children or adults. Indeed, prospective data on this lytic intervention for DVT are limited to two adult studies, which were actually focused more upon CDTI, and PMT was reported in just a few cases in each study. Retrospective studies, on the other hand, are somewhat more numerous. Eight retrospective studies exist, totaling approximately 200 adult DVT patients treated by PMT with/without adjunctive CDTI. However, published experience with a regimen of PMT followed by adjunctive CDTI as described above is limited to three retrospective adult studies.

Regarding the safety of PMT with/without CDTI, only six cases of acute major bleeding and zero cases of acute symptomatic PE were reported among the nine retrospective studies, out of a total of 279 patients. Acute thrombolysis rates were high across the eight retrospective studies, suggesting potential efficacy. However, long-term patency was only reported by Lin and colleagues, who determined a rate of 65%. No cases of acute recurrent DVT were reported among a cumulative total of 62 subjects in the retrospective studies wherein this outcome was assessed. These findings identify PMT with adjunctive CDTI as a therapeutic option worthy of further prospective study as an effective and potentially safer (decreased systemic bleeding risks involving critical sites such as the central nervous system) alternative to systemic thrombolysis in children with occlusive proximal limb DVT who have adverse prognostic biomarkers at acute presentation.

Other Antithrombotic Agents

Various other antithrombotic products await further clinical trials to demonstrate efficacy. For example, as mentioned above, protein C concentrate can be useful as an adjunct to standard heparin therapy for VTE or purpura fulminans due to microvascular thrombosis in severe congenital protein C deficiency or in children with sepsis, particularly in meningococcemia. In addition, various case series have suggested a role for antithrombin replacement in VTE prevention in children and young adults with congenital severe antithrombin deficiency, for the prevention of L-asparaginase-associated VTE in pediatric acute lymphoblastic leukemia (ALL), and as combination therapy with defibrotide in the prevention and treatment of hepatic sinusoidal obstruction syndrome (formerly termed veno-occlusive disease) in children undergoing hematopoietic stem cell transplantation. The potential benefit for VTE risk reduction using a regimen of antithrombin replacement combined with daily prophylactic LMWH during induction and consolidation phases of therapy in ALL has now also been suggested by a historically controlled cohort study of the BFM 2000 protocol experience in Europe. As noted above, antithrombin replacement may also be worthy of consideration in patients receiving heparin therapy for acute VTE in whom significant antithrombin deficiency prevents the achievement of therapeutic anti-Xa levels (i.e., heparin "resistance"). This may be the case in nephrotic syndrome-associated VTE. Additionally, neonates with clinical conditions complicated by antithrombin consumption as described above are particularly predisposed to such heparin "resistance," due to a physiologic relative deficiency of this key intrinsic thrombin inhibitor.

Another complementary therapy to consider in children of appropriate size with persistent prothrombotic risk factor(s) who suffer from recurrent VTE (especially PE) is the placement of temporary vena caval filters. However, recommended use of these devices in pediatric VTE is generally restricted to the setting of inability or contraindication to anticoagulate (typically transient). The impact of

non-retrievable devices upon the vena cava of the developing child has not been well studied, and experience with surgical removal of non-retrievable vena caval filters is quite limited. Consequently, the use of non-retrievable vena caval filters in pediatrics should be undertaken with caution.

Outcomes

Both acute and long-term complications of VTEs, and their associated therapy, must be considered. Short-term adverse outcomes of the thrombotic event itself may include post-thrombotic hemorrhage (in the brain, testis, or adrenal gland), early recurrent VTE (including DVT and PE), SVC syndrome in upper extremity DVT, acute renal insufficiency in RVT, catheter-related sepsis or malfunction (sometimes necessitating surgical replacement) in CRT, severe acute venous insufficiency leading to venous infarction with limb gangrene in rare cases of occlusive DVT involving the extremities, and/or death from hemodynamic instability in extensive intracardiac thrombosis or proximal PE. Additionally, one must consider the major hemorrhagic complications of antithrombotic interventions.

Given the long-term risks of recurrence, disease sequelae, and functional impairment, VTE must also be considered as a chronic disorder in children. Long-term adverse outcomes in pediatric VTE have recently been reviewed, and include: recurrent VTE, chronic hypertension and renal insufficiency in RVT, variceal hemorrhage in portal vein thrombosis, chronic SVC syndrome involving occlusion in upper extremity VTE, and development of the post-thrombotic syndrome (PTS): a condition of chronic venous insufficiency following DVT.

Mortality

While VTE-specific mortality in children is quite low, ranging from 0% to 2%, a considerably higher all-cause mortality reflects the severity of underlying conditions (e.g., sepsis, cancer, congenital cardiac disease) in pediatric VTE. Neonate-specific outcomes data in pediatric non-RVT VTE reflect an all-cause mortality of 12–18%, including one series of premature infants with CRT treated with enoxaparin.

Recurrent Venous Thromboembolism

Registry and cohort study data in all types of pediatric VTE indicate that children appear to have a lower risk of recurrent thromboembolism than adults (cumulative incidences at 1–2 years of 6–11% versus 12–22%, respectively). However, the risk of PTS in children with DVT of the limbs appears to be at least as great as that in adults (cumulative incidences at 1–2 years of 33–70% versus 29%, respectively). Additionally, it should be noted that a German cohort study of children with spontaneous VTE (i.e., VTE in the absence of identified clinical risk factors) revealed that the cumulative incidence of recurrent VTE at a median follow-up time of 7 years was 21%. These findings suggest that, in this subgroup of pediatric VTE, the risk for recurrent events is long-lived.

Major Bleeding

With regard to major bleeding complications occurring during the anticoagulation period, frequencies in children range from 0% to 9% in recent studies.

Post-thrombotic Syndrome

The manifestations of PTS (as described above) may include edema, visibly dilated superficial collateral veins, venous stasis dermatitis, and (in the most severe cases) venous stasis ulcers. A recent systematic review of 19 studies totaling 977 patients with upper and lower extremity DVT, revealed a PTS frequency of 26%. The pathophysiology of PTS is thought to derive from venous valvular reflux and/or persistent thrombotic veno-occlusion following DVT, both of which ultimately result in venous hypertension.

Outcomes by Thrombus Type/Location

A clot's location has been found to be quite important with regard to long-term sequelae. Specifically, outcomes of VTE in children may differ among particular anatomic sites. In a Canadian study of CRT in children from 1990 to 1996, VTE-specific mortality was 4% among all children, and was 20% among those children in whom CRT was complicated by PE. No major bleeding episodes were observed. At a median follow-up of 2 years, the cumulative incidence of symptomatic recurrent VTE was 6.5%, and PTS developed in 9% of children. In other series of RVT (primarily among neonates), VTE-related death has been quite uncommon, and the cumulative incidence of recurrent VTE has ranged from 0% to 4%. The cumulative incidence of chronic hypertension in RVT in these studies

was reported at 22–33%. For CSVT, the pediatric literature reflects a VTE-specific mortality ranging from 4% to 20%, with a cumulative incidence of recurrent VTE of 8% for neonatal CSVT cases and 17% for CSVT occurring in older children. Long-term neurologic sequelae were noted in 17–26% of neonatal CSVT cases and the cumulative incidence of such sequelae in childhood (i.e., non-neonatal) CSVT has ranged widely between 8% and 47%. It should be noted that both the proportion of children anticoagulated, and the duration of therapy, in the aforementioned pediatric series of RVT and CSVT varied considerably across studies. With regard to portal vein thrombosis, few pediatric series reporting outcomes have been published; however, it appears that the risk of developing recurrent gastrovariceal bleeding in this population is substantial, occurring in many cases even after surgical interventions have been undertaken to reduce portal hypertension. For PE in childhood, long-term outcomes such as chronic pulmonary hypertension and pulmonary function have yet to be established, but remain important to evaluate.

Residual thrombus burden is an additional outcome of interest, but of unclear prognostic significance. A correlation has been shown between D-dimer levels and residual thrombosis at time of anticoagulant treatment discontinuation and the risk of recurrence. Additionally, some evidence indicates that persistent thrombosis is associated with the development of venous valvular insufficiency, an important risk factor for (albeit an imperfect correlate of) the development of PTS. The prevalence of residual thrombosis despite adequate anticoagulation in neonatal VTE has ranged from 12% in a small series of premature newborns with CRT to 62% in full-term neonatal VTE survivors. Among primarily older children, the prevalences of persistent thrombosis have ranged broadly from 37% to 68% in the few longitudinal studies that have employed systematic radiological evaluation of thrombus evolution.

Prognostic Factors and Predictors of Outcome

It has been reported that thrombophilia and markers of coagulation activation are common in pediatric VTE, while potent genetic thrombophilia states are less frequently encountered; nevertheless, the latter are more likely to present in the pediatric age than in older adulthood.

Part of the difficulty with treating childhood VTE is lack of knowledge regarding the natural course of the disease in this population. The ability to predict clinically relevant long-term outcomes of VTE at diagnosis and during the acute/subacute phases of treatment is essential to establishing a future risk-stratified approach to antithrombotic management in children.

As VTE becomes increasingly recognized in children, discussion regarding the appropriate laboratory evaluation for thrombophilia continues. Comprehensive thrombophilia evaluation is recommended in children with VTE. In the future, validated global assays of overall coagulative and fibrinolytic capacities may provide an initial diagnostic evaluation tool to direct more specific testing, and could perhaps be prognostically important.

Previous studies have defined the strong associations of homozygous anticoagulant deficiencies and APA syndrome with recurrent VTE. Over the past several years, the presence of multiple thrombophilia traits has been identified as prognostic for recurrent VTE, and the radiologic finding of complete veno-occlusion at diagnosis of DVT has been associated with an increased risk of persistent thrombosis (which in turn has been associated with the development of venous valvular insufficiency, as noted above). A recent meta-analysis of searches of electronic databases from 1970 to 2007 evaluated the impact of certain thrombophilia traits on recurrence of VTE, reported as odds ratios (OR), which ranged from 2.63 for the factor II variant to 9.44 for antithrombin deficiency. Significant association was found for all inherited thrombophilia traits except factor V Leiden (OR 0.64) and elevated lipoprotein(a) (OR 0.81).

In addition, plasma FVIII activity >150 U/dL and D-dimer concentration >500 ng/mL at the time of diagnosis of VTE in children, as well as following 3–6 months of standard anticoagulation have been shown to predict a composite adverse thrombotic outcome, characterized by persistent thrombosis, recurrent VTE, and/or the development of PTS, adding to evidence for the prognostic utility of these markers in adult VTE.

The finding that evaluation of thrombophilic states in children with VTE may be useful in predicting these pediatric thrombotic outcomes provides optimism that a risk-stratified approach to intensity and duration of antithrombotic therapy may soon be established.

338 Incidence, Epidemiology and Survival

H. Stacy Nicholson

Introduction

Compared to cancer during adulthood, childhood cancer is rare. In the USA, the incidence of cancer between ages 0–19 is 16.7 per 100,000 (15.2 per 100,000 for ages 0–14). The most common malignancy is acute lymphoblastic leukemia (ALL) with 3.5 per 100,000 followed by central nervous system (CNS) tumors at 2.9 per 100,000. Over the past three decades, survival has improved for most pediatric cancers. In the USA, 81.4% of children and adolescents diagnosed with cancer between the ages of 0 and 19 between 1999 and 2006 survived for more than 5 years. The incidence rates and chances of surviving at least 5 years for the major childhood cancers are shown in *Table 338.1*.

Cancer in Developing Nations

Childhood cancer incidence and mortality differs in high- vs. low-income nations, and these differences should be further studied in order to better understand etiology, in particular. While cancer survival rates for children are similar in all high-income nations to what is seen in the USA, most of the world's children live in middle- and low-income nations. In developing nations, the proportion of children relative to the total population is greater, and access to health care is often lower. As the treatment for infectious diseases and other more common diseases in children has improved, the impact of childhood cancer in developing counties has increased. We shouldn't accept that survival rates will always remain lower in developing nations. "Twinning" countries – creating partnerships between developed and developing countries in order to improve the treatment of childhood cancer – is an approach that holds great promise for bringing the benefits of effective anticancer therapy to more of the world's children.

Etiology

In most cases of childhood cancer, the cause is unknown. Environmental factors do not play a large causal role in childhood cancer in contrast to many adult malignancies. Cancer in childhood or adolescence differs significantly from adult malignancies. Adult cancers are primarily carcinomas, while children get leukemia, brain tumors, embryonic cancers, and sarcomas. Thus, in children, the etiology is more likely to be genetic, rather than environmental. There are exceptions – benzene can lead to leukemia, and radiation can lead to brain tumors and other solid malignancies. Also, in Sub-Saharan Africa, the Epstein–Barr virus (EBV) is known to cause Burkitt lymphoma, and EBV is also associated with lymphoproliferative diseases in transplant survivors. Human Papilloma Virus (HPV) is associated with cervical, penile, and some head and neck cancers – while these tumors do not often affect children and adolescents, the prevention of these cancers is becoming possible with the advent of

Table 338.1
Incidence and survival of major childhood cancers in the United States (diagnosed before age 20)

Cancer	Incidence (per 100,000)	5 year relative survival (%)
Bone	0.8	70.1
Brain	3.0	74.8
Hodgkin's lymphoma	1.4	96.1
Acute lympoblastic leukemia (ALL)	3.2	85.9
Acute myeloid leukemia	0.8	56.5
Neuroblastoma	1.0	71.7
Non-Hodgkin lymphoma	1.2	84.1
Soft tissue sarcoma	1.1	76.3
Wilms' tumor	0.6	92.1
OVERALL	16.7	81.4

Incidence rates are per 100,000 and are age-adjusted to the 2000 US standard population. 2007 data given. Survival data are for children diagnosed at ages 0–19 between 1999 and 2006

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_338,

vaccines against HPV. HIV is associated with Kaposi's sarcoma and non-Hodgkin's lymphoma, and Hepatitis B and other viruses may be causal in some liver tumors.

Secondary cancers occur in a small proportion of cancer survivors due to therapies such as chemotherapy and radiotherapy and, in some, a genetic predisposition to cancer. Secondary cancers are discussed in the chapter on late complications of therapy.

The incidence of cancer in children who are genetically predisposed to cancer is higher. This predisposition may be due to genetic factors that have either been inherited or develop spontaneously. Some of the more common-known cancer predisposition syndromes are outlined in *Table 338.2*. Rarely, the same cancer may occur in multiple members of a family. Bilateral cancers in paired organs, such as bilateral retinoblastoma or bilateral Wilms tumor, is evidence for a genetic predisposition as are positive family histories. Familial cancers have been most commonly reported in retinoblastoma, childhood leukemia, and Wilms tumor. Mathematical modeling of the earlier

Table 338.2
Cancer predisposition syndromes in children

Condition	Tumors	Genetic defect	Comments
Hereditary retinoblastoma (RB)	Retinoblastoma; osteosarcoma	RB1	80% with bilateral RB will have a negative family history
Down syndrome	Acute lymphoblastic leukemia; acute megakaryoblastic leukemia; JMML	Trisomy 21	Contribution of trisomy to tumorigenesis is not known
Li Fraumeni syndrome	Sarcomas; breast cancer; brain tumors; leukemia	p53	Family history key
Fanconi anemia	Acute leukemia	Multiple Fanconi	Chromosomal breakage syndrome
	Head and neck carcinomas		
	Cervical carcinoma		
Bloom syndrome	Acute leukemias		
Ataxia telangiectasia	Lymphoma	ATM (11q22–q23)	Truncal ataxia; oculocutaneous telangiectasias
	Leukemia		
	Gastric carcinoma		
Neurofibromatosis type I	Neurofibromas; optic nerve gliomas; astrocytomas; pheochromocytoma; AML; myelodysplasia; myeloproliferative syndromes;	NF1 gene (17q11.2)	Variable severity of NF1; very large gene
Neurofibromatosis type II	Vestibular schwanomas; meningiomas;	NF2 (19)	Most often diagnosed in adulthood
Tuberous sclerosis	Subependymal giant cell astrocytomas (SEGA); renal angiomyolipomas	TSC1 (9q34)	Variable intelligence; seizures
		TSC2 (16p13.3)	
Gorlin syndrome	Medulloblastoma	PTCH	
	Basal cell carcinomas		
Turcot syndrome	Colon cancer and CNS tumors (medulloblastoma, high-grade astrocytomas)	APC gene; hereditary nonpolyposis colon cancer (HNPCC)	Family history of colon cancer, particularly at a young age.
WAGR	Wilms tumor	WT1 (11p13)	Wilms tumor, aniridia, genitourinary abnormalities; mental retardation
Beckwith Wiedeman syndrome (BWS)	Wilms tumor	11p15	Screening for liver, adrenal and kidney tumors key during childhood
	Hepatoblastoma		
	Adrenocortical carcinoma		

age at onset of bilateral retinoblastoma led to Knudsen's two-hit model of cancer etiology. Furthermore, children with an underlying cancer predisposition syndrome have an increased risk of a second cancer. Thus, updating the family history for cancer in all first- and second-degree relatives should occur at diagnosis and periodically throughout treatment and follow-up as new cancers occurring in adult relatives may be informative. Finally, children with immunodeficiencies have an increased risk of lymphoma and lymphoproliferative diseases.

Cancer During Infancy

During the first year of life, the types of cancers that occur differ from what is seen in later childhood. While leukemia remains the most common cancer during infancy, its incidence is less than half of what occurs at age 2, and acute myelogenous leukemia (AML) is more common relative to *all* than in older children. As in other ages, brain and other Central Nervous System (CNS) tumors are the most common solid malignancy, and neuroblastoma is also common. Neuroblastoma is the most common cancer in the first month of life.

Adolescent and Young (Aya) Adult Cancers

In the USA, older adolescents (15 years and older) and young adults (up to 40 years) have not seen the same degree of improvement in survival compared to children and older adults. This is likely due to differing tumor biology, impaired access to care, and insufficient supportive care infrastructure. Efforts to improve outcomes in the AYA population are being studied.

339 Evaluation of Abdominal Masses and Enlarged Lymph Nodes in Children

Gregory Blaschke · H. Stacy Nicholson

Abdominal Masses

Childhood tumors that commonly present with an abdominal mass include neuroblastoma, Wilms' tumor, hepatoblastoma, rhabdomyosarcoma, lymphoma, and ovarian tumors. Prompt investigation of suspected abdominal masses leads to more effective and more cost effective treatment.

Often, abdominal masses are discovered by parents or by physicians during health maintenance visits. In order to maximize the chances of discovering abdominal masses, a careful history and physical exam should be part of each health maintenance visit during childhood. In addition to allowing the parents to describe any concerns, including the following items in a review of systems will be helpful in uncovering abdominal masses:

- Abdominal pain
- Hematuria
- Irritability
- Weight loss
- Vomiting
- Changes in bowel habits

The physical examination should include careful palpation of the entire abdomen, and this may be done in any position that ensures cooperation and a successful exam. The history and physical can yield clues as to the diagnosis. Hematuria suggests Wilms' tumor or a rhabdomyosarcoma of the genitourinary system. Hypertension may accompany neuroblastoma, and symptoms of intestinal obstruction suggest a Burkitt's lymphoma of the bowel wall.

Any suspected abdominal mass should be promptly evaluated, and an abdominal ultrasound (US) is useful as the initial imaging modality as it is typically readily available and spares the child from radiation exposure that accompanies computerized tomography (CT).

Once an abdominal mass is confirmed, surgical consultation is warranted. The history, exam, and imaging often suggest a likely diagnosis; based on this presumed diagnosis, any indicated staging tests may be done before surgery. This will assist the surgeon in surgical planning, and a preoperative chest CT eliminates confusion regarding whether findings represent postoperative atelectasis or metastatic disease.

Enlarged Lymph Nodes

Enlarged lymph nodes are a common finding in healthy children, and few such nodes represent malignancy. Lymph nodes are most often enlarged in response to an infection, and one generally sees resolution with successful treatment of the underlying cause. Pyomyositis is more common in many tropical parts of the world. Common infectious causes include staph aureus, tuberculosis, or sarcoidosis. Preceding trauma may be in the history and drainage is part of treatment. Nontender, firm nodes in unusual locations or ones that continue to increase after 2 weeks or fail to regress in 4–6 weeks should lead to biopsy. Tender adenitis may require a trial of antibiotics.

Table 339.1
Typical differences between benign and malignant causes of enlarged lymph nodes

Characteristic	Benign adenopathy	Malignancy
Onset	Rapid and associated with other signs and symptoms of infection, such as fever.	Progresses slowly over time. May be the only symptom present.
Size	Usually <3 cm	Can be small or large; will generally increase in size over time and may become confluent
Consistency	Soft, warm	Firm, rubbery, or hard
Tenderness	Usually present	Usually absent

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_339,

Fluctuant adenopathy may require cautious surgical involvement or drainage, and usually excision to avoid chronic drainage tracks depending on infectious etiology. However, enlarged nodes may be the initial manifestation of leukemia (particularly T-cell acute lymphoblastic leukemia (ALL)), Hodgkin Disease, non-Hodgkin lymphoma, or histiocytosis. Rarely, an enlarged node may represent regional or metastatic spread from an undiagnosed solid tumor. Adenopathy associated with malignancy does not resolve and typically progresses over time. *Table 339.1* lists clinical features that typically accompany both benign and malignant adenopathy.

340 Principles of Diagnosis

Gregory Blaschke · H. Stacy Nicholson

Introduction

When a child is suspected of having a malignancy, there is an urgent need to obtain the correct specific histopathological diagnosis and to fully document the stage (degree of spread). A precise diagnosis and correct staging informs both the prognosis and determines the correct treatment plan. Thus, ensuring that all tissues are handled correctly and that all required staging tests are obtained is crucial. In general, a histopathological diagnosis, either from tumor excision, biopsy, or needle aspiration, must be obtained. Exceptions to this rule include sites where biopsies pose excessive risk (such as brainstem tumors) and some oncologic emergencies, such as when a child with a mediastinal mass presents with severe respiratory and/or circulatory compromise. Each cancer has a distinct panel of diagnostic studies needed for proper staging, and these are discussed in each disease entity. Guiding general principles are the topic of this chapter.

When a primary care physician diagnoses or strongly suspects a childhood malignancy, prompt referral to a center with pediatric oncologists, pediatric surgeons, advanced imaging resources, and pathological resources is indicated.

Diagnostic Studies

Blood, Bone Marrow, and Spinal Fluid

A complete blood count (CBC) is generally performed whenever leukemia or a solid tumor is suspected. Children with leukemia will usually have blasts on the blood smear; however, cytopenias in one or more cell lines may be the only evidence for leukemia. Similarly, solid tumors with metastatic spread to the bone marrow may lead to cytopenias on the CBC.

Serum chemistries should be obtained to ensure adequate hepatic, renal, and other organ function prior to initiating therapy. LDH should be measured if lymphoma is suspected, and uric acid must be measured in leukemias and lymphomas in order to minimize the risk of tumor lysis syndrome with the initiation of therapy. When applicable, serum tumor markers should be obtained. Tumor markers are discussed with each disease entity.

Bone marrow aspiration is required to establish the diagnosis of leukemia and in staging solid tumors that can metastasize to marrow. In addition to standard morphology, cytogenetic studies and flow cytometry need to be obtained. In leukemia, chromosomal number (ploidy), some chromosomal translocations and cell surface markers have prognostic and treatment implications. Bone marrow biopsies are also important in the staffing workup for lymphomas and for some solid tumors.

Performing a lumbar puncture for cerebrospinal fluid (CSF) cytology is indicated in some brain tumors (medulloblastoma, ependymoma, primitive neuroectodermal tumors (PNET)), in leukemia and lymphoma, and in parameningeal rhabdomyosarcomas.

Radiological Studies

Chest X-rays (CXR) are frequently obtained in children with newly diagnosed cancer, and an urgent CXR should be obtained in children with leukemia or lymphoma to check for a mediastinal mass (*Fig. 340.1*). A CXR is typically obtained in children with a solid tumor, but computerized tomography (CT) of the chest should also be done, making a CXR less important. Abdominal ultrasound may be useful as a screening tool, but the degree of information obtained from CT scans or magnetic resonance imaging (MRI) has made these modalities the gold standard. MRI is the imaging modality of choice in CNS tumors, while CT scans are typically better in evaluating bone. Nuclear medicine scans are used to evaluate for bony metastases and are used in staging and following patients with lymphoma.

Tissue Diagnosis

Proper treatment is only possible following a correct pathological diagnosis. Biopsies can be obtained via surgery or by a needle biopsy. Consultation with the pathologist prior to the procedure can be helpful, particularly when a needle biopsy is planned, in order to ensure that enough tissue is available to establish the diagnosis and perform all required studies. Frozen-section examination of the tumor

during surgery can ensure that the tumor has indeed been biopsied and guide the surgeon in making clinical decisions. In some tumors, evaluating the margins of the excised mass for active tumor must be done to assist in determining prognosis and assigning treatment. Providing the pathologist with fresh tissue may be required for cytogenetics, molecular studies and flow cytometry. Such studies are becoming more important with molecular staging of tumors and leukemias. Again, preoperative consultation with the pathologist can ensure that the proper studies are performed.

Family- and Community-Centered Care

While the primary care provider may not make the definitive diagnosis, it is always helpful to collaboratively "break the news" regarding the concern for cancer to the family as part of referral process. Indeed, the desires and abilities in the context of the family and community will often determine the initial referral location. Definitive care may require additional referral to alternative sites that specialize in specific treatments or cancers. Many family, community, and multidisciplinary partners can assist in informing the family and assisting with the process of referral.

341 Principles of Cancer Chemotherapy in Children

H. Stacy Nicholson

Introduction

Children and adolescents with cancer are best treated at a referral center with adequate resources to assemble a team consisting of pediatric oncologists, radiation oncologists, and surgeons, as well as nursing staff and others who support the children and families. The pediatric oncologist typically leads the team, and most pediatric cancers are treated with chemotherapy, either alone or in combination with surgery and radiation.

Chemotherapy simply means using medicines to treat cancer, and there are a few key principles and definitions that broadly apply, regardless of diagnosis. Using chemotherapy in solid tumors following surgery, even without evidence of metastatic disease, is defined as adjuvant chemotherapy. Chemotherapy administered before the definitive surgical procedure is referred to as neoadjuvant chemotherapy. One of the most important advances in the use of chemotherapy was the recognition that combination chemotherapy, using two or more drugs with differing mechanisms of action, would help overcome drug resistance. Dose intensity, the amount of chemotherapy delivered over a specified interval of time, is another key principle of associated with improved efficacy and survival.

Chemotherapy dosing is typically based on the body surface area (BSA), which more closely correlates to the patient's volume than weight. In infants (less than 12 months) or children weighing less than 12 kg, BSA-based dosing often results in an overdose, so weight-based dosing is used. During the first month of life, in particular, drug clearance may be slow due to immature liver and renal function.

Protocol-driven therapy is the standard of care in children with cancer, and randomized phase III clinical trials have resulted in steady improvements in survival. When available, such trials are usually offered to families at diagnosis.

Major Classes of Chemotherapy

Most chemotherapy agents interfere in the process of cell replication. The most commonly used chemotherapy drugs in children are listed in *Table 341.1*.

Alkylating Agents

Alkylating agents are used against most pediatric cancers. These highly reactive compounds form covalent bonds by attaching an alkyl group to DNA, creating DNA-DNA and DNA-protein crosslinks. Alkylating agents include mechlorethamine (nitrogen mustard), cyclophosphamide, ifosfamide, thiotepa, the nitrosoureas, melphalan, and busulfan. Cyclophosphamide and ifosfamide are prodrugs, requiring activation by hepatic metabolism. Their dose-limiting toxicity is hematological toxicity, and all can cause nausea and vomiting and mucositis. Cyclophosphamide and ifosfamide can cause hemorrhagic cystitis, which can be prevented by the concomitant use of mesna.

There are related drugs that also covalently bond to DNA. The platinators cisplatin and carboplatin bind a platinum group to DNA and dacarbazine, procarbazine and temozolomide covalently bind methyl groups to DNA.

Antimetabolites

Antimetabolites are structural analogues of the building blocks or cofactors used in the synthesis of DNA and/or RNA. These agents are active against many childhood cancers and are critical in the treatment for childhood acute lymphoblastic leukemia (ALL). Methotrexate, a folate analogue, can be given by multiple routes: oral (PO), intravenous (IV), intramuscular (IM), or

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_341,

Table 341.1

Chemotherapy agents most commonly used in children and adolescents

Drug	Mode of administration	Precautions	Major toxicity	Major use in pediatric oncology
Alkylating agents				
Nitrogen mustard (NM)	IV	Avoid extravasation	Myelosuppression	Hodgkin disease (HD)
			N/V	
Cyclophosphamide (cytoxan, CTX)	IV, PO	Brisk diuresis, use mesna with high doses	Hemorrhagic cystitis, myelosuppression, infertility	Leukemias
			N/V	Lymphomas
				Sarcomas
				Neuroblastoma
Ifosfamide	IV	Brisk diuresis, mesna must be used	Hemorrhagic cystitis, myelosuppression, infertility	Sarcomas
			N/V	Germ cell tumors
Cisplatin (CDDP)	IV	Brisk diuresis	Renal dysfunction	Medulloblastoma
			Hearing loss	Neuroblastoma

			Anaphylaxis	
			Coagulation issues	
			Pancreatitis	
			Hyperglycemia	
Prednisone	PO		Hyperglycemia	ALL
			Weight gain	NHL
			Hypertension	HD

ALL Acute lymphoblastic leukemia, *AML* acute myelogenous leukemia, *HD* Hodgkin disease, *NHL* non-Hodgkin disease, *N/V* nausea and vomiting

intrathecal (IT). Dosing varies widely, including high-dose therapy with leucovorin rescue. The thiopurines, mercaptopurine and thioguanine, are oral agents active in ALL, during the maintenance phase. Failure to comply with maintenance therapy is associated with relapse, especially in adolescents. Cytarabine, a pyrimidine analog, is active against lymphoid malignancies and can be given IT.

Anthracyclines

The anthracyclines doxorubicin and daunomycin are effective against most childhood cancers, although their poor penetration of the blood-brain barrier limits their use against central nervous system tumors. Anthracyclines have several mechanisms of action, including becoming intercalated into DNA and inhibition of topoisomerase II, a key DNA repair enzyme. Monitoring cardiac function and limiting the cumulative dose is important, as these drugs are associated with cardiomyopathy as a late complication.

Tyrosine Kinase Inhibitors

The use of imatinib mesylate in chronic myelogenous leukemia (CML) has transformed the treatment of CML and is the first broad application of rationally designed therapy. Imatinib inhibits the action of the abnormal tyrosine kinase that is the *BCR-ABL* fusion protein. Imatinib is similarly effective in pediatric CML, and trials

are ongoing in pediatric ALL with the Philadelphia chromosome. Such drugs will be increasingly important in the coming decades.

Other Agents

The vinca alkaloids vincristine and vinblastine bind to tubulin and interfere with the microtubular spindles involved in mitosis. Vincristine is more widely used, and has neurotoxicity (pain and/or weakness) as its dose-limiting toxicity. Etoposide is a topoisomerase II inhibitor active in both solid tumors and leukemia, and asparaginase is an enzyme that deletes asparagine, an essential amino acid in lymphoblasts.

Steroids, including prednisone and dexamethasone, are active against lymphoid malignancies. These medications induce apoptosis, in both malignant and normal lymphoid cells.

342 Pediatric Radiation Therapy

Carol Marquez

Treating children with radiation therapy presents unique challenges. Fortunately, in the last 20 years, many improvements have occurred that address and mitigate these challenges. Those improvements have been in the field of radiation oncology, in the development and results of pediatric clinical trials, and in the care and management of children in designated children's hospitals. Taken together, they represent a significant advance on the prognosis of pediatric malignancies and on the quality of life of the pediatric patients.

Improvements in Radiation Therapy

There have been significant advances in the planning and delivery of radiation therapy in the last two decades. In the early 1990s, treatment planning became based on CT images versus plain x-ray images. This switch allowed for a 3D rendering of the tumor and normal structures and for a "beams' eye view (BEV)" perspective of those relationships (see *Fig. 342.1*). The linear accelerator is designed to deliver dose from a wide variety of table positions and gantry positions. Only by having a BEV can the radiation oncologist visualize the tumor and normal tissue in oblique and noncoplanar angles. With this perspective, the radiation oncologist is able to design a treatment field that may spare more normal tissues. Having the CT information about normal structures also allowed for more accurate information about the dose delivered to those structures. With the development of the multileaf collimator (see *Fig. 342.2*), a device that is part of the linear accelerator that allows for precise, rapid, computer-controlled shaping of the beam of radiation, a treatment planning technique called intensity modulated radiation therapy (IMRT) was possible. The multileaf collimator shapes the beam while the dose is being delivered, thereby varying the intensity of the radiation and the subsequent dose within each beam of radiation that is used. This modulation of the dose produces a heterogeneous dose distribution within the treatment field. With IMRT, doses to nearby critical structures can be significantly reduced, especially in those tumors that wrap around critical normal structures, such as the spinal cord or parotid gland, where a concave dose distribution is desirable. IMRT is very useful in pediatric tumors that arise near these critical structures such as rhabdomyosarcoma or Ewing's sarcoma.

Given the rapid fall off of the dose outside of the target volume in IMRT plans, it is necessary to verify the accuracy of the patient's position immediately prior to treatment delivery. This need required the development of image-guided radiation therapy (IGRT). With IGRT, imaging of the patient is performed on the treatment table and the images are compared to the images obtained at the time of treatment simulation to verify that the patient is in the same position so that the dose is delivered accurately. The imaging modalities that may be used for IGRT include ultrasound, orthogonal films, or a CT that is part of the treatment machine (cone beam CT) (see *Fig. 342.3*). This process of verifying treatment position means that the patient and the target volume are within millimeter accuracy on a daily basis. This level of accuracy provides less variability in day-to-day setup. This decrease in variability and increase in accuracy in turn allows for a decrease in the additional margin placed around the tumor that has been historically necessary. The potential downside for the patient especially in the pediatric population is the increased exposure to x-rays when kV x-rays or cone beam CT is used as the modality for IGRT.

Stereotactic radiosurgery (SRS) is a technique of delivering a high single dose of radiation to a small volume (<2 cm) with high precision using stereotactic guidance often with rigid immobilization such as a frame or a relocatable mask. Multiple intersecting beams are used so that a high dose is given at the point of intersection (the "isocenter") and a lower dose is given to the surrounding brain because multiple beams are used. This technique is ideally suited for intracranial well-circumscribed spherical targets such as brain metastasis but is also indicated in the treatment of primary tumors such as acoustic neuromas, meningiomas or pituitary adenomas, and in the benign conditions of arteriovenous malformations or trigeminal neuralgia. In the pediatric population, SRS has been used for the treatment of astrocytomas, recurrent medulloblastomas, and recurrent ependymomas. Radiosurgery is helpful in the setting of recurrent disease because the

amount of dose given beyond the target is very limited which is important in patients who have previously received a larger field of radiation. There are several technologies that are available to perform SRS and they include gamma knife, cyberknife, and a linear accelerator.

In the last 10 years, the principles of SRS have been applied to extracranial targets such as small primary lung tumors or liver tumors, so-called stereotactic body radiotherapy (SBRT). In SBRT, the treatment is delivered over 2–5 fractions usually separated by several days. Each fraction delivers a dose of 4–20 Gy, which is determined by the volume being treated, the disease being treated, and the location of the target volume with respect to nearby critical structures. With SBRT, the use of IGRT is mandatory because of the high dose being given and the few numbers of fractions delivered. In pediatric patients, SBRT has shown promising results in lung metastases from Ewing's sarcoma but the results are otherwise limited in the pediatric setting.

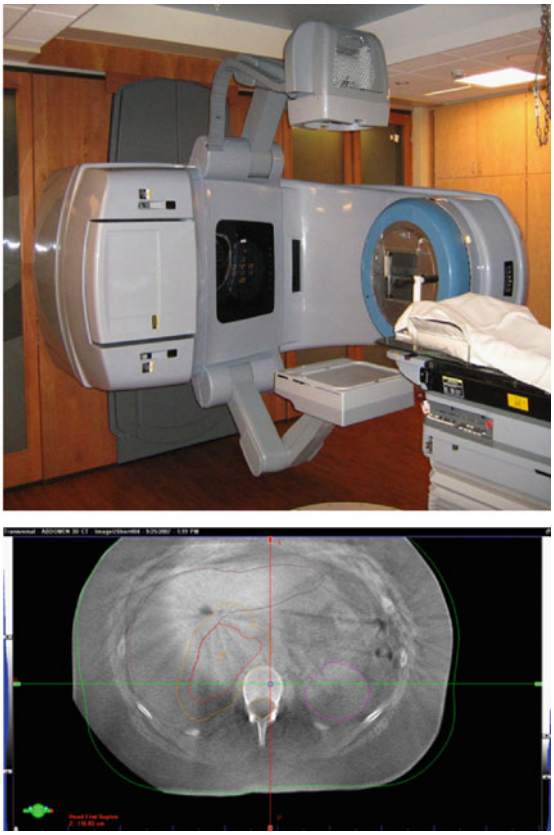

Figure 342.3
(a) Linear accelerator with cone beam CT, arms that are perpendicular to the head of the machine. This device generates kV photons and, when rotated completely around the patient, a CT is generated; (b) CT image generated by the cone beam CT

One of the more promising innovative technologies for the treatment of pediatric malignancies is proton beam therapy. Protons are a particle form of radiation, not photons or x-rays which are produced in therapeutic linear accelerators. The pattern of protons' dose deposition is unique where the dose is deposited at a finite range or depth. When protons reach this depth, they deposit all of their radiation, something called the Bragg peak (see *Fig. 342.4*). This pattern of dose deposition results in a lower entrance and exit dose. Having this Bragg peak means that, if there is a critical structure near a target volume, then proton radiation therapy has the potential to deliver a lower dose to that critical structure. This difference in dose distribution may mean a lower total dose to the entire body as in the craniospinal irradiation for medulloblastoma or to a nearby critical structure in a patient with rhabdomyosarcoma. The limitation on proton radiation therapy is the cost of building and running a facility which has results in a limited number of facilities. Protons have a physical dose distribution advantage over x-rays or photons but no biologic advantage. The next technology that has both a spatial dose distribution and biologic effect advantage is carbon ions. There are very few of these facilities (none in the USA) and little experience in pediatric patients in part due to the concern of lack of long-term follow-up with its use and the potential for increased long-term toxicity given its unique biologic properties.

While technologic improvements have significantly improved the care of pediatric patients, parallel improvements in combined modality therapy have allowed for the reduction of treatment volume, dose reduction, and careful selection of patients for radiation therapy. As stated previously, the use of IMRT and IGRT have provided improved conformity of dose and accuracy of delivery so that normal tissue margins may be reduced. Improvements in imaging of low and intermediate brain tumors and the ability to fuse those images with the treatment planning CT may allow for treatment volume reduction, a critical endpoint in brain tumors. This concept is the study of children's oncology group (COG) protocol ACNS 0221 where patients with low-grade gliodmas who have progressive non-resectable disease are given radiation therapy and the margin of normal brain is reduced from the traditional 2 cm to 0.8–1 cm. This reduction in the volume of normal brain that is within the target volume of radiation may result in a significant improvement in the long-term functional outcome of these patients who have an excellent prognosis. Volume reduction is also achieved through the use of pre-radiation chemotherapy. In Hodgkin's lymphoma when radiation is given with chemotherapy, it is delivered only to the involved field and not to a traditional mantle or subtotal nodal field. This modification allows for (in some patients) a significant reduction in the amount of lung, heart, and, in females, breast tissue that is included in the radiation therapy field.

Dose reduction is another important means of reducing the long-term toxicity of radiation therapy. An excellent example of this concept is medulloblastoma where in patients with standard risk disease who receive chemotherapy, a dose of 23.4 Gy is given to the craniospinal axis as opposed to 36 Gy for those who do not or who have high-risk disease. This dose reduction provides a decrease in overall toxicity while maintaining excellent cure rates, progression-free survival of 79% at 5 years. A further dose reduction is currently being investigated in COG ACNS 0331. In this study, patients with standard risk disease who are less than 7 years old are randomized to

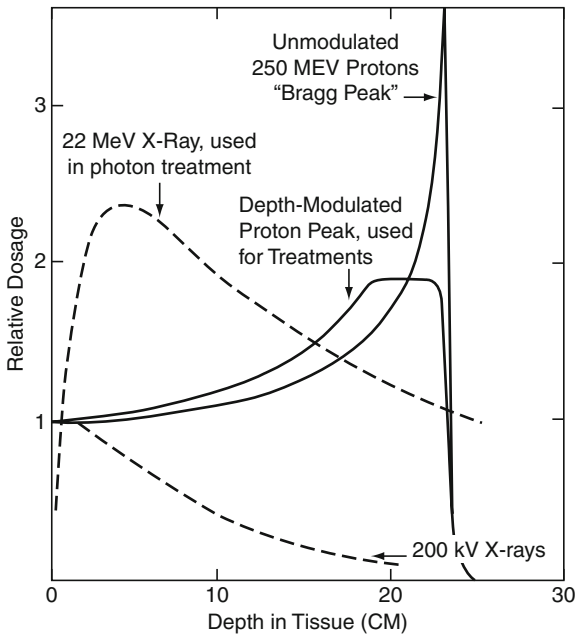

Figure 342.4
Bragg peak for protons demonstrating decrease in both entrance and exit dose when compared to x-rays (photons) of low (200 kV) or high (22 MeV) energy

either 18 Gy or 23.4 Gy for the craniospinal portion of their treatment. In addition, all of the patients regardless of age are randomized to either have the entire posterior fossa boosted to 55.8 Gy or to only the tumor bed plus 2 cm margin. This approach has been piloted at other institutions with success. This age cutoff of 7 years is chosen for the randomization because the deleterious impact of radiation is more evident in younger children.

Patient selection or eliminating radiation therapy altogether in certain groups of patients is probably the most important method of reducing its toxicity. Over the last 20 years, the use of radiation therapy has been stopped in patients with Stage 1, Group I rhabdomyosarcoma, several groups of patients with acute lymphoblastic leukemia (ALL) for prophylactic cranial irradiation, and for Stage I Wilm's tumor with favorable histology. There is a current COG protocol AREN 0533 that investigates the elimination of whole-lung irradiation in patients with Stage IV Wilm's disease, favorable histology with spread to the lungs. For those patients who have a complete response to chemotherapy based on CT performed at 6 weeks and no loss of heterozygosity at 1p16q, no whole-lung irradiation will be given. If successful, this elimination of radiation therapy in this group of patients will decrease both their pulmonary and cardiac toxicity.

Importance of Clinical Trials

One of the most notable contrasts between the management of pediatric and adult oncology patients is the increased enrollment in clinical trials in pediatric patients. It is widely believed that this participation in clinical trials is one of the major factors contributing to the continued success in managing childhood cancers. There are several advantages to a strong clinical trial group such as the COG. These advantages include the ability to ask and answer therapeutic questions reliably, several of which have been outlined above. Another advantage is the relative standardization of care, where a randomized clinical trial clearly outlines what the standard arm is and how it should be followed. A final advantage that is especially important for radiation therapy in the era of emerging technologies is that quality assurance is required prior to the use of any emerging technology. This quality assurance review is performed at a national center, quality assurance review center (QARC) prior to any patient being treated using a technique such as IMRT, SRS, or image fusion, when the patient is being treated on a cooperative group study or a pharmaceutical industry study. In addition, treatment plans are reviewed at a central location and feedback is given to the investigator so that, if necessary, modifications can be made. This same process of central review of treatment fields and plans has also been instituted in the German Hodgkin Study Group (GHSG) with a resultant improvement in the quality of radiation delivered on those studies.

Receiving Care in a Children's Hospital

The care of an ill child requires an array of specialized services. By having a hospital that focuses only on the care of pediatric patients, all of those specialized services can be brought together and together they are improved. In treating a child with cancer, the modalities of surgery, chemotherapy, and radiation therapy all are often part of the treatment regimen. Having these groups of physicians working closely together in multidisciplinary teams allows for improved communication and collaboration. In radiation therapy, young patients often need to be sedated for their daily treatments so it is essential to have pediatric sedation services that are available, reliable, and safe. Also, in most radiation therapy departments, pediatric patients will be the minority of patients treated. Yet it is important that the staff have a comfort level in working with patients and, importantly, their families. For those departments who rarely treat a child, this comfort can be hard

to achieve and both the child and the family find the treatment difficult.

As more children are cured of their cancer, there will be more survivors who will need to transition to care as adolescents and young adults and who may experience the long-term toxicity of radiation therapy. Unfortunately, the effects of radiation therapy may continue to be seen many years after treatment is complete. Issues regarding growth, fertility, and the occurrence of second malignant neoplasms (SMNs) are of particular importance. This area of interest, adolescent and young adult (AYA), is growing and new research and programs are being developed specifically for it. Again, the issues facing these survivors require a multidisciplinary team.

343 Hematopoietic Stem Cell Transplantation

Hassan El Solh · Abdallah Al-Nasser · Eneida R. Nemecek

Hematopoietic Stem Cell Transplantation (HSCT) can cure many malignant and nonmalignant childhood diseases. As new indications for HSCT arise, and donor and stem cell sources expand, the number of bone marrow transplants performed is increasing. This modality, once only available in limited institutions, is now used worldwide. Many pediatric care providers encounter patients in their practice who will or have undergone HSCT, thus it is important for pediatricians to understand the basics of this therapeutic modality, its potential benefits, and acute and long-term risks.

Stem Cell Sources

The main goal of HSCT is to infuse hematopoietic progenitor cells in a host to totally or partially replace host defective cells affected by cancer or other disorders. Bone marrow is the most direct source for hematopoetic progenitor cells, but they can also be obtained from peripheral blood and placental (cord) blood.

Marrow is obtained from donors through a procedure referred to as *bone marrow harvest*. A harvest is performed in an operating room under general anesthesia, and involves directly extracting bone marrow, usually from the posterior iliac crests using bone marrow aspirate needles. The extracted marrow product is filtered to remove debris and collected in a bag mixed with anticoagulant. The amount of marrow volume removed is limited by the weight of the donor (maximum of 15 ml/kg) recipient and usually does not exceed 20 ml/kg of the intended recipient weight. Bone marrow can be harvested from donors of any age. The procedure is usually performed as outpatient procedure or may involve a short overnight hospital stay. The harvest procedure is well tolerated by the donor. The most common side effect is mild to moderate pain at the aspiration sites usually lasting a few days. Blood transfusion to a donor is rarely needed but may be indicated when the donor is substantially smaller than the recipient. The incidence of significant complications for donors has been reported to be very low.

A second source of hematopoietic progenitors is *peripheral blood stem cells*. The donor receives subcutaneous injections of granulocyte colony-stimulating factor for several days to mobilize the stem cells from the bone marrow to the peripheral blood, after which the cells are collected by apheresis. For this procedure, the donor has two venous catheters placed and is connected to an apheresis machine, which separates and collects the stem cells and returns other blood components back to the patient. Some donors, particularly those of small size, require central venous catheters for this procedure and may need transfusions or red cell priming of the apheresis machine to undergo this procedure, making it a less appealing approach to obtain cells from young children donors. Umbilical *cord blood* is a rich source of hematopoietic progenitors. After delivering the baby and clamping of the cord, placental blood can be collected using sterile technique by direct venipuncture of the cord vessels. Cord blood collection poses no risk to the mother or newborn. The collected cord blood can then be cryopreserved and stored until used.

Donor Selection

Hematopoietic cells can be obtained from the recipient, also referred to as *autologous*, or from another donor (*allogeneic*). When the donor is an identical twin sibling, it is referred to as *syngeneic*.

An Autologous transplant is traditionally used to "rescue" patients after high-dose chemotherapy for lymphoma or other solid tumors. Allogeneic transplant is used for treatment of patients with malignancies considered at high risk for relapse with conventional chemotherapy and for some patients with nonmalignant disorders.

An allogeneic donor may be a sibling, a parent, another relative, or unrelated. The selection of an allogeneic donor is determined primarily by compatibility of the human leukocyte antigen (HLA) system. Improvement in the understanding of the genetics of the HLA system has played a major role in advancing the field of transplantation. The HLA system contains a set of tightly linked genes

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_343,

located on chromosome 6. These genes are inherited as one group from each parent, called a haplotype. The overall chance that two siblings inherit the same set of maternal and paternal haplotypes is 25%. Due to heterogeneity in HLA types, in addition to other contributing factors such as the trend towards reduced family size in developed countries, there is only a 30% chance of finding an HLA-identical sibling for a given patient. The chance of a parent or other relatives fully matching a child is very small, but they may serve as partially matched or haploidentical ("half-matched") donors. This latter type of donor is sometimes the only choice available for patients with ethnicities poorly represented in the donor registries. Approximately 45% of all allogeneic transplants performed worldwide are from adult unrelated donors. These individuals join donor registries voluntarily where their HLA typing data become available to search coordinators looking for a match for a potential recipient anywhere in the world. This process is conducted with a great degree of confidentiality to protect the identity and safety of both donor and recipient. Unrelated donors are ideally matched at 8 of 8 HLA loci, or in some cases partially mismatched at one or 2 HLA loci.

Indications for HSCT in Childhood Diseases

The list of diseases for which marrow transplantation is clinically used continues to grow and includes a wide variety of malignant and nonmalignant disorders (Table 343.1). The choice of donor and stem cell source are influenced by the type of disease being treated and time constraints.

Table 343.1
Indications for HSCT in children

Allogeneic	Autologous
Malignant disorders	Ewing sarcoma
Acute lymphoblastic leukemia	Recurrent germ cell tumors
Acute myeloid leukemia	Malignant Brain tumors
Chronic myeloid leukemia	Recurrent Lymphoma
Juvenile myelomonocytic leukemia /Juvenile chronic myeloid leukemia	High-risk Neuroblastoma
Myelodysplastic syndrome	
Lymphoma relapsed after autologous transplantation	
Nonmalignant disorders	
Severe aplastic anemia	
Bone Marrow Failure syndromes	
Hemoglobinopathies (Thalassemia major, Sickle cell disease)	
Primary (congenital) immunodeficiency diseases	
Hemophagocytic lymphohistiocytosis	
Inborn errors of metabolism (Mucopolysaccharidosis, Sphingolipidosis, Malignant osteopetrosis, Adrenoleukodystrophy)	

Allogeneic HSCT

Allogeneic BMT has been proven to be an effective treatment for hematologic malignancies, bone marrow failure syndromes, primary immunodeficiency disorders and inborn errors of metabolism. According to reports from the Center for International Blood and Marrow Transplant Research (CIBMTR), the most common source of allogeneic stem cells for children is bone marrow (52%) followed by peripheral blood stem cells (28%) and cord blood (20%).

In malignancies the primary goal is to eradicate all malignant cells, usually by administering high doses of chemotherapy agents and/or total body irradiation, and infusing the normal blood cells of the donor. The donor cells repopulate the host bone marrow space and may also mediate an immunological response against the cancer cells, referred to as the "graft-versus-leukemia" or "graft-versus-tumor" effect. Many patients with hematologic malignancies not cured with conventional chemotherapy treatment have benefited from allogeneic HSCT. The 3-year probability of survival for patients with acute leukemia younger than 20 years ranges between 70% for those with disease in first remission and 37% for those with more advanced disease at the time of transplant. Acute myeloid leukemia in first or greater remission and acute lymphoblastic leukemia in second or greater remission are the most common indications for allogeneic HSCT In children. Chronic myeloid leukemia (CML), juvenile myelomonocytic leukemia, and myelodysplastic syndrome, are rare malignant hematologic disorders in

children treated with allogeneic stem cell transplantation. The number of transplants for adult CML has significantly decreased since the development of oral tyrosine kinase inhibitors such as imatinib mesylate, and is reserved primarily for patients not responding to treatment with these biological modifiers. For children with CML, the emphasis is still on transplantation.

The indications for allogeneic HSCT for nonmalignant diseases are varied. The goal of HSCT in the nonmalignant setting is to fully or partially replace defective cells of the host with normal cells from a healthy donor. Severe aplastic anemia and bone marrow failure syndromes where one or more of the hematopoietic cell lines are defective such as Diamond-Blackfan anemia, congenital neutropenia and Fanconi anemia have been cured with HSCT. The long-term survival of children undergoing allogeneic HSCT for severe aplastic anemia is 70–80%. Inherited hemoglobinopathies such as sickle cell anemia and thalassemias can also be cured by allogeneic BMT. Around 70% of patients with severe combined immunodeficiency have long-term survival with full immunoreconstitution within 6 months after HLA-matched allogeneic transplant. Similarly, many other primary immundeficiencies can be corrected with HSCT. Inborn errors of metablism such as malignant osteopetrosis and lysosomal storage diseases have been reported to be cured by allogeneic HSCT. However, there is still a paucity of data from prospective clinical trials for these disorders.

Autologous HSCT

Autologous HSCT in children is used in the setting of malignant disorders, usually solid tumors or recurrent lymphomas, to facilitate blood count recovery after administration of high doses of chemotherapy agents. One of the most common indications for autologous HSCT in children is high-risk neuroblastoma. Randomized clinical trials have shown a modest clinical advantage of consolidative therapy with autologous HSCT over conventional chemotherapy, with long-term survival of 50% for patients with disease in complete or good partial remission prior to transplant. Patients with recurrent chemoresponsive Hodgkin or non-Hodgkin lymphoma may also benefit from consolidation with autologous BMT, with long-term survival ranging between 40% and 50% depending on the type of lymphoma and disease burden at the time of transplantation. Other less common indications for autologous BMT include brain tumors and other neoplasms such as germ cell tumors and Ewing sarcoma.

The Transplant Process

Prior to transplant, both patient and allogeneic HSCT donor must undergo extensive multidisciplinary evaluations. This typically includes a comprehensive history and physical exam, laboratory evaluations such as complete blood counts, serum chemistries, and infectious serology testing. The recipient also undergoes testing to confirm disease status, general health status, and organ functions (echocardiogram, electrocardiogram, pulmonary function testing, creatinine clearance, etc.). Assessment of family support and psychosocial needs is also an integral part of the pre-transplant assessment. Once the patient and donor receive medical clearance, the recipient starts the transplant preparative regimen, also referred to as conditioning regimen.

The intensity of the conditioning regimen depends on the disease being treated, type of donor used, and the general health status of the recipient and its predicted ability to tolerate such therapy. Conditioning starts usually about 1 week before the infusion of stem cells. More intense myeloablative regimens are used to treat malignant disorders. Regimens of reduced or minimal intensity may be used to treat patients with nonmalignant disorders and those with malignancies who due to poor health status are deemed unable to tolerate full myeloablative regimens. After conditioning, the patient receives the hematopoietic cells on "day zero."

During the acute phase of transplant, the patient has profound pancytopenia and immunosuppression and may also experience acute side effects from the conditioning therapy. Patients remain isolated in the hospital for about 3–4 weeks until the new donor cells engraft and they are free of major complications from the transplant process. Patients are usually followed by the transplant team until at least 3 months post transplant, after which they return to the care of their primary care or oncology providers.

Early Complications of HSCT

The early complications are related to infections, toxicities related to the preparative regimen, graft-versus-host disease (GVHD), and graft rejection.

The most common cause of morbidity and mortality during the early phase of transplant is infections. Risk factors for infections include immunosuppression, indwelling venous catheters, GVHD, and coexisting toxicities such as mucositis. Various measures have been taken to isolate the transplant patient from possible

infections. Protection measures include hand washing, wearing a mask, minimizing nonessential contacts, and using hospital rooms equipped with high-energy particulate air (HEPA) filters, when available. Infections prophylaxis has significantly improved the outcome of HSCT by reducing the number of infectious complications. Patients should be aggressively monitored and promptly treated for symptoms or signs of systemic infections. The absence of neutropenia does not necessarily mean that the patient is not immunosuppressed. The ability to fight infections is also affected by absence of cellular and humoral responses, and by the multiple medications used to suppress the immune system to prevent GVHD. Infections can be caused by bacterial, fungal, or viral pathogens and can present in any form, from localized to overwhelming sepsis. Empirical broad-spectrum antibiotics should be started during the neutropenic period and continued until neutrophil engraftment is achieved. Patients should receive Pneumocystis prophyalxis, antifungal prophylaxis to cover for Candida species and molds, and antiviral prophylaxis with acyclovir until off immunosuppressive therapy. Cytomegalovirus (CMV) infection or reactivation has decreased significantly with the use of CMV-negative blood products CMV-serosurveillance and preemptive antiviral prophylaxis with ganciclovir or foscarnet. Other viruses such as adenovirus, respiratory syncytial virus, and parainfluenza and influenza virus continue to be causes of major morbidity and infectious mortality in transplant patients. Prevention of infections and, when available, prompt institution of antiviral therapy are the recommended management for these viral pathogens.

Regimen-related toxicities are the second most common cause of death during the first 100 days post transplant. Any organ can be affected during transplant. The most common organ toxicity is mucositis of the oropharyngeal region. Diarrhea and enteritis may also occur in a high percentage of patients, particularly those receiving myeloablative therapy. Some other manifestations of toxicity include noninfectious pneumonitis, veno-occlusive disease of the liver, hemorrhagic cystitis, acute renal insufficiency or failure, and cardiac dysfunction. Veno-occlusive disease of the liver presents as weight gain, fluid retention, hyperbilirubinemia, and right upper quadrant (hepatic) tenderness. Although most toxicities are reversible and respond to supportive medical management, some can be irreversible or fatal. The average incidence of severe/fatal regimen-related toxicities in children is about 15%, ranging from 0 to 50% depending on predisposing factors. Some factors associated with an increased risk for toxicity are age (infants are at higher risk), intense pre-transplant treatment, and use of myeloablative regimens. Aggressive and prompt institution of supportive care and/or intensive care is key to prevent irreversible injury or death from toxicities in transplant patients.

Graft-Versus-Host Disease

As the new allogeneic donor cells establish within their new environment, they can recognize host antigens as foreign and generate an immune response. This response, known as graft-versus-host disease (GVHD), ranges from subclinical to a severe reaction with multiple manifestations.

Acute GVHD typically presents in the first 3 months post transplant. The organs most commonly affected are skin (rash, erythema, bullae formation), gut (anorexia, nausea/vomiting, watery or bloody diarrhea, abdominal cramps), or liver (elevation of hepatic enzymes with hyperbilirubinemia and liver dysfunction). Since acute immune reactions between the donor and host are expected events in the transplant setting, immunosuppressive medications are given prophylactically before and during the first 3 months post transplant. GVHD prophylaxis usually consists of combinations of two or more drugs that act by reducing the number and function of T-cells. The most common combinations are calcineurin inhibitors (cyclopsporine or tacrolimus) with methotrexate, mycophenolate mofetil, anti-thymocyte, or alemtuzumab globulin. Drugs are used at therapeutic doses early during transplant, and then slowly tapered over 3–6 months if there is no evidence of GVHD. Despite prophylaxis, the incidence of acute GVHD ranges from 25% in matched sibling transplants to 70% in unrelated donor transplants. Acute GVHD is graded depending on the extent and areas of disease involvement.

Chronic GVHD usually occurs after the first 3 months post transplant, although in some patients clinical signs and symptoms have been described at an earlier time after transplant. Skin manifestations of chronic GVHD include desquamation, scleroderma-like changes, pigmentation, and lichenoid changes. Chronic GVHD of the liver is characterized by hyperbilirubinemia and elevation of the hepatic enzymes. Patients with chronic GVHD of the intestine may have abdominal pain, diarrhea, malabsorption, wasting syndrome, and, in the late phases, strictures of the gastrointestinal tract. Lungs acan be affected by chronic GVHD, manifesting as obstructive lung disease

or bronchiolitis obliterans. Involvement of the eyes is also common, with keratoconjunctivitis sicca, blurred vision, and photophobia. Oral manifestations include ulcers, leukoplakia, dry mouth, dysphagia, and sensitivity to certain foods. Joints can be affected by serositis or scleroderma. Thrombocytopenia may occur in chronic GVHD, and it is usually one of the poor prognostic factors of the disease.

There are several alternatives for therapy of GVHD. The goal in the treatment of GVHD is to provide therapy that is sufficient to ameliorate the signs and symptoms without excessively compromising the immune system of the host, a challenging task. Drugs and therapies are added/tapered in response to changes in clinical status until the desired effect is observed. Systemic steroids (prednisone, methylprednisolone) are the first line of therapy. About 50% of patients with acute GVHD respond to steroid therapy, but many require extended therapy with steroids or other agents. Prolonged use of steroids is associated with many side effects including weight gain, myalgia, arthralgia, hyperglycemia, hypertension, increased risk for infections, osteopenia, avascular necrosis of the bones typically the hip, and mood changes, among others. Second line therapies for patients not responding to steroids include monoclonal antibodies against T-cells or cytokines (anti-thymocyte globulin, alemtuzumab, daclizumab, etanercept), macrolide antibiotics (sirolimus or rapamycin), and antimetabolites (pentostatin). Localized skin disease can sometimes be treated with topical therapies (tacrolimus or steroid creams) or with ultraviolet light therapy (psoralens and ultraviolet light absorber, PUVA). Extracorporeal photopheresis (ECP) is a new technique that applies the PUVA concept to systemic GVHD, currently reserved for patients resistant to other modalities. This technique consists of removing a fraction of the lymphocytes of the patient by apheresis, exposing the cell fraction ex vivo to PUVA, and returning the treated cells to the patient. Through complex mechanisms, this procedure generates an immunomodulatory effect and increases immune tolerance of the donor T-cells toward the host.

Long-Term Complications of HSCT

With an increasing number of long-term survivors of HSCT and extended observation periods, long-term sequelae are becoming of significant importance and primary concern for all physicians who care for HSCT patients. After engraftment of stem cells and recovery of blood counts, it takes approximately 1 year after HSCT to recover a fully functional immune system; until then, cellular and humoral responses are impaired. Many patients, especially those with GVHD, have hypogammaglobulinemia and require intravenous gammaglobulin replacement. Patients are at risk for reactivation of dormant viruses (Herpes and Varicella) during the first year post transplant. After transplant, most children lose titers to previously administered immunizations. Most cannot mount adequate responses to immunizations for the first year post transplant. After a year post transplant, most children need to be re-immunized for childhood diseases. Live virus vaccines are not given until 2 years post transplant because of the potential risk of acquiring primary viral infections or complications from the vaccine.

As more patients survive the intense transplant process, the incidence of other long-term sequelae increases as well. Risk factors for the development of late effects include younger age at time of transplant, use of radiation in the conditioning regimen, and presence of chronic GVHD. The most frequent late sequelae of transplant are endocrine deficiencies. Manifestations include growth hormone deficiency and growth failure, hypogonadism and infertility, hypothyroidism, adrenal insufficiency, and diabetes. Endocrine problems are much more common in patients receiving TBI and/or cranial radiation. Chronic organ dysfunction may also occur. Lung problems include obstructive or restrictive disease and bronchiolitis obliterans; an inflammatory disease of unknown etiology that is almost always associated with chronic GVHD. Other late effects include cataracts, dental problems, cardiotoxicity, chronic renal insufficiency, learning disabilities, psychosocial adjustment problems, and secondary malignancies.

Monitoring of late effects and guidance significantly improve the quality of life of transplant patients. In addition to routine care by their primary providers, many transplant centers patients offer comprehensive long-term follow-up evaluations. Patients and their primary health care providers are informed of the results of these evaluations, and recommendations are given to address existing problems.

Transplant is a life-changing experience for patients and their families. Although most of the physical effects of transplant resolve within the first years post transplant, patients and families take years to recover from the psychosocial impact of this process. Hence the involvement of support staff such as social workers, child life specialists and counseling, early and through the transplant is extremely important. Despite the many complications

associated with HSCT, most patients and their families report good quality of life post transplant. The pediatrician is an important part of the transplant process by facilitating prompt referral to the transplant center and, once the transplant is completed and the patient has returned back to their care, by providing adequate surveillance for side effects and late effects of bone marrow transplantation.

344 Supportive Care of the Child with Cancer

H. Stacy Nicholson

Introduction

Curing a child with cancer requires prompt and accurate diagnosis and staging, and safe delivery of risk-adjusted therapy. In addition, supportive treatments that decrease side effects, increase patient safety, and support health and healing are also important and ensure improved health and quality of life during anticancer therapy. Supportive care can also be life saving.

Venous Access

Most chemotherapy drugs are administered by the intravenous (IV) route. Repeated IV infusions and blood tests are the norm. IV chemotherapy can be delivered via a peripheral vein or via an indwelling central venous catheter. Using peripheral IVs risk extravasations of medications into surrounding soft tissues, and some chemotherapy agents (particularly the vinca alkaloids and anthracyclines) can cause tissue destruction. The surgical implantation of indwelling central venous catheters facilitates both chemotherapy delivery and blood tests. There are two main types of devices: those that end with an external catheter and those that end in a reservoir under the skin.

Procedures and Sedation

There are several routine procedures associated with childhood cancer. Bone marrow aspirations (BMA) are performed to diagnose and monitor leukemia and are required for staging some solid tumors. Marrow fluid is aspirated using a specially designed needle, and the site most commonly used is the posterior superior iliac spine. During a BMA, children are under deep sedation, delivered by an anesthesiologist or other highly trained provider, or are more lightly sedated (conscious sedation) with the concomitant use of locally injected analgesia. Conscious sedation, often using the combination of an opiate and a benzodiazepine, can be delivered by the practitioner performing the BMA and his or her team. Bone marrow biopsies should always be done with the patient under deep sedation or general anesthesia.

Lumbar punctures (LP) generally require less sedation than BMAs, but local analgesia is important. Preventing pain during procedures will improve comfort and increase compliance with care. In older children, using distraction or other non-medicinal techniques can be very effective for LPs and IV placement.

Pain Control

Pain in children with cancer may be caused by the cancer itself (at diagnosis, relapse, or during the terminal phase of illness), procedures (see above), surgical procedures, or as a side effect of therapy, such as mucositis (mouth sores). Using a pain scale so that the child can effectively communicate his or her pain can be helpful in monitoring the effectiveness of the analgesia. Depending upon severity, pain medications will range from acetaminophen to opiates. When opiates are used for more than a few days, children may develop tachyphylaxis, requiring an increasing amount of medication to achieve the same results. If prolonged use of opiates is required, long-acting formulations may be used to deliver a baseline level of analgesia combined with short acting opiates for breakthrough pain.

Antiemetics

Many chemotherapy drugs and radiation cause nausea and vomiting. Fortunately, the past two decades have brought new antiemetic medications that are highly effective. Drugs used to control nausea in children undergoing chemotherapy include 5-HT_3 receptor inhibitors (ondansetron, granisetron, and dolasetron), steroids (dexamethasone), phenothiazines, and/or metoclopramide. Although expensive, 5-HT_3 receptor inhibitors have become the agents of choice as they are highly effective in most patients and

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_344,

have a low risk of side effects. Children whose nausea cannot be controlled with a single medication may require combination therapy.

Transfusion Therapy

Children with cancer often experience cytopenias, either from disease (in leukemia or solid tumors metastatic to bone marrow) or as a side effect of therapy. Myelosuppression is the most common dose-limiting side effect of chemotherapy. Packed red cells and platelets are most commonly used blood components. Indications for transfusion based on blood count results will vary by institution, but symptoms that warrant red cell transfusions include tachycardia, orthostatic hypotension, and fatigue. The transfusion of prophylactic platelets is supported by some, but many centers only use platelets when children experience bleeding. White cell transfusions are sometime done in neutropenic patients with persistent sepsis; however, white cell transfusions are controversial. All blood products should be irradiated prior to transfusion to prevent graft-versus-host disease, and leukodepletion by filtration can decrease cytomegalovirus (CMV) transmission.

Nutrition

Children are often malnourished at diagnosis, and children need good nutrition to heal following radiation and chemotherapy treatments. Nutritional status should be assessed in all patients and support offered if needed. The oral route is preferred when possible, and success can be enhanced by enriching the calorie content and ensuring effective pain management for mucositis. Appetite stimulants can help in some children. If a patient cannot take sufficient calories by mouth, the use of a nasogastric (NG) tube or gastrostomy tube (G-tube) to facilitate delivery of enteral nutrition may be effective. If enteral nutrition cannot be tolerated, total parenteral nutrition (TPN) can be delivered by a central venous catheter.

Oncologic Emergencies

There are several unique emergencies that occur in children with cancer, including mediastinal masses with respiratory compromise and spinal cord compression. Similarly, anticancer therapy can cause serious side effects that require immediate attention, such as serious life-threatening infections.

Superior Vena Cava Syndrome

The anterior mediastinum in children is rich in lymphoid tissue, and these structures are in close proximity with the trachea and both main-stem bronchi, the heart, and major blood vessels, including the superior vena cava (SVC). Some lymphomas or leukemias are accompanies by rapid lymph node growth. In the anterior mediastinum, such growth can lead to a mass that compresses the SVC, leading to facial plethora, cyanosis, and petechiae. Impairment of venous drainage from the brain may result in somnolence and confusion. Airway compression may lead to severe respiratory compromise and is the greatest concern in these patients. Sedation should be avoided and therapy with steroids and/or radiation needs to be administered as a life-saving measure, even if the ability to make a histopathological diagnosis is compromised.

Spinal Cord Compression

Masses that involve or invade the spinal canal can present with spinal cord compression (SCC), either at diagnosis or at relapse. Symptoms include back pain, weakness, inability to walk, sensory changes, or changes in bowel or bladder function. In children, SCC occurs most commonly in children with sarcomas, neuroblastomas, or brain tumors. The time from symptom onset to treatment is inversely related to the chances of the patient recovering lost function. Thus, treatment decisions must be made promptly and immediately initiated. Treatment can include surgical decompression, steroids, or external beam radiation.

Fever and Neutropenia

Infections are the most common complications of anticancer therapy and can be life threatening. Parents must be educated about the risk of infections so that the child is immediately brought to medical attention immediately upon developing a fever. Upon arrival at the clinic or emergency department, the child should be promptly evaluated with a detailed history and thorough physical examination, blood count, and blood cultures. The physical examination should especially focus on seeking specific sites of infection, and extra attention should be given to the oral cavity, sinuses, lungs, abdomen, perianal region, and any tunneled catheters. If neutropenic (absolute neutrophil count (ANC) $<500/mm^3$ or $<1{,}000/mm^3$ and likely to be decreasing), broad-spectrum antibiotics

should be administered, the child should be admitted to the hospital for further antibiotics and monitoring. Antibiotics will continue until the child is no longer neutropenic. Any signs of septic shock should be promptly addressed with fluid resuscitation and consultation with a pediatric critical care unit.

Infections

Throughout therapy, children with cancer are immunosuppressed and susceptible to infection from bacteria, viruses, and fungi. Serious bacterial infections are more likely when children are neutropenic, and prolonged neutropenia increases the risk of invasive fungal disease. The likelihood of a specific organism varies by institution and may change over time, so knowing which bacteria typically cause sepsis in a given population and hospital will inform the antibiotic choice. Empiric antibiotics for fever and neutropenia should include coverage for gram-negative organisms, including Pseudomonas species and for gram-positive organisms such as Staph aureus and coagulase negative Staphylococcus. If fever persists for 5–7 days, empiric antifungal therapy is indicated. Typical antimicrobial choices are listed in *Table 344.1*.

In addition to bacteremia, immunocompromised hosts are susceptible to other bacterial infections, including sinusitis, pneumonia, perianal cellulitis, typhlitis, and other areas of cellulitis. Invasive fungal disease can include candidal esophagitis, fungal sinusitis, and invasive fungal pneumonia, either with candida or mucor. Mucor has a poor prognosis and must include aggressive surgical management in addition to antifungal medical therapy.

Viral infections that are dangerous in immunocompromised hosts include varicella zoster, herpes simplex, Epstein–Barr virus, and cytomegalovirus (CMV). Disseminated varicella is particularly problematic, with a high degree of lethality from encephalitis, pneumonia, or hepatic failure. Following a Varicella exposure, prophylaxis with varicella immune globulin within 72 h can prevent or ameliorate illness, and if varicella occurs, hospitalization and treatment with acyclovir is indicated. Varicella vaccine, although a live attenuated vaccine, is safe and effective in immunocompromised hosts. Zoster also requires treatment but is less likely than primary Varicella to disseminate.

Immunization with live-attenuated viruses (measles, mumps, rubella, polio (Sabin)) should not be given before the child completes chemotherapy and immune mechanisms are restored. Killed virus vaccines, such as those against diphtheria, tetanus, pertussis, and polio (Salk only), can be used safely in children receiving chemotherapy (*Table 344.2*).

Table 344.1
Common infectious complications in immmunocompromised hosts and treatment

Indication	Treatment of choice	Comments
Fever and neutropenia (F&N)	Third-generation cephalosporin (ceftazadime)	Alternatively, use three-drug combination, including:
		• Anti-pseudomonas penicillin (ticarcillin, piperacillin)
		• Anti-staphylococcal penicillin (oxacillin, nafcillin)
		• Aminoglycoside (gentamycin)
		If a specific site of infection is identified, it should be treated in addition to empiric coverage
Persistent F&N (5–7 days)	Amphotericin B	Alternatively, use may fluconazole
		Lipid encapsulated formulations of amphotericin may be less toxic
Pneumocystis jiroveci	1. TMP/SMX	Must be used as prophylaxis – 2 consecutive days per week
	2. Pentamadine	Used at therapeutic doses for treatment
Varicella	Acyclovir	Use high-dose therapy with sufficient fluids. Monitor renal function closely

Pneumocystis jirovecii (previously known as *P.carinii*) is a yeast-like fungus that causes opportunistic pneumonia in immunocompromised hosts. This pneumonia is universally fatal if not treated but can be easily and effectively prevented with prophylactic trimethoprim-sulfamethoxazole (TMP/SMX) given on 2 successive days each week. In patients with contraindications to TMP/SMX, a monthly infusion of pentamadine is used as prophylaxis. At therapeutic doses, these medications are also used for treatment.

There are additional and unique infectious risks associated with bone marrow transplantation (BMT). These are discussed in the chapter on BMT.

Table 344.2
Antibiotic usage in immunocompromised hosts

Drug	Dose	Organisms	Comments
Antibiotics			
Ceftazadime	100 mg/kg/day divided every 8 h	Pseudomonas	Third-generation cephalosporin
			Most common antibiotic for empiric coverage of fever and neutropenia (F&N)
Cefepime	100 mg/kg/day divided every 8 h	Pseudomonas, gram negative, gram positive	Can be used in setting of resistance to ceftazadime
Imipenem	50 mg/kg/day divided every 6 h	Pseudomonas, gram negative, gram positive	Excellent anaerobic coverage
Aztreonam	100–150 mg/kg/day divided every 6 h	Gram negative	No gram-positive coverage
Vancomycin	25–40 mg/kg/day divided every 6–12 h	Gram positive	Use only when clinically indicated
			Monitor levels and renal function
Antifungals			
Amphotericin B	0.5 mg/kg daily (empiric)	Candida	Monitor renal function closely
	1–1.5 mg/kg daily (therapeutic)	Aspergillus	Sodium loading prior to infusion protective for kidneys
Fluconazole	3–12 mg/kg/day	Candida	Use high doses in life-threatening conditions
Acyclovir	1500 mg/m^2 divided every 8 h	Varicella Zoster (VZV)	May use half this dose for HSV
		Herpes simplex (HSV)	Adequate hydration with high doses will limit nephrotoxicity
Anti-pneumocystis agents			
Trimethoprim – sulfamethoxazole	20 mg/kg/day divided every 12 h	Pneumocistis jiroveci	Monitor for bone marrow suppression
Pentamadine	4 mg/kg/day	Pneumocistis jiroveci	Use in TMP/SMX contraindication or treatment failure

Psychosocial Support

Providing psychosocial support to patients and their families is an important aspect of care in pediatric oncology. Helping them deal with accepting the diagnosis, ensuring compliance with therapy, and adjusting to being a cancer survivor are all important aspects of support. Practical supportive measures may include assisting families with housing for those who must travel to get care and helping ensure access to prescription medications. Supporting the child during procedures with medical play and distractions can help diminish the pain experienced with these procedures.

Support for the medical, nursing, and other staff is also important as there can be an emotional toll in dealing with children who have cancer.

Rehabilitation

Maximizing function and quality of life in children undergoing anticancer therapy may require rehabilitation services. Children with central nervous system (CNS) tumors may require intensive rehabilitation, including physical therapy, occupational therapy, and speech therapy following tumor resection, and this should be done in a way that does not interfere with the timely initiation of adjuvant therapies. Children with CNS tumors and others who receive cranial radiation may have learning difficulties after therapy and may benefit from cognitive remediation and accommodations from their teachers. Children with bone and other extremity sarcomas may also need physical therapy to adjust to amputation or following a limb-sparing surgical procedure.

Unique Aspects in Developing Countries

In developing countries, children often present with higher-stage disease, and they are more likely to be malnourished and impoverished. Medical resources may also be decreased compared to developed nations. Knowing the usual differences for a given country or region will help physicians design local standards of care.

345 Childhood Leukemia

Hassan El Solh · Abdallah Al-Nasser · Asim Belgaumi

Definition/Classification

Leukemias are a group of malignant diseases with a unifying origin from hematopoietic cells. They result from clonal proliferation of a malignantly transformed cell of hematopoietic lineage with differentiation arrest. The type of leukemia is determined by the normal counterpart of the malignant clone and also by the stage of differentiation at the time of arrest. As such, leukemias can be lymphoid or myeloid; and even within these broad categories further sub-classifications can be made based on the particular cell involved. The most common subtype of leukemia seen in children is acute lymphoblastic leukemia (ALL).

Although by far the majority of leukemias originates from and involves the bone marrow, this in itself is not a requisite and in rare cases a diagnosis of leukemia can be made without bone marrow involvement by conventional diagnostic methods.

Etiology

The precise etiology of leukemia in humans is not known. There are, however, several factors which may play a presumed role in the pathogenesis of human leukemia, including genetic predisposition, viral infection, congenital immune deficiency diseases, ionizing radiation, and certain toxic chemicals that can facilitate its development. Leukemia-associated genetic changes have been identified in umbilical cord blood samples, indicating a prenatal initiation of at least common childhood acute lymphoblastic leukemia. However, such prenatal cytogenetic changes are probably only predisposing factors and require post natal events, such as viral infections, to fully realize the leukemic phenotype. Constitutional chromosomal abnormalities are associated with childhood leukemia. Children with trisomy 21 (Down syndrome) are approximately 15-times more likely to develop leukemia, particularly acute myeloid leukemia, than normal children. Congenital syndromes that result in DNA instability, such as Fanconi anemia, Bloom syndrome and ataxia telangiectasia, also result in an increased predisposition to leukemogenesis. Although environmental factors, such as ionizing radiation or toxic chemicals, have the potential to produce leukemias, these are rarely associated with childhood leukemia in practice.

Epidemiology

Leukemias are the most common malignancy in children, constituting about 30% of all pediatric cancers. The average annual incidence of childhood leukemias from developed countries is about three to four cases per 100,000 children. The incidence reported from Saudi Arabia is somewhat lower, between two and three cases per 100,000 children. The data from India report an incidence that varies considerably from 1.5 to 5.6 per 100,000 children, with the lower incidence in the rural areas and the highest in the urban centers. Whether development and urbanization contribute to leukemogenesis or, as is more likely, case acquisition is better in the cities is as yet undetermined. Within the pediatric age group the incidence is highest between 1 and 4 year of age and corresponds to the peak incidence for common childhood ALL.

Acute lymphoblastic leukemia (ALL) accounts for 70–75% of all leukemias seen in this age group. Precursor B-cell ALL constitutes the majority of cases seen, with T-ALL accounting for about 15–20% in most reports. The proportion of T-ALL seems to be higher and significantly variable (20–60%) in less developed rural populations, which may be related to environmental factors. Acute myeloid leukemia (AML) accounts for about 25% of all cases. Chronic myeloid leukemia (CML) and juvenile myelomonocytic leukemia (JMML) are rare and together account for 5% of all childhood leukemias. The peak incidence of ALL occurs at approximately 3–4 years of age. The incidence of AML remains stable from birth to age 10 years and increases slightly during the teen ages.

Pathogenesis

Like all malignant disorders, leukemia is a clonal disease, originating from a single cell. Genetic mutations within this

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_345,

cell provide an evolutionary "survival advantage." Such "advantageous" mutations also result in a predisposition for further genetic mutation which, as they accumulate, result in the development of a malignant phenotype, the leukemic cell. There is clear evidence that the initiating steps in a significant proportion of childhood leukemia begins in utero. This is certainly true for infantile leukemia harboring the *MLL* gene, and has also been noted in a significant proportion of post-infancy childhood ALL and AML. What is also evident is that the leukemic predisposition induced by the in utero genetic changes requires a postnatal "second-hit." Current evidence seems to indicate an aberrant immune response to common infectious exposures which may be one of the intervening events leading to phenotypic leukemia. The pre-leukemic latent phase often lasts 2–4 years but may be as long as 14 years. The monoclonal and intrauterine origin of leukemia is most evident in the concordance of acute leukemia in monozygotic twins, which is estimated to be as high as 25%. The risk is higher in infancy and diminishes with age.

Clinical Manifestations

Presenting signs and symptoms of leukemia are usually nonspecific and are usually a manifestation of the underlying anemia, thrombocytopenia, and neutropenia. Pallor, fatigue, petechiae, purpura, bleeding, and fever are often present. Bone pain particularly affecting the long bones is common. In addition, joint effusions and arthralgias may be present due to leukemic infiltration of the peri-articular bone. Evidence for leukemic infiltration of organs, such as hepatomegaly, splenomegaly, and lymphadenopathy, may be evident on physical examination. Chloromas or granulocytic sarcomas are discrete tumors seen in patients with AML. Central nervous system (CNS) involvement can manifest as seizures, cranial nerve palsy, and/or symptoms and signs of increased intracranial pressure.

Laboratory abnormalities most often reflect the underlying failure of production of normal blood elements. Although white blood cell counts are often increased in patients with leukemia, many patients, in fact, have reduced white blood cells (WBC) counts. Thrombocytopenia and anemia are seen almost universally. Electrolyte abnormalities may also be seen, particularly if there is ongoing tumor lysis syndrome (TLS). In such cases elevated serum potassium, phosphate and uric acid, and hypocalcemia may be seen even prior to initiation of chemotherapy. Leukemic infiltration of the kidneys may result in renal dysfunction with elevation of serum creatinine. Disseminated intravascular coagulopathy (DIC) may occur in any type of leukemia, but this is more common in the acute promyelocytic leukemia.

Differential diagnosis includes nonmalignant conditions like juvenile rheumatoid arthritis, infectious mononucleosis, aplastic anemia, and idiopathic (immune) thrombocytopenic purpura. In infants any infection may result in a marked elevation of WBC counts and a leukoerythroblastic picture, mimicking leukemia.

Diagnosis

Childhood leukemias are systemic diseases that may affect any organ of the body, causing manifestations that may mimic other diseases. Children with leukemia are usually referred to a tertiary care center, where comprehensive programs for treatment of such diseases are available.

Although leukemic blast cells may be present in the peripheral blood, the definitive diagnosis is usually established upon examination of bone marrow aspirate specimens. Most patients have anemia and thrombocytopenia at diagnosis. Leukocyte counts may be elevated, normal, or low. Blast cells may be present in the peripheral blood. Bone marrow aspirate should be done in order to more completely characterize the leukemic cells. On occasion, when the peripheral white blood cell count is elevated the diagnosis can be completed without performing a bone marrow aspirate. The characterization of the leukemic blasts is done by morphologic assessment utilizing special stains, immuno phenotyping, cytogenetic and molecular studies. Establishment of the immune phenotype by flow-cytometric analysis is now considered the cornerstone of leukemia diagnosis. This is essential in defining the cell-type of origin, and helps in determining the treatment strategy that would be used.

Cytogenetic and molecular genetic studies have now become extremely important in determining the prognosis and in risk stratification of therapy. In ALL, genetic abnormalities within the leukemic cell have been shown to confer either a good-risk or a poor-risk genotype. This obviously would determine treatment intensity and outcome. This is probably even more evident in AML, where cytogenetic abnormalities now form the basis for AML subtype categorization, according to the current World Health Organization (WHO) Classification.

Other diagnostic studies include evaluation of the cerebrospinal fluid (CSF), and testicular-evaluation in boys. In patients with T-cell ALL, chest X-ray may show a mediastinal mass.

Treatment

General Concepts in the Initial Management of Childhood Leukemias

Chemotherapy remains the mainstay of therapy for children with leukemias. Over the years the use of radiation therapy, particularly cranial radiation therapy, has lost some of its value, and now indications for radiation therapy are limited. Bone marrow transplantation is used for a limited number of higher risk leukemia patients and does contribute toward achieving a higher cure rate. These treatment strategies are different for the different types of leukemias encountered and are outlined in more detail below.

Supportive measures are critical in stabilizing the patients prior to initiation of therapy. Hydration and correction of electrolyte disturbances are essential. As all patients with leukemia are at risk of tumor lysis syndrome (TLS) and the resultant renal compromise due to hyperuricemia, they all should be well hydrated to maintain a brisk urine output. Although urine alkalinization has been a component of TLS prevention for many years, it is now evident that alkalinization does not add to the beneficial effect of a high urine flow, and is no longer recommended.

Even with normal or high WBC counts, newly diagnosed patients with leukemia should be considered as immunocompromised. Any evidence or even suspicion of infection should be treated aggressively with broad spectrum intravenous antibiotics. While blood product transfusion for anemia or thrombocytopenia is indicated, this should be undertaken judiciously, particularly in patients with markedly elevated WBC count. Hyperleukocytosis, particularly in patients with AML, may result in hyperviscosity and resultant obstruction of small vasculature. Red blood cell transfusions may aggravate the signs and symptoms of hyperviscosity. Adequate hydration is usually sufficient in preventing hyperviscosity, although some patients with very high WBC counts may need leukapheresis in order to induce rapid reductions in the WBC counts. Such patients with high WBC counts and those with massive organomegaly have a large tumor load and with initiation of therapy remain at a high risk for TLS. The best treatment for TLS is its prevention with good hydration and the use of agents such as allopurinol and urate oxidase to decrease uric acid levels.

Good nutritional support, including total parenteral nutrition (TPN) when needed for critically ill patients, should be provided. Psychosocial support of the patient and the family including education about the disease and its therapy is of extreme importance to enable the treating team to deliver therapy.

Acute Lymphoblastic Leukemia

Childhood ALL is a heterogeneous group of leukemias, all sharing a common characteristic of lymphoid origin. This is reflected in the cellular differentiation markers and the morphology. Broadly, ALL can be divided into B-cell and T-cell types; however, the true nomenclature for these should be precursor B-cell and precursor T-cell lymphoblastic leukemias. Mature B-cell ALL, which was previously also categorized morphologically as the FAB L3 subtype, is now no longer included within this group of diseases and is reclassified as Burkitt leukemia/lymphoma. Distinct subtypes of precursor B-ALL with recurrent genetic lesions are now identified.

Central Nervous System (CNS) leukemia is diagnosed by the presence of lymphoblasts in the cerebrospinal fluid (CSF) as detected by centrifugation. For diagnosis of leukemic involvement of the testis, fine-needle aspiration or open biopsy is required to determine the presence of lymphoblasts. In the bone marrow, the lymphoblasts can be characterized by morphologic, biochemical markers, immunologic, and cytogenetic.

Morphology

Morphologic features of the leukemic lymphoblasts are best determined on examination of a bone marrow aspirate specimen. Most often the bone marrow is diffusedly infiltrated with the monomorphic leukemic lymphoblasts, with marked reduction in the normal marrow elements. Occasionally the numbers of lymphoblasts in the bone marrow may be less, making a distinction between ALL and bone marrow involvement of a lymphoblastic lymphoma difficult. An arbitrary cut off of 25% has been used to make this distinction. The lymphoblasts vary in size from small to medium sized cells. The cytoplasm is often scanty, but can be of a moderate amount and occasionally (10% of cases) may have coarse azurophilic granules. Generally, the nuclear cytoplasm (N/C) ratio is high and the nuclei often have prominent nucleoli.

The FAB classification of lymphoblastic leukemias, which is based primarily on the morphological characteristics, is no longer considered to be of clinical significance and is not used any more.

Biochemical Characterization

With current available diagnostic tools, cytochemistry seldom contributes to the diagnosis of ALL. Lymphoblasts

are universally negative for myeloperoxidase, Sudan black, and esterase stains. Periodic acid-Schiff (PAS) reaction is positive in most cases and is present in a coarse granular distribution. Terminal deoxynucleotidyl transferase (TdT) is found in the majority of patients with ALL.

Immuno Phenotype

Immuno phenotyping is the mainstay of ALL diagnosis and is used to characterize the leukemic cell. The leukemic transformation and clonal expansion can occur at different stages of maturation in the process of lymphoid differentiation and this is reflected in the expression pattern of cellular proteins in the malignant cells. Although most immunophenotyping is conducted using flowcytometry, immunohistochemical staining can also be used. The basic principle involves the use of monoclonal antibodies (moAbs) directed at surface and cytoplasmic proteins of the malignant cells. These moAbs are then identified by using fluorescent or chromogenic tags. Expression of lineage-specific markers such as CD19, cytoplasmic CD79a and cytoplasmic CD22 for B-cells, and cytoplasmic CD3 surface CD2 and CD7 for T-cells is indicative. However no individual marker is enough on its own to finalize the diagnosis and most often a pattern of expression is utilized. Some markers have been shown to have a prognostic association, such as CD10 which is commonly seen in patients with B-cell precursor ALL and is indicative of a more favorable prognosis.

Precursor B-ALL constitutes approximately 80–85% of all ALL, while 15–20% of ALL cases are T-cell ALL. This distinction is also of clinical importance as there are differences in disease presentation and response to therapy. T-ALL tends to occur in older children as compared to B-lineage ALL and generally presents with a higher WBC count. T-ALL is also associated with thymic infiltration presenting as a mediastinal mass. Patients with T-ALL require more intensive therapy, in spite of which they have a somewhat worse outcome than B-lineage ALL.

Not all ALL cases adhere to a specific lineage. Although occasional aberrant myeloid marker positivity is seen in ALL, this does not necessarily result in a diagnosis of mixed phenotype acute leukemia (MPAL). Clear guidelines are now available for the diagnosis of MPAL and require the expression of lineage specific markers of more than one cellular lineage. These MPAL tend to confer a worse prognosis, but may be amenable to therapy which includes agents effective against both lymphoid and myeloid leukemias.

Cytogenetic Studies

With the advances in cell culture methodology and improved chromosomal banding techniques, cytogenetic analysis has contributed significantly to the understanding of the biology and treatment of ALL. More recently the availability of molecular tools, such as polymerase chain reaction (PCR) and fluorescence in situ hybridization (FISH), has made it easier to identify genetic lesions. These techniques have also allowed the identification of cryptic translocations that are not evident on routine chromosomal banding. Certain recurrent cytogenetic abnormalities have been identified in ALL that have clinical and prognostic importance and these are now categorized separately.

Numerical abnormalities, with duplications and deletions of whole chromosomes, are seen quite frequently in leukemic blasts. These are non-random with extra copies of chromosomes 21, X, 14, and 4 encountered most often. Children with more than 52 chromosomes in their leukemia cells (hyperdiploid >52) tend to have a significantly better prognosis. This is determined either by routine karyotyping, or by the DNA index (the ratio of the average number of chromosomes in the lymphoblasts/normal diploid number 46) which can be determined by flowcytometry or FISH. Patients with DNA index >1.16 have a good prognosis. Extremes of chromosome numbers, near haploid or near tetraploid, confer an extremely poor prognosis. Recent studies have identified that trisomies of specific chromosomes (chromosomes 4, 10, and 17) rather than the total chromosome number may in fact be more important in determining the prognosis.

Specific structural chromosomal abnormalities also occur in ALL and several are considered clinically significant enough to warrant separate categorization. Precursor B-ALL with the Philadelphia chromosome (t(9:22); *BCR-ABL1* translocation) and those with rearrangements of the *MLL* gene at the 11q23 locus have a poor prognosis. *MLL* gene rearrangements occur due to translocations between chromosome 11 at the q23 locus and several variable partner chromosomes (t(v;11q23)); however, chromosome 4 is the most common. These translocations characterize the leukemias seen in infancy and are related to the poor prognosis of these patients. Translocation (12;21) (p13;q22) (*TEL-AML1 or ETV6-RUNX1*) is a cryptic translocation that is found in 20–25% of precursor B-ALL and is now considered the most common cytogenetic abnormality in ALL. Patients with this translocation have good prognosis. Other encountered translocations include t(1:19) and t(9;11).

Although several translocations are also encountered in patients with T-ALL, none are clearly identified as having a prognostic or clinical impact.

Prognostic Factors

Age at diagnosis and initial WBC count are the most significant clinical prognostic factors identified. In fact, patients with a WBC count$<50 \times 10^9$/L and age between 1 and 10 years are considered to have an especially good risk. Infancy (age <1 year) is universally recognized as a poor prognostic factor, particularly due to its association with *MLL* gene rearrangements. Older patients ($\geq$10 years of age) have a relatively poor prognosis which may be related to a higher proportion of patients with the T-cell phenotype and the absence of good-risk cytogenetic features. Cytogenetic abnormalities, as outlined above, have prognostic significance. Several studies reported that girls have a better prognosis than boys, although with recent treatment protocols this difference is less evident. Immune phenotype also appears to correlate with prognosis, with T-ALL being associated with a worse outcome than precursor B-ALL. Patients with T-ALL tend also to present with higher WBC counts and have more extramedullary involvement, particularly CNS involvement.

Leukemic infiltration of extramedullary sanctuary sites, such as the CNS and testicles, confers a worse outcome. This is especially significant for patients with CNS involvement who tend to have a higher risk of relapse, including bone marrow recurrences. The best outcome is seen in younger, non-infant, patients with B-ALL who have either the t(12;21) or hyperdiploidy with trisomies of chromosomes 4, 10, and 17.

Treatment

Treatment of ALL is primarily chemotherapy based and is risk-stratified. Risk stratification implies the use of higher intensity of therapy for those patients who are at a greater risk for relapse, and less intense therapy for those who at lower risk for relapse in order to avoid treatment-related toxicity. Risk stratification is based on the prognostic features available at diagnosis as outlined above, and also on response to therapy. Early response to therapy is determined by peripheral blood and bone marrow evaluation following 1 and 2 weeks of induction therapy.

Although different ALL treatment protocols utilize somewhat differing chemotherapeutic agents, certain universally applied features are present. Treatment for ALL is composed of well defined phases of therapy. The initial phase is induction, which usually utilizes three or four drugs (vincristine, prednisone, L-asparaginase, and daunomycin). This phase of therapy is aimed at rapid reduction of leukemic infiltrates and results in a 2–4 log reduction in the lymphoblasts burden.This phase is followed by the consolidation phase which further reduces systemic leukemic infiltrates. Therapy during the consolidation phase is also aimed at prevention of relapse in the CNS. The preventive therapy involves administration of intrathecal chemotherapy. Post consolidation the patients are placed on a prolonged continuation therapy phase which primarily includes antimetabolite (mercaptopurine and methotrexate) chemotherapy. This continuation phase is interspersed with either one or two intensification phases which are reminiscent of induction and consolidation. Total duration of therapy is usually between 2 and 3 years.

Radiation therapy was a standard component of ALL treatment; however, over the past 2 decades the need and indications for radiation therapy have been severely restricted. Currently, craniospinal radiation therapy is still required for patients diagnosed with CNS leukemia and testicular radiation therapy is administered to those boys with testicular leukemia. Clinical trials exploring further reductions in these indications are underway. These restrictions are desirable due to concerns that radiotherapy contributes to the long-term neurotoxicity.

Hematopoietic Stem Cell Transplantation (HSCT) is not required for the majority of patients with ALL. However, certain categories of patients with very high risk features, such as those with *BCR-ABLX* translocation or with *MLL* gene rearrangements, do benefit from BMT in first remission.

Outcome and Prognosis

Bone marrow relapse is the principal form of treatment failure in patients with ALL. Other sites of relapse include the CNS and, in boys, the testicles.

Prognosis of patients with ALL has improved significantly in recent years. Currently, approximately 70–80% of children with ALL achieve prolonged disease-free survival ($>$5 years after finishing therapy) and are considered cured. In patients with low risk features, this figure has reached 90%.

Acute Myelogenous Leukemia

The transformation event in AML could theoretically occur in any cell along the pathway from pluripotent

stem cell to committed hematopoietic cells. Although derived from cells of the myeloid lineage, AML is a heterogeneous group that can originate from and be reminiscent of any hematopoietic cell lineage, including erythroid and megakaryocytic.

Morphology

As with ALL, the morphologic classification, according to the FAB system, has lost its reliability and is no longer used. Lineage assignment and prognosis is now better determined by immunophenotype and genetic characteristics. Due to the various cell lineages involved and the fact that AML may occur at any phase of myeloid differentiation, no unifying morphologic characteristics can be enumerated for AML myeloblasts. These myeloblasts are described according to the presumed cells of origin (myeloid, monocytic, megakaryocytic, and erythroid) and the degree of cellular differentiation/maturation. In general, myeloblasts are larger in size than lymphoblasts and have more copious cytoplasm. Granularity is often encountered and Auer rods are considered diagnostic of myeloid malignancy. Myeloperoxidase detection by cytochemistry or flowcytometry conclusively assigns myeloid lineage to the leukemic cells; this however is not positive in all AML subtypes.

Immuno Phenotype

As with ALL, immuno phenotyping is the mainstay of AML diagnosis and subtype assignment. Often a relatively large panel of moAbs is applied, and the patterns of expression are used to reach a diagnosis. Certain markers are seen more consistently, with at least one of the following markers, CD33, CDI3, CD15, CD11b, CD 14, and CD34, being expressed in more than 90% of AML cases.

Cytogenetic Studies

Genetic alterations form the basis of AML subclassification and prognostic risk assignment. Certain recurrent genetic abnormalities are frequently seen in AML cells. These structural changes are associated with specific subtypes of AML and have prognostic implications. Translocation (8;21)(q22;q22)/*RUNX1-RUNX1T1* is the most commonly occurring translocation in de novo AML. This is found mostly in myeloid leukemia with maturation (prior FAB M2 subtype). Related genetic abnormalities include inv(16)(p13.1q22) (p13.1;q22)/*CBFB-MYH11* or the t(16;16), which is often associated with the myelomonocytic subtype of AML. This translocation and t(8;21) involve the genes for the subunits of the heterodimeric DNA binding transcriptional regulator, the Core Binding Factor (CBF), which has been shown to be essential for the normal development of all hematopoietic lineages. The presence of either of these translocations confers a more chemo-sensitive phenotype and results in better disease free survivals. Interestingly, the *RUNX1* gene is also involved in the t(12;21)/*RUNX1-ETV6* translocation in ALL which also results in improved prognosis.

AML with the t(15:17)(q22;q12)/*PML-RARA* translocation is uniquely associated with a more mature myeloid cell type (Acute promyelocytic leukemia; prior FAB M3 subtype). This AML also has a better outcome, which is primarily associated with the use of *all-trans* retinoic acid (ATRA) as a component of treatment. As in ALL the *MLL* gene rearrangements involving translocations of the chromosome 11q23 are often seen and can involve numerous translocation partner genes. These translocations are more often seen in the younger age group and tend to confer a worse overall outcome, except for t(9;11)(p22;q23)/*MLLT3-MLL* which has an intermediate prognosis. In addition to their presence in *de novo* AML, *MLL* gene rearrangements are frequently seen in cases of treatment-related AML, particularly those associated with prior topoisomerase II inhibitor therapy. Numeric changes in certain chromosomes or loss/gain of major chromosomal segments are often seen in AML associated with myelodysplasia. Most commonly associated changes include −7/del(7q), −5/del(5q), and trisomy 8.

Several other gene mutations, in addition to the structural chromosomal abnormalities, are seen in AML. These include mutations in genes such as *FLT3, NPM, WT1*, *and KIT.* These mutations have varying effects on prognosis.

Prognostic Factors

Prognostic risk stratification in AML is determined more by the primary cell of origin and the cytogenetic aberration than by specific clinical features. As mentioned above, t(8;21) and inv(16)/t(16:16) have a favorable outcome, as does APL with t(15;17). Myelodysplastic syndrome (MDS) associated cytogenetic abnormalities such as −7, del(5q) and +8 are associated with a significantly poor outcome, which is probably related to the association with MDS rather than the effect of any particular genetic abnormality. *MLL* gene rearrangements in *de novo* AML is not necessarily associated with a poor outcome, but

confers a particularly bad prognosis in patients with outcome and treatment-related AML (t-AML).

Certain AML subtypes generally are known to have a worse outcome. These include acute megakaryocytic leukemia and erythroleukemia. Interestingly, megakaryocytic leukemia in children with Down's syndrome (DS), 4 years of age, has a particularly good outcome to chemotherapy.

Treatment

The treatment strategy for AML requires therapy to be intensive, multi-agent, and sequential. Although clear phases of therapy are well not defined, as in all treatment, the first two cycles of chemotherapy are generally considered to constitute the remission induction phase. Cytosine arabinoside and anthracyclines are considered to be the effective agents for remission induction. Often other chemotherapy agents, such as thioguanine or etoposide, are included in the induction regime. With current treatment approximately 85% of AML patients are expected to achieve remission following first line induction therapy.

Post remission induction therapy includes either two or three further cycles of multi-agent chemotherapy, or allogeneic hematopoietic stem cell transplantation (HSCT). Most often HSCT is timed to follow either second or third cycle of chemotherapy, depending on the timing of achievement of remission. Indication for HSCT has evolved over the last decade, and not all patients now need transplantation. Patients within the lower risk group, with good-risk cytogenetic changes, can be treated effectively with chemotherapy alone. Most physicians would now offer HSCT to patients with intermediate risk status only if there is a matched related donor. Patients in the poorest risk group, those with MDS-related AML, t-AML, or non DS megakaryocytic leukemia, continue to be candidates for HSCT even from alternative donor sources. Autologous SCT is no longer considered an option for treatment of pediatric AML.

Special consideration must be given to t(15;17) positive APL. In addition to the anthracycline and cytosine arabinoside these patients are induced with ATRA. Pharmacological doses of ATRA act by overcoming the effect of the retinoic acid receptor α (RARA) mutation and inducing cellular differentiation, maturation, and apoptosis. Due to the good outcome with chemotherapy, HSCT is not indicated in APL. Post remission therapy now includes a maintenance phase using antimetabolites (mercaptopurine and methotrexate) with pulses of ATRA.

Prognosis

With current intensive therapy around 50–60% of children with AML are expected to survive long term. This survival is dependent on risk stratification, with over 70% survival for the low risk AML patients and around 30% for those with high risk AML.

Chronic Myeloid Leukemia

Chronic Myeloid Leukemia (CML) is rare in the pediatric age group, accounting for less than 5% of all leukemias. It is a myeloproliferative neoplastic disease that originates in an abnormal pluripotent hematopoietic stem cell. CML is characterized by the presence of the *BCR-ABL* translocation (t(9;22)(q34;q11.2)). This translocation results in the abnormally small chromosome 22, known as the Philadelphia chromosome. Although the initial presentation primarily includes neutrophilic leukocytosis, all myeloid lineages are involved. In fact, some lymphoid and endothelial cells may also harbor the *BCR-AB*[1] translocation.

Patients most often present in the chronic phase with marked hyperleukocytosis, and massive hepatosplenomegaly. As opposed to the acute leukemias, even with very high WBC counts, the platelet count is not reduced and may be elevated. Generalized lymphadenopathy may present and occasionally there is leukemic blast infiltration of skin or other soft tissues. The natural history of CML is triphasic, with the initial presentation usually in the chronic phase; untreated CML progresses on to accelerated and blastic phases. Rarely, patients with CML will present in the later phases, which most often is myeloid in origin and resembles AML. In some cases blastic transformation can be lymphoid and patients may present with disease indistinguishable clinically from ALL.

The *BCR-ABL* translocation driven abnormal Eyrosine kinase activity that defines CML has been the target also resulted in the development of the treatment approach to this disease. Treatment of CML is now based upon the use of tyrosine kinase inhibitors (TKI) that target the abnormally enhanced tyrosine kinase activity of the chimeric BCR-ABL protein. Imatinib mesylate was the first such TKI to be developed and remains the standard agent for fist line therapy. Imatinib mesylate monotherapy has resulted in not only complete cytogenetic remissions, but also in reductions in the leukemic clone to levels less than 1 in 10^5 cells. However, it is still unclear if TKI therapy can achieve durable cures and current treatment approaches recommend indefinite continuation of the TKI therapy.

Allogeneic HSCT remains the only proven curative therapeutic option for patients with CML. However, with the advent of TKI therapy the status of HSCT has become controversial. While transplant has become significantly uncommon in the treatment of chronic phase CML in adult patients, many pediatric oncologists still opt for transplantation for their patients. The need for possible lifelong TKI therapy has to be balanced against the potential toxic morbidity and mortality associated with HSCT. Many pediatric oncologists will now recommend HSCT if a matched related donor is available, and continue with TKI therapy for all other patients. Patients with advanced phase CML need to be treated more aggressively and HSCT remains the unequivocal treatment of choice.

Juvenile Myelomonocytic Leukemia (JMML)

Juvenile myelomonocytic leukemia (JMML) is a clonal proliferative hematopoietic disorder which occurs in infancy or early childhood. It primarily results in monocytosis andgranulocytosis and is distinguished from CML by the absence of the *BCR-ABL* fusion gene. It is quite rare and comprises only 2–3% of all childhood leukemias. Diagnostic criteria for JMML include not only the absence of *BCR-ABL*[1], but also require peripheral blood monocytosis and less than 20% blasts in the blood marrow. Other features that may be seen are elevated hemoglobin F, immature granulocytes in the peripheral blood, elevated WBC count to more than 10×10^9/L, and clonal chromosomal abnormalities including monosomy 7.

While chemotherapy and differentiation agents, such as cis-retinoic acid, have been used for cytoreduction, curative therapy is only achievable with HSCT. Without transplantation most children die of organ dysfunction due to leukemic infiltration at a median survival of less than 1 year.

346 Non-Hodgkin Lymphoma

H. Stacy Nicholson

Introduction

Non-Hodgkin lymphoma (NHL) is the term applied to all solid lymphoid neoplasms other than Hodgkin disease (HD). Some are closely related to acute lymphoblastic leukemia (ALL) and are treated similarly. The incidence of NHL in children below 15 years of age in the USA is 7.4 per 100,000. NHL is much more common than HD in the first decade of life, and children with immunodeficiencies have a greater risk of NHL. NHL is the third most common childhood cancer, following leukemia and brain tumors.

Histological Subtypes

NHL is a group of diverse lymphoid malignancies. Improved understanding of tumor immunology, cytogenetics, and molecular biology has improved both the classification and treatment strategies for NHL. Each major subtype NHL needs to be understood separately. Major subtypes of NHL include Burkitt Lymphoma (BL), lymphoblastic lymphoma (LL), diffuse large B-Cell lymphoma, and anaplastic large-cell lymphoma.

Burkitt lymphoma is a fast-growing B-cell malignancy with a high proliferation rate. The pathology generally shows sheets of homogeneous cells with a classical "starry sky" appearance. Cell surface antigens include CD19, CD20, CD79a, and CD10, and surface immunoglobulin. Most BLs have characteristic translocations, including t(8;14), t(2;8) or t(8;22); these translocations fuse an immunoglobulin component gene with an oncogene.

Lymphoblastic lymphoma (LL) is closely related to ALL and can be either of B or T-cell origin. Cell surface antigens, cytogenetic abnormalities, and molecular biology of LL are identical to the corresponding cell origin ALL.

Diffuse large B-cell Lymphoma accounts for about one-third of all childhood NHLs. Cells express a number of B-cell antigens, including CD19, CD20, CD22, and Cd79a.

Clinical Features

NHL often presents with either persistent, progressive adenopathy, or as a medical emergency, including respiratory distress from a mediastinal mass or intestinal obstruction due to a mass arising from a Peyer's patch in the small intestine (most commonly terminal ileum). Most NHLs have a high rate of growth, and prompt referral to a childhood cancer center is important. Clinical features differ by type of NHL.

There are at least two main types of Burkitt lymphoma. In developed countries, BL often primarily involves the intestine and presents as an abdominal mass with or without intestinal obstruction. African BL is often associated with the Epstein–Barr Virus (EBV) and presents as a large facial mass.

Lymphoblastic lymphoma often presents with a mediastinal mass and may have malignant effusions, often leading to respiratory distress or failure. LL can be of either B- or T-cell origin, and clinical features are similar to ALL of the same lineage. For example, both T-cell ALL and T-cell LL are likely to present with a mediastinal mass and are more likely to involve the central nervous system (CNS).

Diffuse large B-cell lymphomas can present in a large variety of ways, but typically with sizable adenopathy, including mediastinal masses. This subtype is often disseminated and is the subtype most associated with immunodeficiencies.

Laboratory Features

Unless the bone marrow is involved, the complete blood count is usually normal. Similarly, unless there is hepatic involvement or renal failure from the acute tumor lysis syndrome (ATLS), blood chemistries are often normal. Lactate dehydrogenase (LDH) is usually markedly elevated. Uric acid, electrolytes, and renal function must be following closely at diagnosis and during the first few days of treatment, to prevent or treat ATLS.

Diagnostic Studies and Staging

Diagnosis depends upon a biopsy, and pathological tests should include cytogenetics and flow cytometry.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_346,

Table 346.1
St. Jude (Murphy) staging system for non-Hodgkin lymphoma (NHL)

Stage	Description
I	• A single extranodal tumor or single nodal group, exclusive of the mediastinum or abdomen
II	• A single extranodal tumor with regional node involvement
	• Two or more nodal groups, on the same side of the diaphragm
	• Two extranodal tumors with or without regional node involvement on the same side of the diaphragm
	• Primary GI tract tumor (usually ileocecal) with or without regional node involvement
III	• Two extranodal tumors involving both sides of the diaphragm
	• Two or more nodal groups, involving both sides of the diaphragm
	• All primary intrathoracic tumors (mediastinal, pleural)
	• All extensive primary intra-abdominal tumors
	• All paraspinal or epidural tumors
IV	• Any of the above stages, with bone marrow or central nervous system involvement

In children with an effusion, malignant cells from an aspirate will usually yield the diagnosis. Performing the staging workup rapidly is important, given the urgent need to start therapy. Computerized tomography (CT) of the neck, chest, abdomen, and pelvis should be done, including the Waldeyer Ring, and bone marrow and cerebrospinal fluid should be tested in all NHL patients. A modification of the Murphy staging system is used in NHL (see *Table 346.1*), supplemented by a risk stratification schema for B-cell lymphomas (*Table 346.2*).

Treatment

Treatment differs by subtype, but all are treated with chemotherapy. Beyond establishing the diagnosis, there is little role for surgery in the treatment of NHL. Patients with intestinal obstruction need an emergency laparotomy with tumor resection. Radiotherapy is not part of standard therapies for NHL but may be used for palliation in patients with recurrent disease.

Chemotherapy is the mainstay of NHL therapy and has many similarities to treatment strategies used in ALL.

Table 346.2
Risk stratification of B-cell lymphomas

Stratum	Description
A	• Resected stage I and abdominal stage II
B	• Multiple extraabdominal sites, nonresected stage I, II, III
	• Stage IV may be in this group if less than 25% of bone marrow or cells in CSF are malignant
C	• Intra-abdominal stage IV
	• Bone marrow involvement with greater than 25% of cells being malignant

This system is used in addition to the Murphy staging system

CHOP (cyclophosphamide, doxorubicin, vincristine and prednisone) is the most commonly used combination chemotherapy and is effective in Burkitt lymphoma, diffuse large B-cell lymphoma and anaplastic large-cell lymphoma. In addition, COPAD (cyclophosphamide, doxorubicin, vincristine, and prednisone), COPADM (cyclophosphamide, doxorubicin, vincristine, prednisone, and high-dose methotrexate), and COMP (cyclophosphamide, vincristine, methotrexate, and prednisone) are used in BL. COPAD and COPADM are also used in large B-cell lymphoma. These are all dose-intensive combinations with significant toxicities and need to be administered in a pediatric oncology referral center. Lymphoblastic lymphomas are treated very similarly to ALL, and treatment may include CHOP with an ALL-Type maintenance using oral mercaptopurine and methotrexate. Monoclonal antibodies directed at cell surface markers have activity in NHL and are being studied in combination with chemotherapy.

Prognosis

Most types and stages of NHL have an excellent prognosis. Low stage BL has a 90–95% survival rate, and large B-cell lymphoma and anaplastic large-cell lymphoma have 90% survival rates. Even with advanced stages, most children have at least a 70% chance of survival. However, recurrent NHL can be quite difficult to treat.

347 Hodgkin Disease

H. Stacy Nicholson

Introduction

Hodgkin disease (HD) is a B-cell lymphoid malignancy that occurs in 2 per 100,000 children before the age of 15 years in the USA. In the USA and other developed nations, HD is primarily a disease of adolescence and young adults with a second peak in older adulthood (>50 years). In the developing world, the age distribution is shifted toward younger children.

Pathology

HD is diagnosed from a lymph node biopsy and requires the demonstration of the classic Reed–Sternberg (RS) cells in a background of lymphocytes, histiocytes, eosinophils, and plasma cells. The RS cell is the malignant cell of HD and is of B-cell lineage. There are four histopathological subtypes of HD: lymphocyte predominance (LP), nodular sclerosis (NS), mixed cellularity (MC), and lymphocyte depletion (LD). NS is the most common subtype in the USA and Western Europe, and MC is the most common in the developing world. Subtype is related to prognosis – LP rarely disseminates and has a good prognosis, while LD is likely to disseminate and has a poor prognosis (*Fig. 347.1*).

Clinical Features

HD usually presents as painless progressive adenopathy which ultimately will coalesce into a large mass. Most commonly, HD starts above the diaphragm and involves cervical, axillary, or intrathoracic nodes. In one-third of patients, the initial site is below the diaphragm and can include the inguinal and/or intraabdominal nodes. HD can spread to other organs, including spleen, liver, and bone marrow.

Some patients with HD have a classic constellation of symptoms, including fever, night sweats, and weight loss – these are called "B" symptoms and are important in staging newly diagnosed patients. Severe pruritis can also be a presenting symptom.

Diagnostic Studies and Staging

Following histopathological diagnosis, the staging workup in HD requires that all major nodal groups on both side of the diaphragm be imaged. The most common imaging modality is computerized tomography (CT), which should include the neck (including the Waldeyer ring), chest, abdomen, and pelvis. Nuclear scintography (gallium or PET) may be useful, but staging laparatomy and lymphangiograms are no longer routinely used. Bone marrow aspirates and biopsies are done in all but those with stages IA or IIA HD, and bone scans are needed only if symptoms suggest bony involvement.

The Ann Arbor staging system is the accepted standard (*Table 347.1*). Based on the number and site of involved lymph node chains, patients are stratified into four main stages, I–IV. Furthermore, patients are classified as having either A or B disease based on the absence or presence, respectively, of the classic triad of constitutional symptoms (fever, weight loss, night sweats.) Untreated, HD will predictably progress to a higher stage, although stage at diagnosis usually reflects the underlying tumor biology.

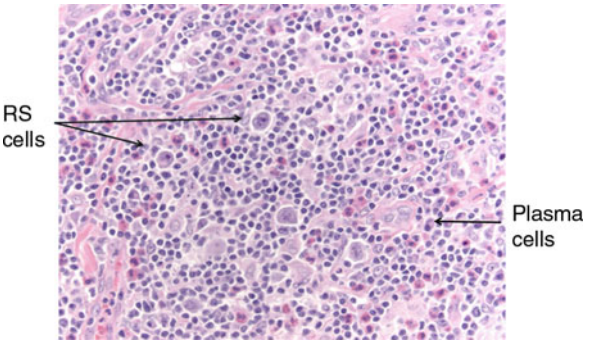

Figure 347.1
Nodular sclerosing Hodgkin disease: Hematoxalin-eosin stain – 20×: Reed–Sternberg cells with binuclear and mononuclear forms in the background of fibrosis, admixed with eosinophils, plasma cells, and small lymphocytes (Courtesy of Guang Fan, MD, PhD)

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_347,

Table 347.1
Ann Arbor staging of Hodgkin disease

Stage	
I	Disease is limited to one lymphatic region or one extra nodal site, excluding liver or bone marrow.
II	Disease involves two or more lymphatic regions on one side of the diaphragm
III	Disease involves lymphatic regions on both sides of the diaphragm (may involve spleen).
IV	Disease involves lymph nodes in any pattern. In addition, liver, bone marrow, lungs, CNS, or other organs are involved.

Treatment

Treatment is based on stage and may involve chemotherapy, radiation, or both. Generally, the role of surgery is limited to establishing the diagnosis. Treatment has evolved over the past few decades, resulting in excellent survival. Chemotherapy is now used in all but very low-stage patients, and radiation is being used more sparingly. With the realization that women who received chest radiation for HD during adolescence have a high risk of breast cancer, treatment strategies for males vs. females have diverged, with radiation being used less in females.

Radiotherapy

Radiation is an effective treatment for HD and has been used since the 1940s and is used without chemotherapy for low-risk patients with low-stage disease. Dosage varies by stage and site but generally does not exceed 40 Gy.

Chemotherapy

MOPP (mechlorethamine, vincristine (Oncovine®), procarbazine, and prednisone) chemotherapy was one of the first combinations of chemotherapy demonstrated to be effective in cancer. MOPP and variations of MOPP are still used in the treatment of HD. However, MOPP has significant long-term toxicities, including infertility and secondary malignancies. A second combination, ABVD (Adriamycin, bleomycin, vinblastine, and dacarbazine) is also effective. Combination therapy for HD continues to evolve, with combinations that use both MOPP and ABVD, and modifications of MOPP, most commonly with cyclophosphamide being substituted for mechlorethamine (COPP).

Prognosis

With stage-appropriate therapy, most children and adolescents with HD will become long-term survivors, and patients with low-stage disease have survival rates in excess of 90%. Even with stage IV disease, most become long-term survivors. However, HD is one of the few childhood malignancies where a relapse can occur more than 5 years after diagnosis. Thus, close follow-up is required through the first decade and lifelong follow-up is advised to monitor for late effects of therapy. Following relapse, some children have been cured using high-dose chemotherapy and autologous bone marrow transplantation.

348 The Histiocytoses

Suman Malempati · H. Stacy Nicholson

Introduction

The histiocytoses of childhood are a diverse and relatively uncommon group of disorders. Despite considerable heterogeneity in clinical manifestations, these diseases have in common the proliferation of cells of the mononuclear phagocyte system. The World Health Organization (WHO) has utilized a general classification scheme that is based on both clinical presentation as well as histologic features (*Table 348.1*). According to this scheme, Class I defines Langerhans cell histiocytosis, Class II includes histiocytoses of mononuclear phagocytes other than Langerhans cells, and Class III denotes malignant histiocytic disorders.

Class I Histiocytosis

Langerhans Cell Histiocytosis (LCH) is characterized by a non-malignant clonal proliferation of a specific-type of dendritic cell, known as the Langerhans cell. Until the 1980s, LCH was known as Histiocytosis X, as the cell of origin was undetermined. Histiocytosis X, which was coined in 1953, was a term used to unify several related clinical syndromes, including Hand-Schuller-Christian syndrome, Letterer-Siwe disease, eosinophilic granuloma, and Hashimoto-Pritzker syndrome into one clinical entity. Despite the wide variation in clinical manifestations, the central role of the Langerhans Cell unites these disorders.

Epidemiology

It is difficult to obtain an exact incidence rate of LCH due to heterogeneity of clinical manifestations of the disease and possible underrecognition of this condition. The annual pediatric incidence of LCH has been estimated to be 2–6 cases per million children. LCH tends to occur in young children with a peak incidence between 1 and 4 years of age. Young children with LCH have a higher frequency of more severe disease, and most cases with multisystem involvement occur before the age of 2 years. Older children and adults are more likely to have disease limited to bony sites. There appears to be a higher incidence of cancer in patients with LCH, although a causal association has never been demonstrated.

Pathogenesis

LCH is characterized by a clonal proliferation of Langerhans cells. Langerhans cells are antigen-presenting cells of monocyte lineage that are normally found in the skin and other organs. The typical LCH lesion contains histiocytes including Langerhans cells, lymphocytes, eosinophils, and sometimes neutrophils and plasma cells. While the disease is thought to be immunologically mediated and result from disordered immune regulation, an exact cause of the disease has not been elucidated. Evidence suggests that the abnormal proliferation of histiocytes, though clonal, is reactive rather than malignant.

Clinical Manifestations

The manifestations of LCH range from an idolent localized lesion to widely disseminated aggressive disease. The most commonly affected system is the skeleton, with bone lesions present in 80% of cases. In the past, eosinophilic granuloma was the term used to describe LCH involving single or multiple bone sites without visceral involvement. A unifocal bone lesion is the most common manifestation of the disease and comprises approximately 30% of cases. Bone lesions are often painless and are usually accompanied by a soft-tissue mass. The skull is the most common site. Skull lesions may be associated with other head and/or neck manifestations such as chronic otitis media, mastoiditis, “floating teeth” with mandible involvement, and cervical lymphadenopathy. Patients with base of skull lesions are also at risk for intracranial complications – most commonly diabetes insipidus (DI). Involvement of the spine can result in vertebral collapse, and there can be risk of spinal cord impingement. Extremity lesions may be painful or painless and can sometimes lead to pathologic fracture.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_348,

Skin is the next most commonly involved organ, and skin rash is often part of disseminated disease. The rash associated with LCH is characterized by a crusting vesiculopustular exanthem with a similar appearance to seborrheic dermatitis. It frequently occurs on the scalp and postauricular region, but can also be seen on the trunk and inguinal region. A syndrome associated with skin-only involvement of LCH in the neonate is known as congenital self-healing histiocytosis or Hashimoto-Pritzker syndrome. As the name suggests, the lesions typically resolve by 3–4 months of age without treatment.

Disseminated LCH usually occurs in children less than 1–2 years of age and can be life-threatening. The organs most commonly involved include the liver, spleen, lymph nodes, and bone marrow. Pulmonary involvement is rare in children, but can occur with disseminated disease. This is in contrast to primary pulmonary LCH that occurs in adults without other systemic involvement. Pulmonary LCH in adults is often associated with smoking tobacco.

Central nervous system involvement of LCH is common and can lead to devastating consequences. DI results from infiltration of LCH cells into the hypothalamus or pituitary stalk and occurs in up to 20% of patients with LCH. DI often occurs after other manifestations of the disease and is typically seen in patients with multisystem disease and those with skull bone involvement. Cranial nerve palsies and lesions in the cerebellum resulting in ataxia can also occur.

Diagnostic Evaluation

The diagnostic evaluation of patients with suspected LCH should begin with a thorough history and physical examination. Evaluation of patients with skull bone lesions and suspected LCH should include appraisal of CNS symptoms as well as symptoms of polyuria and polydypsia. Physical examination must include assessment for skin rash, lymphadenopathy, hepatosplenomegaly, and cranial nerve deficits. Imaging is necessary to characterize any suspected bone lesions. The classic radiologic findings are "punched out" lesions on plain x-rays (*Figs. 348.1* and *348.2*). Lesions are typically well demarcated, and reactive sclerosis is unusual at diagnosis. Other evaluations are helpful to determine extent of disease. A complete bone survey is necessary to evaluate for occult bone lesions in any patient diagnosed with LCH. Cytopenias see on a peripheral complete blood count may indicate bone marrow involvement. Bone marrow aspirates and biopsies should also be performed if cytopenias are present. A brain MRI is important to evaluate for intracranial lesions in patients who have skull bone involvement. Guidelines for diagnostic evaluation for patients with suspected LCH are shown in *Table 348.2*.

While clinical and radiographic features may suggest a diagnosis of LCH, pathologic evaluation of involved tissue is necessary for definitive diagnosis. On light microscopy, LCH lesions will show mixed population of cells that includes large histiocytes with few cytoplasmic vacuoles (Langerhans cells) along with an abundance of eosinophils

• Tissue diagnosis:
– Biopsy of involved lesion or organ
– Bone marrow aspirates/biopsies (if multisystem disease or cytopenias present)

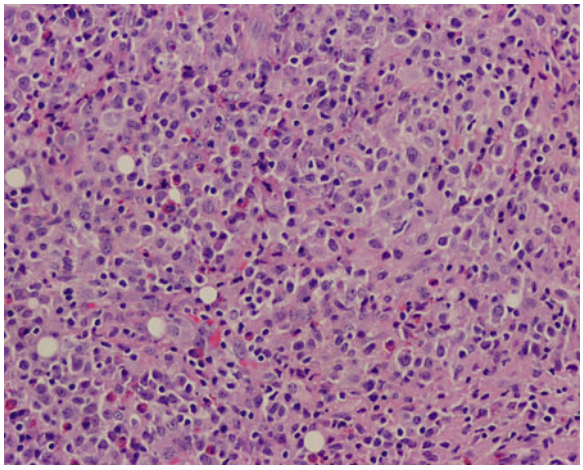

Figure 348.3
Light microscopy of LCH lesion

and lymphocytes (*Fig. 348.3*). Immunohistochemical staining shows positivity for CD1a antigen and S-100 protein. More recently staining for CD207 also known as Langerin has been used. Presence of the typical light microscopic findings along with positivity for CD1a or CD207 is diagnostic of LCH. Demonstration of rod-shaped organelles known as Birbeck granules by electron microscopy is also diagnostic.

Treatment and Prognosis

The appropriate management of patients with LCH depends on the location and extent of disease. The goal of treatment should be control of disease and prevention of long-term consequences rather than complete ablation. Patients with single-system disease may require minimal to no treatment as the natural history can include spontaneous resolution. Solitary bone lesions may be treated with curettage alone. Aggressive surgical resection is not necessary. Low-dose radiation therapy may also be used to treat bone lesions that are in locations that cause risk for permanent damage to underlying structures. Patients with skin-only disease may not need to be treated or can be treated with topical corticosteroids. The prognosis for patients with single-system disease is excellent.

Patients with multisystem disease and organ dysfunction have a significant risk of death and require systemic treatment. Chemotherapy has been used effectively to induce disease regression. Effective agents against LCH include prednisone, vinblastine, mercaptopurine, methotrexate, and more recently, 2-chlorodeoxyadenosine

(2-CDA). Combinations of these agents have been evaluated in multinational randomized clinical trials by the Histiocyte Society. Allogeneic hematopoeitic stem cell transplant has also been used for patients with refractory, progressive LCH.

While the prognosis for most patients with LCH is very good, the risk of late sequelae is high. Long-term complications of LCH occur in up to 30–50% of survivors of LCH. These permanent sequelae include diabetes insipidus and other endocrinopathies, neurologic and developmental abnormalities, orthopedic problems, and hearing impairment. Whether systemic therapy may decrease the frequency of these complications is debatable.

Class II Histiocytosis

The Class II histiocytoses are a heterogeneous group of disorders that are characterized by a proliferation of phagocytic cells. These disorders are thought to be reactive processes which result in infiltration of normal cells of monocyte/macrophage lineage. The major disease in this category is hemophagocytic lymphohistiocytosis (HLH), which has both familial and secondary forms. Other benign disorders in this category include sinus histiocytosis with massive lymphadenopathy (Rosai-Dorfman Disease) and juvenile xanthogranuloma.

Epidemiology

The primary familial form of HLH typically manifests in infancy or early childhood. There are multiple genetic abnormalities that can lead to the clinical manifestations of HLH syndrome. The disease is typically inherited in an autosomal recessive pattern, although there is often no family history. Familial HLH is rare with an estimated incidence of 1 in 50,000 live births. Among familial cases, the most common genetic abnormalities found involve mutations of the *perforin* gene, which are found in about one-third of patients with HLH.

Secondary HLH results from an abnormal immune response to an infection or other process. The incidence of secondary HLH is unclear as the disease is likely underdiagnosed. It is possible that the condition is now being recognized and diagnosed more frequently. Infection-associated secondary HLH has been reported after viral, bacterial, fungal, and parasitic infections. HLH is a known complication of EBV infection, particularly in patients with x-linked lymphoproliferative disease. It occurs more frequently in children with underlying immunodeficiency.

Clinical Manifestations

The most common clinical features of HLH are prolonged fever, hepatosplenomegaly, and cytopenias. Patients also often present with rash, lymphadenopathy, and coagulopathy. The Histiocyte Society has developed a set of diagnostic criteria for HLH based on clinical signs and specific laboratory abnormalities (Table 348.3). These diagnostic guidelines are valid for both familial and secondary HLH. While HLH is a non-malignant disorder, patients are often critically ill at presentation and the disease is often fatal without treatment. Most of the signs and symptoms and HLH are non-specific and the condition can be difficult to distinguish from sepsis or hepatitis. Patients can also have CNS involvement which may manifest as seizures or ataxia.

Diagnostic Evaluation

The presenting signs and symptoms of HLH are non-specific and establishing a definitive diagnosis can be difficult. Physical exam should include evaluation for organomegaly and lymphadenopathy. The splenomegaly is often profound and out of proportion to what would be expected from an underlying bacterial of viral infection. Laboratory evaluation should include a complete blood count, coagulation profile, serum ferritin, and serum triglycerides. Biopsy of bone marrow, lymph nodes, spleen, or liver may show a lymphohistiocytic infiltrate with

Table 348.3
Diagnostic criteria for HLH

Detection of a characteristic genetic abnormality (i.e., perforin or MUNC 13-4 mutations) OR Presence of at least 5 of 8 criteria listed below:
• Fever (persistent daily)
• Splenomegaly
• Cytopenia of at least 2 cell lines
– Hemoglobin < 9 g/dL
– Platelets < 100,000/μL
– Neutrophils < 1,000/μL
• Hypertriglyceridemia and/or hypofibrinogenemia
• Hemophagocytosis in bone marrow, spleen, or lymph nodes without evidence of malignancy
• Elevated serum ferritin (> 500 μg/L)
• Elevated soluble IL-receptor alpha (CD25)
• Low or absent NK-cell function

hemophagocytosis. However, hemophagocytosis is not always identified and is not required for the diagnosis of HLH. Specialized tests that include measurement of soluble interleukin-2 receptor and NK-cell activity may need to be sent to a reference laboratory. A definitive diagnosis of familial HLH can be made by detection of one of the characteristic genetic mutations, which are present in approximately 50% of cases.

Treatment and Prognosis

Initial therapy for HLH consists of chemotherapy with immunosuppressive agents. The Histiocyte Society's HLH-2004 protocol treats patients with a combination of etoposide, cyclosporin A, and dexamethasone. Hematopoietic stem cell transplant is commonly used and is the treatment of choice for patients with familial HLH.

Without treatment HLH is usually rapidly fatal. Survival rates with stem cell transplant for familial HLH are better than 50%.

Other Class II Histiocytoses

Sinus histiocytosis with massive lymphadenopathy, also known as Rosai-Dorfman disease, is a benign, reactive process characterized by enlargement of cervical lymph nodes associated with systemic symptoms. Patients with this condition often have fevers, night sweats, and weight loss. The disease usually resolves spontaneously, but may require treatment due to life-threatening airway obstruction. Effective treatments include corticosteroids, chemotherapy, and radiation.

Juvenile xanthogranuloma is benign histiocytic process that occurs in infants and young children. Lesions are usually confined to the skin, but multisystem involvement can occur. Solitary cutaneous lesions almost always regress spontaneously. Treatment with chemotherapy as has been used for LCH is effective for systemic disease.

Class III Histiocytoses

The Class III Histiocytoses consist of malignant disorders of mononuclear phagocyte lineage, including acute monocytic leukemia, malignant histiocytosis, and histiocytic sarcoma. Acute monocytic leukemia is considered a subtype of acute myelogenous leukemia (M5) and is discussed in more detail in Chap. 345, "Childhood Leukemias". True malignant histiocytosis is a very rare systemic disease. The clinical manifestations may be very similar to HLH. Fever, lymphadenopathy, hepatosplenomegaly, and skin lesions are common signs. It is now recognized that many malignancies previously diagnosed as malignant histiocytosis actually represent anaplastic large cell lymphoma (see Chap. 346, "Non-Hodgkin Lymphoma"). Systemic chemotherapy can be effective in the treatment of the malignant histiocytoses.

349 Central Nervous System Tumors in Children

Rebecca Loret de Mola · Kellie J. Nazemi

Introduction

Brain tumors are the most common solid tumor in children and are the second most common malignancy of childhood. The incidence of brain tumors peaks in the first decade and then again in later adulthood. Supratentorial tumors predominate during the first 2 years of life and then again in adolescence and young adulthood. Throughout the rest of the first decade, infratentorial tumors are more common. Tumors with embryonal histology such as medulloblastoma, supratentorial primitive neuroectodermal tumor (PNET), atypical teratoid rhabdoid tumor (AT/RT), and pineoblastoma occur more frequently in children than adults, and medulloblastoma is the most common type of malignant brain tumor in children. Gliomas can be benign or malignant and can occur anywhere along the neuroaxis.

Cancer arises from mutations that occur in genes that regulate cell growth and death. These mutations can occur in the entire germline or only within the somatic cells of the tumor itself. A small fraction of children with brain tumors have germline mutations, either inherited or de novo, which predisposes them to develop central nervous system (CNS) tumors. Several inherited syndromes, such as neurofibromatosis and tuberous sclerosis, are associated with an increased risk of CNS tumors. There is also an increased incidence of CNS tumors with previous exposure to ionizing radiation. However, in the majority of cases, the cause of a brain or spinal cord tumor in a child is unknown and is likely multifactorial.

CNS tumors and their treatment can cause significant physical, neurocognitive, psychological, and neuroendocrine morbidity. Long-term morbidity often exceeds that of other childhood malignancies, and mortality is the highest of all pediatric cancers.

Signs and Symptoms of Central Nervous System Tumors

The presentation of brain tumors can generally be classified into two categories: increased intracranial pressure (ICP) and localizing signs/symptoms. CNS tumors often cause increased ICP by causing obstruction of CSF pathways. Signs and symptoms of increased ICP can be vague and generalized or can be more severe and life threatening. The classic presentation is early morning headaches relieved with vomiting, and a late finding is mental status decline. The early signs of increased ICP can be similar to other common childhood complaints, so many children with brain tumors have been initially treated for more common childhood illnesses, such as viral gastroenteritis or influenza.

Nearly two-thirds of patients with newly diagnosed pediatric brain tumors have a history of chronic or frequent headaches. In elementary school children, the prevalence of headache is approximately 40–50% and up to 60–80% in adolescents. Typically, headaches associated with a brain tumor worsen over time. Clear indicators that something serious is occurring are headaches that awaken a child from sleep, headaches associated with vomiting, or headaches in addition to an objective neurologic finding. The location of the headache is not typically helpful, but a constant occipital headache and neck pain with hyperextension is an ominous sign of tonsillar herniation. The structures of the posterior fossa and the back of the head are both innervated by branches of the upper cervical roots, so a complaint of worsening occipital headache may be a sign of an infratentorial tumor causing increased ICP. This scenario warrants urgent neuroimaging and referral to a neurosurgeon in the setting of an Emergency Department.

A study conducted by the Childhood Brain Tumor Consortium showed that more than 98% of newly diagnosed brain tumor patients who complained of a headache at presentation also had at least one objective neurologic finding. These included mental status changes, abnormal eye movements, optic disc distortion, asymmetric motor or sensory examination, coordination problems, or abnormal deep tendon reflexes. Therefore, it is very important to do a complete neurologic examination on any child presenting with a headache.

In infants and young children, the signs and symptoms of a brain tumor can be more subtle. Increased ICP can be

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_349,

demonstrated by macrocephaly, irritability, poor feeding, and lethargy. In very young children, cranial sutures can separate due to increased ICP even after closure of the fontanelles. Head circumference should be measured and plotted for all children up to at least 3 years of age. This should be done at every routine primary care visit, as well as any visit for headaches or other unexplained symptoms in a younger child. A late and ominous sign of increased ICP in very young children is the "setting sun sign" of the eyes which is caused by pressure on the nerves that control eye movement. The eyes are forced downward and pupillary responses are typically sluggish.

Localizing signs of CNS tumors may include seizures, cranial nerve dysfunction, endocrine dysfunction, cerebellar dysfunction (ataxia or dysmetria), bowel or bladder dysfunction, abnormal or asymmetric strength, abnormal sensation, or asymmetric deep tendon reflexes. Declining school performance or personality/behavioral changes are other common complaints, but are less easily classified as localizing signs. Lesions of the pineal region are associated with Parinaud's Ophthalmoplegia. This is a triad including severely impaired upward gaze, dilated pupils that react to accommodation but not to light, and a specific form of nystagmus called convergence retraction nystagmus. The latter is more easily recognized by an ophthalmologist, but is best recognized when the patient attempts to look up.

Tumors confined to the optic nerve produce monocular vision loss. Chiasmatic tumors present with complex visual field loss as well as loss of acuity. In infants, these tumors may present with unilateral or bilateral nystagmus with head nodding and head tilt, also known as spasmus nutans. Those that are located more posteriorly in the optic tract present with hemianopsia. Optic pathway tumors are very common in patients with Neurofibromatosis Type I. These patients must be screened by annual ophthalmologic examination, but MRI is only recommended if there is abnormality or change in their vision or visual fields because treatment is only indicated when there is evidence of vision change.

Tumors located in the hypothalamus in infants may present with the diencephalic syndrome, which is characterized by failure to thrive, emaciation, paradoxical euphoric mood, and increased appetite.

Diagnosis of Central Nervous System Tumors

Magnetic Resonance Imaging (MRI) of the brain and/or spine is the best diagnostic study to order when a CNS tumor is suspected. It offers the best diagnostic sensitivity and does not expose the patient to radiation. Although CT scanning does cause radiation exposure, it is sometimes needed for initial urgent evaluation of patients with increased ICP. MRI "quick brain" is a newer technique that may offer the information needed in an urgent situation, without the radiation exposure associated with CT scanning. Indications for neuroimaging with MRI in the child that has a headache include, but are not limited to: association with seizures, association with recumbent position or vomiting, occipital location, exacerbation with straining, presence of other ominous signs such as Cushing's Triad (bradycardia, hypertension, irregular respirations), altered mental status, presence of objective neurologic findings, optic disc distortion or papilledema, asymmetry on physical examination, coordination problems, and macrocephaly in infants and toddlers.

Seizures due to non-oncologic causes are more common than seizures due to brain tumors, so they do not always warrant urgent neuroimaging. However, unless the presentation is clearly consistent with a simple febrile seizure or absence seizure, MRI of the brain is recommended because of the severe consequences that could arise if a brain tumor is not recognized. Any patient with an EEG showing focal abnormalities should be further evaluated with MRI. All simple and complex partial seizures and most unexplained generalized seizures should prompt imaging. Seizure features associated with an increased risk of a brain tumor include a change in preexisting seizure features, status epilepticus as first presentation of a seizure, resistance of seizures to medical control, and prolonged postictal focal symptoms or deficits.

Once a CNS tumor is identified, neurosurgical intervention is often indicated, for diagnostic and treatment purposes. Initial care may require urgent treatment of hydrocephalus. Ultimately, histologic examination of the tumor by a neuropathologist will guide further treatment planning in most cases. There are several scenarios in which neurosurgical intervention may not be appropriate, so it is important that newly diagnosed pediatric brain tumor patients are evaluated at a center that has specialists in pediatric neurosurgery and pediatric neuro-oncology.

Common Types of Pediatric CNS Tumors

Embryonal Tumors: Medulloblastoma, sPNET, AT/RT

Medulloblastoma is an embryonal neuroepithelial tumor and is the most common malignant brain tumor in childhood. It accounts for 20% of all primary pediatric brain

tumors and 40% of posterior fossa tumors. There is a peak incidence in the first decade of life around ages 5–7 and there is a male predominance of 2:1. Medulloblastoma has the greatest propensity of the CNS tumors to metastasize outside of the neuroaxis at a rate of about 4–7%. The most common sites of metastasis are bone, bone marrow, liver, lung, and lymph nodes.

Research continues on the genetic and biologic properties of medulloblastoma, and the most common chromosomal abnormality is isochromosome 17q. Trisomy 7 is the second most common abnormality. Several prognostic features have been identified and influence treatment recommendations. In general, age less than 3 years, residual tumor bulk of >1.5 cm^2 after surgical resection, and presence of metastasis either within or outside of the CNS have been associated with high-risk disease and a worse prognosis. There are newer histopathologic markers of high-risk disease as well.

Supratentorial primitive neuroectodermal tumor (sPNET) has been called cerebral medulloblastoma in the past but recent molecular evidence indicates that this tumor is different from medulloblastoma, though the two are often discussed together. sPNET is a rare type of CNS tumor accounting for only 2–3% of all CNS tumors. It is more common during the first decade and 90% occur in the cerebral hemispheres. Males and females are affected equally. This tumor also has a propensity to metastasize with up to 30% with CSF seeding in some series. It can also metastasize outside of the neuroaxis and has been reported in the bone and lung. Treatment for sPNET has historically been based on treatment for medulloblastoma; however, the overall outcome of these patients is significantly worse than those with medulloblastoma, suggesting inherent biologic differences.

Pineoblastoma is a primitive undifferentiated tumor that is distinguished from medulloblastoma and sPNET by its location. It occurs most frequently in the first decade of life and there is an equal incidence among males and females. These tumors can spread within the CNS; however, seeding outside of the CNS is rare.

Therapy for medulloblastoma, sPNET, and pineoblastoma consists of maximal safe surgical resection, crainospinal radiation with focal boost to the local tumor site, and systemic chemotherapy. Ongoing research is aimed at further delineating clinical and biologic prognostic factors as well as optimization of therapy for these patients.

Historically, atypical teratoid rhabdoid tumor (AT/RT) was probably mistaken for medulloblastoma or sPNET. But further research identified distinct histologic and cytogenetic features that distinguish it from other tumor types. Deletion of chromosome 22 and alterations of the hSNF5/INI-1 gene have been described. Lack of INI-1 expression has been shown to be a characteristic feature of AT/RT, and the immunohistochemical stain is now used routinely by neuropathologists.

AT/RT is a rare tumor that occurs more commonly in young children with a median age of 24 months. About 60% of these tumors are supratentorial and there is a male predominance of 2:1. It is known to metastasize and leptomeningeal spread at diagnosis has been reported to occur in 20–25% of patients. These tumors tend to be very aggressive, with formerly reported median event-free survival reported of 10 months and median survival about 17 months from diagnosis. In spite of the historically poor prognosis and aggressive nature of this disease, a more recent treatment regimen has been reported by Chi et al. showing promising results for many patients. In general, these patients are treated with maximal surgical resection, radiation, and systemic chemotherapy.

Ependymoma

Ependymomas account for approximately 9% of all primary CNS tumors in children. These tumors are generally located within or adjacent to the ependymal lining of the ventricular system or the central canal of the spinal cord. Ninety percent are intracranial, and of these, 60% are located in the posterior fossa. The remaining 10% are located in the spinal cord and these tend to occur in adolescents. The highest incidence of these tumors is in the first 7 years of life and there is a slight predominance in males. Typically, ependymomas are locally invasive, although the reported incidence of systemic metastasis is approximately 7%. The single most important prognostic factor in ependymoma treatment is the degree of surgical resection. Survival rates are higher (about 70%) following a gross total resection compared with 0–50% survival following less than a complete resection. It has also been found that ependymomas of the spinal cord are associated with the best outcome. Children less than age three have had historically poorer outcomes, though the reasons for this are unclear. These patients are more likely to have tumors located in the posterior fossa and gross total resection is often more difficult in this location because of its characteristic wrapping around the brainstem and cranial nerves. Due to their age, these children often receive delayed radiation therapy which may also impact their overall survival. Focal radiation therapy increases survival rates in most scenarios. Chemotherapy has not been shown to improve overall survival for patients with completely or incompletely resected ependymomas.

Low-Grade Gliomas

Low-grade gliomas are a diverse tumor group that includes grade I (pilocytic) astrocytoma, grade II (fibrillary or diffuse) astrocytoma low-grade oligodendroglioma, low-grade ganglioglioma, pleiomorphic xanthoastrocytoma (PXA), and a variety of low-grade mixed glial tumors such as oligoastrocytoma. In general, they are slow-growing tumors with insidious onset of symptoms and relatively benign histologic appearance. Long-term outcomes are most dependent on the ability to achieve complete surgical resection. The average age at diagnosis is between 6 and 9 years and boys are affected more than girls. Dissemination outside of the CNS is very rare and reported in only about 5% of cases.

Most supratentorial and cerebellar low-grade gliomas are astrocytomas. Classic cerebellar pilocytic astrocytomas are the most common type of low-grade glioma and account for 80–85% of low-grade tumors in the cerebellum. Diffuse or fibrillary astrocytomas account for approximately 15% of cerebellar astrocytomas and are more likely to undergo anaplastic transformation compared to the pilocytic variant, though this malignant transformation is observed less in the pediatric population than it is in adults. Prognostic factors for low-grade gliomas are inconsistent in the literature. Complete surgical resection is thought to be very important for long-term disease-free survival in most series, and these tumors tend to be amenable to repeat surgical resection.

The standard of care for this group of tumors is complete surgical resection when possible. When complete resection is accomplished for pilocytic astrocytomas, cure rates are as high as 90–100%. If there is residual disease after initial resection or if there is tumor recurrence, repeat resection should be attempted if it can be done safely and it is felt that a complete resection can be achieved. Adjuvant therapy, such as radiation or chemotherapy, is often used for progressive or symptomatic residual tumors that cannot be completely resected. Radiation is known to be effective in delaying time to further progression, but it has not been shown to significantly affect overall survival in patients with unresectable tumors. Chemotherapy is often used in preadolescent children to avoid radiation in this young population. There are multiple outpatient chemotherapy regimens that offer a modest rate of disease stabilization or partial response. Complete regression of these tumors is rare with chemotherapy and ultimately, many patients experience progression of their disease and require multiple treatment regimens over a period of many years.

Brainstem Glioma

Brainstem gliomas are a heterogenous group of tumors with distinct subtypes. They are subdivided into non-diffuse brainstem tumors and diffuse intrinsic pontine gliomas (DIPG). Non-diffuse tumors of the brainstem account for 20% of all brainstem gliomas and include focal midbrain, dorsally exophytic, and cervicomedullary tumors. The non-diffuse brainstem tumors tend to be slow-growing, low-grade tumors with a more favorable prognosis and treatment response than DIPG. The majority of DIPG arise from the pons and can infiltrate into surrounding structures making them extremely difficult to treat and contributing to their overall dismal prognosis. Brainstem tumors make up 10–20% of all CNS tumors in children less than 15 years of age and the majority occur in children less than 10 years old with a median age of 6–7 years at diagnosis. Ninety percent are of glial origin and there is an equal incidence among males and females. Overall, the 5 year survival for all types of brainstem tumors is between 20% and 30%.

Brainstem gliomas are classified by their location rather than histology. The current standard of care does not include biopsy when radiographic features are classic for a DIPG, but historically most have been found to be diffuse astrocytoma (grades II, III, or IV). The majority of non-diffuse brainstem gliomas are low-grade astrocytomas.

Surgical treatment of non-diffuse brainstem gliomas is dependent on the degree of infiltration into normal structures, and often due to their location, surgical resection is not possible. However, if possible, debulking of dorsally exophytic, tegmental and non-tectal midbrain tumors, and cervicomedullary tumors should be considered. Radiation therapy is the conventional treatment for brainstem gliomas. The role of chemotherapy in the treatment of non-diffuse brainstem gliomas remains unknown and trials are ongoing, but the outpatient regimens of low-grade gliomas are sometimes used.

Diffuse intrinsic pontine gliomas have a universally poor prognosis and treatment of these lesions has historically been directed toward symptom relief rather than cure. The conventional treatment has been radiation therapy and several studies have investigated the use of hyperfractionated external beam radiotherapy (HFRT) versus standard radiotherapy. However no statistically significant difference in progression-free or overall survival was found between patients treated with HFRT vs. standard radiation therapy. The role of chemotherapy in DIPG is not currently known, and there is little evidence to suggest that the use of chemotherapy has a significant impact on the overall outcome of these patients. If left

untreated, the median survival of DIPG patients is 20 weeks. Radiation is thought to increase this median survival by approximately 2–3 months. Due to the overall dismal prognosis of DIPG, any treatment that could provide even a modest improvement in survival would have a large impact in the outcomes of these patients. Clinical trials are ongoing.

Germ Cell Tumors

Two-thirds of germ cell tumors are located in the region of the pineal gland and the remaining one-third are in the suprasellar region. They account for 40–65% of tumors in the pineal region, and are more common in the second decade of life with a peak incidence between 10 and 14 years of age. There is a male-to-female predominance of at least 2:1.

These tumors are a spectrum of embryonal neoplasms and teratomas thought to arise from totipotent germ cells. Sixty percent of these tumors are germinoma, 30% teratomas or mixed nonmalignant histology, and 10% malignant histology such as choriocarcinoma, endodermal sinus tumor (yolk sac tumor), and embryonal carcinoma. Collectively, immature teratomas, mixed germ cell tumors, endodermal sinus tumor, choriocarcinoma, and embryonal carcinomas are referred to as non-germinomatous germ cell tumors (NGGCT). Leptomeningeal spread occurs in approximately 10% of cases and in the highly malignant subgroups, systemic metastases can occur to the lungs, bone, and lymph nodes. Evaluation of the spine with MRI is important in the work up of these tumors due to their propensity to seed the CNS.

The histology of these tumors is prognostically significant. Germinomas are highly curable with 5 year survival rates as high as 95%. However, NGGCT generally have much poorer survival rates ranging from 20% to 75%. Disseminated disease and young age have also been associated with a worse prognosis; however, in younger patients this may be due to the fact that they often have disseminated disease at diagnosis and cannot safely receive crainospinal radiation which may be important in some cases.

Patients with NGGCT often have one or two associated tumor markers present in the serum or cerebrospinal fluid, alpha fetoprotein (AFP), and beta human chorionic gonadotropin (beta-hCG). If so, up-front surgical resection and even biopsy are not indicated. The presence of a pineal and/or suprasellar mass and elevated tumor markers is pathognomonic for NGGCT. Neoadjuvant chemotherapy has become the standard of care for NGGCT because of the high-risk nature of surgical manipulation in the pineal region. Germinomas can also have slightly elevated tumor markers, but the levels are modest compared to the more malignant germ cell tumors. Because the treatment for germinoma differs from that of NGGCT, it is generally recommended that tumor biopsies be obtained when there is not a significant elevation in at least one of the tumor markers.

Due to the location of these tumors, complete surgical resection is often not possible without causing significant morbidity. Surgery is no longer the up-front treatment approach for this group of tumors. Germinomas are extremely radiation sensitive and surgery can often be avoided using chemotherapy and radiation alone. NGGCT are also treated initially with chemotherapy, and definitive therapy is radiation. Surgical resection is often used in germ cell tumors when there is residual tumor following initial chemotherapy. The histology of the residual tumor is often a benign or mature form of germ cell tumor. These tumors are also known to have a propensity for CSF seeding, but there is great debate about the extent of radiation needed to optimize therapy in patients who do not have documented dissemination at the time of diagnosis. Focal radiation at the site of the initial tumor is standard, but debate resides in whether ventricular volume radiation or craniospinal radiation is most appropriate in these patients. Chemotherapy regimens are platinum based, and in combination with other chemotherapy agents and radiation therapy are capable of producing response rates of 48–90% depending on the tumor type. It is important to note that mature teratomas have a unique treatment approach among germ cell tumors. They are not thought to be sensitive to radiation or chemotherapy, and are therefore treated with maximal surgical resection alone.

Supratentorial High-Grade Gliomas

Supratentorial high-grade gliomas account for 7–11% of all pediatric CNS tumors. Sixty-six percent occur within the cerebral hemispheres, 20% are in deep midline structures of the cerebrum midline, and 15% are located in the posterior fossa or brainstem. The median age at diagnosis is 9 years and the male-to-female ratio is 1:1. The most common malignant glial neoplasms are high-grade astrocytomas such as anaplastic astrocytoma (grade III) and glioblastoma multiforme (grade IV), but this broad category can also include anaplastic oligodendroglioma, anaplastic ganglioglioma, high-grade pleomorphic xanthoastrocytoma (PXA), and high-grade mixed glial tumors such as anaplastic oligoastrocytoma. These lesions

tend to be clinically aggressive, locally and regionally invasive, and can rarely disseminate to the lung, lymph nodes, bone, and liver.

The most important prognostic factor in these patients is the extent of surgical resection. As a group, those who have had a near-complete or complete resection experience significantly longer progression-free survival than those with incomplete resections. Disease site has also been shown to be prognostic of outcome. Patients with tumor in deep midline structures have poorer survival rates compared to those with hemispheric lesions, presumably due to the inability to safely resect tumors in the deep midline structures.

Radiation therapy is considered a standard component of therapy for these patients. It is rarely curative, but when used in combination with chemotherapy has been shown to provide a small improvement in survival. Many different combination regimens have been studied in both the adult and pediatric populations with little to no improvement in prolonging time to progression. Regimens using myeloablative chemotherapy with peripheral stem cell rescue have a high up-front morbidity/mortality and have not shown improvement in outcomes for these patients. Multiple phase I and II trials are underway in the adult and pediatric populations in an effort to identify effective therapeutic agents.

Choroid Plexus Tumors

Tumors of the choroid plexus account for approximately 1–4% of brain tumors in children. These are tumors of young children and the median age at diagnosis is 10–32 months, with males and females being equally affected. Eighty-five percent arise in the lateral ventricles, 10–15% in the fourth ventricle, and 5–10% in the third ventricle. These tumors are classified as either choroid plexus papilloma (CPP) or choroid plexus carcinoma (CPC). CPP are more common, accounting for 80–90% of choroid plexus tumors, are typically very slow growing, and are treated with surgical resection only. CPC accounts for 10–20% of choroid plexus tumors and behave more aggressively because they are less differentiated and more anaplastic. Leptomeningeal spread can be seen in CPC and in atypical CPP, a form of papilloma with some anaplastic features.

The degree of surgical resection and tumor histology are the important prognostic factors in these tumors. With complete resection of a CPP, long-term survival is almost 100%. In CPC, outcomes tend to be less favorable due to local invasion and propensity of this tumor to disseminate throughout the CNS. However, studies of CPC treatment have shown that complete resection does appear to affect long-term survival and this should therefore be the surgical goal. Ventriculoperitoneal shunting may be required following tumor resection because of persistent hydrocephalus, which can occur in up to 60% of patients postoperatively. Radiation therapy is frequently used postoperatively in patients with CPC if there is evidence of residual disease and/or leptomeningeal dissemination, but its use must be carefully considered in this young patient population and can often be delayed by using chemotherapy. It has been difficult to clearly define the role of chemotherapy in CPC because it is so rare and therefore difficult to establish clinical trials with enough power to answer questions about efficacy. Treatment protocols for malignant brain tumors in children under the age of 3 years are often used.

Optic Pathway Gliomas

Optic pathway tumors arise in the optic nerves, optic chiasm, or optic tracts. They account for 5% of pediatric CNS tumors. Seventy-five percent occur in the first decade of life and males and females are equally affected. The incidence of optic pathway tumors is increased in patients with Neurofibromatosis Type I (NF-1) with up to 28% of patients with NF-1 being affected in some reports. Involvement of the optic chiasm appears to be more common in patients without NF-1 and unilateral or bilateral optic nerve involvement is more commonly seen in patients with NF-1. Histologically these tumors are typically low-grade pilocytic or fibrillary astrocytomas and malignant degeneration is very rare. Tumor growth tends to be slow, though there can be local spread of disease into surrounding brain parenchyma, and vision decline can sometimes occur in the absence of radiographic increase in tumor size. Serial ophthalmologic evaluation is at least as important, if not more important, than the routine imaging that is done after diagnosis of an optic pathway tumor.

Three prognostic variables have been shown to have an impact on outcome in optic pathway tumors. Tumors involving the chiasm and hypothalamus tend to have a worse prognosis, as do those that occur in children younger than 3–5 years of age. Optic gliomas in the setting of NF-1 tend to have a more indolent course and can even regress without any treatment. For this reason, optic gliomas in NF-1 patients are monitored with serial MRIs and ophthalmologic exams including visual fields. When a decline in vision is documented, chemotherapy should

be initiated to prevent any further impact on vision. Regimens including alkylating agents should be avoided in NF-1 patients because of the increased risk of second malignancies.

Biopsy of these tumors can cause vision impairment, so biopsy of these lesions must be considered very carefully. Because these tumors are so common in patients with NF-1, this diagnosis can be made based on radiographic appearance of an optic pathway tumor alone. For patients who do not have NF-1, biopsy is often recommended in order to define the histological type and further direct therapy. In cases in which a unilateral tumor has already caused severe vision changes, then surgical resection could be considered. Radiation therapy has been shown to be effective in stabilizing or improving existing disease, and it has been shown to improve vision in some patients and can also prevent further vision loss. Toxicity from radiation therapy should be taken into consideration as up to 50% of prepubertal patients will experience endocrine toxicity due to radiation of the adjacent hypothalamic-pituitary axis. In preadolescent children, delaying radiation therapy by using chemotherapy may help avoid or decrease the endocrinologic sequelae that can occur after radiation to this region. Chemotherapy is also used for patients with NF-1 who require treatment for an optic pathway tumor, in order to avoid radiation altogether in this patient population, if at all possible. The risk of second malignancy associated with radiation, such as glioblastoma multiforme or sarcomas, is likely higher in patients with NF-1. All patients with optic pathway tumors should undergo serial ophthalmologic exams regardless of the treatment or observation approach.

Craniopharyngioma

Craniopharyngiomas account for 6–9% of all childhood primary CNS tumors. There is a bimodal age distribution with a peak at age 8–10 years and again in older adults (50–74 years). This tumor is rarely seen in children less than age 2. There is an equal predominance among males and females. These tumors are generally suprasellar in location. Histologically, they are benign, but they often become functionally malignant due to the location and impairment of the hypothalamic-pituitary axis.

The extent of tumor resection is an important prognostic factor in craniopharyngioma. Those with complete resection have significantly better survival rates compared to those with incomplete resection. Tumor size has also been shown to be of prognostic significance; however, this may be secondary to degree of resectability. Patients with pure cystic lesions appear to have better survival than those with solid or mixed solid and cystic tumors, and children less than 5 years of age seem to have a worse prognosis compared to older children.

Surgical resection is the mainstay of treatment for craniopharyngioma. Approximately 90% of children with craniopharyngioma will have neuroendocrine deficits at the time of presentation, and 50–90% will have visual field defects. Tumor resection may exacerbate neuroendocrine deficits and their management needs to be optimized prior to surgery. Preoperative stress dosing of steroids followed by a postoperative taper are important in the management of these patients. Due to the location of these tumors, significant morbidity can be encountered if a radical complete resection is attempted. Debate continues in the neurosurgical literature regarding radical resection of these tumors versus less radical surgery and postoperative radiation therapy. Approximately 50–75% of patients will have recurrence of their disease after a partial resection; however, cure rates improve to 60–85% if radiation therapy is given postoperatively. Chemotherapy has no established role in the treatment of craniopharyngioma.

Late Effects of Childhood CNS Tumors

The 5 year overall survival of a child with a brain tumor has improved to 60% over the past several decades. However, despite successful treatment for a brain tumor, many children will experience significant long-term side effects either directly because of their tumor or as sequelae from treatment. These patients may experience physical, cognitive, neurologic, and endocrinologic side effects that may diminish their overall quality of life.

Radiation therapy alone is responsible for several adverse side effects including endocrine dysfunction, neuropsychological deficits, radiation necrosis, vasculopathy such as stroke or Moya Moya disease, and an increased risk of a secondary tumor. Radiation effects are inversely related to age at treatment; those who are treated at a younger age experience a higher degree of sequelae from their treatment. Full brain irradiation to children less than 3 years of age has been associated with severe intellectual deficits and significant impairment diminishing the likelihood that they will be independent, functioning adults. For this reason, full cranial radiation therapy should be avoided in children less than 3 years of age.

Growth failure is also a common side effect seen in patients who undergo radiation therapy. Radiation therapy impairs the secretion of growth hormone, decreases the growth of the spinal cord and vertebral column in

those undergoing spinal radiation, and can induce precocious puberty which prematurely fuses bony epiphyses. The concomitant use of chemotherapy further exacerbates the severity of growth failure experienced in these patients. Due to the concern of stimulating tumor recurrence, the use of growth hormone replacement remains controversial and is generally not recommended until many years after disease control or stabilization.

Secondary to the use of platinum agents in the treatment of many pediatric brain tumors, sensorineural hearing loss is a frequent complication among survivors. Radiation therapy can also exacerbate these deficits.

Management of survivors of childhood brain tumors should include a multidisciplinary team consisting of pediatric oncologists, endocrinologists, neurosurgeons, radiation oncologists, neuroradiologists, nurses, nurse practioners, neuropsychologists, psychologists, physical and occupational therapists, speech therapists, school teachers, and social workers. The child should be seen at least yearly for both physical and neuropsychological exams for at least the first 5 years after therapy is completed. Surveillance for recurrence of disease is also an important part of the long-term management of these patients. Recurrence or progression can occur several months to years after therapy has been completed.

A childhood diagnosis of a brain tumor or spinal cord tumor is a major challenge in the lives of patients and their families. Treatment of these types of cancers requires a highly specialized team to treat not only the acute disease process, but also to manage the long-term physical and emotional effects these tumors and their therapies have. Therapies for CNS tumors of childhood have improved over the past several decades, but there is still much work to be done. Further research is mandatory to better understand these tumors biologically, improve therapeutic approaches, and ultimately, improve survival and quality of life for these patients.

350 Neuroblastoma and Other Sympathetic Nervous System Tumors

Stephen S. Roberts

Definition

Tumors of the sympathetic nervous system in children consist of neuroblastoma and its variants, ganglioneuroblastoma, and ganglioneuroma, as well as pheochromocytoma/paraganglioma. Pheochromocytomas and paragangliomas are very rare in children, with an incidence of less than 0.3 cases per million per year. They are called pheochromocytomas when arising from the adrenal gland and paragangliomas when extra-adrenal and can occur anywhere from the neck to the pelvis. The majority of these tumors are benign (∼90%) and present because of systemic symptoms such as hypertension due to catecholamine secretion. Because these tumors are quite rare and usually benign, we will confine the remainder of this discussion to neuroblastoma only.

Few tumors exhibit such diversity of behavior and outcome as neuroblastoma. This varies from spontaneous regression and differentiation, often without therapy, to aggressive, treatment-resistant disease that is frequently fatal despite intensive multimodality therapy.

Etiology

The etiology of neuroblastoma is unknown. Although several studies have investigated potential links between environmental factors, maternal drug exposures, and parental occupations and increased risk of neuroblastoma, to date, no consistent and definitive associations have been identified. Neuroblastoma has been positively associated with various congenital anomalies, especially urogenital and cardiac abnormalities, and in patients with congenital central hypoventilation syndrome (CCHS) and Hirschsprung's disease. Presumably this represents disordered development in shared neurodevelopmental pathways but the exact cause and relationship remains unknown.

Epidemiology

Neuroblastoma is the most common extracranial solid tumor of childhood and the most common cancer of infancy, accounting for 8–10% of all childhood cancers. In industrialized countries, the prevalence is roughly 1 case per 7,000 births, with an incidence of approximately 8–10 per million per year. This incidence appears to be similar throughout the developed world. Rates in developing countries are less clear; several reports have suggested that rates are lower, particularly in sub-Saharan Africa. However, it is unknown if this represents true lower incidence or underreporting. There is a very slight increase in incidence among boys versus girls (1.1:1).

Because neuroblastomas generally produce and secrete catecholamines whose metabolites (vanillylmandelic acid, VMA and homovanillic acid, HVA) are detectable in the urine, there have been several attempts at mass screenings of infants. These screenings were conducted in Japan, Germany, and Montreal, Canada in the 1980s and 1990s with the hope of detecting neuroblastoma at an earlier stage. Unfortunately, while these screening efforts did lead to an increased detection of low-stage neuroblastoma in infants, they did not lower the prevalence or the mortality rates of those children over 1 year of age with higher stage disease. Therefore, at this time, routine screening of infants for neuroblastoma is not recommended. It is possible that in the future, screening may be recommended for children with identifiable predisposition syndromes.

Pathogenesis

Neuroblastoma serves as a model disease where detailed genetic analyses have enabled biology-based risk stratification and treatment. There are multiple genetic changes that have been identified in NB, several of which are strongly correlated with disease outcome and are an integral part of our understanding of the development and treatment of this disease. Recently, several different groups

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_350,

reported germline mutations in the anaplastic lymphoma kinase (ALK) and PHOX2B genes in a small subset of neuroblastoma patients with familial predisposition. Mutations in these genes strongly predispose to development of neuroblastoma. However, the vast majority of children with NB do not have heritable risk factors predisposing them to the development of the disease. Instead, acquired somatic changes in neural crest stem cells appear to be the underlying cause leading to NB development.

Most neuroblastomas contain genomic level aberrations, including amplifications, translocations, and whole chromosome losses and gains. Many of these changes are nonrandom and have prognostic significance. Detailed analysis of these recurrent changes has led Maris et al. to propose a model for neuroblastoma development and progression. This model proposes that all neuroblastomas arise from a common precursor but that different types of genomic changes lead to two distinct subtypes of NB with very different clinical behaviors. Further, their model suggests that neuroblastomas that are biologically unfavorable do not evolve from favorable tumors but are distinct subtypes from the beginning. The first type of NB is characterized by loss and gain of whole chromosomes and few or no segmental chromosome abnormalities. These NBs are generally hyperdiploid, lack genetic changes associated with biologically unfavorable disease, and are most common in young children under 18 months of age. The prognosis for these tumors is generally excellent, with many undergoing spontaneous differentiation and/or apoptosis. In contrast, the second type of NB is characterized by recurrent segmental chromosome abnormalities. Nonrandom alterations of numerous chromosomes have been identified, including deletions of 1p36 and 11q and unbalanced gain of chromosome 17q. However, the most important genomic alteration is amplification of the MYCN oncogene, which tends to portend a particularly grim prognosis. MYCN amplification is associated with advanced disease, older age (>18 months), and poor outcome. The overall prevalence of MYCN amplification is approximately 20% and is essentially always present at the time of diagnosis, strongly suggesting it is an inherent feature of a subset of aggressive neuroblastomas and not an acquired late event. Thus, determination of MYCN amplification status is a standard part of neuroblastoma characterization at diagnosis due to its clear biological importance.

Pathology

Neuroblastoma is classically defined as a small, round, blue-cell tumor of childhood. Other malignancies in this group include non-Hodgkin lymphomas, Ewing sarcoma family tumors, and soft tissue sarcomas such as rhabdomyosarcoma. There are three histopathological subtypes: neuroblastoma, ganglioneuroblastoma, and ganglioneuroma. These three types represent a spectrum of differentiation from malignant to benign. Typically, the cells are small and uniform in size, with dark nuclei and little cytoplasm. Nearly all neuroblastoma form neuropil, collections of primitive neurites, and the Homer-Wright pseudorosette, a classic finding, is a ring of neuroblasts surrounding a core of eosinophilic neuropil. These pseudorosettes, however, are found in a minority of tumors. Ganglioneuromas represent a fully mature, benign collection of ganglion cells, Schwann cells, and neuropil. Ganglioneuroblastomas represent the spectrum of differentiation between malignant neuroblastoma and mature, benign ganglioneuromas.

Histopathology has been used to prognostically classify neuroblastomas; the most common system was developed by Shimada et al., and utilizes patient age, Schwannian cell stroma, mitosis-karyorrhexis index, and differentiation state to classify tumors as favorable or unfavorable. This system was recently modified with the goal of making it more reproducible around the world and is now known as the International Neuroblastoma Pathology Classification (INPC) system.

Clinical Manifestations

The clinical manifestations depend on the primary site of the tumor as well as any metastases that may be present. Approximately 65% of primary tumors arise in the abdomen; most of the remainder are thoracic or cervical in origin. No primary tumor is found in about 1% of patients. Most children with NB are diagnosed by age 5 and nearly all occur before age 10. Neuroblastoma is often disseminated at diagnosis, with spread most commonly involving locoregional lymph nodes as well as bone, bone marrow, liver, and skin. Lung and central nervous system metastases are rare.

Abdominal neuroblastoma may present with abdominal pain or fullness but is often asymptomatic and discovered incidentally, frequently by a caregiver. Thoracic neuroblastoma is frequently discovered incidentally on chest radiographs obtained for other reasons. Rarely, large thoracic tumors can cause mechanical obstruction and lead to compression of the superior vena cava and/or trachea (superior vena cava and superior mediastinal syndromes, respectively). High-level thoracic lesions and cervical neuroblastomas can cause Horner Syndrome

(unilateral ptosis, myosis, and anhydrosis). Any paraspinal neuroblastoma may extend through the neural foramina of the vertebral bodies and cause nerve root or spinal cord compression. This may lead to symptoms such as weakness, paralysis, bowel and/or bladder dysfunction, and radicular pain. Bone marrow involvement may lead to anemia and bleeding, while widespread cortical bone metastases are frequently seen and cause pain, limp, and significant irritability in younger patients.

Neuroblastoma is classically associated with several distinct presentations. Tumor infiltration of the periorbital bones causing proptosis and periorbital ecchymoses is a frequent manifestation of disseminated disease (*Fig. 350.1*). Likewise, infants less than 1 year of age will frequently present with multiple bluish, painless, subcutaneous nodular lesions. These are generally associated with stage 4S disease, spontaneous regression, and an excellent prognosis.

Two distinct paraneoplastic syndromes have been associated with neuroblastoma. The first, opsoclonus-myoclonus syndrome, is found in 2–4% of patients with neuroblastoma and is characterized by rapid, jerking eye movements, myoclonus, and ataxia. Thought to be an immune-mediated cross reaction between antibodies against the tumor and elements of the normal nervous system, these children tend to have low-stage disease and an excellent prognosis. Unfortunately, as many as 80% will have long-term neurologic sequelae, including significant cognitive deficits. The other paraneoplastic syndrome is intractable secretory diarrhea, hypokalemia, and dehydration caused by tumor secretion of vasoactive intestinal peptide, known as VIP syndrome. These tumors are usually ganglioneuroblastomas or ganglioneuromas and removal of the primary tumor generally leads to resolution of the diarrhea and excellent long-term survival.

Systemic manifestations such as hypertension, tachycardia, and flushing are rarely seen with neuroblastoma, as opposed to pheochromocytomas, because they do not secrete epinephrine.

Figure 350.1
Periorbital ecchymoses in a child with high-risk neuroblastoma

Diagnosis

All patients suspected to have neuroblastoma require a comprehensive evaluation to ensure accurate staging and risk stratification. The diagnosis of neuroblastoma is made by either pathologic identification of neuroblasts from tumor biopsy or unequivocal presence of neuroblastoma in a bone marrow aspirate along with the presence of elevated serum or urine catecholamine levels. Whenever feasible, every effort should be made to perform a tumor biopsy, especially in young children under 18 months of age, as the biological information obtained is critical in proper determination of risk category and subsequent therapy planning.

A thorough physical exam should include evaluation of any masses, palpation for presence of hepatomegaly, neurological evaluation for weakness or paralysis, and examination of lymph nodes, skin, and skull for evidence of metastases. The imaging modality of choice for delineation of the primary tumor is CT scan. In general, most patients should receive a CT of the chest, abdomen, and pelvis, with evaluation of the head, neck, and spine if clinically indicated. All patients should have bilateral bone marrow aspirates and biopsies to evaluate for the presence of marrow disease. Likewise, evaluation of the bony skeleton should be performed. This has classically been done with plain radiography and Technetium-99 scintigraphy. More recently, radiolabeled metaiodobenzylguanidine (MIBG) scans, using either ^{123}I- or ^{131}I-MIBG, have become increasingly important in evaluating NB. ^{123}I-MIBG is more sensitive and specific than a Tc-99 bone scan or ^{131}I-MIBG. Whenever possible, both Tc-99 and ^{123}I-MIBG scanning should be performed at diagnosis as approximately 10% of tumors are not MIBG avid. Positron emission tomography is generally less sensitive than MIBG scanning and does not currently play a role in routine diagnostic imaging of neuroblastoma.

Tissue samples obtained should be evaluated for the presence of specific cytogenetic abnormalities, DNA ploidy, and the presence of MYCN amplification. Standard cytogenetic testing or specific fluorescent in situ hybridization techniques are routinely used. This information is

critical for subsequent risk stratification, with all major cooperative groups worldwide incorporating this information in their schema.

Differential Diagnosis

The differential diagnosis includes ganglioneuroma, which occurs in the same sites as its malignant counterpart. Intrathoracic neurofibromatosis tumors can mimic neuroblastomas radiologically, but they tend to be more nodular in outline, and grow along the course of the intercostal nerves, which results in characteristic indentations along the inferior costal margin. Tumors arising in the retroperitoneum may be confused with Wilms' tumor; the latter, however, tend to feel smooth to palpation in contrast to the nodular feel of a neuroblastoma and generally lack the characteristic intratumoral calcifications seen in imaging studies of neuroblastomas. Cervical neuroblastomas may be confused with cervical adenitis or lymphomas. Lack of tenderness upon palpation of the mass is a key finding allowing differentiation between NB and infectious etiologies. Additionally, neuroblastomas may present with weakness or paralysis of the lower extremities due to tumor extension through the neural foramina causing spinal cord compression. A thorough history, physical exam, and imaging studies are needed to differentiate NB from other primary neurologic causes of weakness and paralysis. Since NB frequently metastasizes to bone marrow, its presenting symptoms can mimic leukemia with pallor, fatigue, recurrent fevers, and bruising and petechiae being common; bone marrow aspiration will distinguish between these entities.

Pathologically, neuroblastoma must be distinguished from the other small round blue-cell tumors of childhood mentioned above. This can be done by identification of neuropil and pseudorosettes and more specifically by immunohistochemical staining for neural markers such as neurofilament proteins, synaptophysin, and neuron-specific enolase (NSE).

Treatment

Treatment is determined by risk group stratification. Currently, all of the major cooperative groups use similar risk group classification schemes that include disease stage, patient age (less than 12–18 months versus greater than 12–18 months) at diagnosis, and MYCN amplification status. DNA ploidy, additional cytogenetic analyses, and histopathology are incorporated with some variability. Stage of disease is a key component of risk group assignment.

Table 350.1
International neuroblastoma staging system

Stage 1	Localized tumor confined to the area of origin; complete gross excision, with or without microscopic residual disease; identifiable ipsilateral and contralateral lymph nodes negative microscopically
Stage 2A	Unilateral tumor with incomplete gross excision; identifiable ipsilateral and contralateral lymph nodes negative microscopically
Stage 2B	Unilateral tumor with complete or incomplete gross excision; positive ipsilateral regional lymph nodes; identifiable contralateral lymph nodes negative microscopically
Stage 3	Tumor infiltrating across the midline with or without regional lymph node involvement, or midline tumor with bilateral regional lymph node involvement
Stage 4	Dissemination of tumor to distant lymph nodes, bone, bone marrow, liver, and/or other organs (except as defined in stage 4S)
Stage 4S	Localized primary tumor as defined for stage 1 or 2 with dissemination limited to liver, skin, and/or less than 10% of bone marrow; limited to infants less than 1 year of age

Currently, the international neuroblastoma staging system (INSS) is used around the world as the primary staging system (*Table 350.1*). Recently, an international consensus group developed a newer staging and risk stratification system called the international neuroblastoma risk group (INRG) staging and classification systems. These will likely be the future international standards.

All of the risk stratification systems used allow assignment into one of generally three risk groups: low, intermediate, and high risk.

Low-risk patients include those with low-stage (INSS stage 1 or 2) disease, and are generally of a younger age (<18 months) and do not have MYCN amplification. Treatment for this group involves surgical resection only. Importantly, complete resection is not necessary in these low-risk patients and therefore aggressive and potentially morbid surgeries should be avoided. Chemotherapy and radiation therapy are rarely needed and should be reserved for the patient that experiences disease recurrence. Some patients with low-risk disease (INSS stage 4S and incidentally found perinatal tumors) are successfully managed through observation only with no active intervention.

Treatment of intermediate risk patients is somewhat more complex and includes local control surgery followed

by moderately intensive chemotherapy, with the precise regimen varying by cooperative group. Radiation therapy is reserved for those intermediate risk patients with residual disease that has not responded to chemotherapy.

High-risk neuroblastoma is treated with aggressive, multimodality therapy including surgery, radiotherapy, chemotherapy, and biological/immunotherapy. The current standard therapy for high-risk patients in North America, Europe, and Japan includes intensive induction chemotherapy followed by surgery, radiation therapy, and autologous stem cell supported myeloablative therapy. This is then followed by a period of biological/immunotherapy targeting remaining minimal residual disease that uses 13-*cis* retinoic acid as a differentiating agent. Additionally, the Children's Oncology Group recently reported that the addition of immunotherapy directed at the neuroblastoma tumor antigen GD2 significantly improved survival in these patients, and future therapies will likely include some form of immune-based treatment.

Prognosis

Prognosis varies greatly by risk group. Currently, with observation and/or surgical resection alone, patients with low-risk disease have survival rates in excess of 95% in the developed world. Intermediate risk patients also do very well with moderate chemotherapy and have survival rates of over 90%. Prognosis for high-risk disease, however, remains poor. Historically, 5-year event-free survival rates have been less than 20%. Using the current intensive, multimodality therapy regimens, survival rates have increased to 40–50%. While this is an improvement over historical rates, there is room for substantial improvement. Additionally, significant long-term side effects of intensive therapy remain a large issue for those high-risk patients that are cured of their disease.

Prevention

Currently, there is no known preventive strategy for neuroblastoma.

351 Wilms' Tumor and Other Primary Renal Neoplasms

Susan J. Lindemulder

Definition/Classification

Wilms' tumor is the most common primary tumor of the kidney in children. There are several other tumor types including clear cell sarcoma of the kidney, rhabdoid tumor of the kidney, congenital mesoblastic nephroma, and renal cell carcinoma that also arise from the kidney, but they are much less common. The development of modern treatment regimens using a combination of surgery, chemotherapy, and radiation therapy has greatly improved the cure rate for Wilms' tumor.

Epidemiology

Wilms' tumor is typically diagnosed in children younger than 15 years and approximately 500 new cases are diagnosed per year in the United States. The prevalence worldwide is approximately 1 in 10,000 children under the age of 15 years. Globally, the incidence is substantially lower in Asian populations. Although various studies have explored environmental risk factors, it is likely that genetics play a larger role than the environment.

Wilms' tumor most often occurs in previously healthy children; however, there is a higher incidence of Wilms' tumor in children with certain recognized syndromes which are associated with other congenital malformations. These syndromes can typically be grouped into either overgrowth syndromes or non-overgrowth syndromes. The overgrowth syndromes are characterized by malformations such as macroglossia, nephromegaly, and hemihypertrophy, and include: Beckwith–Wiedemann syndrome, isolated hemihypertrophy, Perlman syndrome, Sotos syndrome, and Simpson-Golabi-Behemel syndrome. The non-overgrowth syndromes are characterized by various other malformations and include: isolated aniridia, trisomy 18, WAGR syndrome, Blooms syndrome, Alagille syndrome, Denys–Drash syndrome, and Frasier syndrome. The phenotypic characteristics of these syndromes are summarized in ❯ *Table 351.1*.

Pathogenesis

Multiple genes have been identified as playing a role in the development of Wilms' tumor. The first gene identified and the most studied is WT1 which was discovered through the study of patients with WAGR syndrome. WT1 is located on chromosome 11p13 in a region which also contains the gene responsible for aniridia. The gene is a tumor suppressor gene which codes for a transcription factor responsible for regulating other transcription factors important in cell growth and differentiation. A second gene important to the development of Wilms' tumor was discovered through the study of BWS patients. The WT2 gene is located on chromosome 11p15, and Wilms' tumor develops when there is loss of heterozygosity. The loss of heterozygosity is thought to upregulate an oncogene, resulting in tumor formation.

There is a recognized familial predisposition for Wilms' tumor which is rare and only accounts for a small percentage of new cases. Two genes have been identified as playing a role in familial Wilms' tumor, FWT1 located on chromosome 17q and FWT2 located on chromosome 19q.

Other chromosomal abnormalities are seen with increased incidence in studies of Wilms' tumor samples. Loss of heterozygosity in chromosome 16q and 11p have been suggested to be associated with poor prognosis unrelated to stage of disease. The role of p53 in the development of Wilms' tumor is also under investigation, although Wilms' tumor is not commonly seen in the Li Fraumeni syndrome.

Pathology

Three cell types are commonly seen in the histology of Wilms' tumor: blastemal, stromal, and epithelial. These three cell types reflect stages of normal renal development. A single specimen does not need to include all three cell types to be diagnostic for Wilms' tumor. Histology is further classified as

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_351,

Table 351.1
Characteristics of syndromes associated with Wilms' tumor

Syndrome	Phenotypic characteristics
Overgrowth syndromes	
Beckwith–Wiedemann syndrome	Macrosomia, macroglossia, visceromegaly, embryonal tumors, omphalocele, neonatal hypoglycemia, ear creases/pits, adrenocortical cytomegaly, renal abnormalities
Isolated hemihyperplasia	Asymmetric growth without other abnormalities
Perlman syndrome	Polyhydramnios, neonatal macrosomia, visceromegaly, nephromegaly, distinctive facial appearance, renal dysplasia
Sotos syndrome	Typical facial appearance, tall stature, learning disability, behavioral problems, congenital cardiac anomalies, neonatal jaundice, renal anomalies, scoliosis, seizures
Simpson-Golabi-Behemel syndrome	Macrosomia, distinctive craniofacial features, mental retardation, skeletal anomalies, hand anomalies
Non-overgrowth syndromes	
Isolated aniridia	Panocular abnormalities
Trisomy 18	Prominent occiput, short eye fissures with droopy eyelids, micrognathia, external ear variations, rocker-bottom feet, redundant skin on back of neck, congenital heart defects, hand anomalies
WAGR syndrome	Wilms' tumor, aniridia, genitourinary anomalies, mental retardation
Blooms syndrome	Small body size, immunodeficiency, sun-sensitive facial erythema
Alagille syndrome	Bile duct paucity, congenital cardiomyopahty, facial dysmorphy, vertebral defects, ocular abnormalities, renal anomalies
Denys–Drash syndrome	Ambiguous genitalia, congenital nephropathy leading to renal failure
Frasier syndrome	Complete gonadal dysgenesis and nephritic syndrome

"favorable" or "unfavorable" based on the absence or presence of anaplastic nuclear changes. Anaplasia is characterized by multipolar mitotic figures and marked nuclear enlargement. Nephrogenic rests can also be found within areas of the kidney not affected by Wilms' tumor and increase the risk for developing tumor in the remaining kidney.

Clear cell sarcoma of the kidney is the second most common renal cancer in children and has a poorer prognosis than Wilms' tumor. It requires more aggressive treatment and has a wider range of metastatic spread (lungs, bone, brain, soft tissues). Clear cell sarcoma was named for the classic pale-stained tumor cells that are seen in cords and nests separated by vascular septa.

Rhabdoid tumor of the kidney is highly aggressive and occurs more commonly in children less than 2 years. Patients often present with widely metastatic disease, and the majority die within 1 year. Cells in rhabdoid tumors have nuclei with a large single nucleolus, giving the appearance of an "owl's eye."

Congenital mesoblastic nephroma occurs in infants with a median age of 2 months. There are three histological types: the classic type, the cellular type, and the mixed type. The cellular type is the most common and shares histologic features with infantile fibrosarcoma and also has the chromosomal translocation t(12;15) which is seen in infantile fibrosarcoma. Congenital mesoblastic nephromas tend to grow into the hilar areas and perirenal soft tissues, and they require radical surgical excision for cure.

Renal cell carcinoma is the most common primary cancer of the kidney in adults but it is rare in children. The histologic features are papillary, clear cell, and mixed. The papillary subtype is the most common in children. Renal cell carcinoma is difficult to treat, and survival is often limited to weeks or months after diagnosis.

Clinical Manifestations: Symptoms, Signs

The most common clinical presentation of renal masses in children is painless abdominal swelling or mass noted by the parents. At diagnosis, abdominal pain or hematuria are often also present. Hypertension is diagnosed in a significant percentage of patients during the initial work-up of a renal mass.

On physical exam, a large mass can be palpated, and it is noted to arise from the flank. It often will not move with respiration. Signs of venous obstruction can be noted if tumor thrombus has invaded the renal vein or inferior vena cava. Given the link between Wilms' tumor and various syndromes, physical examination should include assessment for the stigmata of these syndromes including: aniridia, facial dysmorphism, hemihypertrophy, macroglosia, genitourinary abnormalities, cryptorchidism, and pseudohermaphroditism.

Diagnosis

The diagnostic work-up for a renal mass includes laboratory evaluation, radiology studies, and pathologic analysis of tissue. A complete blood count, liver, and renal function testing should be done to evaluate organ function. A urinalysis should be done to evaluate for hematuria.

Imaging studies are very important in the diagnosis of a renal mass as, in some cases, treatment is initiated based on the characteristic imaging of these tumors. Commonly, an abdominal ultrasound is the first study completed and shows whether the mass is solid or cystic in character, the size of the mass, involvement of other organs and, if Doppler measurement is done, the presence of tumor thrombus in the inferior vena cava. These are all vital aspects in considering initial surgical management. Computed tomography (CT) scan with contract enhancement is often also done to further evaluate the extent of the mass and further define involvement in the other kidney. The typical appearance of a Wilms' tumor on CT is a well-defined mass pushing other structures out of the way but not invading them. The remaining normal kidney is often seen appearing like a "claw" on one aspect of the mass. This can often distinguish Wilms' tumor from neuroblastoma arising from the adrenal gland as neuroblastoma often has an ill-defined margin and almost always invades the surrounding structures. Abdominal MRI may be useful to characterize nephrogenic rests in the other kidney. Chest x-ray is done to evaluate for presence of pulmonary metastases, and CT of the chest can be done to evaluate for masses which may not be seen on chest x-ray.

Other radiologic studies may be indicated based on the diagnosis. Clear cell sarcoma and renal cell carcinoma can spread to the bones, and therefore a bone scan and skeletal survey should be done for patients with clear cell sarcoma and bone scan for those with renal cell carcinoma. Clear cell sarcoma, rhabdoid tumor, and renal cell carcinoma can also spread to the brain, and a MRI or CT with contrast should be done to assess for metastases.

Once all diagnostic studies have been completed to confirm the diagnosis, the patient is staged to determine the appropriate treatment. The staging characteristics for Wilms' tumor are documented in *Table 351.2*.

Differential Diagnosis

The differential diagnosis includes both benign and malignant etiologies. Primary renal cancers would include Wilms' tumor, congenital mesoblastic nephroma, clear cell sarcoma of the kidney, rhabdoid tumor of the kidney, and renal cell carcinoma. Neuroblastoma is a childhood cancer often arising from the adrenal gland which is also included in the differential diagnosis. Benign etiologies include polycystic kidney disease, renal abscess, and hydronephrosis.

Treatment

Surgery is required for all patients with Wilms' tumor and other renal tumors. The objective of surgery is to remove the entire tumor without rupturing the tumor capsule. This almost always requires a nephrectomy. In addition, the surgeon can visually examine the abdomen for other suspicious lesions in the lymph nodes and other structures and biopsy as needed. There are two approaches to the timing of surgery. North American practice is to attempt pretreatment resection whenever possible to facilitate careful examination of histologic characteristics before treatment related changes occur. The approach outside of North America has been resection after delivery of some chemotherapy to lessen the risk of intraoperative rupture and facilitate an easier surgical procedure. The results with combined modality therapy are very good with both surgical approaches.

Table 351.2
Staging for Wilms' tumor

Stage	Characteristics
I	• Tumor limited to the kidney and completely resected • Renal capsule intact (no previous biopsy) • No involvement of renal sinus vessels or evidence of tumor beyond the margin of resection
II	• Tumor extends beyond the kidney but is completely resected (margins negative) • One of the following: penetration of renal capsule, invasion of renal sinus vessels
III	• Gross or microscopic tumor remaining • Tumor spillage before or during surgery • Lymph nodes within the abdomen or pelvis involved by tumor • Extension of tumor thrombus within the vena cava • Previous biopsy
IV	• Hematogenous spread or lymph node metastases outside of the abdomen
V	• Bilateral tumor at diagnosis

The surgical approach to bilateral disease is different with a goal to salvage as much renal function as possible. Therefore, patients undergo an initial biopsy and staging of both kidneys with exploration for suspicious lymph nodes or other lesions. Then, preoperative chemotherapy is given to allow for response before surgery is undertaken to remove the tumors and maximize the amount of kidney remaining.

Radiation to the flank is indicated for Stage III tumors. The recommended dose is 10.5 Gy of radiation to the affected flank. Whole abdomen radiation is only indicated for patients who have ascites positive for tumor cells or tumor rupture. Whole lung irradiation at a dose of 12 Gy is recommended for patients presenting with lung metastases seen on diagnostic chest x-ray. Irradiation of other involved metastatic sites, including the brain, liver, bone, and lymph nodes, is also indicated for patients who have metastatic involvement. In patients with anaplasia, clear cell sarcoma or rhabdoid tumor, radiation is recommended for the flank and all involved sites of disease.

For favorable histology Wilms' tumor the treatment regimen involves combined chemotherapy treatment with Vincristine and Dactinomycin for Stage I and II disease with the addition of Doxorubicin for Stage III and IV disease. Cyclophosphamide or cyclophosphamide and etoposide have been studied for patients with stage IV disease, anaplasia, or clear cell sarcoma. The prognosis for rhabdoid tumor and renal cell carcinoma remain poor and no optimal chemotherapy regimen has been determined. The benefit of chemotherapy in the treatment of congenital mesoblastic nephroma is under investigation.

Prognosis

Overall, all stages of Wilms' tumor are highly curable. Specific prognostic considerations are based on tumor size, patient age, histology, lymph node mestastases, and local features. The most important prognostic feature is the presence of anaplasia. Although the outcomes of patients with Stage I disease do not vary significantly according to anaplasia, for all other stages, the presence of anaplasia confers a worsened prognosis. Patients younger than 2 years of age appear to have a much better prognosis than older children.

The prognosis for clear cell sarcoma of the kidney has improved with the addition of chemotherapy agents. Congential mesoblastic nephroma has an excellent prognosis often with surgery alone. The prognosis for rhabdoid tumor of the kidney and renal cell carcinoma remains very poor in children.

Prevention

Screening ultrasound is recommended every 3 months until the age of 8 years for children with recognized syndromes which carry a predisposition for Wilms' tumor.

352 Hepatic Tumors

H. Stacy Nicholson · Suman Malempati

Introduction

Primary liver tumors are rare in children, and in the USA, occur at a rate of 1.8 per million before the age of 15 years. In infants and children less than 5 years of age, hepatoblastoma (HB) accounts for nearly all liver tumors, and hepatocellular carcinoma (HCC) becomes more common in older children; HCC is the primary hepatic tumor in adolescents. In areas where Hepatitis B is prevalent, the incidence of primary liver tumors in children is higher, and the relative proportion of tumors that are HCC is higher. Benign primary liver tumors also occur and include hemangiomas and hamartomas. The liver is also a common site for metastases of other childhood malignancies, including neuroblastoma. This chapter focuses on the malignant hepatic tumors.

Pathology

Diagnosis is made by histopathological examination of the resected tumor or biopsy. HB is further divided into pure fetal, embryonal, or mixed fetal-embryonal histology. Alpha-fetoprotein (AFP), the predominant protein in serum before birth, is produced by embryonic hepatocytes and remains present for the first few months of life; thus, one must take care in interpreting AFP levels in infants. Serum AFP is elevated in 40% of children with HCC and in nearly all patients with HB. AFP should be measured at diagnosis in all patients, and if elevated, should be followed during treatment and follow-up. Normal or low AFP levels at the diagnosis of HB is associated with worse prognosis.

Clinical Features

Hepatoblastoma most commonly occurs in infants and very young children. Patients typically present with an abdominal mass, most often noted by a parent or physician. However, children with advanced disease may also present with abdominal pain, malaise, and weight loss. Jaundice is rare, and when present, suggests a primary hepatobiliary tumor, such as rhabdomyosarcoma.

Diagnostic Studies and Staging

Ultrasound is often used as the initial imaging modality in a child with an abdominal mass; however, computerized tomography (CT) or magnetic resonance imaging (MRI) of the abdomen is needed to define the extent of the mass and its relationship to hepatic landmarks. The importance of this imaging cannot be overemphasized, as surgical planning will be dependent upon this information. Abdominal radiographs are rarely helpful. All patients should be evaluated for metastases with a chest X-ray (CXR) and CT of the lungs.

Treatment

Once the imaging studies indicate a primary hepatic tumor, a team approach to treatment planning, involving the pediatric surgeon and pediatric oncologist, ensures that a coordinated plan for surgery and chemotherapy is in place. Radiotherapy is of limited use and is typically limited to a few children with unresectable disease or following recurrence.

Surgery

For patients with HB and HCC, complete resection is necessary for cure. Patients who undergo primary complete resection of HB have an excellent prognosis with a 90% long-term survival rate. However, only one-third to one-half of liver tumors in children can be safely resected at initial diagnosis. For children with hepatoblastoma, chemotherapy can induce significant tumor shrinkage, which may allow a tumor becoming resectable in up to two-thirds of patients. Chemotherapy is less effective for HCC. In children without metastatic disease but whose primary tumor remains unresectable, liver transplantation can be curative. Finally, in some patients, surgical excision of pulmonary metastases has improved survival.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_352,

Chemotherapy

Cisplatin-based chemotherapy has greatly improved the survival of children with HB, and the use of combination chemotherapy is recommended for most children with HB or HCC, including those who have had a complete resection. In addition, chemotherapy may make a previously unresectable tumor amenable to surgery. Chemotherapy is not necessary for children with resectable pure fetal histology HB, as complete surgical resection alone is curative. Agents with the most activity against HB include doxorubicin, cisplatin, 5-fluorouracil, and vincristine, which are commonly used in combination. While similar approaches are used in both HB and HCC, HCC is much less chemosensitive.

Prognosis

Prognosis is related to the extent of disease at diagnosis, the histologic subtype, and whether the tumor can be surgically excised. Multi-modality therapy has resulted in long-term survival rates in excess of 75%.

353 Soft Tissue Sarcomas

Suman Malempati · H. Stacy Nicholson

Introduction

As a group, soft tissue sarcomas are the most common solid tumor in children outside the central nervous system (CNS). In general, these tumors arise from the primitive embryonic mesenchyme, and include neoplasms of muscle, connective tissue, supportive tissue, and vascular tissue. Tumors may arise anywhere in the body where these tissues occur, but are most commonly seen in the extremities, head and neck regions, and genitourinary tract. Rhabdomyosarcoma is the most common soft tissue sarcoma in children and is the primary focus of this chapter.

Rhabdomyosarcoma

The cause of rhabdomyosarcoma is unknown; however, improved understanding of its biology may lead to an improved understanding of its etiology and to new treatments. The annual incidence in the USA in children less than 20 years of age is 4.3 cases per million. Rhabdomyosarcoma occurs in all ages, from birth to adulthood, but there are two distinct age peaks. Two-third of cases of rhabdomyosarcoma are diagnosed in children less than 6 years of age, but a second peak occurs in adolescents between the ages of 14 and 18 years. Adolescents with rhabdomyosarcoma are more likely to have tumors of the extremities. Rhabdomyosarcoma is slightly more common in males, and compared to Caucasians, rates are lower in African-Americans and in Asian populations. Rhabdomyosarcoma occurs more frequently in certain familial cancer predisposition syndromes, including Li–Fraumeni, neurofibromatosis type 1, and Gardner syndrome.

Histologic Types and Histopathology

Rhabdomyosarcoma is one of the "small round blue cell" tumors of childhood, and requires a skilled pathologist to confirm the diagnosis. The primary histopathological subtypes are embryonal (including botryoid), alveolar, and pleomorphic histologies. Alveolar rhabdomyosarcoma is associated with a specific chromosomal translocation, t(2;13), resulting in Pax3-FOXO fusion transcription factor that drives pathogenesis. Alveolar rhabdomyosarcoma more commonly occurs in extremity sites in adolescents and young adults and is associated with a worse prognosis. Pleomorphic rhabdomyosarcoma typically occurs in adults and can be very difficult to treat.

Clinical Features

Although rhabdomyosarcoma is a tumor of primitive skeletal muscle cells, it can occur in sites in the body that do not normally contain skeletal muscle. Common sites of involvement are the head and neck region (orbit, nasopharynx, sinuses, and superficial face), the genitourinary tract (bladder, vagina, and testis), extremities, and the trunk including retroperitoneum. Adolescents with rhabdomyosarcoma are more likely to have tumors of the extremities.

Signs and symptoms depend upon the site of the primary tumor. Head and neck tumors may present with pain, proptosis, orbital swelling, nasal obstruction, sinusitis, epistaxis, dysphasia, or hoarseness. Acquired denasalized speech, asymptomatic serous otitis media, persistent earache or aural discharge or unexplained facial palsy should raise the suspicion about such tumors. Approximately 25% of head and neck rhabdomyosarcoma in children occur in the orbit, and 50% occur in parameningeal regions.

Hematuria or urinary retention may be the presenting symptoms of tumors arising in the bladder or prostate, which are common sites in young children. Vaginal rhabdomyosarcoma, often called botryoides, due to the characteristic grapelike cluster of tumor may present with bloody mucoid discharge in young girls before a mass is seen. Paratesticular tumors are usually painless and can be mistaken for hydroceles. Patients with rhabdomyosarcoma of the extremities typically present with a painless mass.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_353,

Diagnostic Studies and Staging

Diagnosis is made by histopathological examination of a tumor or biopsy, and all patients need to be evaluated for metastases. Rhabdomyosarcoma may involve regional lymph nodes, and distant spread most often involves the lungs, bone, and bone marrow. Imaging of the primary site may involve X-rays, computerized tomography (CT), and/or magnetic resonance imaging (MRI). To evaluate for metastases, CT scanning of the chest, abdomen and pelvis, bone scan, and bone marrow biopsies are typically done. Imaging of regional lymph nodes is important and lymph node sampling may be necessary for complete staging. For parameningeal tumors, a lumbar puncture should be performed to evaluate CSF cytology. Correct staging is important in assigning treatment and in counseling the patients and families about prognosis.

Treatment

Treatment needs to be assigned based on site, histology, and extent of metastatic spread. The clinical grouping system developed by the Intergroup Rhabdomyosarcoma Study (*Table 353.1*) is used to assign treatment, which generally includes surgery and chemotherapy, with or without radiotherapy.

Table 353.1
Intergroup rhabdomyosarcoma study clinical grouping system

Group	
I	Localized disease, completely resected. Regional nodes not involved. No metastases. (a) Confined to the muscle or organ of origin. (b) Infiltration outside the muscle or organ of origin – continuous with primary tumor.
II	(a) Grossly resected tumor with microscopic residual disease. No lymph node involvement; no metastases. (b) Regional disease, completely resected. Lymph nodes can be positive or negative; no metastases. (c) Regional disease with completely resected involved lymph nodes, with microscopic residual disease; no metastases.
III	Incomplete resection or biopsy. Gross residual disease is present.
IV	Metastatic disease present at onset.

Surgery

When the primary tumor can be surgically removed with negative margins, that is the preferred initial approach. However, tumors at many sites, including most head and neck tumors, cannot be completely excised and are simply biopsied. The initial surgical approach is key in assigning patients to the appropriate clinical group (*Table 353.1*).

Radiotherapy

External beam radiation is used in combination with surgery and chemotherapy in most patients with rhabdomyosarcoma. However, if the initial surgery results in a complete resection with negative margins, radiation may not be needed. Conversely, if only a biopsy is performed at diagnosis, radiation is often part of the treatment plan, even if a second surgery results in a complete resection. Doses are typically between 3,600 to 5,000 cGy.

Chemotherapy

The use of combination chemotherapy with vincristine, actinomycin-D, and cyclophosphamide (VAC) has improved the survival rates for children with rhabdomyosarcoma and has been the standard since the 1970s. VAC chemotherapy is typically given every 3 weeks and the duration of therapy depends upon clinical group and histology. Patients with embryonal histology occurring in "favorable" sites may be treated with vincristine and actinomycin-D alone. There are other active chemotherapy drugs in rhabdomyosarcoma, but addition of these agents has generally not improved survival compared to VAC. As more is understood about the biology of rhabdomyosarcoma, targeted therapy will increasingly be studied and may be added to combination therapy with surgery, chemotherapy, and radiation.

Prognosis

Prognosis varies by histology, clinical group, and, increasingly, molecular characterization. Patients with Group I disease have a 5-year survival rate that exceeds 90%. At the other end of the spectrum, those with Group IV disease (distant metastases) have a 5-year survival rate of approximately 25%. Favorable sites include orbital and paratesticular tumors, and masses in the trunk and extremities typically have a worse prognosis.

Other Soft Tissue Sarcomas

Other soft tissue sarcomas that occur in children include synovial sarcoma, malignant peripheral nerve sheath tumor, undifferentiated sarcoma, fibrosarcoma, liposarcoma, leiomyosarcoma, and others. These tumors typically arise in the extremities and trunk, and, unlike rhabdomyosarcoma, are unusual in the head and neck. Non-rhabdomyosarcomatous soft tissue sarcoma (NRSTS) usually presents as a painless mass. NRSTS can occur as secondary malignancies within a field of prior radiation in patients previously treated for cancer. While the surgical approach is similar to that used for rhabdomyosarcoma, these tumors are typically less susceptible to chemotherapy in particular. These tumors also vary in degree of aggressiveness and propensity to spread. The rarity of these tumors has impaired the ability to conduct robust clinical trials, and surgeons and oncologists must collaborate closely in determining the best treatment approach for each patient.

354 Primary Malignant Tumors of Bone

Suman Malempati

Introduction

As a group, malignant bone tumors account for 5% of all cancers in children (age 0–19 years) in the USA. The vast majority of bone cancers that occur in the pediatric population are osteosarcoma and Ewing sarcoma. Both of these are aggressive high-grade malignancies that are diagnosed most frequently in the second decade of life. Chondrosarcoma can occur in children, but is much less common. There are a variety of nonmalignant conditions from which bone malignancies must be distinguished.

Epidemiology

Osteosarcoma is the most common malignant tumor of bone with an annual incidence rate of approximately five cases per million children in the USA. The incidence of osteosarcoma is similar in many Western European countries, but tends to be lower in Asian and many African countries. The annual incidence of Ewing sarcoma is approximately 3/million children in the USA, and is almost exclusively diagnosed in Caucasians. Ewing sarcoma very rarely occurs in persons of African or Asian descent. There is a slight male predominance of both osteosarcoma and Ewing sarcoma. Chondrosarcoma is diagnosed much less frequently with an annual incidence rate of 0.3–0.4/million children.

The peak incidence of malignant bone tumors is during the second decade of life. Both osteosarcoma and Ewing sarcoma are most commonly diagnosed around the time of the adolescent growth spurt. The average age of onset for Ewing sarcoma is younger than for osteosarcoma. In contrast to osteosarcoma, which very rarely occurs before the age of 8, Ewing sarcoma may be diagnosed in younger children and infants. Both Ewing sarcoma and osteosarcoma also occur in young adults in the 3rd and 4th decades of life. Osteosarcoma diagnosed in older adults is typically associated with previous radiation exposure.

Pathogenesis

The cause of bone malignancies is unknown in most cases. However, a variety of genetic and environmental factors predispose patients to the development of osteosarcoma (*Table 354.1*). Hereditary retinoblastoma with germline mutations of loss of the Rb tumor suppressor gene, germline p53 mutations (Li-Fraumeni syndrome), and Rothmund–Thompson syndrome are all associated with a very high risk of osteosarcoma. In addition, children with Paget's disease of bone and osteogenesis imperfecta, and those who have been exposed to ionizing radiation have a higher incidence of osteosarcoma.

In contrast, Ewing sarcoma is not typically associated with radiation exposure or cancer predisposition syndromes. The pathogenesis of Ewing sarcoma is related to chimeric proteins that are the result of recurrent translocations involving the *ews* gene at 22q12 locus and members of the *ets* family of transcription factors. It is now known that the EWS-ETS fusion proteins play an essential role in the tumorigenesis of Ewing sarcoma.

Clinical Manifestations

The most common presenting symptom in patients diagnosed with bone tumors is pain with or without swelling at the involved site. Initially, the pain is often intermittent, but becomes more constant and more severe over time. There is often a history of trauma at the onset of symptoms, but there is no evidence that trauma is causative. The trauma likely draws the patient's and caregiver's attention to the affected site. Patients eventually diagnosed with bone tumors are often initially treated with rest, ice and anti-inflammatory medication for presumed injury. It is common for there to be delay of several months from onset of symptoms to diagnosis of a bone tumor. A malignant bone tumor should be suspected with any "pathologic fracture" that occurs in an unusual site or after seemingly minor trauma. Systemic symptoms such

as fever and weight loss may be seen, particularly with Ewing sarcoma.

Osteosarcoma typically arises at the metaphyses of long bones, with almost one-half of primary tumors occurring around the knee joint (distal femur or proximal tibia). The proximal humerus is the next most common site. In contrast, Ewing sarcoma more commonly occurs in flat bones. When long bones are affected with Ewing sarcoma, the diaphyses are usually the involved sites rather than the metaphyses. The bones of the pelvis are the most frequently involved sites of Ewing sarcoma, accounting for approximately 25% of cases.

Diagnostic Evaluation

The initial evaluation of patients with suspected bone tumors should include a thorough history and physical examination. Signs and symptoms may be nonspecific. *Table 354.2* lists a variety of conditions that mimic

Figure 354.1
Lateral radiograph of the knee showing "Codman's triangle" resulting from elevation of periosteum from underlying bone

malignant bone tumors. A history of fever, weight loss, and/or night sweats should alert the physician to the possibility of cancer, although patients with bone tumors often have no symptoms other than pain. Suspected bone tumors must be distinguished from injuries. Injury-associated pain usually gets better with rest, whereas pain due to a malignant bone tumor does not remit and progressively worsens over time. Pain that is severe enough to wake a child or adolescent from sleep deserves further evaluation. Physical exam reveals tenderness at the involved site. There is also often a soft-tissue mass associated with primary tumors of bone.

The initial radiographic evaluation should be a plain radiograph of the involved bone. Plain x-ray will show a destructive lesion in the involved bone with disruption of the cortex. A classic radiographic finding in osteosarcoma and Ewing sarcoma, known as "Codman triangle," results from elevation and detachment of periosteum from bone along with subperiosteal new bone formation (*Fig. 354.1*). A "sunburst" periosteal reaction is often seen in osteosarcoma due to a rapidly growing mass (*Fig. 354.2*).

In order to better determine the extent of bone involvement of a suspected bone tumor, either magnetic resonance imaging (MRI) or computed tomography (CT) is necessary. In regard to surgical planning, MRI is more accurate and useful for evaluating intraosseus tumor

Figure 354.2
Radiograph showing the classic "Sunburst" pattern of periosteal reaction in a patient with osteosarcoma of the proximal humerus

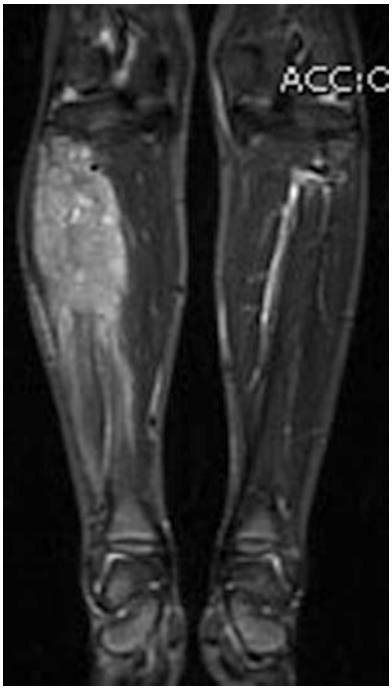

Figure 354.3
T1-weighted MRI image of Ewing sarcoma of the fibula with large soft-tissue component

extent, joint involvement, subcutaneous fat planes, and association with neurovascular structures (*Fig. 354.3*).

Evaluation for distant metastases is critical. Approximately 20–25% of patients with Ewing sarcoma and osteosarcoma have detectable metastases at diagnosis. The most common site of metastases is the lungs. While plain radiographs of the chest can often detect metastatic lesions, chest CT scan is considerably more sensitive (*Fig. 354.4*). Radionuclide bone scan (technetium-99m) is also standard in the USA for detection of bone metastases, which occur in approximately 10% of patients with newly diagnosed malignant bone tumors. In addition, approximately 10% of patients with Ewing sarcoma will have detectable metastases to bone marrow. Therefore, bone marrow biopsies from bilateral posterior iliac crests are critical.

While presenting signs and symptoms, location and pattern of the lesion, and characteristic findings on imaging may suggest the presence of a malignant bone tumor, definitive diagnosis requires biopsy and histologic assessment. The approach to the biopsy is critical as the biopsy tract will also need to be resected at the time of surgical resection. Biopsy without consideration of planning for the definitive local control surgery can hinder the ability to perform a future limb-salvage procedure in the patient.

Histologic evaluation of conventional osteosarcoma reveals a high-grade malignant lesion with large spindle-shaped cells, irregular nuclei, and mitotic figures intermixed with a stroma containing areas of osteoid. Conventional high-grade osteosarcoma is often further characterized as osteoblastic, chondroblastic, or fibroblastic based on the pattern of differentiation. This distinction, however, is clinically meaningless. Other variants that are similar to conventional osteosarcoma include telangiectatic, small cell, and periosteal osteosarcoma. An additional variant, parosteal osteosarcoma, is similar to periosteal in that it arises from the cortex of bone, but does not invade into the medullary cavity. Parosteal osteosarcoma tends to behave more indolently than conventional osteosarcoma and does not metastasize.

Ewing sarcoma is one of the "small round blue cell tumors" of childhood. It can be distinguished from rhabdomyosarcoma, neuroblastoma, and lymphoma based on the pattern of histochemical staining. The pattern of staining shows some evidence of neural differentiation with typical expression of CD99, S-100, and neuron-specific enolase.

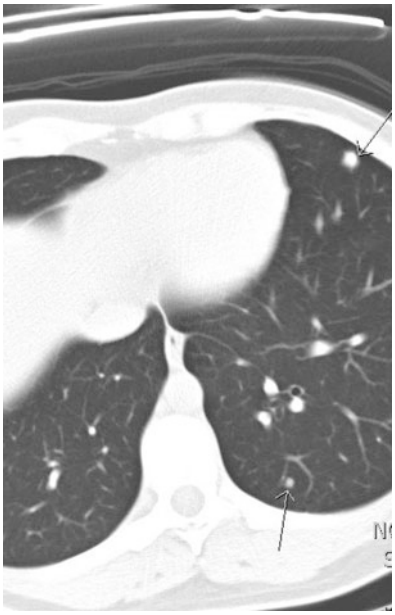

Figure 354.4
Chest CT scan demonstrating metastatic osteosarcoma

Fluorescent in situ hybridization or chromosome analysis of tumor cells is critical to assess for rearrangements of the *ews* gene on chromosome 22, which can be detected in more than 95% of cases of Ewing sarcoma. The most common rearrangement is the characteristic t(11;22)(q24;q12) reciprocal translocation, which results in the chimeric EWS-FLI1 transcription factor. Presence of this translocation is pathognomic for Ewing sarcoma.

Treatment and Prognosis

Treatment of malignant bone tumors involves both systemic and local therapy. Significant improvements have been made in both systemic therapies as well local control techniques over the past few decades. Currently, at least two-thirds of patients with Ewing sarcoma and osteosarcoma without detectable metastatic disease can be cured. A comparison of clinical features, treatment, and prognosis between Ewing sarcoma and osteosarcoma is shown in *Table 354.3*.

Osteosarcoma

Since the 1970s, chemotherapy has been a vital component to the treatment of patients with osteosarcoma. Prior to the use of chemotherapy, survival rate with surgical resection alone was less than 20%. Most patients died from metastatic disease to lungs. Neo-adjuvant chemotherapy is now standard. Chemotherapy given before surgical resection allows for early initiation of systemic control as well as the histologic assessment of tumor necrosis in response to chemotherapy. Degree of tumor necrosis after initial chemotherapy has been shown to be prognostic, as patients with 10% or greater viable tumor at the time of definitive surgery have a significantly higher risk of recurrence.

Chemotherapeutic agents that are most active against osteosarcoma are doxorubicin, cisplatin, methotrexate, and ifosfamide. Standard therapy in North America and Europe involve combinations of these agents before and after definitive surgery. While chemotherapy has improved prognosis, complete surgical resection of all tumor with clear margins remains essential for cure. Amputation has been a traditional approach and remains effective. However, improved surgical techniques and neo-adjuvant chemotherapy allow a higher proportion of patients to undergo limb-sparing procedures (*Fig. 354.5*). Radiation therapy is not considered a viable option for local control as osteosarcoma tumors are relatively radioresistant. However, for tumors that not resectable (such as primary tumors of the pelvis), radiation therapy can be effective as palliation.

Patients who present with metastatic disease have a poor prognosis. Less than 20% of patients with metastatic disease will be long-term survivors. Along with standard chemotherapy, local control to all metastatic sites, including pulmonary metastatecomy, is critical to offer any chance of long-term cure.

Patients diagnosed with parosteal osteosarcoma have a much more favorable prognosis with complete surgical resection alone. These tumors can recur locally without complete resection with wide margins, but metastatic spread is not typically seen. These patients can be treated without chemotherapy.

Ewing Sarcoma

Current treatment for Ewing sarcoma involves multimodal therapy. Neo-adjuvant chemotherapy is now standard. For patients with localized disease, the addition of Ifosfamide and Etoposide to Vincristine, Doxorubicin, and Cyclophosphamide has been shown to improve survival. Dose intensity is critical and a recent study has shown that delivering the agents on a compressed every 2 week schedule is more effective at preventing disease recurrence.

Table 354.3
Comparison of osteosarcoma and Ewing sarcoma

	Osteosarcoma	Ewing sarcoma
Annual incidence rate (age 0–19 in Western countries)	~5/million	~3/million
Race	All races	Caucasian (rare in persons of African or Asian descent)
Primary tumor site	Metaphyses of long bones	Flat bones
		Diaphyses of long bones
		Extraskeletal
Radiographic signs	"Sunburst"	"Onion-skinning"
	Sclerotic destruction	Lytic lesion
Treatment	Chemotherapy	Chemotherapy
	Surgery	Surgery
		Radiation
Prognosis (long-term survival)		
Localized	~65%	~75%
Metastatic	<20%	~20–30%

Figure 354.5
Radiograph demonstrating limb salvage surgery with reconstruction using a composite allograft/metal prosthesis

As with osteosarcoma, local control is also critical. In general, complete surgical resection with clear margins is considered the most effective means of local control. However, Ewing sarcoma is much more radiosensitive than osteosarcoma. Therefore, radiation therapy may be an effective means of local control if the alternative would be a mutilating operative surgery. Prognosis depends on site of primary tumor and presence of metastatic disease. Up to 75% of patients with localized extremity tumors can be cured. Patients with centrally located tumors (such as in the pelvis) and those with metastatic disease have poorer outcomes.

Chondrosarcoma

The only known curative therapy for chondrosarcoma is surgical resection. Chemotherapy has no proven benefit in regard to preventing recurrence if complete surgical resection is achieved. Prognosis is poor for patients in whom surgical resection cannot be achieved. Chemotherapy and radiation therapy may be used to slow tumor progression, but neither modality has been shown to affect long-term outcome.

Summary and Future Directions

As malignant tumors of bone are relatively uncommon in children, diagnosis can be difficult. Both Ewing sarcoma and osteosarcoma most commonly occur in adolescents during the second decade of life. While there is a higher incidence of osteosarcoma in some familial cancer predisposition syndromes and after radiation exposure, the

etiology of most cases of bone tumors is unknown. Bone malignancy should be suspected for persistent pain, swelling, and palpable mass as well as if a pathologic fracture occurs. The outlook for patients with malignant bone tumors has improved considerably with multimodal therapy. Future advances in treatment will likely include better risk stratification of patients based on tumor biology, improved local control techniques (both surgical and radiation therapy), and the incorporation of molecular targeted therapies into current treatment plans.

355 Retinoblastoma

H. Stacy Nicholson

Retinoblastoma (RB) is a highly malignant tumor of the retina, occurring in infants and young children. Many cases are probably congenital, and RB occurs in 1 of 18,000 live births in the USA. RB can be either genetic or sporadic. Familial RB occurs at an earlier age and is often bilateral. It can be inherited from a parent, usually in an autosomal dominant fashion, or can develop from spontaneous mutations. An estimated 15% of unilateral RB is genetic, with the remainder being sporadic. The RB1 gene is located at 13q14.

Histology

Retinoblastoma is one of the embryonal neoplasms of childhood. Often the histological examination shows sheets of malignant cells, similar to other small round blue cell tumors. The degree of retinal differentiation varies.

Clinical Features

The most common presentation is of leukocoria, or of a "white reflex." Sometimes, the child may present with a "squint." Untreated, RB will cause complete loss of vision, globe destruction, and direct extension into the orbit, orbital bones, and central nervous system. Metastases can occur in lymph nodes, bone, and bone marrow (*Figs.355.1* and *355.2*).

Figure 355.1
Leukocoria in a 3-year-old girl with newly diagnosed unilateral retinoblastoma (Courtesy of Tim Stout, MD, PhD)

Diagnostic Studies and Staging

The diagnosis is initially established by an examination of the retina under anesthesia by an ophthalmologist. Biopsy is not done, in order to prevent seeding of the orbit. To assess the degree of tumor, orbital ultrasound or computerized tomography (CT) may be used. In patients with suspected optic nerve invasion or extensive choroidal invasion, a magnetic resonance image (MRI) of the orbits and brain should be obtained, as well as cerebrospinal fluid (CSF) for cytology. The MRI should show whether the pineal gland also is involved – this is known as "trilateral" retinoblastoma. Bone scan and bone marrow aspirates should be performed if distant metastases are suspected clinically.

Treatment

Treatment needs to be individualized and may involve surgery, cryotherapy and photocoagulation, radiation, and/or chemotherapy. Close collaboration between the pediatric ophthalmologist and pediatric oncologist in creating an individualized treatment plan is needed.

Surgery and Other Local Therapies

For advanced RB, enucleation is the treatment of choice. This includes tumors with invasion of the optic nerve, choroid or obits, as well as anterior chamber invasion. In small tumors that are away from the macula, cryotherapy, thermotherapy, and/or photocoagulation can be used as a means of saving the globe.

Radiotherapy

Retinoblastoma is radiosensitive and external beam radiation is used in children with advanced disease. Brachytherapy can also be delivered using "plaque radiotherapy."

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_355,

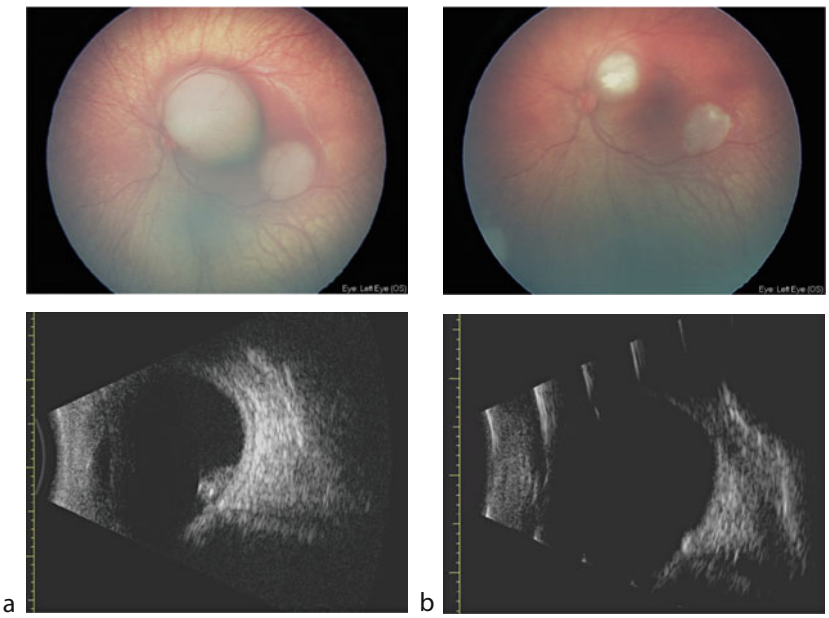

Figure 355.2
Unilateral retinoblastoma in a 6-month-old boy. The upper panels show the retina and the lower panel shows the ultrasound: (a) is at presentation and (b) shows the results following treatment with laser combined with chemotherapy (etoposide, vincristine, and carboplatin) (Courtesy of Tim Stout, MD, PhD)

Radiation carries a substantial risk of secondary cancers, especially in children with bilateral or other forms of genetic RB.

Chemotherapy

Chemotherapy is used in all patients with metastatic disease. Furthermore, chemotherapy is increasingly being used to shrink tumors so that they are amenable to local globe-sparing therapy. Agents that are active in RB include carboplatin, vincristine, etoposide, teniposide, cyclophosphamide, and doxorubicin.

Prognosis

In early stage unilateral disease, the prognosis is excellent, with more than 90% of children surviving. Most of these will have intact vision. Follow-up examinations of the retina under anesthesia to ensure that disease does not develop in the contralateral eye should be done until age 3. Patients with metastatic disease at diagnosis have a poor prognosis.

356 Germ Cell Tumors

Suman Malempati · H. Stacy Nicholson

Introduction

Germ cell tumors in children develop from the primordial germ cells, and arise in either the gonads or in sites associated with the normal migration of germ cells during embryogenesis. When these tumors occur outside the gonads, presumably they arise from germ cells that did not migrate properly. Germ cell tumors in children are rare, occurring at a rate of 10.7 per million children less than 19 years of age. When combined, these tumors represent 2–4% of all childhood malignancies in the USA. Extragonadal germ cell tumors typically occur in the pelvis, retroperitoneum, mediastinum, and in the central nervous system (CNS). CNS germ cell tumors are covered in the CNS tumor Chap. 349, "Central Nervous System Tumors in Children".

Pathology

The category of germ cell tumors is comprised of a variety of histologic subtypes. However, regardless of site, there are common pathological features that all germ cell tumors share. As the name suggests, germ cell tumors arise from primordial germ cells that undergo embryonal or extraembryonic differentiation. Histologic subtypes include benign and mature teratomas, yolk sac tumor, choriocarcinoma, and germinomas (also known as dysgerminomas or seminomas) among others. All of the different subtypes can be components of a mixed malignant germ cell tumor. Benign teratomas commonly occur soon after birth, yolk sac tumors typically occur between the ages of 1 and 5 years, and dysgerminomas and malignant teratomas occur predominately in adolescents. Teratomas have well-differentiated tissues from all three germ layers – endoderm, ectoderm, and mesoderm – and can be either cystic or solid. Many germ cell tumors may produce tumor markers that can be used in establishing the diagnosis and in monitoring for therapeutic response and disease recurrence. Tumors with a trophoblastic element (such as choriocarcinoma) may produce beta-human chorionic gonadotrophin (β-hCG) and those with a yolk sac element may produce alpha-fetoprotein (AFP).

Treatment Issues Common to All Sites

Complete surgical resection is the goal for all tumors and is often curative in benign teratomas and low-stage malignant germ cell tumors. However, as germ cell tumors are typically chemosensitive, surgeons should avoid an operative approach that would be disfiguring or compromise fertility. For a given patient, treatment is guided by both site and histology.

Testicular Germ Cell Tumors

Although most testicular tumors in children (75%) are germ cell tumors, one must also consider the possibility of a paratesticular rhabdomyosarcoma or leukemic infiltration when evaluating a new patient with a testicular mass. Typically, a testicular germ cell tumor will present as a rapidly growing, nontender, scrotal mass. While most testicular germ cell tumors in children are localized, a metastatic workup should be performed, including computerized tomography (CT) of the chest, abdomen, and pelvis, and a bone scintigraphy. Following surgery, a scrotal ultrasound within a month should be performed, and AFP should be followed in those with elevated levels at diagnosis.

For those without metastatic disease, treatment requires orchiectomy with a high excision of the cord via an inguinal approach. Retroperitoneal node dissection is not indicated and chemotherapy is not necessary. Patients with metastatic disease respond well to chemotherapy consisting of cisplatin, bleomycin, and etoposide (PEB) or cisplatin, bleomycin, and vinblastine (PVB). The prognosis is generally excellent with up to 90% survival even in patients with metastatic disease.

Ovarian Germ Cell Tumors

Ovarian germ cell tumors typically occur in early adolescence, and most ovarian tumors in children are of germ cell origin. Patients present with either abdominal pain or a mass, and other causes, such as ovarian torsion, should be considered. Ultrasound of the abdomen is usually

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_356,

the initial study obtained. Additional studies should include measurement of serum levels of AFP and β-hCG and CT scan of the chest, abdomen, and pelvis, and bone scintigraphy. There are four main histological subtypes: mature (benign) teratoma, immature (malignant) teratoma, dysgerminoma, and yolk sac tumors. Treatment may include surgery, with or without chemotherapy, depending upon the tumor type and extent of disease. Standard chemotherapy is the same as for testicular germ cell tumors and the prognosis is excellent.

Sacrococcygeal Tumors

Although rare (one per 40,000 live births), sacrococcygeal teratomas are among the most common tumors in the newborn. Females are more often affected than males (4:1), and the presentation is typically a large mass between the coccyx and rectum. Complete excision, including the coccyx, is usually curative. Most of these are benign teratomas, but a small percentage may have malignant components. Close follow-up after surgery is necessary because of a small risk of recurrent tumor with malignant elements. Serial measurements of the serum AFP level are recommended as persistently elevated AFP for age may be a marker of previously unrecognized malignant elements.

Mediastinal Tumors

Thoracic germ cell tumors typically occur in the anterior mediastinum in adolescent males and occur at a higher frequency in those with Klinefelter syndrome (47, XXY). Histology can be mixed and often includes yolk sac tumor, germinoma, choriocarcinoma, and teratoma. Tumor markers including AFP and β-hCG are often elevated in serum. Treatment usually includes surgery and chemotherapy, and if a complete resection can be accomplished, this improves survival. Rarely, these tumors are sometimes associated with hematological malignancies or can contain foci of sarcomatous elements.

357 Late Effects of Cancer Chemotherapy in Children

Susan J. Lindemulder

Introduction

Overall 5-year survival rates for childhood cancer in developed countries is approaching 80%, and while the overall survival rates for childhood cancer in developing countries is significantly lower, improvements are being made. These improved survival rates are the result of improvements in treatment, access and delivery of care, adherence to treatment regimens, and improvements in supportive care. As the survival rates continue to grow globally there is a growing population of children, adolescents, and young adults who are at risk for late effects related to their cancer therapy.

While children generally tolerate the acute effects of cancer therapy relatively well compared to adult patients, cancer therapy received at an early age can lead to complications that may not be seen for many years. The Childhood Cancer Survivor study follows a large cohort of long-term childhood cancer survivors treated in the United States and found that 65% of patients had at least one chronic health condition, and 28% had a severe or life threatening health condition. These results are being confirmed by large cohort studies of long-term survivors, being conducted in multiple other countries around the world.

The late effects of childhood cancer therapy involve almost every organ in the body including the heart, lungs, kidneys, gastrointestinal tract, musculoskeletal system, hearing, and vision. There are also effects on growth and development, neurocognitive function, potential for future fertility, and psychosocial impact.

Treatment Summary

Given the wide variety of medications and other modalities utilized in treating childhood cancer and the multiple treatment protocols being used, the potential for late effects can vary greatly between different survivors of childhood cancer. There are many approaches to delivery of survivorship care, but all approaches require an accurate outline of what treatment the patient has received. This is commonly referred to as a Cancer Treatment Summary. *Table 357.1* details the items that should be included. The treatment summary should be created by the primary oncologist after the treatment is complete and is reviewed with the patient. This can then be used by any provider in combination with published screening guidelines such as the Children's Oncology Group Long-Term Follow-Up Guidelines to guide follow-up care and screening.

Common Late Effects

Some of the most common late effects are detailed in the rest of this chapter and are summarized in *Table 357.2*.

Infection

Children and adolescents often require at least one transfusion of a blood product during the course of their cancer treatment. Exposure to blood products increases the risk of transmission of blood born infections including Hepatitis B, Hepatitis C, Human Immunodeficiency Virus (HIV), and others. Screening of the blood supply varies by country with regard to the types of infection screened and the methods by which screening is done.

According to the World Health Organization (WHO) 2007 Blood Safety Survey, 42 countries collected less than 25% of their supply from voluntary unpaid donors (considered the safest source) and 31 countries reported still using paid donations (the least safe source). WHO recommends that at minimum, all blood be screened for HIV, Hepatitis B, Hepatitis C, and syphilis but 41 one out of 162 countries are not able to screen all donated blood for one or more of these infections.

Given these statistics, practitioners should determine whether the patient received any blood product during treatment and where that transfusion was given. Based on transfusion information, information regarding other

high risk health behaviors, living in a hyperendemic area, and available blood product screening information, patients may need to be tested for one or more infectious complications. All screening can be done on a sample of peripheral blood. Recommended screening for Hepatitis B is a Hepatitis B Surface antigen and Hepatitis B core antibody, for Hepatitis C is a Hepatitis C Antibody, and for HIV is antibodies for HIV-1 and HIV-2.

Cardiopulmonary

Pulmonary fibrosis and interstitial pneumonitis with resultant restrictive or obstructive lung disease can occur after treatment with various chemotherapy agents or after receiving radiation to the chest. The most recognized chemotherapy agent causing pulmonary effects is bleomycin, but other agents including carmustine (BCNU), lomustine (CCNU), and busulfan are also recognized as having these effects. These agents produce effects in a dose-dependent fashion with higher doses and more intensive treatment regimens resulting in higher risk. Chemotherapy combined with radiation doses greater than 15 Gy are associated with the highest risk.

Some patients will have clinical symptoms of pulmonary disease including cough, shortness of breath, dyspnea on exertion or wheezing, but many are diagnosed through screening pulmonary function testing, which shows lung volumes consistent with either restrictive or obstructive disease or decreased DLCO. Patients at risk should be interviewed yearly for symptoms such as chronic cough and shortness of breath. They should be evaluated by a physical exam and, where available, patients should have baseline pulmonary function testing with follow-up testing for abnormal results or new clinical symptoms.

Cardiac late effects are emerging as a growing concern as the survivor population ages. All cause cardiovascular events and are behind only cancer recurrence and development of second malignancies as a leading cause of mortality in this population. The mechanism and pathology vary with treatment exposure. Anthracycline chemotherapeutic agents cause cardiomyopathy with potential for congestive heart failure and radiation produces effects such as valvular disease, pericardial disease, and coronary artery disease.

Anthracycline chemotherapy agents include doxorubicin, daunorubicin, idarubicin, mitoxantrone, and epirubicin. They are thought to cause damage and death of cardiac myocytes during treatment. This leads to hypertrophic changes in the remaining myocytes, ultimately leading to inadequate left ventricular mass and decreased function. While some patients experience an acute decrease in function during treatment, this effect is often not seen for years, on average at least 15–20 years, and onset can be insidious or clinically dramatic. The risk of cardiomyopathy increases with increasing cumulative anthracycline dose, defined in doxorubicin dose equivalents.

Radiation to the heart can increase the risk of cardiomyopathy when part of a treatment regimen that includes anthracycline chemotherapy, but radiation alone causes pericardial disease, valvular disease and coronary artery disease. It is important to remember that many radiation fields include the heart. In addition to the obvious fields of chest, whole lung, mediastinal, mantle and total body, fields such as flank, spleen, whole abdomen, and paraaortic also include the heart. The risk increases with increasing dose and is highest for those who have received greater than 30 Gy (with anthracycline) or 40 Gy (without anthracycline). Other medical conditions that often result

Table 357.2

Common long-term effects, risk factors, and screening recommendations[a]

Late effect	Therapy exposure	Screening recommendations
Cataracts	Corticosteroids, busulfan, radiation (orbit)	– Yearly fundoscopic and visual acuity exam – Full ophthalmologic exam for those exposed to radiation
	Modifiers: combined treatment, higher radiation dose	
Dental problems	Chemotherapy, radiation	– Dental exam and cleaning every 6 months
	Modifiers: younger age (<5 years)	
Hearing loss	Cisplatin (highest risk with cumulative dose $\geq$360 mg/m^2), radiation (cranial)	– Baseline audiology exam – Routine follow-up audiology exam if hearing loss is detected
	Modifiers: combined treatment, other ototoxic drugs (aminoglycosides, loop diuretics), younger age (<4 years)	
Pulmonary fibrosis	Bleomycin (highest risk with cumulative dose $\geq$400 U/m^2), carmustine, radiation (chest)	– Yearly exam and history – Baseline pulmonary function testing (spirometry and DLCO) – Repeat pulmonary function testing as indicated
	Modifiers: combined treatment, younger age	
Cardiomyopathy/ congestive heart failure	Anthracyclines (highest risk with cumulative dose $\geq$300 mg/m^2), high dose cyclophosphamide, radiation (heart)	– Yearly exam and history – Baseline echocardiogram – Interval echocardiograms determined by risk (every 1–5 years)
	Modifiers: combined treatment, younger age, female gender, obesity, pregnancy	
Blood-borne illness (Hepatitis B, C or HIV)	Transfusion of unscreened blood product	– Hepatitis B surface antigen and hepatitis B core antibody – Hepatitis C antibody – HIV 1 and 2 antibodies – Other as indicated
	Modifiers: living in hyperendemic area, other lifestyle high risk behaviors	
Impaired sexual maturation/function	Alkylating agents, radiation (craniospinal, pelvic, gonadal)	– Yearly exam for secondary sexual characteristics – Baseline evaluation (LH, FSH, estrodiol, testosterone) timing dependent on age and gender – Additional evaluations as indicated (semen analysis)
	Modifiers: combined treatment	
Secondary leukemia or myelodysplastic syndrome	Epipodophyllotoxins (etoposide), alkylating agents, anthracyclines	– Yearly CBC until 10 years from exposure
	Modifiers: older age, less than 5 years from exposure	
Neurocognitive deficits	Intrathecal chemotherapy, cranial radiation	– Baseline neuropsychological testing – Vigilance regarding educational and vocational progress
	Modifiers: combined treatment, female gender, younger age	
Renal/urinary	Cyclophosphamide, ifosfamide, cisplatin, radiation (abdomen/pelvis)	– Yearly blood pressure – Baseline BUN, creatinine, electrolytes and urinalysis – Follow-up as indicated for risk
	Modifiers: combined treatment, higher dose	
Growth	Cranial radiation or radiation to epiphyses of long bones	– Measurement of height and weight every 6 months until sexual maturity – Referral to endocrine for growth hormone evaluation if cross one percentile on growth curve
	Modifiers: younger age, higher radiation dose, surgery to the suprasellar region	

Table 357.2 (Continued)

Late effect	Therapy exposure	Screening recommendations
Musculoskeletal	Corticosteroids, high-dose methotrexate, radiation	– Encourage good calcium and vitamin D intake – Baseline bone density evaluation at maturity – Follow-up bone density evaluation as indicated
	Modifiers: combined treatment, older age, prolonged corticosteroids, growth hormone deficiency, hypogonadism	

[a]Screening recommendations taken from Children's Oncology Group Long-Term Follow-Up Guidelines for Survivors of Childhood, Adolescent, and Young Adult Cancers, www.survivorshipguidelines.org

from treatment can potentiate the cardiovascular risks including hypertension, obesity, dyslipidemia, and diabetes mellitus.

Screening for cardiovascular disease should include a yearly interview for symptoms of shortness of breath, dyspnea on exertion, orthopnea, chest pain, palpitations, and abdominal symptoms for younger patients. A complete physical exam should include careful evaluation of the heart for murmur, extra heart sounds (S3, S4 and increased P2), and pericardial rub and careful evaluation for signs of cardiac failure including rales, wheezes, jugular venous distention, and peripheral edema. Screening testing should include echocardiograms at intervals from every year to every five years depending on risk, a baseline EKG, and periodic fasting glucose and lipid profiles.

Genitourinary

Genitourinary late effects are generally related to specific chemotherapy agents or single kidney status after surgery. The chemotherapy agents with the most potent renal effects are cisplatin and ifosfamide. Both agents damage the ability of the kidney to filter efficiently. Cisplatin damages the distal renal tubule causing electrolyte wasting of magnesium, calcium, potassium, and sodium. Ifosfamide damages the proximal renal tubules causing wasting of potassium, phosphorus, glucose, protein, and bicarbonate (Fanconi's renal syndrome). Treatment with multiple chemotherapy agents increases risk, as does concomitant treatment with other nephrotoxic antibiotics or medications, radiation, or surgery. Children should be screened yearly with a blood pressure, creatinine, blood urea nitrogen, and chemistries, as well as urinalysis. Electrolyte replacement should be given to patients with ongoing wasting. Patients should be counseled to avoid further injury to the kidneys including avoiding nephrotoxic medications and injury to the remaining kidney (if single kidney status), and early treatment for hypertension and urinary tract infections.

Treatment with the chemotherapy agents, cyclophosphamide and ifosfamide, can cause hemorrhagic cystitis during treatment due to the accumulation of the toxic metabolite acrolein in the bladder. Bladder cancer can develop in patients who have received these agents or radiation to the pelvis. Yearly urinalysis should be done to evaluate for microscopic hematuria.

Musculoskeletal

Chemotherapy agents including corticosteroids and antimetabolite chemotherapy such as methotrexate can lead to musculoskeletal abnormalities, most notably osteoporosis or osteopenia which increase risk for future fracture. This risk is potentiated by the evidence that increasing proportions of the general population are calcium and vitamin-D deficient. In survivors of childhood cancer, these effects can also be increased due to treatment-related gonadal and growth-hormone deficiency, hyperthyroidism, chronic wasting of calcium and phosphorus due to treatment-related renal injury, and by increased body weight.

Another source of chemotherapy-related musculoskeletal damage is avascular necrosis (AVN) related to treatment with corticosteroids. AVN typically occurs during treatment but new cases can be diagnosed for many years after treatment. Clinically, children usually present with pain and limitation of activity. The large joints of the lower extremities, hip and knee, are most commonly affected, but AVN can occur in any bone.

Radiation to any bone or soft tissue can result in poor growth and tissue wasting which can contribute to the chemotherapy-related effects as well as producing effects in isolation. Children should be screened by interview yearly for symptoms of bone pain and a careful physical exam of all bones and tissues looking for asymmetry or decreased range

of motion. All children should be encouraged to maximize calcium and vitamin-D intake and possibly have vitamin-D levels measured in the blood. Medicines to increase bone density are not currently approved for use in children, except in extreme circumstances. Any bony abnormality or concern for AVN should be further evaluated by plain x-ray or MRI with referral for surgical intervention as indicated.

Sensory

Platinum-based chemotherapy agents can cause long term ototoxicity. The hearing loss is sensorineural loss, but may also manifest as tinnitus or vertigo. The risk of hearing loss is increased when treatment occurs before the age of 4 years and when chemotherapy is combined with radiation or other ototoxic agents such as aminoglycoside antibiotics or loop diuretics. Children who have risk for hearing loss should undergo yearly interview for symptoms of hearing difficulty, tinnitus or vertigo as well as a complete audiological evaluation to follow loss. There should also be an emphasis on preventing further injury including avoidance of loud noises, using ear protection where indicated and avoiding further exposure to ototoxic medications.

Some treatment regimens can result in visual impairment. Children treated with chemotherapy agents such as busulfan or long-term corticosteroids are at life-long risk for the development of cataracts. This risk is increased when radiation to the total body, brain, head, or orbit was also given. Corticosteroid treatment can also increase the risk for developing glaucoma. Radiation increases the risk of chronic dry eye (Sjogren's syndrome) due to effects on the lacrimal glands. Children who have risk for these complications should be screened through a collaborative effort between ophthalmology and the primary provider and early intervention should be considered for any visual disturbance with the ultimate goal of preserving vision.

Dental

Treatment regimens including chemotherapy and radiation therapy can cause damage to or loss of teeth. Chemotherapy agents can damage the enamel of the teeth leading to an increase in the number of dental caries a patient experiences. This damage is seen in the erupted teeth, as well as the unerupted teeth. High dose chemotherapy regimens can also lead to the loss or misalignment of the adult teeth if treatment was received at a young age. Radiation therapy contributes to dental damage if the salivary glands are in the field of radiation. Damage to the salivary glands causes a decrease in saliva production leading to chronic dry mouth. The saliva plays an important role in cleaning the mouth and a decrease in saliva potentiates the damage done by other agents. It is recommended that all patients receive regular dental evaluation every six months for preventative maintenance and early intervention for dental caries.

Growth and Development

Children show a significant decreased in linear growth during and after cancer therapy. Most often, this decrease is due to radiation therapy. Chemotherapy alone can lead to decreased growth velocity while on treatment, but this is usually temporary and children experience an increased linear growth velocity after treatment and often catch up to children of a similar age.

Radiation therapy can contribute to decreased linear growth in a number of ways. First, whole brain radiation can damage the hypothalamus or pituitary gland leading to short stature. Risk factors include increasing dose, greater than 18 Gy and younger age children (age less than 5 years) showing more damage. This is thought to occur due to growth hormone deficiency or disturbance in the gonadal axis leading to early closure of the epiphyseal growth plates. Radiation also decreases linear growth through a direct effect on bones including the spine and femoral heads. This direct inhibition can lead to impaired growth locally, sometimes resulting in asymmetric growth patterns (decreased sitting height, decreased leg length, etc.). These effects are seen at doses of 20 Gy to the epiphyses.

Children at risk for decreases in linear growth should be followed carefully. If possible, height should be measured at least twice yearly until sexual maturation is complete. An accurate height should be obtained and recorded on a standardized growth curve and followed for trends. If a patient has a risk factor and crosses percentiles or is less than the third percentile, early referral for an endocrine evaluation is recommended.

Neurocognitive Function

The effects of cranial radiation on neurocognitive functioning are well documented. There is evidence that some chemotherapeutic agents also have an impact on neurocognitive functioning. These agents include intrathecal chemotherapy such as intrathecal methotrexate, high-dose cytarabine, and high-dose methotrexate. A wide array of neurocognitive effects have been described and can vary as the patient ages. Vigilance is recommended with regard to academic performance and vocation. When possible and available, neuropsychological evaluation early in treatment

with repeat testing over time can inform intervention to help with deficits.

Fertility

Exposure to various chemotherapy agents and radiation in males produces gonadal dysfunction by damage to both the germ cells and leydig cells in the testicle, resulting in variable effects on spermatogenesis, testosterone production, and sexual function. As with males, exposure to chemotherapy and radiation produces impairment of gonadal function of the ovary in females. All chemotherapy agents are thought to pose some degree of risk but the largest risk is seen after treatment with the alkylating agents (cyclophosphamide, ifosfamide, procarbazine, etc.). These agents are commonly used for all cancers but notably for treatment of Hodgkin's lymphoma and solid tumors. Cumulative doses of cyclophosphamide greater than 7.5 g/m^2 are thought to greatly increase the risk for future infertility. Both the testicle and ovary are radiosensitive such that even low doses can impact function and radiation to the brain can interfere with the normal hypothalamic-pituitary-gonadal axis function, also resulting in impaired gonadal function.

There has been a focus on developing treatment regimens which limit the dosing of agents thought to have the highest impact on fertility outcomes, but this is not always possible. This has most notably been attempted in the treatment for Hodgkin's lymphoma. Other approaches are pretreatment fertility preservation techniques such as sperm cryopreservation for post-pubertal males and embryo cryopreservation for females with an identified partner and time to complete the in vitro fertilization process. Currently there are not good options for pre-pubertal males and females and females without identified partners.

Second Cancers

Longitudinal cohort studies of childhood cancer survivors from multiple countries have consistently demonstrated an increased risk of second cancers. This risk shows a steady increase with increasing time since completion of treatment. Treatment with chemotherapy agents can increase the risk for development of acute myelogenous leukemia or myelodysplatic syndromes. The chemotherapy agent, etoposide, appears to pose the greatest risk but this is seen with multiple categories of chemotherapy including the anthracyclines, alkylating agents, and the heavy metals. This risk appears to be greatest in the first 5 years from diagnosis and is thought to be virtually gone after 10 years. Screening recommendations include a yearly Complete Blood Count (CBC) for 10 years after treatment and follow-up for clinical symptoms.

The risk for other second cancers is mainly due to radiation exposure. There is increased risk for any skin cancer, soft tissue, or bone tumor in a previously irradiated field and this requires close monitoring for suspicious skin lesions and masses. In particular, radiation to the breast tissue increases the risk for development of breast cancer and this has been most notable in survivors of Hodgkin's lymphoma who underwent chest radiation. Women with a history of radiation to breast tissue should begin annual screening mammogram and/or breast MRI usually at the age of 25 years. Similarly, there is an increased risk of colorectal cancer in those patients who previously received radiation to the abdomen or pelvis and screening colonoscopy should begin usually at the age of 35 years. There should be a low threshold for investigation of any unusual mass or lesion in a previous radiation field.

Conclusion

As therapy improves for childhood cancer, there is a growing population of childhood cancer survivors at risk for late effects related to their treatment. Providers caring for these patients must be aware of these late effects and the screening recommendations to provide optimal care and prevent future morbidity and mortality.

Neurology

Generoso G. Gascon

358 Clinical Approach to Infants, Children, and Adolescents with Neurologic Problems

Generoso G. Gascon

Neurological symptoms comprise approximately 10% of presenting complaints to primary care practitioners, family medicine physicians, and general pediatricians. Generalists can manage these efficiently by developing a systematic approach. This chapter takes a developmental, age-related, symptom-oriented approach to evaluating and managing a child presenting with neurologic complaints. Detailed treatment and management of specific disease entities mentioned in this introductory chapter is covered in the subsequent chapters.

The clinical approach needs to be flexible, depending on the age of the patient, and the informants giving the history. The setting, whether it is the normal newborn nursery, neonatal or pediatric intensive care unit, the emergency room, the hospital clinic or private office determines the pace and sequence of different parts of history taking and the neurological examination. A complete history and neurological examination need not be done in the first encounter. A focused neurological exam, sufficient enough to make an acute management decision, whether diagnostic or therapeutic, is appropriate for an acute triage situation, such as the emergency room. The presenting problem, whether acute or chronic, and the setting also influence the amount of time spent explaining the working diagnosis and management plan, as well as that spent on educating and counseling patients and families.

In this chapter the developmental ages introduced are arbitrarily divided into:

The neonate
The infant and toddler
The preschool child
Elementary school child
The middle school child
The high school child and adolescent

Clinical Approach to the Newborn with Neurological Problems

The most common acute neonatal neurological symptoms in the neonatal intensive care unit (NICU) are seizures, with or without impaired sensorium, qualifying as encephalopathy. The most common etiologies are hypoxia and/or ischemia, infection, stroke, metabolic abnormalities (hypoglycemia, hypocalcemia). Less common are metabolic diseases like aminoacidurias (maple syrup urine disease), organic acidurias (methylmalonic and propionic aciduras), and urea cycle and fatty acid oxidation disorders. Rarely, genetic epilepsies (benign familial neonatal convulsions) present in the newborn period.

In the normal newborn nursery, the common problems for which neurological consultation is sought are brachial plexus palsy (Erb's), and various involuntary movements that mimic seizures, such as benign familial neonatal myoclonus, benign nocturnal myoclonus, jitteriness, abstinence syndromes, or phasic movements normally seen in active (rapid eye movement [REM]) sleep.

History and examination of the newborn are covered in detail in the Chaps. 360, "Neonatal Neurological Disorders" and 361, "Neonatal Seizures".

History in the NICU is most commonly obtained from the bedside nurses, though the neonatologist poses the question. Parents need to be queried for the prenatal and perinatal history, and family history. One symptom, seizures, is highlighted here.

Seizures. The first important decision is to decide whether the events observed are, in fact, seizures. If so, the next decision is to classify the seizures, whether only of one kind, such as focal motor, or of many different kinds, such as focal clonic, myoclonic, focal onset but migrating, or subtle seizures. This can be done by retrospective history from the observing nurses or parents, or prospective

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_358,

observation using seizure charts. In tertiary care centers that have the technology and neurological expertise, the gold standard is continuous video-EEG monitoring.

Classifying seizures has a practical aspect. Focal clonic seizures bode, generally, for a good prognosis, because focal clonic seizures are often secondary to a transient metabolic abnormality, such as hypocalcemia. Myoclonic and subtle seizures bode for a guarded prognosis since they are usually due to hypoxia-ischemia, neurometabolic disease or brain dysgenesis.

For those working in secondary or tertiary care centers, having a once yearly teaching session with nurses on the classification of neonatal seizures, using videotapes of such seizures, if available, would be a good practice for obtaining consistent and accurate observations. Bedside nurses and nurse practitioners should be sensitized to the onset, progression of movements, whether there is more than one kind of seizure, duration, and postictal findings.

Neurological Examination

In the *general physical examination*, most important for neurology are size and shape of the head and dysmorphic features. The tape measure surrounds the head from the occipital protuberance to the forehead. Head circumference is plotted on a standard growth chart. Recognizing dysmorphic facial features may, by itself, make a diagnosis; for example, Down syndrome, Zellweger syndrome (see Genetics section and chapters).

The *mental status* exam in the newborn is essentially a determination of the level of consciousness or sleep state and general responsiveness. In a two to three-day full term infant, parts of the Brazelton neonatal assessment exam can be applied, in a clinical fashion.

Cranial nerve examination. The most important functions to determine immediately are vision (C.N. II) and hearing (C.N. VIII); then, the muscles necessary for sucking and swallowing (motor V, VII, IX, X, XII).

Motor examination. The most reliable motor exam is performed while the neonate is in Brazelton State 4. States 1 and 2 are sleep states (active and quiet sleep). State 3 is drowsiness-arousal. State 4 is awake, relaxed, and alert. State 5 is awake and active. State 6 is awake, active, and crying.

Developmental reflexes. The most important newborn developmental reflex is the Moro. It is best elicited by cradling the newborn in the horizontal supine position, with one hand under head, then suddenly letting the head drop in neck extension. There are two parts to the Moro: initial abduction and extension, then adduction and flexion, of the arms. One looks for its presence or absence. If present, any asymmetry is noted, then that suggests a hemi-syndrome.

The asymmetric tonic neck reflex (ATNR) is not normally present in the newborn, but is usually seen between 2 and 6 months of age. If present, it is abnormal because it is too obligatory. Other developmental reflexes that should be present, and best elicited about the third day of life after the neonate has "recovered" from the trauma of birth, are the grasp and traction responses, elicited by the pull-to-sit maneuver, watching also for excessive head lag. Plantar grasps are elicited by pushing the thumb into the balls of the feet and watching the toes flex. Placing and stepping reactions are elicited by holding the infant in the vertical suspension position and brushing the dorsum of the feet up against the examining bed. Automatic walking is elicited by holding the newborn upright, then pulling forward with the infant leaning forward, letting the toes brush the examining bed.

One sign, hypotonia, is highlighted here.

Hypotonia may occur with or without weakness, may be variable according to state, and may even coexist with increased tone (for example, axial hypotonia with appendicular spasticity). Central hypotonia must be distinguished from peripheral/neuromuscular causes. Weakness may be lateralized (as in a hemiplegia), or localized (as in a brachial plexus palsy, or congenital absence of the depressor anguli oris). Weakness may be bilateral and localized, as in Moebius syndrome (bilateral peripheral facial palsies).

Generalized profound hypotonia is seen in some metabolic diseases (peroxisomal disorders like Zellweger's, aminoacidurias like non-ketotic hyperglycinemia (NKH)). Neuromuscular diseases like congenital myotonic dystrophy, congenital myasthenia, and congenital myopathies, present in the newborn period with hypotonia, and definite weakness. CAVEAT: Some diseases have both brain and muscular involvement, such as mitochondrial disorders, and rare congenital muscular dystrophies (Fukuyama, muscle-eye-brain disease).

Ancillary Investigations

In many hospitals in the USA and around the world, newborn screening for treatable congenital metabolic diseases by sending blood spots for tandem mass spectroscopy, usually in regional laboratories, and other blood tests (thyroid) is now being done. This is an enormous advance in the prevention and early treatment of otherwise crippling and disabling diseases (see ❯ Chap. 38, "Disorders of Organic Acid and Amino Acid Metabolism").

Continuous video-EEG monitoring is the gold standard not only for diagnosis, but also to follow results of

treatment, in neonatal seizures, since clinical-EEG dissociation is not uncommon in neonatal seizures.

Doppler ultrasound is noninvasive and portable, and is particularly useful for intracranial hemorrhages and conditions which change ventricular size. CT brain adds gray-white matter differentiation, with higher resolution than ultrasound, and fast acquisition speed. CT angiography has increasing utility in stroke. MRI, with its various sequences–FLAIR, DWI, along with its permutations–MRS, MRV, and MRA, gives the highest resolution, visualizes the brainstem, and has the advantage of being repeatable without exposing the infant to radiation. Neuroimaging in hypoxic ischemic encephalopathy is discussed in detail in the Chap. 360, "Neonatal Neurological Disorders".

Infant and Toddler (Up to 3 Years of Age)

The general approach to history taking in the infant and toddler with a neurological problem is to elicit a prenatal and perinatal history that might point to possible brain damaging events, an interval history since birth for acquired brain damaging events, and a family history that might point to genetic or familial conditions. The examination is both a neurodevelopmental assessment as well as a neurological examination (see Chap. 42, "Normal Child Development").

Milestones: The two most important milestones that physicians can determine just from history and examination are motor and speech/language. Infants should be rolling over by 4 months, sitting alone by 6 months, reaching out at 6 months, and walking alone by 14 months. A shovel grasp is followed by a pincer grasp by the early second year.

Regarding speech, babies should be cooing at 3 months, interactive babbling till 7–8 months, consonant-vowel combinations, like "da-da" by 8–9 months, single words by 16 months, short sentences by 24 months. Conditioning games such as waving bye-bye, "peek-a-boo," clapping hands occur around 12 months. Putting blocks into a 3-hole form board is usually achieved by 18 months. However, these milestones may be achieved at different times in cultures with infant-raising practices different from that of North America (see Chap. 49, "Global Perspectives on Child Development and Behavior").

Examination

In this age group, the exam needs to seem like play in order to establish rapport. The least invasive items, such as testing the teloreceptors (hearing and vision) should be done first. Examination items that require actual handling of the baby—muscle tone (pull-to-sit maneuver), deep tendon reflexes, and the developmental reflexes should be done last.

Measuring head circumference and looking at the shape of the head is mandatory. Nowadays, with the standard of practice being to advise mothers to lay infants supine to lessen the risk of sudden infant death syndrome (SIDS), the incidence of positional plagiocephaly, flattening of the skull posteriorly, is increasing. This needs to be recognized early, since molding helmets are not effective after the sutures have fused, after about 8 months of age. Microcephaly and macrocephaly usually requires that the head circumference be two standard deviations above or below the mean expected for that age. Another clinical guideline would be whether there is a 50 percentile difference between head circumference and length or weight. In babies with enlarged heads, and in geographic areas where CT head scans are not easily available, percussing the skull and listening for a "cracked pot" sign due to split sutures can still be useful. Auscultating for bruits, using the bell portion of a stethoscope, over the orbits and the skull may detect vein of Galen malformations or large arteriovenous malformations.

Of the four items of classical physical diagnosis, observation, palpation, percussion, and auscultation, observation is the most important at this age. Observations include the interrelatedness between the baby and parents and the baby and the examiner, degree of eye contact, presence of spontaneous speech, and nonverbal communication (pointing, gestures) in toddlers who have delayed speech.

General: Specific parts in the general physical examination that may suggest neurological disease are the skin, looking for neurocutaneous stigmata, and the abdominal exam, looking for hepatosplenomegaly.

Occasional café-au-lait spots are fairly common, but six or more should raise suspicion for neurofibromatosis Type I, in which case parents' skin should be examined. Ultraviolet light by a Wood's lamp can bring out the vitiliginous or hypopigmented spots of tuberous sclerosis, particularly in light-skinned patients. Hepatosplenomegaly would raise the possibility of a storage disease (see Chap. 39, "Lysosomal Storage Diseases").

When a toy is held before the child, one can watch to see if only one hand reaches out, suggesting hemiparesis, and whether tremor is present. In observing crawling, a hemiparesis is suggested if the infant pulls forward using only one side of the body. Walking on tiptoes suggests a spastic diparesis, muscular dystrophy involving calf muscles, or autism.

Cranial nerves: Infants are more likely to follow visually interesting objects, such as the distorted human face, finger puppets, or rotating concentric circles, such as pinwheels. Similarly, hearing behavior can be elicited with a bell, a clacker, or toys that reproduce animal sounds. Infants turn their head toward sound at 6 months. Prior to that they may merely become still and have an alert, listening facial expression.

Developmental reflexes: The ATNR, elicited by turning the head of the supine infant to one side, appears about 2 months and should disappear completely by 6 months. The ATNR begins to recede at 4 months, when the body-righting reflex replaces it. At 6 months, the infant is transitioning from the reflexes of a quadripedal animal, to that of a bipedal animal who stands on two legs in the upright position.

The first bipedal reflexes appear at 6 months. If the infant in the sitting position is suddenly pushed backward, the legs should kick out; if the infant is pushed sideways to either side, the arms should thrust out sideward. The parachute response appears at 8 months. It is elicited by holding the infant at the chest, face down, and propelling toward the examining table. Both arms should suddenly thrust forward (as if to break a fall) at the same time. This is a good reflex to observe any asymmetries that suggest hemiparesis. Proximal weakness at the shoulder girdle can be determined by leaving the child momentarily in the resulting wheelbarrow position, and see if the baby can bear its weight, temporarily.

Common Problems

Common problems in the infant and toddler are:

1. Delayed development.
2. Seizures. The most severe epilepsy syndromes are infantile spasms; Lennox-Gastaut; and infantile myoclonic epilepsies. The most common seizure disorder, however, is febrile seizures (see ❯ Chaps. 361, "Neonatal Seizures" and ❯ 362, "Epilepsy in Infancy and Childhood").
3. Breath-holding spells (see ❯ Chaps. 361, "Neonatal Seizures" and ❯ 362, "Epilepsy in Infancy and Childhood").
4. Movement disorders. Most common are transient tics, dystonic-like postures secondary to gastroesophageal reflux, similar to Sandifer syndrome (see ❯ Chap. 363, "Movement Disorders").
5. Sleep-related rhythmic movement disturbances (head-banging, tremors upon awakening, shuddering attacks), parasomnias (night terrors at age 3) (see ❯ Chap. 364, "Sleep and Its Disorders in Childhood").

Delayed development. (For the perspective of developmental pediatricians, see ❯ Chap. 42, "Normal Child Development", and Nancy Lamphear, Disorders of Learning and Attention.) The physician must distinguish between global developmental delay and specific developmental delay. Global usually means in two or more domains, usually specified as motor, language, social, and adaptive. When the etiology is neurological, delayed motor development, most commonly, has a cerebral cause, the most important of which is cerebral palsy–atonic in infancy, which may evolve into diplegic, hemiplegic, or choreoathetotic. Motor developmental arrest and/or deterioration, with relative preservation of mental functions, point to neuromuscular conditions such as spinal muscular atrophy, muscular dystrophy, or congenital myopathies.

Delayed language development, with preservation of motor function, intact hearing, and normal intelligence, may signify a developmental language disorder (developmental dysphasia). Delayed language may also suggest an autistic spectrum disorder, particularly if there is language regression in the second year of life. Language regression may also occur in rare conditions like the Landau-Kleffner syndrome and Continuous Spike Waves in Slow Wave Sleep (CSWSS).

At some point, usually in the preschool years, if an infant who is globally delayed shows no evidence of catching up to a normal developmental curve, mental retardation, mild, moderate, or severe needs to be considered. Although the Bayley Infant Scales are used by psychologists, formal IQ testing does not begin to be reliable until the preschool age, when the Wechsler Pre-Primary Scale for Children (WPPSI) is available. However, the primary care physician can approximate IQ, using the concept of DQ (developmental quotient). The formula is:

$$\text{DQ} = \text{developmental age}/\text{chronological age} \times 100.$$

For example, if an infant is 12 months old, and has the first bipedal reflexes and is just beginning to sit unsupported (6 month developmental milestones), the motor DQ is $6/12 \times 100$, or 50 (on borderline between moderate to mildly delayed, if parallel to IQ). This should lead to a recommendation for infant stimulation programs.

Because of the reported worldwide increase in prevalence of the autistic spectrum disorders, autism needs to be distinguished from mental retardation. The American Academy of Pediatrics, in its July, 2006 policy statement, recognizes the benefits of early detection. It recommends developmental screening at 9, 18, 24, and 30 months.

Table 358.1
Absolute indications for diagnostic referral for autism

No babbling by 12 months
No gesturing (pointing, wave bye-bye) by 12 months
No single words by 16 months
No 2 word spontaneous phrases (not echolalia) by 24 months
Loss of ANY language or social skills

There is some controversy about what constitutes quality screens, although the Denver Developmental Screening Tests are commonly used in practice. In the state of Massachusetts, screening for autism is mandated at 18 months, with a choice of various standardized screens, although the M-CHAT is probably the most widely used (Table 358.1).

The "Parents' Evaluations of Developmental Status (PEDS)" is a screening questionnaire that can be easily completed by parents in a few minutes in the waiting room. Printed in English, Spanish, and Vietnamese, additional translations like Hmong, Somali, Russian, Chinese, Thai, etc, can be licensed by e-mailing the publisher. The online application also offers the Modified Checklist of Autism in Toddlers (M-CHAT), automated scoring and ICD-9 codes.

Developmental screens requiring direct elicitation of children's skills are the Bayley Infant Neurodevelopmental Screener (BINS), the Brigance Screens II, and the Battelle Developmental Inventory Screening Test (BDIST), 2nd edition. Busy pediatricians rarely have the time to administer these, so in practice, they are most often administered by psychologists, although office personnel such as nurses, nurse practitioners, and probably even medical assistants could probably be trained to do these. Internationally, for validity and reliability, screens like these, and, I.Q. tests for later ages, should be standardized for language and culture.

In the USA, pediatricians can refer infants with developmental delays for publicly funded Early Intervention services, where developmental specialists, physical and occupational therapists, speech and language therapists provide services in the home, up to the age of 3 years. After the age of 3, if delays have not resolved, children are eligible for early education services in the public schools, where individual education plans (IEPs) are made and carried out. These services are a resource for pediatricians, as well as sources for obtaining up to date ongoing observations of developmental progress.

Developmental regression should always bring up the possibility of a progressive encephalopathy, discussed in detail in the chapter by G. Gascon.

The Preschool Child (3–6 Year Olds)

The approach to history taking is to listen carefully to the concerns of parents, other caretakers in the home, and elicit histories, when appropriate, from day care workers or preschool teachers. If complaints are unfocused, the physician's task is to help the historians clarify their concerns and priorities. The initial explicit chief complaint may mask underlying implicit concerns that are not verbalized, for fear that the child may have something viewed as devastating, such as mental retardation or autism.

The common problems at this age are global and specific developmental delays, febrile seizures and breath holding spells, and behavioral problems, from high functioning autistic spectrum disorders, to disruptive behavioral disorders, which may present first with hyperactivity and impulsivity (Attention Deficit Hyperactivity Disorder [ADHD] plus). The term "sensory integration problems" is not a diagnosis by itself, but is seen in different disorders such as autism or in children with obsessive-compulsive traits or disorder.

With video capabilities practically universal in cell phones and digital cameras, parents can help, in questions of seizures or abnormal involuntary movements, by recording the events. Having them keep sleep logs can establish a baseline, as well as help in diagnosis (see Chap. 364, "Sleep and Its Disorders in Childhood").

Asking children what television shows they watch, and asking them to name favorite characters, asking parents whether the child pays attention and follows the story lines, laughs at the appropriate situations, and a sense of humor can reveal intelligence.

Asking about how well the child plays with playground equipment, such as swings, slides, and jungle gyms, as well as when the child was able to ride a tricycle and a bicycle can give a good idea about motor coordination. How complicated a puzzle the child can manage tells something about visual perceptual motor skills. Asking about favorite toys and how the child plays with them and with other children can give an idea of rigidity, imagination, symbolic play, and development of parallel versus interactive play.

Accident proneness and sleep difficulties in this age group, particularly difficulty falling asleep after going to bed (increased sleep latency), are not uncommon antecedents of ADHD.

Finally detailed family histories and drawing a three generation family pedigree, looking not only for single gene disorders, but also paroxysmal and neuropsychiatric disorders, should be routine.

Neurological Examination

At this age one still approaches the examination in the office as if it is play. Having toys in the examining room appropriate for this developmental age helps, for example, puzzles, form boards for visual perceptual motor and fine motor coordination; cars, trains, dolls, a doll house if space warrants for imaginative play; large balls for general motor coordination. These reinforce the ambience of a child-friendly environment, put the child at ease, and enhance cooperation in the more formal parts of the neurological examination performed later.

Much can be learned from observing the child with these toys, while obtaining the history from the parents. Special attention to speech and language is important, to distinguish developmental articulation problems from developmental language disorders and the characteristic disorders of pragmatics in the language of high functioning autistic children. Whether they can remember words while singing and keep in tune should be noted. Universal songs, like the "Happy Birthday" song, are part of the repertoire.

The simplest pre-academic readiness skills to predict early literacy skills is the ability to name colors and letters of the alphabet., which nowadays is usually achieved before kindergarten. By then most middle class children have book awareness, having been exposed to books being read to them by parents, and some early phonics.

In pre-academic math skills, one to one correspondence, that is, the ability to match numbers to objects (one sock to one shoe), counting from one to ten, and understanding of measurement, length and weight, big and small, and some elementary understanding of money predict acquisition of elementary mathematics.

Visual perceptual motor skills can be tested by having the child copy shapes–circle (age 3), distinguishing + and x (cross from x) (age 4), triangle (age 5), square (age 6), diamond (age 7), British flag (age 8). Another way is putting together and taking apart constructional toys, like Legos and building blocks. Spatial relations. Up/down, in front of/behind, over/under.

In gross motor testing, children should be able to stand on one foot for a few seconds, and then hop in place for a few hops, at 4 years. They should be able to kick a soccer ball. Throwing a small ball like a baseball may still not be accurate. Preferred handedness and footedness should be noted.

Common Problems

Global Developmental Delay

Global developmental delay is taken to mean delay in at least two of the four usual domains–motor, language, social, and adaptive. In the preschool child, persisting global developmental delays since infancy would warrant etiological investigation for mental retardation or autism, if not previously done.

The American Academy of Neurology has published a practice parameter with an algorithm on how to proceed stepwise. Nonsyndromic mental retardation, characterized by the absence of associated morphologic, radiologic, or metabolic features, comprises the majority of cases. The genetic factors underlying nonsyndromic MR are not presently understood. The present standard of care, therefore, is to order the highest resolution chromosome studies available, chromosomal microarrays. Since Fragile-X Syndrome accounts for a significant fraction of MR and the characteristic morphological features are not obvious at this age, fragile-x gene studies are recommended.

As of early 2009, linkage and cytogenetic analyses have identified 29 X-linked and five autosomal recessive genes associated with nonsyndromic mental retardation, which account, however, for less than 10% of cases. Autosomal dominant genes have yet to be identified. However, *de novo* chromosomal rearrangements, usually involving a change in copy number of genomic regions, are the most commonly recognized cause of mental retardation. This suggests that monoallelic lesions are sufficient to cause MR, and therefore raises the possibility that *de novo* genetic lesions, such as point mutations, may explain a number of cases of MR. Nonsyndromic MR is not amenable to linkage or association approaches, and therefore relies on the sequencing of candidate genes. The hypothesis that *de novo* mutations of autosomal genes, involved in synaptic plasticity, recently found support in the discovery of mutations in SYNGAP1.

Specific Developmental Delay

Specific developmental delays are delays in one domain only. When two, or more, domains are involved, however, the question arises on whether these are independent, comorbid specific delays, rather than global developmental delay, which often implies cognitive subnormality.

For example, specific delays in language, that is, developmental language disorders, may be comorbid with

ADHD, or visual-perceptual motor difficulties, or excessive incoordination (developmental coordination disorder), in a cognitively normal child. Language delay must be distinguished from language regression, the loss of previously acquired speech and language. The differential diagnosis then includes progressive encephalopathy, autistic regression, Landau-Kleffer syndrome or Continuous Spike Waves in Slow Wave Sleep (CSWSS).

In the motor sphere, arrest and regression, as in the dystrophinopathies (Duchenne-Becker muscular dystrophy), need to be distinguished from just delay, as in spastic diparesis due to nonprogressive encephalopathies (cerebral palsy).

Behavioral Problems

Behavioral issues, like persisting temper tantrums, sleep issues like parasomnias, and hyperactivity always bring up the question as to whether these are still within the wide variation of normal behavior at this age, or whether they are at risk behaviors for other disorders. The child with disruptive behavior may just be having prolonged "terrible two's," but then again, may be exhibiting the beginnings of an oppositional-defiant disorder.

Incessant hyperactivity and impulsivity, excessive tantrums, more than the terrible two's, irritability, easy to anger yet repentant and overly loving afterward, cruelty to pets, hitting out to peers in day care, rapid mood swings, sometimes multiple in a day, suggest a severe disorder of mood regulation in the bipolar spectrum. However, one should make this diagnosis with caution, in the absence of a family history of bipolar disorder.

Higher functioning autistic disorders, like pervasive developmental disorder not otherwise specified (PDD. NOS), may have escaped detection before the age of three, but should not be missed in the preschool child. These two disorders – autism and childhood bipolar disorder, parallel the two poles of mental illness in adolescents and adults, schizophrenia and affective disorders (depression, bipolar disorder).

Paroxysmal Disorders (See Gaitanis Chapter)

The most common paroxysmal disorders in the preschool age group are febrile seizures and breath holding spells (BHS). Assuming that seizures with fever are not symptomatic of a CNS infection like meningitis or encephalitis, and they are not focal in onset, they would be classified as simple febrile seizures. However, they may be an expression of a familial genetic syndrome, generalized epilepsy febrile seizures plus, if there are other members of the family with febrile seizures and generalized epilepsies. Fortunately, response to antiepileptic medications for generalized seizures is very good.

The course needs to be watched, however, because, rarely, myoclonic and non-febrile generalized convulsions may follow febrile seizures, simple or complex, with developmental arrest, and evolution into the syndrome of severe myoclonic epilepsy (SME, Dravet syndrome).

This is also the age where the two most common benign epilepsies of childhood may begin, benign Rolandic epilepsy and benign occipital epilepsy (the Gastaut type).

BHS are either cyanotic (blue type), where the child cries so hard, often stimulated by denial of something she/he wants, that they turn blue, hold their breath, and then go limp. Pallid syncope (the pale type) usually occurs after sudden, unexpected painful stimuli, such as hitting the head, or stubbing a toe, where the child turns white, then falls limp. Sometimes tonic stiffening occurs, but this is usually an anoxic seizure, caused by temporary ischemia of the brain stem, mimicking "brain stem fits." Rarely does a convulsive seizure occur after a breath-holding episode, and the coexistence of both must be considered.

Screens

The same screening tests mentioned in the previous section (0–3 years old), except for the Bayley Infant Neurodevelopmental Screen, are still applicable as developmental screening tests for the preschool child (age 3–6 years).

Elementary School Child (KG Through 3rd Grade)

At this age many children are able to describe their symptoms. So, to establish rapport with the child, start with the child. Greet the child first, start with some easy banter (Whose idea was it that you come to see me? How's school?) This emphasizes that they are the center of attention, even though much of the rest of the visit may be eliciting history from the parents, and later giving information and counseling. Determine whether the child's chief concerns are the same as the parents. This gives some idea of their awareness of the presenting complaint.

In the examination, starting off with gross motor activities often loosens up the patient. Ordinary walking,

walking on tiptoes, heels, side of the feet, hopping on one foot, walking tandem, also doubles as an initial screening exam, looking for hemisyndromes and general coordination. Starting right off with mental status questions may intimidate the child and should be left till later when the child is at ease.

Common Problems

Problems often presenting for the first time at this age are absence seizures versus nonepileptic staring, tics, headaches, and learning and behavioral disorders.

Attention Deficit Hyperactivity Disorder (ADHD)

History-taking in ADHD focuses first on eliciting a history of the four major symptoms–short attention span, distractibility, impulsivity and hyperactivity, and determining whether they occur in two different environments, usually home and school and whether such behavior occurs in social settings (family gatherings, playground, play dates, and organized sports activities). Whether these are occurring in the physician's office requires observation of the child while taking a history from the parents, and watching how the child responds to commands during the physical/neurological exam. Do you have to repeat commands (inattention)? Does the child start to respond before you finish giving a command (impulsivity)? Does the child interrupt the doctor-parent conversation inappropriately (verbal impulsivity)? Does the child wander around the room touching things inappropriately (hyperactivity)?

There are questionnaires which can be filled out by parents before a physicians' visit, but some, like the Vanderbilt parent and teacher assessment scales, are proprietary and take time for the primary care physician to score. A common one used by schools in the USA is the Conners rating scales, which may come already scored to the physician, if the school is the instigator for the referral.

Special examinations looking for minor neurological dysfunction ("soft sign exams") again usually take more time than a busy pediatrician has, if he/she has not been trained in such exams, and interpretation depends on experience, and is best left to subspecialists (like developmental pediatricians, pediatric neurologists, or developmental neuropsychiatrists).

Headaches (See Ken Mack chapter)

The PedMIDAS (Pediatric Migraine Disability Scale) questionnaire, filled out by parents or patients prior to a visit, will cut down history-taking time, since it asks about frequency and severity of headaches, and degree of disability, as manifested by days missed going to school or other social or sports events.

In history taking the temporal profile of a headache distinguishes between two major patterns; that of a typical migraine attack (rapid rise, slower resolution, over hours), and that of tension-type headaches (low grade waxing and waning). At this age, however, recurrent headaches are almost always migraine-vascular.

If a verbal description of a visual aura is unclear, the child can be asked to draw it, using colored pencils or crayons, on a plain sheet of white paper. Children find it difficult to describe the quality of the headache pain. Nonverbal clues – milking hands or pounding fists that connote a throbbing or pulsating quality help. Another tactic is to give the child multiple choices – squeezing, bursting, sharp and stabbing, throbbing or pounding.

Learning Disorders

By third grade, learning disabilities should be evident – in reading (dyslexia) or arithmetic (dyscalculia). A specific learning disability is a marked delay in the acquisition of basic academic skills (reading, writing, arithmetic) despite normal intelligence, adequate hearing and vision, and adequate teaching. Operationally, schools usually use the criteria of, for example, reading level 2 years below grade level (see Nancy Lamphear, Disorders of Learning and Attention).

Neurobehavioral Disorders

The primary care physician can be aided in suspecting these conditions by using rating scales, such as:

Vanderbilt Parent and Teacher Assessment Questionnaires (ADHD, Oppositional Defiant Disorder, Conduct Disorder, Anxiety, Depression)
PARS (Pediatric Anxiety Rating Scale)
YMRS (Young Mania Rating Scale), for bipolar spectrum disorders
YBOCS (Yale-Brown Obsessive Compulsive Scale), children's version
Weinberg Affective Scale, for depression
Australian Asperger Scale, for Asperger's Disorder

Epilepsy

Common epilepsy syndromes apt to occur at this age are primary generalized absence seizures (Petit Mal Epilepsy) and benign Rolandic epilepsy. Non-epileptic staring, usually in children with attention deficit disorders are often mistaken by school personnel for absence seizures. Absence seizures can often be elicited in the office by having the child hyperventilate for at least 1 min One can determine that there is loss of consciousness by reciting a nursery rhyme ("one, two buckle my shoe, three, four, shut the door," etc.) and asking the child what she recalls hearing, if anything. Both of these epilepsy syndromes have characteristic epileptiform EEG patterns – synchronous and symmetrical three cycles per second spike waves in absence seizures, and sharp waves or spikes in the central-temporal areas that are sleep-activated.

For any kind of seizure syndrome, the use of seizure calendars which log seizure type and frequency, are a useful management tool.

The Middle School Child (4th Through 7th Grades)

At this age, children can give histories and usually cooperate with a formal neurological exam.

Common Office Problems

1. ADHD, inattentive subtype (attention deficit disorder without hyperactivity)
2. Migraine, and its variants
3. Syncope
4. Neuropsychiatric disorders – anxiety, OCD, Asperger's disorder

ADHD, Inattentive Subtype

This syndrome usually does not come to the attention of teachers until the middle school years. It affects girls more than boys and often presents as "underachieving for their potential" or "reading comprehension" difficulties, when there has been no earlier dyslexic difficulties. Executive function deficits become more evident. Executive skills are mediated through the frontal lobe, the last part of the brain to fully develop, and their deficits appear in middle school because of the requirement for more planning and organizational skills. It shows up in deficient homework management, low grades because of not handing in book reports, theme papers, or science projects on time. Medications alone do not correct executive dysfunction. Some schools recognize this by offering organizational skills training classes, but many children need daily monitoring at school and at home. Behavior management techniques, that is, the use of reward and punishment, are not effective. Executive function skills have to be taught.

Migraine and Variants

Idiopathic stabbing headaches, also called "ice pick headaches" or "indomethacin responsive headaches" can be missed, because they present as head pains more than headaches. Acute confusional migraine tends to occur around puberty and early adolescence. Headache calendars, which log frequency, severity, presence of triggers, and results of medication can clarify history taking.

Neuropsychiatric Disorders

Asperger's disorder may not be diagnosed until this period when the magnitude of social skills deficits becomes recognized. Delay in diagnosis is often due to the high I.Q.'s these children have. Parents commonly say "he has no friends," is considered weird, has "off the wall" conversational talk, and highly focused interests. Guidance counselors and school psychologists may offer social skills training classes.

Anxiety disorders, obsessive-compulsive disorder (OCD) may also become evident, if disruptive behavior is a symptom. Children with suspected neuropsychiatric disorders usually take too much time to be handled well by primary care physicians, and should, therefore, be referred to developmental pediatricians, pediatric neurologists with interest in behavioral neurology, or child and adolescent psychiatrists.

Tics which may have been minor may now become more prominent and evoke secondary emotional reactions. More likely, the highly associated disorders are apt to emerge as obstacles in school performance; particularly ADHD, but also OCD.

High School and Adolescents

As much as possible, histories should be obtained by talking directly with adolescents alone, separate from the parents. This immediately establishes that they are the focus of attention, not their parents, but also conveys

to them their responsibility for managing their condition. One has to judge the capacity to introspect, and therefore, the reliability of their views. Parents can be called in later, prior to performing the neurological exam, to hear "their side of the story."

A characteristic adolescent issue is sleep. A detailed review of systems checklist filled out before the office visit can insure that the primary care physician does not miss an issue like sleep, which may not be the initial chief complaint. A complaint of fatigue or ADHD-like symptoms affecting school performance might be traced to sleep deprivation.

Another characteristic issue with adolescents is compliance – in keeping headache, seizure, or sleep logs, or even doctor's appointments, as well as in taking medication. The motivation to keep a driver's license can be used to insure compliance with taking antiepileptic medication.

Substance abuse, particularly alcohol, can be the reason for a variety of neurological symptoms, and should be inquired about in the history.

In the neurological examination, at this age a good adult type mental status examination can be done, testing orientation; immediate, short-term, and long-term memory, digit span forward and backward, serial-7 subtractions from 100, a three word retention test, interpretation of proverbs, and general information. Adolescents are also able to fully cooperate in detailed muscle testing.

Common Problems

Head Trauma – Concussions (See Chapter by Tsze and Chun)

With children and adolescents participating more and more in recreational and competitive contact sports such as football (both American and soccer), basketball, ice hockey, and lacrosse, the long-term consequences of repeated concussions has emerged as a major concern. Return to play guidelines have been changing over the years, starting with the Cantu concussion grading schemes and two subsequent international modifications, to the relatively recent use of guidelines for trainers to use on the field at the time of the accident, then on the sidelines, and then the use of ImPACT (immediate post-concussion assessment and cognitive testing). ImPACT is a computer administered neuropsychological test battery, originated at the University of Pittsburgh that measures aspects of attention, memory, reaction time, and processing speed. Athletes are not returned to play until testing has returned to their baseline, obtained at the start of the season. Even then, return to play involves a gradual return, from light aerobic, full aerobic, light contact, to full contact participation.

Chronic Daily Headache syndrome (See Chapter by Ken Mack)

A majority, about 60%, are due to transformed migraine. The rest is due to tension-type headaches, or a mixture of migraine and tension-type. Emotional factors may be present – anxiety, depression. Medication overuse may have contributed to the formation of this pattern. It is defined as headaches occurring at least 15 days out of 30, for at least 3 months. The primary care physician needs to recognize this syndrome early because it is very difficult to break and warrants referral to a neurologist or specialty headache clinic.

The most common complicated migraine syndrome at this age is the basilar migraine syndrome, commonly affecting mid-teenage females. The other occurring in puberty or early adolescence is acute confusional migraine.

Special headache examination

1. Tap over frontal, maxillary, ethmoid sinuses, for acute sinusitis.
2. Examine for possible cranio-cervical junction problems. Hold a palm on the head, then pound slightly on the palm with the other fist. Ask for any pain when testing face-turning (sternocleidomastoid) and trapezius against resistance. Check for a Lhermitte Sign.
3. Palpate occipitalis and frontalis muscles for isometric contraction, as in muscle contraction (tension-type) headaches.
4. Have patient keep jaw open, while trying to close, or push from either side for temporal-mandibular joint problems.
5. Check the fundus, looking primarily for papilledema, as in pseudotumor cerebri.

Syncope

Vasovagal syncope is the most common cause. There is often a history of breath holding spells in early childhood, a family history of syncope, and of migraine. What they have in common is they are all disorders of neurovascular instability. Cardiac syncope, due, for example, to the Long Q-T syndrome, will require an EKG and pediatric cardiology consultation. Orthostatic syncope can be documented by tilt table tests.

A special form of vasovagal syncope, reflex syncope, may occur at this age. This is fainting triggered by physically or emotionally painful stimuli, such as drawing blood or hearing bad news. A preceding history of pallid syncope, the pale type of breath holding spells, in early childhood can often be elicited.

Epilepsy

The generalized epilepsy syndromes that can begin at this age are generalized convulsions upon awakening, juvenile absences, and juvenile myoclonic epilepsy (JME) Complex partial seizures due to temporal lobe epilepsy (TLE) often begin at this age. A surgically treatable epilepsy, if refractory to antiepileptic drugs, is TLE due to mesial temporal sclerosis occurring in patients with early childhood history of febrile seizures.

Conversion Reactions

Pseudoseizures are not an uncommon symptom at this age. They may be psychogenic, but the challenge here is that patients who present with pseudoseizures often also have true epilepsy. Other common conversion symptoms are inability to stand and walk, called astasia-abasia, which looks like a pseudo-ataxia; sensory symptoms because the sensory examination, relying on subjective responses, may be a subtle presentation of demyelinating disease; and intermittent weakness, even with a normal neurological examination, may be an early presentation of myasthenia gravis. DOPA-responsive dystonia may be missed if the patient is examined in the morning, and the diurnal pattern is not appreciated.

Demyelinating Disease (See Tanuja Chitnis Chapter)

Although relatively rare, multiple sclerosis can present for the first time in adolescence. More common are post-infectious demyelinating diseases, such as Guillain-Barre syndrome, transverse myelitis, or acute demyelinating encephalomyelopathy (ADEM).

ADHD Complications

By this time the behaviors which comprise conduct disorder, which are essentially pre-delinquent behaviors (fire setting, cruelty to animals), should have been recognized and treated, because conduct disorder complicating earlier ADHD is the most important risk factor for the subsequent development of substance abuse, delinquent and criminal behavior. By the same token neuropsychiatric disorders which may have presented in early childhood with an ADHD symptom complex and disruptive behavior, which may evolve into the bipolar disorder spectrum, are a risk for impulse control problems ("anger issues") and even explode into homicide, witness the Columbine school mass shootings.

Disorders Occurring at any Age

Some neurological disorders can occur at any age, but may have different etiologies at different ages:

Stroke
Demyelinating disorders, post-infectious like ADEM, transverse myelitis, Guillain-Barre syndrome
Head trauma
Progressive encephalopathies
CNS infections
Acute toxic-metabolic encephalopathies

Seizure incidence is greatest in early childhood and late life, but partial or focal seizures, or focal-onset secondarily generalized seizures can occur at any age due to any congenital or acquired focal brain structural lesion, such as brain tumors, vascular malformations, gliosis, secondary to cerebral contusions, CNS infections, progressive cerebral degenerative disease, or stroke.

Modifications of Clinical Approach According to Clinical Setting

In the Emergency Room

The priorities are – *Treatment first (save life and limb) then diagnosis.* Cone down on the chief presenting complaint, perform a focused exam, treat immediately if necessary (for example, status epilepticus), and then go back to get more complete history of the present illness, family history (draw a family pedigree), prenatal/perinatal/developmental history, allergies (Table 358.2).

In the P ICU

The priorities are *stabilization, recovery, and then acute rehabilitation* (See Chap. 379, "Pediatric

Table 358.2
Pediatric neurologic emergencies

Status epilepticus
Status migrainosus
Metabolic-toxic coma
Acute stroke
Acute weakness
Acute ataxia
Head and spinal cord trauma

Neurorehabilitation"). Intensivists put much reliance on monitoring devices for vital signs, cardiac and respiratory functions. Patients cannot have a "complete neurological exam" because they often have impaired consciousness or are in coma, and because of the monitoring equipment, intubation, and IV lines they cannot be moved. The mental status exam is essentially a classification of the level of consciousness, and standardized scales, such as the pediatric version of the Glasgow Coma Scale. Of the cranial nerve examination, reaction to visual threat, which can come centrally or peripherally, is a gross way to ascertain vision and field defects. The ophthalmoscopic exam needs to be repeated frequently to look for papilledema, which supplements intracranial pressure monitoring. The motor examination is limited to observation of spontaneous movement and passive range of movement for muscle tone. Sensory examination is limited to applying noxious stimuli, often to gauge level of consciousness, rather than test for distribution of sensory loss. Criteria for brain death can be found in the Chap. 365, "Coma".

In the Office

The priorities are *screening, diagnosis, and prevention*. For the busy pediatrician, developmental screening is easiest with parent-answered questionnaires, filled out prior to the visit or in the waiting room. Equipping the examining room with developmental toys, or having a playroom, enhances the "child friendliness" of the doctor's office.

Primary care physicians need to become familiar with school and community resources for early intervention, preschool early education, rehabilitation facilities with multidisciplinary services like physical therapy, occupational therapy, and speech and language therapy, parent education and support groups, and consumer organizations in the USA like the Epilepsy Foundation, the Muscular Dystrophy Association, Children and Adults with Attention Deficit Disorder, the Tourette Syndrome Association, or their equivalents in the rest of the world.

Perspectives

Common diseases are common, and physicians should think of these first, before looking for exotic or rare causes.

However, what is common and what is rare depends on which part of the world one practices. Subacute sclerosing panencephalitis is endemic in Turkey, India, and the Philippines, while so rare to the point of near extinction in North America. Glutaric aciduria Type 1 is a relatively common organic aciduria in Saudi Arabia, while relatively rare in North America (except among the Amish) and Europe. Tuberculomas are common in South and Southeast Asia, while a rarity in North America. Genetic neurometabolic diseases are common in the Middle East, while rare in North America. The neurologic complications of AIDS may be seen more frequently in Africa, where HIV is still an epidemic and where the latest combination of drugs is not highly available. Neurocysticercosis is much more common in Central and South America, than in North America. Seizures and epilepsy, headaches, and cerebral palsy are common neurological problems in children all over the world. A relatively rare disease, spinal muscular atrophy, is still the most common neuromuscular disease of infancy and early childhood throughout the world.

In developed countries, where the premium on education as a means of upward mobility in society is high, ADHD, learning and neurobehavioral problems take up a large portion of the office practice of pediatricians. In developing countries where the health care mind-set, in providers as well as patients, is often crisis-oriented, and centers around life and death issues, developmental neuropsychiatric disorders may receive short shrift.

The art of medicine begins with attentive listening to the patient and family. The primary care physician needs to inquire about the psychosocial and environmental circumstances in which they live, their dietary habits, and, in genetic diseases, elicit a detailed family history and draw a three-generation family pedigree. A 10+ systems review completes the history taking. This brings into conscious differential diagnosis the possibility that symptoms attributable to the nervous system are manifestations of a systemic disease. Symptoms in other systems, together with neurologic signs and symptoms can bring to mind a syndrome or disease involving multiple systems.

An important trend that will make it easier for primary care practitioners in office practice to care efficiently

for their patients is the use of hospitalists devoted entirely to inpatient care, freeing more time for the office-based physician to practice preventive measures and counseling. Another growing trend is the use of electronic medical records, which will reduce medication errors, avoid duplication in laboratory studies and investigations, and ease communication between specialists and primary care physicians.

Developmental Screening Tests

Pediatrics, 2006 (July), 118(1):413 Table of developmental screening tests.

359 Congenital Brain Malformations and Hydrocephalus

John N. Gaitanis

Classification

This chapter arranges cortical malformations according to the earliest embryological stage in which the abnormality has its origin. Yet, this is an artificial distinction since the stages of cortical development overlap in time and lack discrete boundaries. Moreover, some gene defects exert influence in more than one developmental stage. Thus, the classification system presented here will undoubtedly be modified as understanding of these conditions evolves.

Overview of Embryology

The brain and spinal cord form from the dorsal aspect of the embryo in the third and fourth weeks of gestation through neurulation, the process of neural tube formation. In the fifth and sixth weeks, prosencephalic development, the process by which the brain takes shape, begins. Cortical formation in humans spans weeks 8–24 of gestation and can be divided into stages of cell proliferation (both neural and glial precursor cells are formed), neuronal migration (cells travel to their designated destination), and cortical organization (cell networks are determined). Myelination is the final step of brain development and continues well beyond birth. As noted above, assigning strict temporal divisions is misleading, since different stages take place concurrently.

Disorders of Neurulation

Fusion of the neural tube begins at the level of the hindbrain (medulla and pons) and proceeds rostrally and caudally. Failure of rostral fusion results in dysraphic states of the brain (anencephaly and encephalocele), and incomplete caudal fusion causes spinal dysraphism (myelomeningocele). The anterior end of the neural tube closes by 24 days and posterior closure happens by day 26. Disorders of neurulation differ in severity depending on the timing of the disruption. The most severe disorder, craniorachischisis totalis, in which the brain and spinal cord fail to develop because of a complete absence of neurulation, occurs no later than 20–22 days of gestation. Anencephaly, a complete failure of anterior neural tube closure resulting in an absence of brain formation, occurs no later than 24 days. Encephalocele, a restricted failure of anterior neural tube closure, happens around day 26. Likewise, myelomeningocele, a restricted failure of posterior neural tube closure, also occurs by day 26.

Myelomeningocele is the most clinically important disorder of neurulation since patients with it usually survive. Its incidence in the United States is approximately 0.2–0.4 per 1,000 live births. The neurological features of myelomeningocele relate to the level of involvement, presence of hydrocephalus, and other associated malformations.

Impairment of motor, sensory, and sphincter function relates directly to the level of involvement. Ambulation is one of the most important clinical concerns, and retained strength of the iliopsoas and quadriceps muscles are required for walking. Lesions at or below S1 rarely affect ambulation, whereas higher defects, above L2, almost always do. Among patients with intermediate lesions (L3, L4, L5), approximately half will walk, but braces or other assistive devices may be required.

Hydrocephalus is seen in approximately 90% of patients with lumbar lesions. The usual signs of increased intracranial pressure (lethargy, irritability, limited upward gaze, rapidly expanding head circumference) are not essential for diagnosis and are present in only 15% of newborns with myelomeningocele. If clinical signs are present, they usually develop 2–3 weeks after birth and are almost certain to be present by 6 weeks. Their frequent absence necessitates serial neuroimaging for the prompt diagnosis of hydrocephalus. Infants demonstrating hydrocephalus at birth require shunt placement immediately following myelomeningocele closure. The closure stops CSF leakage, and can therefore worsen hydrocephalus if a shunt is not placed.

When myelomeningocele and hydrocephalus are combined with inferior displacement of the medulla and lower

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_359,

cerebellum through the foramen magnum, it is termed the Arnold–Chiari malformation (Chiari type II). Other features of this disorder include elongation and thinning of the upper medulla and pons and bony defects of the foramen magnum, occiput, and upper cervical vertebrae. Brain stem and cortical malformations are common. Resulting brainstem dysfunction is a significant cause of morbidity and mortality. It may result in apnea, stridor, cyanotic spells, and dysphagia. The overall mortality rate in patients with brainstem dysfunction is 21%, but when all four symptoms are present, the mortality rate is as high as 60%. Cortical malformations are an important cause of morbidity such as intellectual disability and epilepsy. They are also very common in patients with Arnold–Chiari malformations, being present in as many as 92%.

Disorders of Prosencephalic Development

Prosencephalic development is the process by which the forebrain takes shape. It begins during the fifth week and continues through the second and third months of gestation. Prosencephalic development influences formation of the face, so severe disruptions at this stage result in facial anomalies. Development of the forebrain can be divided into three stages: formation, cleavage, and midline development. The resulting disorders depend on the stage affected.

Holoprosencephaly

In holoprosencephaly (HPE), disruption of the roof plate and absence of hemispheric separation result in a single, large, forebrain ventricle. In its most severe form, alobar HPE, the brain is a single spherical structure with a common ventricle and a malformed cortical mantle. The optic nerves are dysplastic and the olfactory bulbs and tracts may be absent. The hypothalamus does not separate normally into two halves. Facial anomalies, ranging from cyclopia to a single central incisor, are observed. Less-severe forms, semilobar and lobar HPE, have milder degrees of the same anomalies. For instance, in semilobar HPE, the frontal and parietal lobes remain fused and the interhemispheric fissure is only present posteriorly. In contrast, with lobar HPE most of the left and right hemispheres and lateral ventricles are separated and fusion is seen only at the most ventral aspect of the frontal lobes.

Clinical severity relates to the degree of structural change. Neurological dysfunction inversely correlates with the degree of hemispheric separation, with less separation resulting in greater impairment. Endocrinopathies correlate with the severity of hypothalamic separation. Associated cortical malformations frequently cause epilepsy, which is often refractory. Careful attention to neuroimaging is necessary for providing an accurate prognosis.

HPE is a heterogeneous condition, with both genetic and environmental causes. The most common environmental cause is maternal diabetes, which carries a 1% risk of HPE. Cytogenetic abnormalities account for approximately 25–50% of cases, with trisomy 13 and 18 being the most common. Single-gene mutations are found in roughly 25% of patients. Several genes are known to be causative. The first gene discovered, the sonic hedgehog gene at 7q36, is the most common. The evaluation typically begins with a karyotype followed by molecular genetic testing if the karyotype is unremarkable.

Abnormalities of midline prosencephalic development are less severe than HPE. They include agenesis of the corpus callosum and septo-optic dysplasia (SOD). Agenesis of the corpus callosum can be either partial or complete. With partial agenesis, the posterior portion is more affected. It is commonly associated with other brain anomalies including Arnold–Chiari II malformations and neuronal migration disorders. SOD, on the other hand, is characterized by optic nerve hypoplasia in combination with the absence of the septum pellucidum and pituitary dysfunction. Clinically, it presents with visual impairment, endocrinopathies, or both. The causes are heterogeneous, including both environmental and genetic etiologies (*Fig. 359.1*).

Disorders of Neuronal Proliferation

Neuronal proliferation takes place between the second and fourth months of gestation. Neurons and glia have their origin in the ventricular and subventricular zones. In the earliest phases of neuronal proliferation, neuronal-glial stem cells divide to form further stem cells. Later, stem cell division becomes asymmetric so that one daughter cell is postmitotic, while the other remains a stem cell. Eventually, fewer and fewer stem cells are produced and all of the neurons within the proliferative unit are postmitotic. Abnormal neuronal proliferation results in conditions characterized by too many or too few neurons.

Figure 359.2
Hemimegalencephaly

Decreased Proliferation

Microcephaly/microlissencephaly primary microcephaly (microcephaly vera) is diagnosed when the head circumference at birth is three or more standard deviations below normal. Primary microcephaly is a heterogeneous condition and can be caused by in utero brain injury or from a genetically determined reduction in neuronal proliferation. Most genetic forms are recessively inherited. Microcephaly is sometimes associated with a more simplified gyral pattern or, in severe cases, with a smooth cortex, termed microlissencephaly. Seizures and global developmental delays are uniformly present.

Disordered Proliferation

Hemimegalencephaly

When there is enlargement of just one cerebral hemisphere, it is termed hemimegalencephaly. It probably results when a disturbance of cellular differentiation and proliferation interacts with the genetic expression of body symmetry. In addition to increased size of the affected hemisphere, neuroimaging may reveal abnormal gyration, ventriculomegaly, and increased T2 signal of the white matter. Histology reveals disorganized cortical lamination, subcortical heterotopia, and large, dysmorphic neurons, termed balloon neurons. The opposite hemisphere may be normal or have mild dysplasia and heterotopia. All patients have epilepsy, and hemispherectomy is often required for intractable cases (*Fig. 359.2*).

Abnormal neuronal differentiation/maturation in abnormalities of maturation or differentiation, neurons exhibit immature or glial features. Balloon neurons contain abnormally large amounts of cytoplasm and stain for both neuronal and glial markers, indicating a failure to commit to a specific cell lineage. Balloon and dysplastic neurons are seen in cortical dysplasia and in the cortical hamartomas of tuberous sclerosis complex. Evidence of disrupted neuronal migration, including disorganized or absent lamination, malpositioned neurons, and heterotopic neurons within the white matter, are also present in these disorders. Such conditions must, therefore, involve abnormalities of both maturation and migration, indicating that dysplastic and balloon neurons lack the cellular machinery to migrate properly through the cortical plate.

Tuberous Sclerosis Complex

Tuberous sclerosis complex (TSC) is a multisystem, dominantly inherited condition. It has a high rate of

spontaneous mutations and approximately half of all patients do not have an affected parent. Two genes have been cloned for TSC. Both result in similar clinical features. The TSC1 gene, located on chromosome 9q34, codes for a novel protein called hamartin, which indirectly links the cell membrane to the cytoskeleton. TSC2, located at chromosome 16p13.3 encodes for the protein tuberin, which may function in cellular signaling pathways. Hamartin and tuberin interact together as part of a larger protein complex which functions to negatively regulate mTOR. When tuberin or hamartin is nonfunctional, mTOR is active, resulting in increased cell growth and proliferation. Rapamycin acts as an mTOR inhibitor and has shown efficacy in the treatment of subependymal giant cell astrocytomas in patients with TSC (*Fig. 359.3*).

The clinical diagnosis of TSC is divided into three subheadings: definite, probable, and suspect based on the type and number of abnormalities. The clinical expression of TSC is based on the location and severity of organ involvement. The primary targets are the skin, kidneys, heart, and central nervous system. Hypopigmented macules are the most common skin lesions and are present in as many as 90% of affected patients. Adenoma sebaceum, an angiofibromatous lesion occurring in a butterfly distribution about the nose and cheeks, is seen in 50%. Other skin lesions include the shagreen patch over the lumbosacral region, café au lait spots, and subungual fibromas. Tumors are common and include renal angiomyolipomas, cardiac rhabdomyomas, and retinal hamartomas.

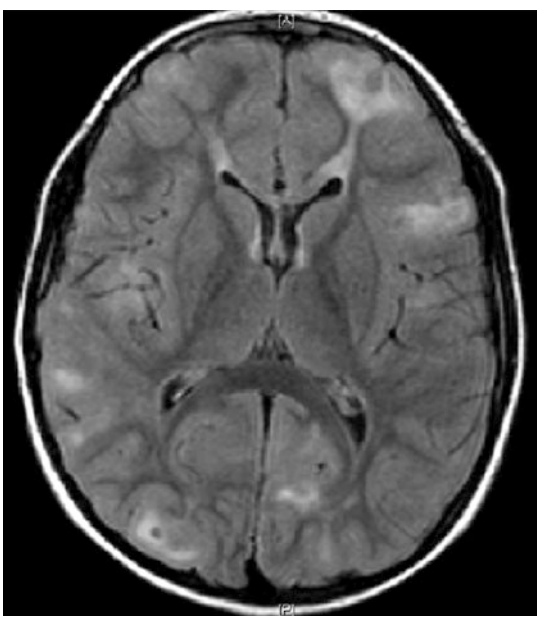

Figure 359.3
Tuberous sclerosis in a 4-year-old girl with multiple, bilateral cortical tubers

In the brain, the characteristic features include cortical hamartomas (cortical tubers), subependymal hamartomas (subependymal nodules), and giant cell astrocytomas. Cortical tubers are firm and nodular, with a consistency resembling the potato tubers for which they are named. On MRI, cortical tubers appear as enlarged, atypically shaped gyri with abnormal signal intensity in the subcortical white matter. Microscopically, they resemble focal cortical dysplasia with disorganized lamination and balloon neurons. Beneath the cortex, subependymal nodules are at risk of transforming into subependymal giant cell astrocytomas.

Cortical tubers often result in epilepsy. Under 1 year of age, infantile spasms predominate. Vigabatrin is a particularly effective treatment for infantile spasms in TSC patients, and is widely considered to be first-line therapy in this setting. Later in life, generalized tonic–clonic seizures predominate, but simple and complex partial seizures are also common. Refractory epilepsy is a common problem in TSC; surgical resection of an epileptogenic cortical tuber is possible, and is most successful when a single epileptogenic area is identified.

The presence of epilepsy is a predictor of cognitive impairment – this is particularly true when seizures develop under 2 years of age or when infantile spasms occur. Cognitive impairment can also be predicted by the burden of cortical tubers, with more tubers correlating with greater impairment.

Autism is common in patients with TSC. It is more likely to develop in those with temporal tubers, seizure onset before age 3, or a history of infantile spasms. Attention, language, and behavioral problems are also observed. In general, TSC patients who are cognitively normal are seizure free and vice versa.

Subependymal nodules are common in TSC and consist of periventricular collections of small cells resembling candle drippings. In some instances, they transform into subependymal giant cell astrocytomas (SEGAs). SEGAs typically develop in the region of the foramen of Monro and can obstruct cerebral spinal fluid flow, resulting in hydrocephalus. Presenting symptoms include headache, vomiting, obtundation, or focal neurological deficits. Early recognition is important. Incompletely calcified periventricular nodules greater than 5 mm and nodules demonstrating gadolinium enhancement are at greater

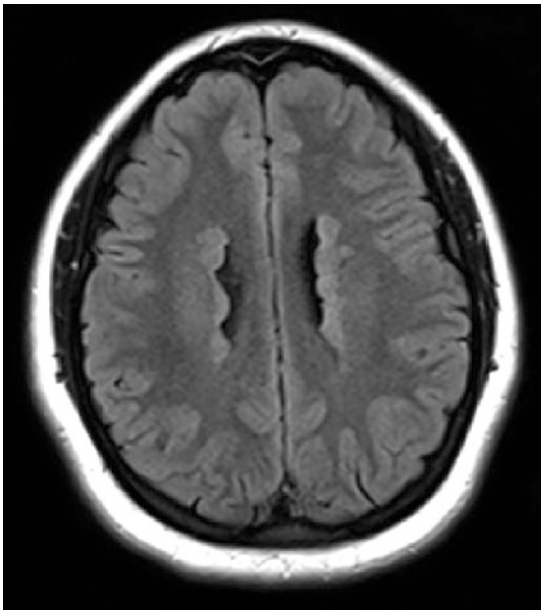

Figure 359.4
Periventricular nodular heterotopia in a 20-year-old woman

risk of transformation. Yet, the most important criterion for recognizing SEGAs is a progressive enlargement of the lesion. Neuroimaging is recommended prior to 2 years to screen for such lesions, and yearly follow-up may be necessary if suspicious periventricular nodules are observed (*Fig. 359.4*).

Focal Cortical Dysplasia

Focal cortical dysplasia (FCD) is essentially indistinguishable from the cortical tubers of TSC. Macroscopically, the lesions display wide gyri and blurring of the gray–white junction. Microscopic findings include disordered cortical lamination with dysplastic neurons and balloon cells. The underlying white matter is hypomyelinated and contains radially oriented balloon cells. The histology of FCD resembles tuberous sclerosis to such an extent that they have been postulated to be the same entity, with FCD representing a forme fruste of TSC. On MRI, FCD are slightly hyperintense on T2-weighted sequences. The hyperintense regions have a funnel-shaped appearance, with the base of the funnel oriented toward the pial surface and the tip extending to the white matter. Seizures resulting from FCD are commonly refractory to pharmacotherapy and surgical resection may be required to control the seizures.

Hypomelanosis of Ito

The brain malformations of hypomelanosis of Ito (HI) include abnormalities of neuronal differentiation (cortical dysplasia and hemimegalencephaly) and migration (heterotopia and polymicrogyria). The skin lesions of HI consist of whorls and streaks of decreased pigmentation, which follow the lines of Blaschko. There are no preceding inflammatory or vesicular eruptions as in incontinentia pigmenti, and the palms, soles, and mucous membranes are spared. The skin lesions are more prominent over the ventral surface of the torso and on the flexor surface of the extremities. They may be unilateral and exibit a midline cutoff. In patients with HI and hemimegalencephaly, the skin lesions are contralateral to the brain abnormality. Systemic manifestations include ophthalmologic, cardiac, musculoskeletal, and genital anomalies.

The neurological manifestations include epilepsy and mental retardation. Generalized tonic–clonic seizures are the most common, but infantile spasms, focal, and myoclonic seizures are also observed. Autistic behaviors are sometimes seen and are usually present in children with epilepsy. Pathology may reveal polymicrogyria, heterotopia, cortical dysplasia, or hemimegalencephaly. The etiology of HI is likely to be heterogeneous since several different choromosomal abnormalities have been associated with it.

Schizencephaly

The term "schizencephaly" refers to a cleft extending between the pial and lateral ventricular surfaces. Lining the cleft on both sides are polymicrogyria (abnormally small gyri). The presence of polymicrogyria helps distinguish this malformative lesion from the destructive disorder porencephaly, which has a similar appearance. Schizencephaly is heterogeneous in appearance. Lesions vary in size from small close-lip to large open-lip malformations. They may occur in one or both hemispheres. Possible etiologies are similarly heterogeneous. Environmental causes include fetal hypotension, exposure to organic solvents, and viral infections. Vascular anomalies have also been reported in association with schizencephaly. Familial cases exist, indicating a genetic mechanism in some patients. Mutations in the homeobox gene EMX2 have been reported in some cases.

The clinical severity relates to the degree of structural involvement. Unilateral clefts commonly present with hemiparesis and mild cognitive delay. Bilateral clefts, on the other hand, are associated with quadriparesis and

significant cognitive impairment. Likewise, the size of the lesion is an important determinant of outcome. For example, patients with large or medium open-lip schizencephaly display significantly worse motor and intellectual function than patients with close-lip or small open-lip lesions. The severity of epilepsy, however, is generally unrelated to the structural findings.

Disorders of Neuronal Migration

Neuronal migration takes place between the third and fifth months of gestation. During migration, postmitotic neurons move from the ventricular and subventricular layers to their final sites within the cerebral cortex. Migration occurs in radial (perpendicular to the pial surface) and tangential (parallel to the pial surface) fashions.

Heterotopia

Heterotopia are collections of ectopic neurons located outside of the cortex. Unlike cortical dysplasia, the neurons within heterotopia are normal. On imaging, heterotopia are isointense with normal gray matter, lacking the abnormal signal intensity seen in dysplasia. The cortex overlying heterotopia is abnormally thin with shallow sulci.

Familial periventricular heterotopia (PH) are characterized by periventricular nodules of neurons resting beneath an otherwise normal-appearing cortex. In PH, some neurons migrate fully to form a normal-appearing six-layer cortex, while others have a complete failure of migration and remain in nodular collections within the subependymal region. Most patients have normal intelligence, but epilepsy is common and generally develops in the midteenage years.

Familial PH commonly displays X-linked dominant inheritance and is lethal in hemizygous male embryos. Approximately half of patients have a de novo mutation. Because epilepsy is mild or absent in approximately one-quarter of all patients, a family history is not always confirmed until neuroimaging of a patient's mother is performed. PH results from a mutation of the filamin A (FLNA) gene, which encodes a large actin-binding protein involved in structuring actin networks at the leading edge of motile cells.

Lissencephaly

Lissencephaly refers to a paucity of normal gyri and sulci resulting in a "smooth brain." It is a heterogeneous condition, which is traditionally divided into two pathologic subtypes: classical (type I) and cobblestone (type II). Radiographically, the cortex appears smooth in both types, but beyond that, few similarities exist. Classical lissencephaly results from an arrest of neuronal migration, whereas cobblestone lissencephaly results from overmigration. In both cases, lissencephaly is associated with epilepsy and severe developmental delay (*Fig. 359.5*).

Classical Lissencephaly (Agyria–Pachygyria Complex)

Most patients with classical (type I) lissencephaly have a combination of agyria (a total absence of gyri) and pachygyria (a reduced number of abnormally large gyri). Radiographically, the surface of the brain appears smooth in agyria, with diminished white matter and shallow sylvian fissures. In pachygyria, gyri are reduced in number and are abnormally broad and flat. Microscopically, agyria has a disorganized outer cortical layer and a thick layer of ectopic neurons in the periventricular region, whereas pachygyria displays better cortical organization. Clinical severity is largely related to the degree of structural abnormality, with greater gyral simplification resulting

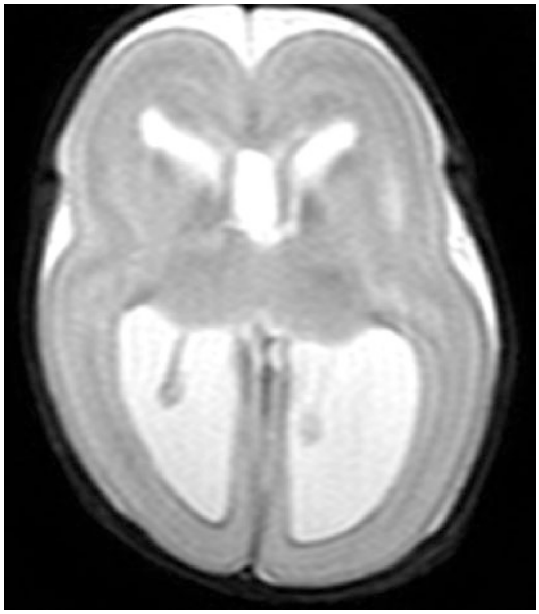

Figure 359.5
Classical lissencephaly in a patient with Miller–Dieker syndrome

in greater neurological impairment. In agyria, neurodevelopmental disabilities are severe. Patients exhibit mental retardation, spastic quadriparesis, and microcephaly. Epilepsy is universal and infantile spasms are a particularly common seizure type. In patients with pachygyria, epilepsy and developmental delays are common but are less severe. Electroencephalography reveals characteristic, high-voltage beta activity.

Classical lissencephaly is most commonly caused by a disruption of the platelet-activating factor, acetylhydrolase gene (PAFAH1B1; also known as LIS1) located on chromosome 17p13.3. Almost all patients have spontaneous, heterozygous deletions of LIS1, which are not present in the parents. The risk of having a second affected child is therefore low. When a large deletion occurs, other congenital anomalies (craniofacial, renal, cardiac, or gastrointestinal malformations) can result and together are termed the Miller–Dieker syndrome.

Abnormalities of the doublecortin (DCX or XLIS) gene, located on the X chromosome, are also known to cause classical lissencephaly. In hemizygous males, the phenotype is nearly indistinguishable from LIS1. Yet, in heterozygous females, a disorder termed double cortex (DC), also known as subcortical band heterotopia, results (*Fig. 359.6*). In DC, the outer cortex displays normal six-layered architecture, but an inappropriate accumulation of neurons exists in the subcortical white matter. Random inactivation of the X chromosome accounts for this pattern. Half of the neurons express a normal copy of the doublecortin gene and undergo normal migration, whereas the other half express the mutant copy and remain arrested in the subcortical white matter. In males, only one X chromosome exists, so the mutation affects all neurons. Hence, the more severe phenotype of classical lissencephaly occurs in males.

Figure 359.6
Double cortex (subcortical band heterotopia) in a 6-year-old girl with a heterozygous mutation of the doublecortin gene

Cobblestone (Type II) Lissencephaly

Cobblestone lissencephaly develops from an overmigration of neurons beyond the pial surface and onto the overlying subarachnoid tissue. Cobblestone lissencephaly is associated with congenital muscular dystrophy and eye abnormalities in Fukuyama congenital muscular dystrophy (FCMD), Walker–Warburg syndrome (WWS), and muscle–eye–brain disease (MEB). These disorders result from an impairment of glycosylation. They affect O-mannosylation, which is important to brain, nerve, and skeletal muscle, accounting for the distribution of involved tissues in these disorders.

Of all three disorders, WWS has the most severe phenotype and is often fatal in the first year of life. Genetically, WWS is recessively inherited. MEB is also an autosomal recessive condition and is most prevalent in Finland. The clinical severity is intermediate to WWS and FCMD as is the radiographic appearance. FCMD is the mildest of the three disorders. It presents with hypotonia and global developmental delays. Seizures develop in the first year of life in half of patients. FCMD is seen primarily in Japan, where 94% of the affected individuals share a common haplotype, indicating a single founder in the Japanese population. Patients who are homozygous for the founder mutation have a higher residual activity of fukutin and a milder phenotype than patients with a spontaneous point mutation on the second allele (compound heterozygotes).

Symmetric Polymicrogyria

Polymicrogyria is thought to develop at the latest stages of neuronal migration. It often results from external causes such as intrauterine cytomegalovirus infection or impairments in placental perfusion. Genetic causes also exist and tend to result in focal but symmetrical lesions in the frontoparietal, perisylvian, or parieto-occipital regions. Epilepsy and cognitive delays are common among all of

the syndromes; additional symptoms depend upon the specific areas involved.

Disorders of Myelination and Cortical Organization

Cortical organization and myelination are the final steps of brain development and continue well after birth. Abnormalities at these stages may be less obvious on neuroimaging than earlier malformations, but they nonetheless have profound effects. Cognitive and motor impairments are associated with both abnormalities; spasticity is more specific to problems with myelination, whereas hypotonia is more likely in disorders of cortical organization.

Cortical organization begins in the fifth month of gestation and continues through the first several years of life. Abnormalities of cortical organization are commonly associated with mental retardation. The most consistent anatomical correlates of mental retardation are dendritic anomalies, such as deficient branching. Such abnormalities cannot be detected by neuroimaging, explaining why many patients with mental retardation have normal MRIs.

Myelination begins in the second trimester of pregnancy and continues into adulthood. Myelination is impaired when oligodrendrocytes are deficient in number or in myelin deposition around axons. Insufficient oligodendrocytes are observed in periventricular leukomalacia, in which differentiating oligodendroglia are injured and therefore unable to produce myelin. Other disorders, such as hypothyroidism, malnutrition, and organic acidopathies, cause functional impairment of myelination. Primary disturbances of myelination are distinguished from leukodystrophies in that leukodystrophies result from injury to previously myelinated axons.

Neurofibromatosis Type I

The primary disorder in neurofibromatosis relates to oncogene regulation and tumor formation. Given the white matter abnormalities in NF, it is categorized here as a disorder of myelination, but increased gray matter volume is also seen, highlighting a larger disorder of brain overgrowth in neurofibromatosis.

Neurofibromatosis type 1 (NF1), also known as peripheral neurofibromatosis, is an autosomal-dominant, single-gene defect affecting multiple organ systems. The NF1 gene localizes to chromosome 17q11.2 and encodes the protein product neurofibromin. The incidence of NF1 ranges between 1 in 3,000 and 1 in 4,000. Approximately 50% of patients with NF1 lack a family history and likely represent new mutations. The diagnosis is based on NIH consensus criteria and requires two or more of the following: six or more café au lait spots (0.5 mm or larger in prepubertal and 1.5 mm or larger in postpubertal individuals), two or more neurofibromas of any type or one plexiform neurofibroma, axillary or groin freckling, two or more Lisch nodules, optic nerve glioma, dysplasia of the sphenoid bone or long bone cortex, or a first-degree relative with NF1. Of these features, café au lait spots are the most easily recognized and are often the presenting feature of the disease. They are evenly pigmented macules, which increase in size and number with age. They may be the only sign present in infancy, making a definitive diagnosis difficult to establish until later in life.

In childhood, the most common complication of NF1 is cognitive impairment. A broad range of effects are seen including low IQ, behavioral problems, and learning disabilities. IQ scores in NF1 patients have a bimodal distribution; some children have intellectual impairment, whereas others do not. This separation may have its basis in the white matter T2 hyperintensities, also known as unidentified bright objects (UBOs), common to NF1 patients. They represent dysplastic glial proliferation and aberrant myelination in the underdeveloped brain. When compared to children without T2 hyperintensities, those with the lesions have significantly lower mean values for IQ and language scores and significantly impaired visuomotor integration and coordination. T2 hyperintensities in childhood are also a predictor of cognitive dysfunction in adulthood. A correlation is also seen between increased white matter volume and visual-perceptual deficits, suggesting that brain overgrowth is a factor in the associated cognitive deficits.

Tumors and malignancies are common in NF1, and are a major cause of morbidity. Neurofibromas, the tumors for which the disorder takes its name, are peripheral nerve sheath tumors with unpredictable growth patterns. They are benign tumors without risk of malignant transformation, and typically develop in adolescence. Although they are unlikely to cause neurological deficit, spinal neurofibromas arising from the dorsal nerve roots can lead to severe pain. Plexiform neurofibromas, on the other hand, are more likely to be present at birth. They can be found anywhere within the body and cause a variety of presenting symptoms depending on their location. Serious complications include pain, spinal cord compression, and spread to the orbit with resulting sphenoid wing

dysplasia and pulsating exophthalmos. Plexiform neurofibromas can undergo transformation to malignant peripheral nerve sheath tumors.

Optic nerve gliomas are pilocytic astrocytomas involving the optic nerve, chiasm, or tract. They usually develop prior to age 7 and can be insidious in their onset. Yearly ophthalmologic assessments are important for early diagnosis and management of these tumors. Abnormalities on the ophthalmologic exam necessitate an MRI. Other malignancies observed in NF1 include CNS tumors (particularly astrocytomas), pheochromocytomas, and leukemia. Given the prevalence of tumors in NF1, it should come as no surprise that neurofibromin functions as a tumor suppressor protein, the loss of which promotes tumor formation.

The workup for NF1 is aimed at the early identification of potential complications, with tumor formation being the main concern. The American Academy of Pediatrics Committee on Genetics recommends yearly physical examinations and ophthalmologic assessments. The physical examination focuses on the organ systems involved. The skin is screened for new neurofibromas or plexiform neurofibromas. Blood pressure is followed to assess for renal or endocrine abnormalities. A skeletal examination looks for pseudoarthrosis of the tibia, bowing of the long bones, scoliosis, and orbital defects. The neurological examination may reveal macrocephaly, learning disabilities, or cognitive impairment. The ophthalmologic evaluation helps exclude optic nerve gliomas, choroidal hamartomas, and Lisch nodules.

Neurofibromatosis Type II

Like NF1, neurofibromatosis type II (NF2) is an autosomal-dominant, single-gene deficit, which, in NF2, localizes to chromosome 22. The gene product, merlin, also has tumor suppressor function. Tumors and malignancies are, therefore, common in both conditions. Beyond that, few similarities exist. Café au lait spots are rarely seen in NF2 and neurofibromas are uncommon. NF2 is much less common than NF1, with an incidence of only 1:30,000–1:40,000.

Common tumors in NF2 include schwannomas (which are usually multiple), meningiomas, ependymomas, and gliomas. Vestibulocochlear schwannomas are particularly common and sometimes bilateral. Roughly half of NF2 patients present because of hearing loss, tinnitus, and vertigo resulting from a vestibulocochlear schwannoma. The peak age of diagnosis is the third decade. In children, ocular abnormalities are the most common presenting symptoms. These are caused by hamartomas of the retina, optic nerve sheath meningiomas, or juvenile posterior subcapsular lenticular opacities. Meningiomas at a young age should also raise a suspicion of NF2. Schwannomas and ependymomas may develop in the spine, in which case back pain and paraplegia may result.

Vascular Disorders

The following disorders result from vascular abnormalities, and therefore cannot be organized within the embryological classification presented above even though each results in developmental abnormalities of the brain.

Bilateral Parasagittal Parieto-Occipital Polymicrogyria

Unlike the other symmetrical polymicrogyria syndromes, bilateral parasagittal parieto-occipital polymicrogyria is unlikely to have a genetic basis. Of the patients described, none had a familial distribution. Given that the lesion occurs in a vascular watershed region, perfusion failure is postulated to be the cause. All patients develop seizures and cognitive abilities range from normal to mild retardation.

Incontinentia Pigmenti

Incontinentia pigmenti is a rare, X-linked, dominant, neurocutaneous disorder with the onset of skin changes in the first 6 weeks of life. The cutaneous disorder follows a characteristic evolution from vesicular to verrucous to hyperpigmented and finally atrophic changes. The vesicles and bullae from the original eruption in infancy later give rise to the characteristic swirling pattern of hyperpigmentation. Hair, nail, dental, and ophthalmologic abnormalities are also observed. Neurologically, these infants may develop epilepsy, mental retardation, microcephaly, spasticity, or ataxia. The gene for incontinentia pigmenti is NEMO (NF-kappaB essential modulator)/IKKgamma (IkappaB kinase-gamma) and is located on Xq28. NEMO is 200 kilobases proximal to the factor VIII locus and is important for immune, inflammatory, and apoptotic pathways. The disorder is lethal in most males, accounting for its 20:1 female-to-male predominance. Males with IP have been described, but commonly have

only a limited distribution. Somatic mosaicism is a likely mechanism in such cases.

Sturge–Weber Syndrome

Sturge–Weber syndrome is characterized by angiomata of the leptomeninges and skin. The cutaneous lesion, also known as a port-wine stain, typically involves the ophthalmic and maxillary distributions of the trigeminal nerve. The leptomeningeal angiomata may be either unilateral or bilateral, but unilateral lesions are more common. The specific neurological effects are dependent on the location of the lesion, which is most commonly parietal or occipital. Neurological impairment results from stasis and a vascular steal phenomenon. Laminar cortical necrosis with neuronal loss, gliosis, cerebral atrophy, and calcifications are seen histologically. The calcifications take on a classic train-track appearance on plain films and CT. MRI, if done, should be performed with gadolinium to allow for diagnosis of the angiomata. The clinical manifestations include hemiparesis, stroke-like episodes, mental retardation, epilepsy, and headaches. Epilepsy is present in 75–90% of patients, and the seizures are typically focal. Many patients have refractory epilepsy, in which case cortical resection or hemispherectomy are considered. An important non-neurological effect is glaucoma, which can occur at any age.

Conclusion

For children with disorders of nervous system development, there are few specific therapeutic interventions available beyond physical, occupational, and speech therapy and remedial education. Epilepsy resulting from brain malformations is often refractory to pharmacotherapy, but surgical resection of epileptogenic cortical malformations may be an option for some of these children. A crucial role for the treating physician is to provide counseling and guidance. This is particularly important in newly diagnosed children whose parents are burdened by uncertainty. A thoughtful, compassionate approach to the radiographic and genetic assessment can offer the parents insight into their child's condition, and the genetic evaluation is particularly important for purposes of family planning.

360 Neonatal Neurological Disorders

William D. Brown · Mara G. Coyle

Introduction

At no time in life are the limitations of the neurological assessment more obvious than during the neonatal (0–28 days) period. The reflex hammer, light, and bell do no justice to the transformation taking place within the nervous system. Myelination exposes already present reflexes to the possibility of change and allows for new abilities to evolve, though the function of many unmyelinated systems is well established and acquisition of function is not always related to the occurrence of myelination. Within related functional systems, myelination generally progresses in a predictable pattern from the neuron along the axon in the direction of information flow, with the important exception of the optic system that proceeds in the reverse direction (see ❯ *Table 360.1*). In this context, the neurologist is frequently called upon to interpret the meaning of subtleties within the examination, and to divine prognosis from them. Rapid advancement in imaging techniques is allowing for more informed divination, but the use of technology to inform clinical judgment is necessarily imprecise.

This is not to say that the neurologist or pediatrician is without tools. Assessment of the neonate begins with an accounting of antecedent events that may or may not modify the clinical situation. Family history and the maternal medical history prior to pregnancy may be relevant. The quality of the gestational environment – maternal nutrition, exposure to prescription or over-the-counter medications, drugs of abuse, or physical trauma – should be assessed. Perinatal factors such as the use of forceps or vacuum extractors, the presence of a nuchal or knotted umbilical cord, placental abruption, or need for emergency caesarean section could be important to the neurological outcome. If cardiopulmonary resuscitation of the infant is required, a detailed chronological recitation of events should be reviewed.

Basic Physical Examination

The physical examination begins with simple observation, using the presence or absence of dysmorphic features or skeletal abnormalities, the facial appearance, and head shape and size to determine further actions. This examination is best performed during times of quiet wakefulness as is found between feedings although in the preterm or acutely ill neonate such an opportunity may not exist.

In order to interpret physical findings, accurate gestational age estimates are important. First trimester ultrasound examination is the most accurate way of estimating gestational age, with a range of error of 3 days. Additional methods used to estimate gestational age include the date of the mother's last menstrual period and the Dubowitz or Ballard examination, all of which have a range of error in the postnatal period of ± 2 weeks.

Healthy term infants will present a position of limb flexion while preterm or sick term infants are likely to appear more flaccid. Growth parameters should be documented at the time of delivery in order to determine if the infant is appropriate, small, or large for gestational age. This determination may direct the clinician to look for size-specific patterns of medical and neurological complications. Large for gestational age infants (LGA, birthweight >2 SD above the mean for age), for example, are at risk for hypoglycemia, polycythemia, and shoulder dystocia with or without brachial plexus injuries, while growth-restricted infants are at risk for long-term developmental and academic morbidities, including a fivefold to tenfold risk of death.

For those infants suspected of being small for gestational age (SGA, birthweight <2 SD below the mean for age), the occipital frontal circumference (OFC, measured using the middle of the forehead and the inion as reference points) will determine if they are symmetrically or asymmetrically growth restricted, an important distinction since variations in growth imply a risk for certain morbidities. Growth restriction affects up to 10% of all newborn infants, but it should be remembered that an infant designated as having intrauterine growth retardation can still be size-appropriate for gestational age.

When *symmetric* growth restriction is present (weight, length, and head circumference all <10th percentile for age) the cause is often related to chromosomal anomalies,

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_360,

Table 360.1
Correlation of brain and organ development with neurological function and gestational age in neonates

Gestational age (weeks)	Organ development	Brain development			Neurological function		
		Sulci and Fissures	Gyri	Myelination	Arousal	Examination	Reflexes
20–21		Rolandic, collateral superior temporal; Germinal matrix still increasing in size	Parahippocampal, superior temporal	Medullary and pontine MLF			
22				Mesencephalic MLF			
23				Medullary MLF, trapezoid body	Eyes tend to remain closed, opening briefly only in response to sustained noxious stimulation		
24	Surfactant formation begins	Pre- and postrolandic, middle temporal, interparietal, superior frontal, lateral occipital; Germinal matrix begins rapid phase of volume loss at 26 weeks, losing half of volume between 26 and 28 weeks of gestational age	Pre- and postrolandic, middle temporal, superior and inferior parietal lobules, superior and middle frontal, superior and inferior occipital, cuneus and lingual, fusiform	Inferior cerebellar peduncle, spinal trigeminal tract, pontine and mesencephalic lateral lemniscus, pontine medial lemniscus			
25				Pontine medial lemniscus		Extraocular movements present to Dolls' eyes maneuver	Extraocular movements present to Doll's Eye maneuver
26				Pontine and mesencephalic superior cerebellar peduncle		Blinks to light	
27	Pulmonary primitive alveoli appear			Parasagittal cerebellum		Response to noxious stimulus present	Pectoralis major reflex present
28		Inferior temporal, inferior frontal	Inferior temporal, triangular, medial and lateral orbital, callosomarginal, transverse temporal, angular and supramarginal, external occipitotemporal	Ansa lenticularis, amiculum	Eyes tend to remain closed, opening for prolonged periods of time with gentle stimuli; eyes open spontaneously	Sucking and swallowing but not breathing coordinated; resistance to passive limb manipulation minimal	Blinks or startles to sudden noise, rooting reflex present; palmar grasp present

29	Glomerular filtration rate 0.3–0.5 cm^3/min			Optic tract, capsule red nucleus			
30	Active alveolation begins; glomerular filtration rate 0.5–1.0 cm^3/min					Pupils may constrict to light	Cold calorics cause ipsilateral eye deviation
31							
32	Bowel motility allows passage of contrast through small bowel to colon;	Marginal, secondary superior, middle, inferior frontal, temporal, parietal, occipital, insular; germinal matrix involution nearly complete	Paracentral	Posterior limb internal capsule, optic chiasm	Eyes open spontaneously, with roving eye movements present; sleeping and waking periods are observable	Eyes closed as long as light shone in them; visual fixation present, pupils consistently constrict to light, spontaneous movements present; some lower extremity flexor tone present	Incomplete response to Moro
33							Achilles, patellar, biceps, thigh adductor, brachioradialis reflexes present
34				Corona radiata, mesencephalic corticospinal tract		Visual tracking present; sucking, swallowing, and breathing coordinated for limited oral feeding	
35				Transpontine middle cerebellar peduncle, pontine corticospinal tract, pyramid		Some visual pattern preference present	Tonic neck response present

Table 360.1 (Continued)

Gestational age (weeks)	Organ development	Brain development			Neurological function		
		Sulci and Fissures	Gyri	Myelination	Arousal	Examination	Reflexes
36	Bilirubin no longer found in amniotic fluid	Secondary transverse and inferior temporal and cingulate, tertiary superior, middle inferior frontal and superior parietal sulci; germinal matrix absent	Anterior and posterior orbital		Crying may accompany waking periods	Flexor tone present in upper and lower extremities; head remains briefly upright when held in sitting position	Head turning to noxious stimulation of face
37						Visual orientation to light, opticokinetic nystagmus present	Classic Moro reflex present; placing and stepping reflexes present. Palmar grasp strong enough to lift trunk off the bed
38				Cingulum, anterior limb internal capsule, rostral optic radiation and lateral mesencephalic peduncle, cerebellar hemisphere			
39							
40	Glomerular filtration rate (<24°) 2–3.5 cm^3/h; (>72°) 4–8 cm^3/h	Secondary orbital, callosomarginal, and insular, tertiary inferior temporal and superior and inferior occipital			Orients to both visual and auditory stimuli	Visual fixation and following present; acuity 20/150; flexion tone obvious; fists remain closed; little head lag when pulled to sit;	Symmetric unsustained ankle clonus and Babinski reflex present

environmental toxic exposures especially alcohol, and intrauterine infections. These infants are at risk for neurodevelopmental delay, neurosensory deficits, and academic impairment.

Asymmetric growth restriction results in weight and length measures below the 10th percentile for age, but preserves head growth. This occurs in the last trimester and is usually associated with placental insufficiency. These infants are at a significant disadvantage with respect to growth potential and cognitive performance. More than 80% of these infants will "catch up" in their growth during the first year, but those who do not by age 2 years have an even chance of being short adults. For both symmetric and asymmetric growth-restricted infants, the ratio of head circumference to birth weight $\times$ 100 (cephalization index) has the most significant correlation with both neurodevelopmental status and cognitive performance by 10 years of age.

In addition to the OFC, the shape of the head should be assessed. Excess scalp edema, swelling, or subgaleal hemorrhage can contribute to the circumference so the OFC should be remeasured after their resolution. Head shape may also affect the circumference, as is seen in the various craniosynostoses: premature closure of the sagittal suture will result in dolichocephaly while early closure of the coronal sutures results in brachycephaly. The majority of children with these lesions do not have associated genetic syndromes. The presence of visible cutaneous tracts, dimples, or palpable subcutaneous masses should raise the suspicion of an encephalocele or tumor, especially when they are in the midline near the nasion or inion. The spine should be inspected to look for dimples, pimples, pits, and tufts of hair, with the level of suspicion for associated spinal dysraphism (lipomas, spina bifida, dermal sinuses, and tethered spinal cord) increasing with more rostral lesions.

Palpation of the skull is important when traumatic lesions such as a cephalohematoma, caput succedaneum, or skull fracture are suspected. The diamond-shaped anterior fontanel should be flat and its center gives way to gentle manual compression, while the borders of the triangular posterior fontanel may not always be appreciated particularly if the sutures are overriding. The presence of a large or bulging fontanel can suggest a skeletal dysplasia or increased intracranial pressure. The final assessment of the head should include the hair pattern. The location of the hairline (widow's peak, low hairline), absence or sparsity (alopecia), quality (wiry, curly, twisted), or color of the hair (gray, blonde, white forelock) is important to note, as these may be associated with genetic or metabolic disorders.

Evidence of minor malformations such as abnormally positioned or rotated ears or eyes, syndactyly, or polydactyly should suggest the possibility of a major systemic malformation since there is a 90% chance of a major malformation when three or more "minor" malformations are identified. When examining the mouth, particular attention should be given to the palate and tongue. A large tongue can be seen in multiple disorders with neurological implications including hypothyroidism, *Beckwith–Wiedemann Syndrome*, and lysosomal storage disorders, while fasciculations of the tongue can be seen in lower motor neuron disease such as Werdnig–Hoffmann (*spinal muscular atrophy, type I*). A high arched palate in a newborn implies hypotonia preceding delivery.

Dermatoglyphics are the dermal ridges on the palmar aspect of the digits, palms, and soles; when abnormal, a variety of syndromes are implicated. The two general categories of dermatoglyphic alterations are an aberrant pattern or unusual frequency or disruption of a typical pattern on the fingertips.

Organomegaly can be seen in infectious diseases as well as storage disorders. The skin exam is important when considering infectious illnesses (petechiae, purpura) or neurocutaneous disorders. Loose or redundant skin can be seen in the SGA infant with a paucity of subcutaneous fat, or in connective tissue disorders such as *Ehlers–Danlos Syndrome*. Disorders of skin color (hyperpigmented, hypopigmented, café-au-lait, nevi) may, depending upon their number or distribution, represent a multitude of diagnoses or be of no clinical significance. Vascular malformations such as the strawberry hemangioma may not always be evident right at birth, or be quite obvious. A port wine stain or capillary hemangioma on the face should always suggest diagnosis of leptomeningeal capillary venous angiomatosis, which can be associated with seizures or glaucoma.

The shape of the thorax may suggest the presence of neurological disease. A narrow superior thorax with a flared, wider base suggests the possibility of pulmonary hypoplasia and respiratory weakness associated with spinal muscular atrophy.

Evaluation of the extremities should include the presence or absence of contractures or arthrogryposis. Limitation of movement in utero can be due to a primary neurological abnormality (meningomyelocele, anencephaly, holoprosencephaly), a muscle disorder (fetal myopathies, myotonic dystrophy, muscle agenesis), a joint or tissue disorder (synostosis, lack of joint development, laxity of joint), or external constraint as is seen in twin or triplet pregnancies.

Neurological Examination

Level of Arousal

The neurological assessment is best performed without overhead lighting directly in the neonate's eyes, as this will in many cases preclude the examiner's ability to visualize the retina and optic disk, or to obtain papillary reflexes. If the infant will not open the eyes, then it will not be possible to make any statements about visual tracking or fixation or to record the presence or absence of even basic observations such as nystagmus or papillary responses. The notion of a level of arousal in a newborn infant does not have the same meaning as in an older infant, but Brazleton's descriptions of six states of arousal: (1) deep sleep (eyes closed, no spontaneous movements except for respirations, limbs flaccid), (2) quiet sleep (eyes closed, eye movements present rare spontaneous limb or head movements, limbs demonstrate some tone), (3) active sleep (frequent spontaneous movements, eyes closed), (4) quiet awake (eyes open, rare spontaneous movements), (5) active awake (eyes open, spontaneous limb movements), and (6) crying – are useful in consideration of an infant's arousal state. Most normal term infants tend to fluctuate between the active sleep and quiet awake states, with other states achieved only briefly or with stimulation. The infant with an encephalopathy, drug toxicity, or neonatal abstinence will tend to assume one of the other states, and be more difficult to coax to the quiet awake or active sleep states. Coaxing may require a soothing voice, dimming of the lights, a gentle touch, pacifier, swaddling, or pharmacological intervention; the difficulty or ease with which calming may be induced may also shed light on the infant's "state."

Habituation

Habituation is the extinction of an observed behavioral response to repetitive external stimulation and may be considered in the assessment of the neonate. A blinking response to light or glabellar tapping, withdrawal of the foot to stroking, or the sudden upper extremity extension and abduction response to noise (Moro reflex) are examples of reflex behaviors that are normally present. Repetition of the stimulus in a normal newborn will reliably produce a response over a limited number of trials (usually 4–8), but then the response disappears. Obligatory occurrence of the response beyond this is abnormal and suggests an impairment of neurological functioning, but should be considered in the context of the rest of the examination.

Eye Examination

Any attempts to examine the eyes should be done in a quiet, darkened room, with the intensity of the ophthalmoscope at the minimum to allow for adequate visualization; high intensity halogen light sources will simply produce lid closure, a resistant baby, and a frustrated examiner. The infant should be swaddled, recently fed if possible, and held in front of the examiner at a 45° vertical angle to facilitate spontaneous eye opening and looking. Retinal hemorrhages may occasionally be seen after a vaginal delivery; their presence is important to note along with the presence of a normal optic disk. Optic atrophy may be the first indication that a more significant neurological disorder such as septo-optic dysplasia may be present. Ipsilateral dilation of the pupil in response to noxious stimulation of the skin is the ciliospinal reflex and may be very useful to the examiner when the integrity of the spinal cord is in doubt as the pupillary dilation response will be absent at spinal segments below the level of the lesion.

Convincing demonstration of visual tracking may require a bright red or highly contrasting white and black object such as a ring target since visual acuity of the newborn is poor. A dimmed pinpoint or penlight light source moved across the visual field in a darkened room may also elicit a visual "grasping" reflex. The twisted end of a sterile cotton swab may be used when necessary to elicit a corneal reflex. Using the vertical axis of the examiner as a reference, clockwise or counterclockwise rotation of the baby will produce leftward or rightward deviation of the infant's eyes, respectively, for the duration of the rotation.

The Face

Useful landmarks are the nasolabial folds, angles of the mouth, and eye lids. Observation of facial symmetry should be performed during differing arousal states, with the quiet awake and crying states most useful. A common source of concern is drooping of the lower portion of the mouth, noted best when the infant cries. When this is the only abnormality on examination, the most likely explanation is hypoplasia or aplasia of the depressor anguli oris muscle of the *opposite* side rather than a central parenchymal or peripheral nerve injury. The presence of a triangular or persistently open mouth should suggest the possibility of a myopathy or muscular dystrophy. The palpebral fissure is the vertical distance between the upper and lower eyelids, and may be difficult to assess in the

recently delivered infant due to edema of the eyelids; attempts to pry the eyelids open will generally result in their eversion. When the eyes are open, the presence or absence of unilateral or bilateral ptosis should be combined with the eye examination to determine whether the ptosis is likely to be related to a focal brain stem or nerve injury rather than generalized weakness as is seen in maternally acquired or congenital myasthenia gravis. Pinching the toes may produce crying: this is a good opportunity to compare the symmetry of movement of both sides of the face as well as the nasolabial folds and forehead creases to the spontaneous facial movements of the awake infant at rest.

The Oropharynx

In utero movements of the tongue will tend to mold the hard palate into a gentle arch during gestation; when oropharyngeal or lingual muscle strength is deficient, the palate develops into a shape like a furrow with a high arch and narrowed distance between the maxillary alveolar ridges. Insertion of a finger into the mouth of a term baby will induce a sucking reflex wherein the finger is forced into the hard palate by the tongue and an undulating anterior to posterior movement of the tongue is combined with a suctioning action. The undersurface of the tongue is a good place to look for muscle fasiculations suggestive of anterior horn cell disease in the weak patient. Mechanical or sensory stimulation of the soft palate, posterior tongue, or superior oropharynx will produce coughing or gagging in the awake infant. The presence of a cleft in the soft or hard palate should alert the observer to the possibility of other midline malformations affecting the hypothalamus or pituitary when clinically suspected. The presence of a single midline incisor or the absence of the upper lip frenulum should raise suspicions that a disorder of prosencephalic development such as holoprosencephaly is present.

The Ear

The shape, size, and orientation of the auricles should be noted; the superior attachment of the ear should be tangential to a line extended from one lateral eye canthus to the other. Malformations of the ear should suggest the possibility of branchial arch anomalies and raise suspicions of accompanying malformations of the middle and inner ear. These may be easily confirmed by computed tomography of the temporal bones. The external auditory meatus receives sensory input from four nerves: the second and third cervical, trigeminal, and vagus nerves. The presence of aberrant sensory input from the vagus nerve may rarely account for unexplained coughing or gagging when the external auditory meatus is stimulated. Bedside tests of audition with a bell, shouting, or a striking of the bed with an open palm are unreliable predictors of intact hearing; any suspicions that a hearing deficit is present should be confirmed by auditory evoked potentials.

Motor Examination

No voluntary motor movements are possible in the newborn of any gestational age, so the traditional methods of assessing muscle strength may not be applied. All movements are involuntary, reflex, or spontaneous; it is the spontaneous movements that are most relevant to the condition of the nervous system. Small for gestational age and premature infants will normally have decreased muscle bulk which in turn affects the ability to hold up the head or resist traction maneuvers, and this may falsely suggest muscle weakness. When hypotonia is present, care must be taken not to assume that muscles must therefore have diminished strength, for both hypotonia and normal strength may be simultaneously present.

Traction maneuvers are the traditional method to assess motor tone in the newborn as well as to make a subjective estimate of relative muscle strength. In the lower extremity the malleoli are grasped between the thumb and first fingers with the baby supine, and the heel is gently lifted upward until the buttocks begins to leave the bed. The popliteal angle so generated is noted, and compared with normal values enumerated by Amiel-Tison for each gestational age. An angle less than specified suggests increased tone; greater suggests relative hypotonia. A similar procedure is possible for the upper extremities: the wrist is gently pulled upward until the shoulder comes off the bed, and the angle at the elbow estimated.

There is by necessity some subjectivity involved in these assessments of tone, leading some authors to question their usefulness. However, observation of posture alone does not always inform the examiner of the degree of muscle tone present since an assessment of tone (intrinsic resistance to passive movement offered by the ligaments, tendons, and muscles) requires actually moving the limbs. Spasticity (an increase in the degree resistance to passive movement when the velocity of induced movement is increased) is rarely present in the newborn, as its appearance implies a passage of time in weeks or months since the causative injury occurred; when marked hypertonia, rigidity, or spasticity is present, other causes such as

severe diffuse cerebral injury, meningitis, posterior fossa lesion, increased intracranial pressure, or the pharmacological abstinence syndrome should be suspected. Finally, hypertonia may be present because of excessive intrinsic muscle contractions seen with myotonic and paramyotonic disorders as well as hyperkalemic periodic paralyses.

Reflexes

Three general categories of reflexes are present in the infant: tendon reflexes, postural reflexes, and brain stem reflexes. Tendon reflexes are generally easy to obtain at the pectoralis, biceps, knee, and ankle jerks. In the term newborn, reflex spread (occurrence of a muscle contraction more than one joint away from the tested reflex) in the form of crossed adductors at the knees is normally present as is ankle clonus, though clonus is always abnormal when sustained or asymmetric. Postural reflexes are the intrinsic changes in tone or posture induced by movement, tactile stimuli, or the position of a body part. These include the rooting, glabellar, palmomental, palmar and plantar grasping, Moro, tonic neck, righting, placing and stepping, Landau, Galant, Santmyer swallow, vertical and horizontal suspension reflexes. Postural reflexes generally disappear with time and may reappear late in life either as a part of normal aging or in the context of various progressive or degenerative disorders as "release" phenomena. Brain stem reflexes have been described elsewhere in this chapter. The presence or absence and symmetry of the reflex responses should be noted.

Sensation

The sensory examination is of limited value in the newborn, as there are few ways to determine whether stimulation is perceived. Gradations of sensory stimulation (tickling, touching, firm pressure, or forceful pinching) may be used to generate responses varying from toe flexion, head turning, limb withdrawal, or crying, and are of most use in two situations: determining level of responsiveness and in assessing whether sensation is present in a paretic limb.

Clinical Problems

The seven categories are:

1. Excessive spontaneous motor movements
2. Diminished spontaneous motor movements
3. Alteration of mental status
4. Changes in head size and pressure
5. Hypoxic-ischemic encephalopathy
6. Imaging abnormalities
7. Brain death determination

Excessive Movements (Non-epileptic)

Jitteriness

Neonates often display abnormal movements that may suggest the possibility of seizures such as jitteriness, excessive startling, pedaling or stepping movements of the limbs, oral-lingual-buccal movements, or transient dystonic posturing. The traditional definition of seizures requires that neuronal paroxysmal discharges as documented by the electroencephalogram accompany the behavior in question. When such discharges are present, the diagnosis of seizures is not in doubt. When discharges cannot be documented in the neonate, however, the diagnosis of seizures is called into question but not necessarily excluded. This particular situation is discussed in the chapter on neonatal seizures. This section concerns movements that are *not* epileptic in origin.

Jitteriness is a low frequency, large amplitude tremulousness of the limbs and jaw that may be both spontaneous and provoked by innocuous visual, sensory, or auditory stimulation. Eye movements and gaze are normal, and help to distinguish jitteriness from seizures. While jitteriness may be regarded as a sign of central nervous system irritability, it may also be seen in up to 40% of normal term newborn infants. Tendon reflexes, a spontaneous Moro, and clonus are concomitantly exaggerated and easy to elicit. Gentle suppression of the limb movements with the examiner's hand will generally inhibit jitteriness; when it does not, seizures should be suspected. The more common causes of jitteriness include perinatal asphyxia, hypocalcemia, hypoglycemia, hypoxic-ischemic encephalopathy, and drug withdrawal. Correction of hypocalcemia or hypoglycemia will usually abolish jitteriness.

Neonatal Abstinence

Infants withdrawing from maternal drug exposure may develop seizures if their abstinence is severe, but more often they have tremors, jitteriness, and irritability, and are very difficult to console due to a heightened level of

arousal with persistent crying. The common maternally used drugs known to cause neonatal abstinence include opiates, cocaine, benzodiazepines, nicotine, and the selective serotonin reuptake inhibitors. Many infants may require only environmental comfort measures to reduce the symptoms, while others require pharmacotherapy. Opiates alone or in conjunction with phenobarbital are used to treat opiate withdrawal, while phenobarbital is the drug of choice for non-opiate withdrawal. Withdrawal behaviors typically appear within the first 3 days of life, although withdrawal signs and symptoms sufficient to require medication have been reported to occur as late as 1 week of age and may persist for months. While only small amounts of maternal opiates are known to cross into breast milk, if an opiate-using mother nurses her infant then abruptly stops, the infant can develop withdrawal symptoms.

Myoclonus and Clonus

Myoclonus is a sudden, brief contraction of a muscle or muscle groups. It can be generalized and can occur in the neonate as a non-epileptic paroxysmal phenomenon. Benign neonatal sleep myoclonus occurs only with (non-rapid eye movement) sleep and begins in the first week of life, with episodes lasting several minutes. They may be provoked during sleep by jarring or rocking the bed or by exposure to benzodiazepines, and disappear upon awakening. EEG is normal with no electrographic correlate, and spells generally end before the third month of life. No other neurological or developmental impairment is present.

In otherwise healthy full-term infants, persistent multifocal clonic movements appearing toward the end of the first week of life and lasting a day or so (rarely up to 2 weeks) may suggest benign idiopathic neonatal seizures or "fifth day fits." This poorly understood condition has a generally good prognosis and a normal outcome, though the paroxysms may progress to status epilepticus and require anticonvulsants.

Hyperekplexia is an exaggerated provoked startling followed by rigidity and stiffness. Innocuous sensory stimulation brings the resting infant into an appearance of repeated startling, then increasing truncal and extremity tone, jitteriness, and dystonic posturing. Apnea may result when stiffness is excessive, and in this way hyperekplexia may be life threatening. "Breaking" the tone by forcibly overcoming the stiffness may abort the attack, and benzodiazepines may prove to be useful in reducing all symptoms. EEG during the attacks shows no electrographic correlate. Hyperekplexia has been linked to abnormal functioning of the alpha-1 subunit of glycine receptors, with inhibition of the inhibitory interneurons within the brain stem reticular formation resulting in excessive startling.

When cerebral anoxia is both prolonged and severe and the resulting encephalopathy profound, persistent spontaneous and stimulus-evoked myoclonus (Lance–Adams syndrome) may be present. The myoclonic jerks in this circumstance are generalized, frequent, and give the appearance of status epilepticus, though the electroencephalogram shows no accompanying paroxysmal discharges; anticonvulsants generally have no effect and do not modify the neurological outcome, which is uniformly poor.

Torticollis

There are two components to true torticollis: there is a tilting of the head on the neck as well as a cervical rotational component so that the chin is turned toward the shoulder. Head tilting alone should not be considered as torticollis; other causes for head tilting such as nuchal or posterior fossa masses, anatomical anomalies of the craniovertebral junction, or cervical vertebral malformations should be investigated. Shortening or limitation of movement of the ipsilateral sternocleidomastoid muscle is the final common pathway to torticollis, with the precipitating causes ranging from intrauterine malpositioning or constraint and breech presentation to intramuscular fibrosis with or without hemorrhage. When fibrosis is present, palpation of the affected muscle or ultrasound may identify the lesion. Physical therapy in most cases will result in improvement, as long as both rotational components of the torticollis are addressed independently. Untreated or unrecognized torticollis may lead to ipsilateral usually posterior plagiocephaly and may rarely result in anterior displacement of the ear, ipsilateral forehead, temporomandibular joint, and orbit.

Opisthotonos

The opisthion is the anatomic posterior-most point of the foramen magnum. In opisthotonic posturing, the head is persistently and abnormally retroflexed about this point (retrocollis), and the trunk is arched posteriorly due to abnormal contraction of the midline truncal extensor muscles. Opisthotonos may be seen in meningismus, in the presence of large posterior fossa mass lesions, in aminoacidopathies, urea cycle defects, organic acidurias,

disorders of trace elements, the porphyrias, and when intracranial pressure is elevated. Opisthotonic posturing should not be confused with the similar but more transient posturing of the term infant delivered with a face presentation. Opisthotonos has been associated with acute bilirubin encephalopathy and kernicterus, but in this circumstance is more of a dystonic posturing of extrapyramidal origin than a phenomenon related to obstruction of cerebrospinal flow or meningeal inflammation.

In the newborn period and during infancy, gastroesophageal reflux is commonly associated with more transient episodes of opisthotonic and frankly dystonic truncal posturing. This association is frequently mislabeled as the Sandifer syndrome and has entered common usage this way although Sandifer's original description was in older children with both episodic dystonia and hiatus hernia; when the hernia was surgically corrected, the movement disorder disappeared. Episodic opisthotonus or dystonia in a newborn may be easily confused with seizures and may have no direct relationship with feeding, though prone positioning frequently exacerbates the reflux and subsequent motor behaviors. Treatment with histamine-2 receptor blocking agents does not generally reduce reflux, but may reduce the acidity of the refluxed fluid. Pharmacologic agents that modify gastrointestinal motility are more effective treatments for reflux, especially when combined with reverse Trendelenburg positioning of the infants. Some commonly used agents such as metoclopramide must be used with care, since drug-induced extrapyramidal side effects may be difficult to differentiate from the GER-induced dystonic or opisthotonic posturing.

Myotonia

Myotonia is a transient but sustained (seconds long) contraction of a muscle or muscle group in response to percussion. This is most easily done with a triangular (Taylor) or ball type (Tromner) reflex hammer. The thenar eminence of the hand is the most accessible group of muscles, with percussion producing a visible tonic opposition of the thumb. Percussion of other large muscles such as the biceps or quadriceps may not result in visible movements, though palpation of the just-percussed muscle will easily detect the local contraction. Myotonia is most closely associated with myotonic dystrophy; when myotonic dystrophy is present in the newborn period, the most likely genetic donor is the mother as discussed later in the chapter.

Muscle Fasciculations

Fasciculation is a spontaneous irregular contraction of the muscles subserved by a motor unit, and does not generally result in visible movement of a joint, the contractions limited instead to the muscle itself. Fasciculations are best observed in the newborn on the undersurface of the tongue of the newborn. Irregular contractions of the superior surface of the tongue of the otherwise normal newborn should not be confused with the "bag-of-worms" appearance of the inferior tongue surface in the infant with anterior horn cell or lower motor neuron disease. In type I *spinal muscular atrophy*, the presence of significant weakness, reduced or absent tendon reflexes, and abnormal shape of the thorax are regularly present and should suggest the diagnosis.

Deficiency of Movement

Brachial Plexus Injuries

In the newborn, deficiency of movement implies muscle weakness. Weakness can be of myogenic or neurogenic origin, and be limited to a single limb or portion of the body or be generalized. When weakness is isolated to a single limb, the weakness is unlikely to be myogenic. Paresis of a single arm at delivery is a fairly common cause for neurological consultation, especially in large infants or when excessive traction has been applied to the arm during delivery. There are five spinal segments and nerve roots from which the brachial plexus originates: cervical segments 5–8 and the first thoracic. These nerve roots combine to form upper, middle, and lower nerve trunks which, with the insertion of the roots into the spinal cord, are the most common sites of injury when traction is excessive.

Two general patterns of injury are seen in the term infant. When upper cervical roots (C5, C6) are injured, the pattern of weakness is as originally described by Erb: weakness or paresis of shoulder abduction and external rotation, biceps, brachioradialis, and supination. Wrist and finger extensors may sometimes be weak as well. Ipsilateral diaphragmatic weakness may be present when the C4 and C3 roots are simultaneously affected. The biceps reflex is absent in the affected arm, and the Moro is typically asymmetric. The best way to demonstrate the Moro is as he originally described it: to strike the bed next to the infant with the palm of the hand. Finger and palmar grasp reflexes are unaffected in Erb palsy.

When the lowermost roots and trunks of the brachial plexus are injured, the distal upper extremity is paretic with no finger or wrist movements elicitable, as described by Klumpke. This is an uncommon injury in the newborn, for whom a lack of finger movements usually implies a lesion involving the entire origin of the plexus at the spinal roots. In this circumstance an ipsilateral Horner syndrome is typically present.

While outcome is generally good unless nerve roots are avulsed, treatment options are limited and intended to minimize the possibility of joint contractures developing during the weeks or months required for recovery at a time when the infant is simultaneously growing. Range of motion exercises for all of the upper extremity joints including the shoulder, and splinting, where necessary, are generally sufficient. Most infants have recovery of function to the point where a routine neurological examination shows no deficits by 6 months of age, with the majority of improvement within the first few weeks to months. When weakness is present still at 6 months of age, a permanent degree of weakness becomes increasingly likely. Surgical intervention should be considered earlier rather than later, although the most appropriate time of surgery is still uncertain. The first consideration of neurosurgical referral for lysis of fibrotic tissue, neuromas, and grafting of viable roots should be considered at 2 months of age so that surgical intervention by 4 months of age can be performed in the event that weakness still has not improved.

Lumbosacral Plexus Injuries

Paralysis of a leg is seldom seen in the newborn, and occurs when traction of the leg during frank breech deliveries results in injury to the lumbar (L2-4) or sacral (L4-S3) plexuses. The rarity of this injury should lead to consideration of other causes such as occult dysraphism, though spinal dysraphism is very unlikely to involve a single limb alone. Prognosis for complete recovery is much less optimistic for the paretic leg than for the acutely paretic arm in the newborn.

Unilateral Facial Weakness

Congenital aplasia or hypoplasia of the depressor anguli oris results in an abnormal appearance of the crying or, in an older infant, smiling face. The corner of the mouth does not move inferolaterally, giving the illusion of a contralateral facial weakness. This is usually an isolated phenomenon, but may rarely be associated with other congenital defects or as a sign of the *Cayler cardiofacial syndrome* in which various cardiac defects may be present.

The facial nerve is vulnerable to traumatic injury; its emergence from the stylomastoid foramen just inferior and medial to the inferior attachment of the ear and subsequent branching to supply the muscles of facial expression makes it especially susceptible to compressive injury by external forces. Unilateral facial weakness is most frequently noticed shortly after delivery and involves both the upper and lower halves of the face. A flattening of the nasolabial fold and forehead creases may be noted, especially during crying, and feeding may be complicated by the leakage of milk from the ipsilateral corner of the mouth. In the context of the use of forceps during delivery, mechanical pressure on the nerve at its emergence may result in weakness, but facial weakness can also be seen when no forceps or vacuum-assisted extraction has occurred. Prolonged intrauterine impaction of the angle of the jaw onto the ipsilateral shoulder, a bony projection of a twin, or the maternal sacrum may result in a facial paresis; in such cases the normally excellent prognosis for a complete recovery is not as optimistic. Treatment with artificial tears or forced closure of the ipsilateral eyelids with gauze and tape is directed at preventing corneal ulcerations because of the inability to blink.

Bilateral Facial Weakness

Paresis of both sides of the face is evident when the child has an expressionless face even when provoked to the point of crying by noxious stimulation. Acquired transient weakness in the form of maternal myasthenia gravis should be differentiated from other forms of generalized motor weakness such as myotonic and other muscle dystrophies, and from the *Möbius sequence*, classically described as the presence of bilateral facial and abducens paresis in a newborn. The source of the paresis is aplasia or hypoplasia of two or more pairs of cranial motor nuclei within the dorsum of the brain stem, so the classic signs of the Möbius sequence should provoke a clinical search for weakness mediated by involvement of the other cranial nerves including the hypoglossal nerve which will affect feeding. Causation is unknown, and may be developmental or acquired. Treatment is directed at finding a method of feeding that allows for sufficient intake, since inability to seal the lips around a nipple poses a major hazard to the

infant. Associated incomplete eyelid closure is managed in the same way as in unilateral facial paresis.

Ophthalmoplegia

Ophthalmoplegia and ptosis may occur independently, and can be acquired or "congenital." In contrast to older children with myasthenia gravis, infants with maternally acquired transient myasthenia gravis do not typically have either ophthalmoplegia or ptosis, presenting instead with hypotonia, generalized weakness, and feeding difficulties in the first hours of life. Administration of cholinesterase inhibitors may be necessary for this condition, one that generally abates by 3 weeks of age. Cholinesterase inhibitors may or may not be useful in the treatment of *congenital* myasthenic syndromes, which are *not* transient and *do* present with prominent ptosis and ophthalmoplegia.

The congenital myasthenic syndrome comprises a heterogeneous group of rare disorders that reflect genetically determined defects of the neuromuscular junction, with only a few generating clinical suspicion in the newborn period and are discussed later in the chapter in the section on Weakness.

Waxing and waning paresis of extraocular muscles in the newborn, especially in the presence of other signs such as internuclear ophthalmoplegia, facial weakness, or glossopharyngeal dysfunction should suggest the possibility of a metabolic encephalopathies such as *maple syrup urine disease*.

The clinical signs of Möbius sequence have already been discussed, and should be differentiated from congenital third nerve palsy, familial congenital ptosis, and the Duane syndrome, in which the pareses are generally restricted to the oculomotor system. In the *Duane retraction syndrome*, there is partial abduction of the eye and upon attempted abduction, retraction of the globe of the eye into the orbit causing the palpebral fissure to narrow. This is caused by a usually unilateral absence of the abducens nerve along with its nucleus in the pons. There is often an accompanying fibrosis of the lateral rectus muscle, linking this syndrome with other conditions leading to fibrosis of the extraocular muscles such as Congenital Fibrosis of the Extraocular Muscles (*CFEOM*) in which the eyes are fixed in a position of strabismus, and ptosis is prominent. Coaxing the newborn infant to voluntarily move the eyes in order to make any of these clinical diagnoses is difficult; the examiner may have to resort to the use of oculovestibular maneuvers, caloric stimulation of the tympanic membranes, or retreat to a dark room as described in the section on the neurological examination.

Laryngeal, Vocal Cord, and Pharyngeal Weakness

Abnormalities of sucking, swallowing, crying, and breathing are not uncommon in the newborn. Apart from the normal developmental evolution of the coordination of sucking, swallowing, and breathing in the preterm infants, the presence of such dyscoordination in the term infant may be life threatening. The laryngeal nerve has two branches of interest, the recurrent laryngeal and superior branches. The recurrent branch may be injured when the thyroid cartilage is forced against the cricoid cartilage during prolonged lateral neck flexion in utero or during delivery causing unilateral vocal cord paresis and an abnormal stridorous cry. The superior branch may be similarly compressed by the thyroid cartilage against the hyoid bone, causing trouble with swallowing and a substantial risk of aspiration with feeding. Isolated pharyngeal weakness is probably more common than the literature would suggest, and is not always evident until the first feeding when cyanosis, choking, and aspiration simultaneously appear (Table 360.2). The most useful diagnostic testing is with direct laryngoscopy and videofluoroscopy; magnetic resonance imaging is necessary when other malformations are present, there are focal neurological findings on examination, or when cerebral malformations are suspected.

Hemiparesis and Stroke

Hemiparesis resulting from large middle cerebral arterial infarctions may be clinically unapparent in the neonate, with no obvious limb use asymmetry until the infant begins to crawl or walk. The cause of large cerebral arterial

Table 360.2

Stridor	+	+	–

infarctions, which occur in more than 5% of infants, remains unknown in the majority of cases. Ischemic stroke is more common in the newborn than in older children, and has been estimated to occur in 1 of every 4,000 live births. Although the timing of stroke discovered in the newborn period has been considered as *fetal* (focal ischemic, thrombotic, and/or hemorrhagic event occurring between 14 weeks gestation and the onset of labor resulting in delivery) or *neonatal* (occurring between labor resulting in delivery and 28 days of life), this distinction may be somewhat arbitrary since clear etiologic or prognostic differences for strokes in these two epochs are not present. Most infarctions are ischemic and unilateral, with the majority of these involving the middle cerebral artery. The remainder is related to hemorrhage and cerebral venous sinus thrombosis. Unexplained is why the left middle cerebral arterial distribution is affected more commonly than the right side. Infarction from arterial occlusion is more common in the term than the preterm infant with the incidence increasing from 5% of infants between 28 and 32 weeks gestational age to 15% in infants between 37 and 40 weeks.

Two patterns of arterial occlusion are present on neuroimaging when hemiparesis is present, and they do offer some guidance in an investigation of cause. Most identifiable causes are related to adverse maternal conditions (i.e., diabetes, hypercoagulable states, anticonvulsant or warfarin use, gastroenteritis with fever, idiopathic thrombocytopenic purpura), pregnancy disorders (i.e., preeclampsia, abruption, in utero growth retardation, twins, oligohydramnios, chorioamnionitis), or fetal disorders (i.e., TORCH-type infections, Rh isoimmunization, alloimmune thrombocytopenia, protein C deficiency).

The presence of multiple arterial infarctions should suggest the possibility of congenital heart disease, polycythemia (venous hematocrit of >65% or hemoglobin >22 g/100 mL in a symptomatic term infant), disseminated intravascular coagulation, or perinatal distress.

Single artery distribution infarctions should raise the possibility of a focal arterial vascular anomaly or thrombotic occlusion, ischemic proliferative vasculopathy when twins are present, or vasospasm related to maternal substance abuse, especially cocaine.

When the infarctions are remote, there is an increasing recognition that genetic factors may be present, such as the *hypoprothombinemia, 5, 20-methylenetetrahydrofolate reductase*, and *COL4A1* genetic deficiencies. The latter has been associated with familial cases of *porencephaly*.

Mechanical occlusion of cerebral arteries may occur during or after delivery, resulting in ischemic parenchymal injury and focal neurological symptoms. When the neck is hyperextended and rotated, the lumen of the internal carotid artery may be narrowed or occluded as it passes over the lateral portion of the upper cervical vertebrae. A similar injury may occur in the *posterior* circulation during hyperextension and rotation of the neck. At birth, the foramen magnum is almost its adult size, but both the lateral mass of the atlas and the atlantooccipital condyle are hypoplastic. These conditions result in a narrowing of the spinal canal within the atlas. In addition, the ligaments between atlas, occiput, and axis are lax, so that the vertebral arteries are vulnerable to compression between the bony lamina of the atlas and the exoccipital bone when even mild hyperextension of the neck occurs. The compressed vertebral arteries will reduce blood flow to the brain stem, cerebellum, and upper cervical cord, and may result in stroke.

Acute strokes of either venous or arterial origin most often present as focal motor seizures involving a single extremity rather than hemiparesis, and have been estimated to account for up to 10% of all seizures in neonates.

Weakness associated with remote (weeks to months old) arterial occlusions may not be immediately apparent. The abrupt appearance of weakness in an arm and leg (face is usually not affected) when normal movement had been documented previously should suggest an acute arterial occlusion and should provoke a more energetic investigation as to cause than remote occlusions, for which an etiology can only rarely be discovered. A suggested diagnostic panel is given in Table 360.3. One purpose of a diagnostic workup, even when the chances of discovery of an etiology is unlikely, is to estimate the risk of stroke recurrence. Recurrent thromboembolism, acute ischemic stroke, and cerebral venous sinus thrombosis do occur, and are more likely when factors promoting thrombosis such as complex congenital heart disease, sepsis, or hypovolemia are present.

Treatment of neonatal stroke is supportive. The safety of medical thrombolysis is unproven in the neonate, and the deployment of agents to promote thrombolysis such as unfractionated or low molecular weight heparin is not common. The exception to this is when cardiac or multiple systemic thrombi or a clear tendency to prothrombosis is present. Low platelet counts and coagulation factor deficiencies should be corrected. Vitamin K should always be administered to the newborn, especially when exogenous pharmacological agents such as warfarin, barbiturates, or phenytoin have been administered to the mother during the pregnancy or when biliary atresia is present.

Outcome and prognosis in neonatal stroke is variable, with estimates of disability differing widely. A "normal" outcome is possible, but so too is mild to dense

hemiplegia. Most children with a history of neonatal stroke will learn to walk independently before the end of the second year of life. Epilepsy after the neonatal period, even when seizures are the presenting sign of stroke, is uncommon. Cognitive impairment may range from severe to none at all. The possibility of clinically and academically significant disabilities should be anticipated including cognitive and learning deficits, non-progressive impairment of motor functioning (cerebral palsy), sensory and visual deficits, and epilepsy. When hypoxic-ischemic injury is complicated by or superimposed upon stroke, outcome is generally worse.

Paraparesis

Simultaneous weakness of both legs is rarely seen in the neonate. Congenital malformations of the caudal spinal cord, conus medullaris, and cauda equina may produce variable degrees of asymmetric weakness, tendon reflexes, and sensory impairment, making it difficult to differentiate central from peripheral causes of paraparesis on clinical grounds alone. Cerebral lesions may produce weakness of the legs. Parasagittal primary motor cortex corresponding with the lower extremities may be injured after prolonged hypotension and hypoperfusion, causing a borderzone infarction between the middle and anterior cerebral arterial supplies. Arm weakness may be similarly produced with more lateral anatomical displacement of the borderzone area. Cystic or hydrocephalic disruption of periventricular white matter tracts in the preterm infant will produce bilateral leg weakness although this is not generally clinically apparent in the newborn period. Disruption of the spinal cord may occur when excessive spinal traction has taken place during delivery, and cause a flaccid weakness and areflexia below the torn spinal segment.

Quadriparesis, Generalized Weakness, and Hypotonia

Quadriparesis is rare in the neonate. Posterior fossa lesions and upper cervical spinal cord injuries should be suspected and excluded by appropriate neuroimaging. Quadriparesis should be differentiated from generalized weakness and hypotonia wherein the presence of muscle tone can generally be documented. When it is present in the newborn period, quadriparesis due to compressive or disruptive spinal cord injuries results in a relative *absence* rather than an *increase* of tone. Spasticity and hypertonia following quadriparesis will frequently appear in the weeks to months after injury but are not seen during the first month of life unless the cerebral injury has preceded delivery by the same time interval.

Inability to move the limbs may occur when their joints are limited in their excursion as is seen in the clinical entities described by the term *arthrogryposis multiplex congenita*. This is not a single disease but a final common clinical observation for a number of disorders that may affect any part of the nervous system. Many additional congenital anomalies are often present along with the joint limitations and reflect underlying muscle hypotrophy or atrophy, weakness, and hypo- or areflexia. More than 150 distinct clinical syndromes are known to result in the

physical finding of arthrogryposis. Talipes equinovarus, micrognathia and retrognathia, clinodactyly, and camptodactyly occur when there is insufficient in utero movement of the joints; polyhydramnios and a high arched palate with narrowed alveolar ridges reflect weakness and lack of movement of the muscles of deglutition. Arthrogryposis has been associated with central nervous system malformations at every level, from migrational disorders in the brain and cerebellum to dysplasia of anterior horn cells and meningomyelocele in the spinal cord, to myasthenic syndromes, merosin-related dystrophies, glycogen storage disorders, and mitochondrial cytopathies affecting muscle, to hypomyelination syndromes affecting the peripheral nerves.

Transient maternally acquired myasthenia gravis occurs in as many as one in five infants born to myasthenic mothers. The weakness is usually apparent within the first hours of birth, but may become evident after an initial brief period during which no weakness can be observed, and may rarely become evident as late as the second postnatal day. The predominant clinical feature is feeding difficulty, with sucking and swallowing problems quickly leading to respiratory distress. Mechanical ventilatory support and gavage or nasogastric tube feedings are required in about one in three infants. The remainder of treatment is generally supportive since duration of symptoms does not generally last for more than 3 weeks. Circulating maternal acetylcholine receptor protein antibodies may be transmitted across the placenta to the infant and exert their pathogenic effect on acetylcholine receptors at the postsynaptic muscle membrane causing receptors to be degraded, displacing acetylcholine from the receptors, and inducing local degradation of the receptor expressing muscle membrane via complement. Diagnosis is made clinically, and may be confirmed by demonstrating an electrodecremental response to repetitive stimulation on electromyography. Expertise in neonatal electromyography is not widely available, and is not therefore practical for the vast majority of hospitalized infants throughout the world. An alternative confirmatory procedure is the test administration of an anticholinesterase agent such as the short acting edrophonium (0.15 mg/kg administered intravenously in fractions over a several minute period after an initial dose of 0.03 mg/kg) or the longer acting neostigmine methylsulfate (0.04 mg/kg administered intramuscularly or subcutaneously). Each medication yields a positive result when clinical improvement in the form of sucking or swallowing, crying, breathing, or facial movement is seen. The duration of improvement is short lived, with edrophonium-induced improvement appearing within 5 min and persisting for up to 15 min. Neostigmine-induced improvements may not appear for up to a half hour after administration. For administration of either anticholinesterase there is risk of excessive muscarinic side effects, and so atropine should be simultaneously available at the moment of injection.

Neonatal maternally acquired myasthenia gravis is a transient phenomenon; while the infant may become quite ill and require complete ventilatory and feeding support, improvement will occur and prognosis for normal outcome is excellent. It is common practice to use exogenous anticholinesterase medications such as neostigmine (intravenous dose of 0.04 mg/kg or nasogastric dose of 0.4 mg/kg) a half hour before feedings for the first weeks of life.

A complete discussion of the congenital, non-acquired myasthenic syndromes is beyond the scope of this chapter. More than a dozen such syndromes are known, variously affecting individual steps within the pathway associated with the assembly of acetylcholine, its vesicles within the presynaptic terminal, or its receptor on the postsynaptic membrane. A clinical response to the administration of acetylcholinesterase may not be seen in the congenital myasthenic syndromes, and should not be used to exclude the diagnosis that requires electrophysiologic investigation.

Other genetic causes of generalized hypotonia include myotonic dystrophy and Prader–Willi syndrome; these are common enough that genetic testing should be considered in all infants presenting in the neonatal period with symmetric muscle weakness and hypotonia. In *Prader–Willi syndrome*, hypotonia is severe, reflexes diminished or absent, feeding and crying weak, and subtle dysmorphic features such as a narrow bifrontal diameter, almond shaped eyes, small mouth, or hypogonadism present. There is frequently a history of diminished movement preceding delivery.

Although *congenital myotonic dystrophy* is an autosomal dominant disorder, when it is present in the newborn the parent contributing the trait is almost always the mother. It is one of a number of disorders known to be associated with an increased number of CTG trinucleotide repeats, in this case in an unstable DNA sequence on the 3′ untranslated end of the myotonic dystrophy gene on chromosome 19. While paternal transmission of the gene does rarely occur in the newborn period, maternal transmission is the rule, and the severity of disease is highly correlated with the total number of repeats. With each female transmission, the number of repeats increases, further worsening severity and causing symptoms earlier in life, a phenomenon referred to as anticipation. Prognosis is dependent at some level on the number of CTG

repeats, and further determined by the severity of weakness, respiratory compromise, gastrointestinal motility, and cognitive impairment universally present. The *mother's* appearance should therefore give the first clinical clues as to the potential presence of myotonic dystrophy in the hypotonic infant; upon shaking her hand at the first meeting, her hand may not immediately release its clasp due to myotonia.

Diaphragmatic Paresis

Persistent unexplained respiratory difficulty in the first hours of life may be caused by unilateral diaphragmatic paralysis. Cyanosis and arterial blood gas determinations may suggest the possibility of hypoventilation and congenital heart or primary pulmonary disease. Routine chest radiographs may not show the familiar hemidiaphragmatic elevation characteristic of paresis in the older child or adult. After an initial period of respiratory distress, there may be a stabilization or improvement with oxygen supplementation, but a more severely paretic infant may instead acutely deteriorate. Diagnosis is made by ultrasonic or fluoroscopic real time imaging of respirations, demonstrating the paradoxical upward movements of the affected hemidiaphragm with breathing. Any such imaging will yield a false negative result if positive pressure ventilation is in use at the time of the test. Diaphragmatic paralysis results from injury to the 3rd, 4th, and 5th cervical nerve roots, and thereby complicates about 5% of brachial plexus injuries, but it may occur without arm weakness as well. Long-term prognosis depends upon the response to ventilatory interventions such as intermittent positive pressure ventilation, but when it becomes clear that there has been no improvement, surgical plication of the hemidiaphragm may be indicated.

Alteration of Consciousness

Encephalopathy

The traditional definition of encephalopathy as the clinical condition resulting when any two of (1) seizures, (2) alteration in the state of consciousness, or (3) alteration in cognition or personality are present cannot be applied easily to infants, for whom changes in cognition are not possible to detect and personality is not present. Instead, neonatal encephalopathy may be better defined as a condition in which there is altered consciousness, difficulty in initiating and maintaining spontaneous respirations, and associated depression of reflexes and muscle tone with or without seizures. Major categories of causes for neonatal encephalopathy can be separated into *intrinsic* deficiencies (genetic, enzymatic, subcellular organelle dysfunction) and *acquired* disorders (infection, cerebral hemorrhage or thrombosis, hypoxic-ischemic).

The clinician should be aware that other conditions such as congenital heart disease, neuromuscular disorders, congenital myopathies, and cerebral malformations may give the infant the *appearance* of an encephalopathy because of accompanying profound hypotonia or weakness when an *actual* encephalopathy, best determined by electroencephalography, is absent.

Important enzymatic deficiencies producing encephalopathy in the newborn, especially the amino and organic acidopathies, are covered in the chapter on metabolic disorders. These generally evolve over the first days of life, and yield as clues altered levels of glucose, ammonia, serum ketones, and sometimes an obvious clinical deterioration after feedings. Deficient levels of glucose, sodium, calcium, and magnesium are commonly present in the newborn and need to be recognized and treated before the encephalopathy is corrected.

Incipient or evolving infection, especially in the context of diminished peripheral perfusion, tachycardia, and hypotension should always be considered as an emergent cause for encephalopathy. A well-appearing infant can be dead in a matter of hours from certain bacterial infections, with Group B *Streptococcus*, *Escherichia coli*, and *Klebsiella* being the most notorious. A complete septic workup including lumbar puncture, blood cultures, and urine culture is necessary to identify and properly isolate the offending bacterium. Congenital cytomegalovirus and herpesvirus infections are usually readily identifiable in retrospect on clinical grounds but may pose diagnostic dilemmas if they are not considered or when typical ocular or cutaneous lesions are absent.

Herpesvirus infections are usually acquired during delivery when asymptomatic maternal vaginal lesions are present, when there are active lesions in a mother not known to have had prior herpes infections (type II), or from infected hospital personnel or family members handling the infant (type I). The resulting symptoms in the newborn appear by the end of the first week of life in the form of poor feeding and lethargy. Irritability or its opposite, somnolence, is followed by focal seizures with rapid progression to stupor and coma. Lumbar puncture should be performed in all such infants with care taken to distinguish traumatic lumbar puncture (many red cells, clear, colorless supernatant) from the xanthochromia, white

blood cell pleocytosis, and elevated protein in cerebrospinal fluid when herpes is present. Treatment with acyclovir should never be postponed or delayed until laboratory testing or PCR results are returned as the acyclovir is viro*static* rather than viro*cidal*, and the hemorrhagic encephalitis-induced destruction of brain parenchyma is already under way. Prognosis in such an event is grave.

Intracranial Hemorrhage and Post Hemorrhagic Hydrocephalus

Intracranial hemorrhage is an important cause of altered mental status and neurological debilitation in the newborn, and has many sources. Subdural, subarachnoid, intraparenchymal, and intraventricular hemorrhages are the most common. During vaginal delivery, especially when vacuum extractors are applied, the relative motion of the bones of the deforming cranial vault may exert traction on the major venous sinuses affixed to them. The confluence of the straight and transverse sinuses, vein of Galen, and the free tentorial edges at the junction of the double layered falcine and tentorial dura is especially vulnerable to tearing, with leakage of venous blood into the juxtatentorial or parafalcine spaces. There may be a rapid and extensive accumulation of venous blood, with a full fontanel, depressed level of consciousness, skew eye deviation, pupillary asymmetry, abnormal response to light, and nuchal rigidity. Coma, fixed dilated pupils, and respiratory rhythm disturbances follow over the next hours. A similar progression of events follows the disruption and displacement of the occipital bone (occipital osteodiastasis) with difficult breech deliveries; in this circumstance, the transverse sinuses or the vein of Galen may be disrupted and death follows.

Subdural blood may appear in the *infratentorial* space without producing any clinical symptoms and be noted incidentally upon routine neuroimaging. Blood also may slowly accumulate in the posterior fossa leading to signs of brain stem dysfunction (apnea, bradycardia, eye deviations) and compression (irritability or lethargy, full fontanel, increasing OFC) suggestive of increased intracranial pressure. No clinical signs may be present when subdural blood appears in the *supratentorial* space or there may be clinical signs (hemiparesis, eye deviation, dilated pupil) of an evolving herniation when the volume of blood is large. The volume of subdural blood present may be easily underestimated on neuroimaging, especially when the width of the observed blood on MR or CT slices is small but the number of images showing blood present is large.

Subarachnoid hemorrhages are relatively common in the newborn. They may be seen incidentally on imaging in an infant with no clinical signs, or be associated with focal seizures in an otherwise healthy looking infant. Diagnosis is made by CT or MRI, and may be suspected when the spinal fluid of an infant with seizures shows an excessive number of RBCs and an elevated protein. Lumbar puncture is usually done in such an infant for other reasons such as to exclude infection and the abnormal CSF is found incidentally; care should be taken to differentiate this clinical presentation from that described in extensive subdural supratentorial or infratentorial hemorrhage, for which lumbar puncture may provoke cerebral herniation. Prognosis in most cases of subarachnoid hemorrhage is generally good and seizures can be expected to remit spontaneously.

Intraparenchymal hemorrhage in the newborn is not uncommon and disproportionately affects premature infants, with the most premature among them bearing the greatest risk. Primary hemorrhage may be conceptually distinguished from hemorrhage that secondarily complicates venous infarction or ischemic parenchyma, but from a clinical and management standpoint there is little to distinguish them. The cerebellar hemisphere is a common location for hemorrhage in very premature infants, and produces signs and symptoms similar to infratentorial subdural hemorrhage already described. CT and MRI are preferred to ultrasound at documenting the extent and location of cerebellar hemorrhage. Surgical intervention other than ventriculoperitoneal shunting when obstructive hydrocephalus complicates cerebellar hemorrhage does not demonstrate clear advantages over medical management in term infants, and probably contributes to morbidity and mortality in preterm infants. Recent evidence suggests that prior assumptions regarding the benign nature of cerebellar hemorrhage are incomplete. Long-term follow-up of such infants suggests that there is a markedly increased risk of significant cognitive impairment including pervasive developmental disorder, and reflects an evolving recognition of the importance of the cerebellum to cognitive processes other than coordination including emotional affect, language development, and mathematical abilities.

Intraventricular hemorrhages are relatively common in the term infant, and should not be confused with the entity of the same name as applied to premature infants. The latter should be more appropriately described as germinal matrix hemorrhages, even when blood within the germinal matrix escapes into the ventricle. In term infants, the source for the intraventricular blood is usually the choroid plexus. Some authors have attributed the source

of intraventricular blood in term infants to the germinal matrix, although the normal involution of the germinal matrix is mostly complete by 32 weeks, and the germinal matrix is absent by 36 weeks (see *Table 360.1*). Another locus of intraventricular hemorrhage in the term infant is the thalamus. Venous sinus thrombosis in the vein of Galen and straight and transverse sinuses may be complicated by thalamic infarction and secondary hemorrhage, suggesting a role for coagulation disorders in the genesis of intraventricular hemorrhage. Outcome is dependent upon the degree to which symptoms are present and medical or surgical intervention is necessary.

Changing Head Size and Increased Intracranial Pressure

Hydrocephalus

Small intraventricular hemorrhages in the term newborn may be asymptomatic; larger hemorrhages may obstruct CSF outflow and be complicated by hydrocephalus. Other neonatal causes of obstructive hydrocephalus such as aqueductal stenosis will generally be apparent upon delivery. Clinical evidence of increased intracranial pressure includes a tense or bulging fontanel, splitting of coronal, sagittal, or metopic sutures, apnea, bradycardia, extraocular dysmotility, hypertonia, lethargy or irritability, and blood oxygen desaturations. A head circumference growth velocity of more than 2 mm/day is highly suggestive, and ultrasound or CT/MRI is confirmatory.

Hydrocephalus may require medical or surgical intervention. Ventriculoperitoneal shunting is the conventional management for obstructive and communicating hydrocephalus. Surgical shunting adversely affects outcome, especially when it is performed in very small infants or complicated by infection and the subsequent need for external ventricular drainage and repeated shunt revisions. Management should therefore be directed towards minimizing the need for surgical intervention.

A common practice has been to perform serial lumbar punctures, despite a lack of evidence that such a practice reduces the need for later surgical intervention or disability. The small volume of the CSF space relative to the size of the patient should be considered, and excessive amounts of CSF should not be removed without increasing the likelihood of producing clinically significant apnea, bradycardia, or blood oxygen desaturations. Extraction of less than 20 mL/kg of CSF at a rate of less than 1 mL/kg/min is recommended to minimize the risk of iatrogenic symptoms. Pharmacological reduction of CSF production with acetazolamide and diuretics does not yield any measurable clinical benefit and may worsen outcome. Another strategy for the management of hydrocephalus is to use an Ommaya reservoir. This is an implanted device with a subcutaneous reservoir and a tubular channel that can be inserted into the ventricular space. When CSF continues to accumulate to the point where head circumference continues to grow excessively and symptoms of increased intracranial pressure recur, an Ommaya reservoir can be placed to allow easier access for repeated CSF removal. In expert neurosurgical hands, complication rates are low, even in very small infants. Daily taps of 10 mL/kg from the reservoir are recommended in the first days after implantation, with up to 20 mL/kg once or twice a day after this to control head enlargement. If this degree of CSF removal still fails to control excessive head enlargement and head circumference growth exceeds 2 mm/day, ventriculostomy may be necessary. Prognosis is heavily dependent upon the need for ventriculoperitoneal placement, duration of the hydrocephalus before recognition and treatment, and the occurrence of surgical complications.

When the degree of head enlargement due to hydrocephalus is large and ventriculoperitoneal shunting is required, the acute relative reduction in the size of the dilated ventricles can result in a collapse of the head with overriding bony sutures and redundancy of the scalp. If the degree of collapse is excessive, bridging cortical veins may be ruptured and subdural bleeding may occur as a complication. This is less likely to occur when more gradual reduction of head size occurs for other reasons such as cerebral parenchymal dissolution and absorption after severe global parenchymal injury due to infection, prolonged asphyxia, ischemia, or bilateral hemispheric infarction.

Hypoxia, Ischemia, and Encephalopathy

Acquired newborn encephalopathy is the final manifestation of a number of pathophysiologic sequences, only one of which is hypoxic-ischemic injury. Pure ischemia (insufficient blood flow) or hypoxia (insufficient quantity of dissolved blood oxygen) virtually never occur in isolation, since both are almost always accompanied by hypercarbia. This in turn influences cerebral arterial caliber via autoregulation, a response that may be lost when hypercarbia is progressive – especially in the ventilated preterm newborn.

Ischemia not only fails to deliver a sufficient supply of oxygen to the tissues but it prevents the removal of the

metabolic byproducts of aerobic metabolism, allowing local accumulation of toxic metabolites including lactic acid and excitatory neurotransmitters, as well as the loss of ionic homeostasis. ATP and phosphocreatine are depleted, impaired osmoregulation follows, and calcium is released activating tissue lipases, proteases, and endonucleases. This first phase of hypoxic-ischemic injury is best viewed as a failure of energy production and supply.

A second phase of injury can occur at a later time and differs from this first failure of energy production and supply in that it occurs in the absence of cerebral acidosis. In this phase, the initiating event alters cerebral metabolic pathways linking neuronal and glial protein synthesis, growth factor production, and inflammatory byproducts to produce parenchymal injury. The most obvious form of this type of injury is when asphyxia is present. Although the complication of asphyxia is as old as childbirth, our understanding of it is incomplete in part because it is defined in so many disparate ways in the literature, making comparisons of treatment strategies and outcomes difficult. The most recent consensus definition of neonatal asphyxia is that of the American Academy of Pediatrics and the College of Obstetricians and Gynecologists: (1) fetal acidemia, (2) umbilical cord pH <7.0, (3) Apgar score of 0–3 after 5 min, (4) neurological dysfunction, and (5) multisystem organ dysfunction.

The occurrence of asphyxia as defined does *not* inevitably lead to permanent injury such as cerebral palsy, since so many other variables also influence outcome. These include the extent of encephalopathy present along with obstetric risk factors, perinatal events, and neonatal signs. Genetic factors may also play an important role in long-term outcome. Heterozygosity for endothelial protein C receptor single nucleotide polymorphism in term infants and possession of the variant A allele of interleukin 8 and heterozygosity for the β-2 adrenergic receptor in preterm newborns have been associated with the spastic diplegic form of cerebral palsy.

The interval between the first and second phases of cerebral energy depletion does provide an opportunity for therapeutic intervention. Numerous treatments have been proposed with generally disappointing results (see *Table 360.4*). Benefits of various treatments demonstrated in animal models of asphyxia do not generally translate well into the human newborn, so that none of the interventions listed can be endorsed as effective or recommended as a standard of care for the asphyxiated newborn.

This leaves supportive care as the treatment standard, with careful attention to ventilatory and blood gas management, fluid and electrolyte status, maintenance of perfusion, and careful manipulation of serum glucose levels so that they neither drop below 40 mg/dL nor rise above 200 mg/dL. Both hyperglycemia and hypoglycemia will worsen the extent of cerebral parenchymal injury due to hypoxia and ischemia.

There has been recent interest in and research into the possibility that cerebral cooling of the asphyxiated newborn may be a treatment modality that can be implemented before the second stage of energy depletion occurs. Using highly selected cohorts, both systemic cooling and systemic + head cooling have been shown to reduce adverse outcome, with a relative risk for death or moderate/severe disability of 0.69 compared with control groups. Target core temperatures in both studies were 33.5–35°C achieved by cooling over a 2 h period for a duration of 72 h. The rate of rewarming was 0.5°C/h in

both studies. In both studies, cooling was started before 6 h of age. Further investigation and standardization of selection criteria are necessary before brain cooling can be widely deployed as an intervention for hypoxic-ischemic encephalopathy in a non-research setting.

Neuroimaging Abnormalities in the Neonate

A full recitation of possible acquired cerebral imaging abnormalities in the newborn is beyond the scope of this chapter. Congenital infections and malformations are covered in other chapters. The use of neuroimaging in the setting of three common brain injuries in the neonate, however, will be described. These are germinal matrix hemorrhage, hypoxic-ischemic encephalopathy, and periventricular leukomalacia.

Germinal Matrix Hemorrhages

Between 10 and 20 weeks gestation, the subependymal germinal matrix is interposed between the caudate nucleus, the caudothalamic groove, and the ventricle, and is the primary generator of cerebral neuronal and glial cell precursors during this time. By 23 weeks, the germinal matrix (GM) begins an involution that will not be completed until about 36 weeks, with the process mostly completed by 32 weeks gestation (see *Table 360.1*). The dissolution of the GM is an apoptotic process taking place within a gelatinous structure that is devoid of arteries, veins, or capillaries. The GM does have a disorganized sponge-like internal structure that is suffused with blood, and has major vessels such as the superior thalamostriate (terminal) vein embedded within it. The minimum age of viability of the premature neonate unfortunately coincides with the occurrence of the weeks long dissolution of the GM; the unique generative and devolving structure of this metabolically active tissue poses an especially high risk for hemorrhage (*Table 360.5*).

Some GM hemorrhages may occur prenatally, but the majority of all GM hemorrhages occur within the first 72 h of life in a preterm infant who may be critically ill. For this reason the most commonly deployed neuroimaging tool is ultrasound, with an initial scan performed in a preterm newborn at 24° and again at 72°, with follow-up scans at a week and at hospital discharge. Grading the severity of germinal matrix hemorrhages is based upon the schema as first described by Papile, and best visualized by cranial ultrasound. Grade I GM hemorrhages are confined to the anatomical boundaries of the subependymal germinal matrix. The greatest volume of the GM is anatomically correlated with the greatest volume of the caudate nucleus at its head in the frontal portion of the lateral ventricle, but the GM does follow the head, body, and tail of the caudate into the temporal horn of the ventricle so that GM hemorrhages may rarely be seen in the temporal GM.

Grade II GM hemorrhages differ from Grade I in that blood escapes from the GM into the cerebrospinal fluid *without* causing ventricular dilatation. In a Grade III hemorrhage, not only does blood escape into the ventricle, but the resulting impairment of cerebrospinal drainage through the narrow aqueduct of Sylvius and of absorption through the arachnoid granulations causes ventricular enlargement.

Grade IV GM hemorrhage should not properly be considered as an "extension" of a Grade III hemorrhage since its pathological correlate, periventricular hemorrhagic infarction, has a different set of antecedent risk factors and markedly different implications for prognosis. In addition to the destruction of local white matter, the germinal matrix is itself ablated with consequences for cerebral development as production of neuronal and glial precursors is still under way. Grade IV GM hemorrhage significantly increases the risk of permanent neurological injury, with major cognitive and motor deficits likely if the infant survives the initial injury.

Hypoxic-Ischemic Encephalopathy

Imaging abnormalities suggestive of hypoxic-ischemic encephalopathy (HIE) will not occur without a suggestive clinical history, but imaging can be quite helpful. Magnetic resonance imaging (MR) is the most useful diagnostic tool in the setting of HIE. Important advantages of MR over other imaging modalities in this setting include superior anatomical resolution and localization and, based upon the pattern of abnormality seen, an ability to make inferences about the mechanism of injury.

Three general patterns of cerebral injury related to HIE may be seen in the *term* infant. These are (1) parasagittal arterial borderzone lesions, (2) structure-specific ("selective") neuronal necrosis, and (3) focal or multifocal neuronal necrosis. The first of these is associated with pre- or perinatal systemic hypotension of sufficient duration to impair distal flow of cerebral arteries and, because major cerebral arteries (middle [MCA], anterior [ACA], posterior [PCA]) in their termini supply the same parenchymal tissues, those tissues are deprived of blood flow and are susceptible to injury. Parasagittal cortex and adjacent

subcortical white matter are affected with a posterior to anterior severity gradient due to the additional susceptibility of the posterior cortex to injury since this is the borderzone between three (MCA, ACA, PCA) rather than two (MCA, ACA) arteries. An unrecognized nuchal umbilical cord with restriction of arterial flow represents one possible cause.

The duration and extent of the hypoxic-ischemic event will influence the type of injury seen on imaging. Very severe, very prolonged events will lead to diffuse injury of the entire neuraxis, with diffuse neuronal necrosis present. When the duration of the event is less prolonged, and the extent moderate to severe, "selective" injury to the cerebral cortex, basal ganglia (putamen in the term, globus pallidus in the preterm infant), and thalamus is prominent. Severe but less lengthy events will lead to a different pattern of "selective" necrosis involving the basal ganglia, thalamus, and brain stem with relative sparing of the cerebral and cerebellar cortex. Event etiologies include uterine rupture, placental abruption, and umbilical cord prolapse.

Focal and multifocal cortical necrosis is readily distinguished from the parasagittal and selective patterns because the associated injury occurs within an arterial vascular distribution rather than a regional injury that does not conform to a particular arterial or venous supply. Systemic circulatory insufficiency at any time prior to, during, or immediately after delivery promotes this type of hypoxic-ischemic parenchymal injury.

Periventricular Leukomalacia

Two general patterns of periventricular white matter injury may be imaged in neonates. The first is a blush of periventricular white matter echogenicity seen on cranial

ultrasound. The location of the echogenicity is adjacent to the frontal horns and atria of the lateral ventricles. This early finding has an MR correlate of increased T1W, T2W, and FLAIR signal. The second pattern is that of small or sometimes large cystic cavitations (leukomalacia) in the same anatomical distribution. It is likely that these two patterns represent opposite ends of a continuum of injury that begins with focal areas of *microscopic* white matter gliosis and necrosis, and ends with *macroscopic* cystic degeneration of periventricular white matter. While white matter gliosis is commonly seen in the brains of *dead* premature infants, the incidence of cystic periventricular leukomalacia (PVL) in *live* preterm infants is by comparison rare. So too is the observation of PVL in the *neonate*, as this imaging finding has few clinical correlates in the newborn period, and is most commonly documented in infants with emerging neurological deficits or signs *after* the neonatal period.

Neonatal Brain Death Determination

Death occurs when the heart stops, the lungs no longer allow for respiration, *and* the brain ceases to function. With modern therapy, the heart and lungs can recover from injury and remain functional for extended periods of time, leaving a need to better define when brain functioning has ceased *and no recovery is possible*. The American Bar Association, the American Medical Association, the National Conference of Commissioners on Uniform State Laws, the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research and the Academy of Pediatrics (AAP) have all endorsed the following language in determining brain death: "An individual who has sustained either (1) irreversible cessation of circulatory and respiratory functions or (2) irreversible cessation of all functions of the entire brain including the brain stem, is dead. A determination of death must be made in accordance with accepted medical standards."

In the United States, as in most countries, the clinical neurological exam is the standard used to determine whether brain death has occurred. There are two important prerequisites that must be satisfied before determining that brain death has occurred. The first is that all possible alternative causes for the clinical presentation of brain inactivity be excluded, and the second is that the examination must be unchanged at two different points in time. Therefore, the following conditions must be excluded: toxic and metabolic disorders, use of sedative-hypnotic or paralytic drugs, hypothermia, and hypotension.

In the neonate, the maternal and perinatal history is important in helping to rule out reversible or remediable causes of coma. According to the Special Task Force convened by the AAP, the criteria used in older children to confirm brain death are useful in the *term* infant ($\geq$38 weeks) but not until 7 days *after* the insult, as the brain death examination and understanding the proximate cause of the insult can be difficult to determine prior to this time.

Application of these criteria to the *preterm* infant is much more difficult. Hypotonia and apnea, for example, may be normal findings in the very preterm infant, so that there are no indisputable criteria for these patients. The British Pediatric Association believes that it is difficult to confirm brain death at all in the *full-term* newborn, and does not recognize an acceptable definition of brain stem death in the *preterm* infant.

The clinical examination for brain death determination in the term newborn has the following minimum elements:

1. Normothermia ($\geq$36.5°C) and normal blood pressure (or positive fluid balance in the previous 6 h) must be present.
2. Intoxicant levels are within a range that would not normally be expected to interfere with consciousness. Sedative drugs, aminoglycosides, tricyclic antidepressants, anticholinergics, antiepileptic drugs, or neuromuscular blocking agents should all be considered.
3. Absent pupillary responses to light and ciliospinal stimulation. Pupils should be fixed and either midposition or dilated.
4. Absence of spontaneous eye movements.
5. Absence of evoked eye movements (caloric, oculovestibular stimulation). Caloric stimulation is generally performed with cold water to minimize the possibility of thermal injury. A minute after water infusion should be allowed before determining a negative response, and 5 min allowed between sides.
6. Absence of facial or tongue movements, as well as absent swallowing, cough, gag, sucking, and rooting reflexes. Stimulation of the posterior pharynx should elicit no response.
7. Absent corneal reflexes.
8. Absent spontaneous motor movements. Reflex withdrawal to noxious stimulation and reflex myoclonus are allowable.
9. Absent respiratory activity. This requires the completion of an apnea test upon conclusion of the second clinical examination. Pure oxygen is delivered into the trachea. Arterial PO_2, PCO_2, and pH are determined

after 5 min. If PCO_2 is 60 mm Hg or is $\geq$20 mm Hg greater than baseline, and no respiratory movements are present, the apnea test is positive, supporting the diagnosis of brain death. If respiratory movements occur, the test is negative, and brain death is not supported.

10. Two examinations separated by at least 48 h must show identical findings.
11. Additional testing is not necessary unless anatomical abnormalities of the face, brain, or pharynx are present, cardiac dysrhythmias during the apnea testing, or other factors preclude the completion of the examination. In that case confirmatory testing may be deployed.

Confirmatory testing may include EEG, nuclear brain scanning, somatosensory evoked potentials, transcranial Doppler ultrasonography, and angiography. These may be of limited utility in the newborn, and have the potential to be unhelpful, so their use should be carefully considered. Cerebral angiography is rarely used in newborns, and is not recommended due to the small size of the patient and the potential for severe renal injury. Somatosensory evoked potentials (SEP) may show the absence of N20-P22 responses, but few neurophysiologists have any experience with SEP in newborns and the test interpretations may be unreliable.

EEG and radionuclide scanning may be misleading as well, since in newborns both types of tests can fail to confirm clinically determined brain death in nearly half of cases. Persisting EEG activity may be present even when brain death is certain, so EEG activity does not obviate the diagnosis of brain death. Conversely, electrocerebral silence does not always imply brain death, particularly when phenobarbital levels are supratherapeutic ($\geq$25 mg/dL), hypothermia is evident, or a brain malformation is present. Term infants who meet clinical criteria for brain death for 2 days, and preterm infants who meet clinical criteria for brain death for 3 days do not survive independent of their EEG or cerebral blood flow status, so an unchanged clinical examination remains the most reliable indicator of an irreversible lack of brain function.

Despite the absence of clear and clinically reliable criteria for the determination of brain death in critically ill preterm newborn infants, neurological prognosis is grave when brain activity is persistently absent, and this needs to be clearly imparted to the family who is invested on many levels in the decision making process, the outcome, and subsequent care of the child.

361 Neonatal Seizures

Juan Piantino · John N. Gaitanis

Definitions

Seizures are self-limited clinical events resulting from an abnormal and excessive firing of cortical neurons. Neonatal seizures (NS) occur within the first 4 weeks of life in a full-term infant and up to 44 weeks from conception in premature infants. Neonatal seizures can be classified as symptomatic, cryptogenic, or idiopathic. Symptomatic seizures are associated with identifiable brain insults. Cryptogenic seizures are believed to be symptomatic, but the underlying insult has not been confirmed. Idiopathic seizures are not associated with an underlying brain lesion and are generally presumed to be genetic in origin. Most seizures in neonates are focal, arising from one region of the brain, or multifocal, arising independently from multiple different regions. Generalized seizures, which originate in deep midline structures and spread rapidly through both hemispheres, are uncommon in neonates. The clinical appearance of seizures can be described as tonic, clonic, myoclonic, or subtle. Tonic seizures involve sustained contraction of one or more muscle groups, whereas clonic seizures refer to contraction alternating with relaxation with a frequency generally ranging between 1 and 3 Hz. Myoclonic seizures involve a rapid, nonrhythmic jerking movement of one or more extremities. Subtle seizures are the most difficult to clinically diagnose. They involve alterations of behavior, motor, or autonomic function that can be difficult to distinguish from normal neonatal patterns. Examples of subtle seizures include bicycling or sucking movements, extraocular movement abnormalities, and apneic spells.

Etiology

In the neonatal period, the development of seizures most often represents a manifestation of an underlying neurological insult (*Table 361.1*). However, in some cases, NS occur in the absence of any identifiable cause. Identification and treatment of the primary cause of NS is the most important determinant of outcome. Four major etiologic groups have been described in previous classifications: neonatal encephalopathy (including hypoxic-ischemic encephalopathy), metabolic disturbances, CNS or systemic infections, and structural brain lesions (see *Table 361.1*).

Neonatal Encephalopathy

Neonatal encephalopathy is a heterogeneous syndrome characterized by central nervous system dysfunction, affecting term or near-term infants ($\geq$36 weeks gestation). These infants may have an abnormal state of consciousness (i.e., hyper-alertness, irritability, lethargy, obtundation), respiratory difficulties, hypotonia, or seizures. The causative factors of neonatal encephalopathy are varied, and although its true incidence is unclear, birth asphyxia is a well-known contributor to this condition. Administration of chest compressions for >1 min, onset of regular respirations >30 min after birth, and a base deficit >16 mmol/L on any blood gas analysis within the first 4 h from birth are predictors of severe adverse outcome (death or severe disability).

Permanent neurologic sequelae vary from learning difficulties and attention deficit, to cerebral palsy, epilepsy, visual impairment, and severe cognitive and developmental disorders. The severity of neonatal encephalopathy can be categorized as follows: mild (hyper-alertness, hyper-exitability, normal muscle tone, no seizures), moderate (hypotonia, decreased movements, and seizures), and severe (stuporous, flaccid, absent primitive reflexes, and frequent seizures). There is a correlation between the degree of encephalopathy and neurologic outcome. Mild neonatal encephalopathy carries a good prognosis, with a high probability of normal neurological outcome. Moderate encephalopathy carries a 20–35% risk of later sequelae. Neonates with severe encephalopathy have a 75% mortality risk in the neonatal period, and neurologic consequences are almost universal in this group. In addition to clinical predictors,

Epilepsy syndromes			
Epileptic encephalopathies (early myoclonic encephalopathy, early infantile epileptic encephalopathy)			
Benign familial neonatal convulsions			

Relative Frequency: +++ = most common; ++ = less common; + = least common. If no +, then uncommon

MRI and EEG abnormalities have been linked to poor neurologic outcome.

Metabolic Disturbances

Metabolic abnormalities are among the most common causes of seizures in the neonatal period. Electrolyte imbalances such as hypocalcemia, hypomagnesemia, and hypoglycemia have been linked to the development of seizures. In addition, rare but potentially treatable metabolic causes of seizures are biotinidase and pyridoxine deficiency. Inborn errors of metabolism such as aminoacidurias, urea cycle defects, and organic acidurias are other rare causes of neonatal seizures.

CNS Infections

Bacterial as well as viral infections are common causes of seizures in the newborn period. Infectious agents

transmitted vertically during pregnancy also put neonates at risk for developing seizures (*Table 361.2*).

Structural Brain Lesions

Structural brain lesions such as hemorrhages (intracerebral, subarachnoid, and intraventricular), infarctions, and anomalies of brain development are associated with seizures.

Epidemiology

The incidence of seizures in neonates is higher than in any other age group and is estimated to be 1–3.5 per 1,000 live births in full-term newborns. In the third world, the risk may be much higher. One study in rural Kenya reported an incidence of 39.5 per 1,000 live births. Preterm infants have the greatest risk, with an incidence as high as 227 per 1,000 live births. In the first world, the most common etiology is hypoxic-ischemic encephalopathy, which accounts for approximately two-thirds of cases. In third world countries, infectious causes are more common and account for up to three-fourths of cases. The risk of seizures is higher in male infants. Other risk factors for seizures in full-term newborns include nulliparity, diabetes, maternal infection, or fever, and delivery after 42 weeks gestation.

Pathogenesis

The mechanisms underlying neonatal seizures are distinct from those of other age groups. There are several major differences between neonatal and adult brains that are relevant to the development of seizures. In the balance between inhibition versus excitation, the neonatal brain tends toward excitation. This shift occurs, in part, because neurotransmitter systems are not yet fully developed.

Inhibition

Gamma-aminobutyric acid (GABA) is the primary inhibitory neurotransmitter of the central nervous system. Unlike glutamate receptors, which may have reduced expression in neonates, GABA receptors are present very early in development and are even expressed at embryonic stages. Once released into the synaptic cleft, GABA binds to its target receptors on the postsynaptic cell. Two classes of GABA receptors exist: ionotropic and metabotropic. Activation of ionotropic GABA(A) receptors results in opening of the ion channel, which, in adults, causes influx of chloride. Yet, in neonates, intracellular Cl^- concentrations are elevated when compared to adults. Hence, activation of GABA(A) receptors results in an efflux rather than an influx of Cl^-. The net result is that GABA(A) activation is excitatory in the neonate rather than inhibitory. This paradoxical effect of GABA receptor activation in newborns results from the developmental expression of the two Cl^- transporters responsible for determining intracellular Cl^- levels. In neonates, the Na+-K+-Cl^- cotransporter (NKCC1), which causes Cl^- influx, is highly expressed. Conversely, expression of the K+-Cl^- cotransporter (KCC2), resulting in Cl^- efflux, is virtually absent. The net result is an elevation of intracellular Cl^- in newborns. Hence, activation of GABA receptors in neonates results in Cl^- efflux and is thus excitatory. GABA becomes inhibitory as neuronal efflux of Cl(–) increases throughout development.

Excitation

Considering the rapid rate of learning and development in newborns, it should come as no surprise that neonatal brains are balanced toward excitation. Glutamate, the most abundant free amino acid in the brain and the predominant excitatory neurotransmitter of the central nervous system, is necessary for synaptogenesis and plasticity. It contributes to learning and memory through use-dependent changes in synaptic function, such as long-term potentiation and depression. Glutamate receptors can be divided into two types: ionotropic and metabotropic. Ionotropic receptors are cation channels with varying permeabilities for Na^+ and Ca^{2+}. By contrast,

metabotropic glutamate receptor (mGluR) activation occurs through second-messenger pathways. For the most part, glutamate receptors are overexpressed in the developing brain, and the timing of that heightened expression overlaps with the ages of greatest seizure susceptibility. Thus, an overexpression of glutamate receptors may predispose the neonate to heightened excitation and seizure susceptibility.

Glutamate transporters, referred to as excitatory amino acid transporters (EAATs), are necessary for ending glutamatergic transmission and keeping glutamate levels below a toxic range. EAATs are present in both neurons and glia. Dysfunction of glutamate transporters can result in cell death and has been implicated in a number of neurological disorders, including epilepsy. Both temporal and regional differences occur throughout development in the expression of EAATs. Hypoxic-ischemic encephalopathy, the most common cause of neonatal seizures, induces a loss of glutamate transporters in specific brain regions, such as the CA1 region of the hippocampus. Such reductions in EAATs further promote excitotoxic injury and seizures. This is observed in animal models in which diminished expression of glutamate transporters results in a reduced seizure threshold.

Clinical Manifestations

In neonates, seizures are difficult to recognize since they often mimic non-epileptic behaviors (See *Table 361.3*). Thus, video EEG is often required to confirm the diagnosis. The most difficult type of seizures to diagnose are termed subtle seizures. These consist of behavioral, motor, or autonomic alterations that appear similar to normal newborn behaviors. They include chewing, bicycling, ocular movements, and apnea. The sudden or sustained onset of these behaviors combined with their frequent recurrence help distinguish them from non-epileptic events. The most reliable seizures to diagnose clinically are clonic seizures. They consist of rhythmic movements (generally ranging between 1 and 3 Hz) of one or more extremities. They are also likely to have an EEG correlate. Tonic seizures, which involve sustained muscular contraction, may involve one extremity or the whole body. Myoclonic seizures, on the other hand, consist of rapid jerking movements and may be either focal, multifocal, or generalized. Myoclonus can also result from non-epileptic causes in newborns.

Neonatal seizures are further characterized by their relationship to findings on EEG (See *Table 361.4*). An electrographic seizure is a discrete event visualized on EEG that has a definable beginning, middle, and end.

Table 361.3
Clinical characteristics, classification, and presumed pathophysiology of neonatal seizures (From Mizrahi EM, Kellaway P (1998) Diagnosis and management of neonatal seizures. Lippincott-Raven, Philadelphia, p 181. Copyright © 1998 Lippincott Williams & Wilkins)

Focal clonic
Repetitive, rhythmic contracts of muscle groups of the limbs, face, or trunk
May be unifocal or multifocal
May occur synchronously or asynchronously in muscle groups on one side of the body
May occur simultaneously, but asynchronously on both sides
Cannot be suppressed by restraint
Pathophysiology: epileptic
Focal tonic
Sustained posturing of single limbs
Sustained asymmetrical posturing of the trunk
Sustained eye deviation
Cannot be provoked by stimulation or suppressed by restraint
Pathophysiology: epileptic
Generalized tonic
Sustained symmetrical posturing of limbs, trunk and neck
May be flexor, extensor or mixed extensor/flexor
May be provoked or intensified by stimulation
May be suppressed by restraint or repositioning
Presumed pathophysiology: nonepileptic
Myoclonic
Random, single, rapid contractions of muscle groups of the limbs, face, or trunk
Typically not repetitive or may recur at a slow rate
May be generalized, focal, or fragmentary
May be provoked by stimulation
Presumed pathophysiology: may be epileptic or nonepileptic
Spasms
May be flexor, extensor, or mixed extensor/flexor
May occur in clusters
Cannot be provoked by stimulation or suppressed by restraint
Pathophysiology: Epileptic
Motor Automatisms
Oral-buccal-lingual movements
Random and roving eye movements or nystagmus (distinct from tonic eye deviation)
Progression movements (rowing, swimming, bicycling)
May be provoked or intensified by stimulation
Presumed pathophysiology: nonepileptic

Table 361.4
Classification of neonatal seizures based upon electroclinical findings (Modified from Mizrahi EM, Clancy RR (2000) Neonatal seizures: early-onset seizure syndromes and their consequences for development. Ment Retard dev Disabil Res Rev 6:229. Copyright © 2000 Wiley-Liss)

Clinical seizures with a consistent electrocortical signature (pathophysiology epileptic)
Focal clonic
Unifocal
Multifocal
Hemiconvulsive
Axial
Focal tonic
Asymmetrical truncal posturing
Limb posturing
Sustained eye deviation
Myoclonic
Generalized
Focal
Spasms
Flexor
Extensor
Mixed extensor/flexor
Clinical seizures without a consistent electrocortical signature (pathophysiology presumed nonepileptic)
Myoclonic
Generalized
Focal
Fragmentary
Generalized tonic
Flexor
Extensor
Mixed extensor/flexor
Motor automatisms
Oral-buccal-lingual movements
Ocular signs
Progression movements
Complex purposeless movements
Electrical seizures without clinical seizure activity

Electroclinical seizures are those clinical seizures that occur in correlation with electrographic seizure activity. If the seizure does not correlate with EEG seizure activity, it is denominated clinical only. A significant number of infants have electrographic seizures only. These seizures occur in infants who have severe encephalopathy, those who have received antiepileptic drugs (AEDs), or in infants with drug-induced paralysis.

Diagnosis

As mentioned above, neonatal seizures are symptomatic and most likely secondary to an underlying abnormality. More rarely, these seizures are part of a more extensive epilepsy syndrome. Four neonatal syndromes have been described: benign neonatal convulsions (BNC), benign neonatal familial convulsions (BNFC), early myoclonic encephalopathy (EME), and early infantile epileptic encephalopathy (EIEE). The first two syndromes are considered benign, and are associated with relatively good prognosis and survival. The latter two exhibit a suppression-burst pattern on EEG and are categorized as catastrophic for their poor prognosis.

Benign Neonatal Convulsions

The cause of this syndrome, which comprises 2–7% of all neonatal seizures, is unknown; however, acute zinc deficiency in the cerebrospinal fluid (CSF) of affected neonates as well as rotavirus infection have been postulated as possible etiologies. The seizures affect mostly term or near-term infants after an uneventful pregnancy and delivery, and with no family history of seizures. The incidence is higher in the first 7 days of life, with 90% occurring between days 4 and 6. The seizures are brief and self-limited, although some evolve to prolonged seizures. They are most commonly focal clonic or focal tonic, and usually recur in a period of 24–48 hours. EEG findings associated with these seizures include nonreactive rhythmic activity, discontinuity, interhemispheric asynchrony, and multifocal sharp waves. This pattern is known as "theta pointu alternant"; it is nonspecific, and is seen only in 60% of the patients. Due to the resemblance of this syndrome with other seizure types, this diagnosis remains a diagnosis of exclusion, after other most common etiologies have been ruled out. Diagnostic criteria have been proposed for this syndrome, which include an Apgar score greater than 7 at 1 min, a typical interval between birth and seizure onset (4–6 days), a normal neurologic examination before and between the seizures, normal laboratory findings (e.g., metabolic studies, neuroimaging, and cerebrospinal fluid analysis), and no family history of neonatal seizures. The treatment of these seizures is similar to other seizures in

the neonatal period. If AEDs are used, they can be stopped once the infant is beyond the 24–48 hours period of recurrence risk. The prognosis of this syndrome is relatively good in terms of neurologic status, development, and postneonatal epilepsy. However, some data suggest a variable outcome, with 15% of infants manifesting transient "psychomotor delay" at 4–6 months of age, implying that the seizures may adversely affect the infant.

Benign Familial Neonatal Convulsions (BFNC)

This is an autosomal dominant disorder that affects approximately 14.4 per 100,000 live births. There are two types of BFNC: EBN1 is the result of a mutation in the voltage-gated potassium channel KCNQ2, whereas EBN2 is the result of a deletion in the chromosome 8q24, which encodes for another potassium channel known as KCNQ3. This syndrome is characterized by focal or multifocal clonic or tonic seizures, a family history of neonatal seizures, and no other neurologic abnormalities. It is characterized by brief seizures, which in some cases may recur until the age of 2–3 months, when spontaneous resolution typically occurs. The interictal EEG is usually normal. The treatment of this syndrome is similar to that of other neonatal seizures. Even if this syndrome is thought to be benign, recent data suggests an increased rate of postnatal epilepsy in these patients.

Early Myoclonic Encephalopathy (EME)

This disorder peaks in the early neonatal period. Its etiology is unknown, but it has been associated with inborn errors of metabolism, such as non-ketotic hyperglycemia, D-glycemic academia, methylmalonic academia, propionic academia, and hyperammonemia due to carbamyl phosphate synthetase deficiency. This syndrome is characterized by myoclonic seizures in the first week of life. This is followed by partial seizures, myoclonus, infantile spasms, and infrequently, tonic seizures. The EEG shows a characteristic suppression burst pattern (S-B; bursts of spikes, sharp waves, and slow activity lasting 5–6 s, alternating with 4- to 12-s periods of attenuation), that progresses to a hypsarrythmic pattern or a markedly abnormal background with multifocal spikes and sharp waves. Neonates with this syndrome present with an altered state of consciousness, with manifestly delayed milestones, hypotonia, and microcephaly from cerebral atrophy. The myoclonus present at birth tends to resolve; however, the focal motor seizures become refractory to antiepileptic therapy. Approximately 50% of the infants die, most within the first year of life. The focal motor seizures are treated with standard AEDs.

Early Infantile Epileptic Encephalopathy

This disease is characterized by intractable tonic seizures in the neonatal or infantile period. On EEG, a suppression-burst pattern is seen. The bursts are relatively prolonged (2–6 s) and shorter periods of suppression is seen when compared to EME. There is associated synchronization with the tonic spasms, with an initial high-voltage slow wave followed by generalized fast activity. The EEG abnormalities in EME and EIEE are similar, and the etiologies may overlap. The majority of anomalies associated with EIEE, however, are structural in origin, that is, porencephaly, Aicardi's syndrome, cerebral atrophy, hemimegalencephaly, dentate-olivary dysplasia, and migrational defects. Inborn errors of metabolism are rarely associated with EIEE. This is in contrast to disorders associated with EME, which are mostly metabolic in origin. This syndrome occurs during the first months of life. Affected infants have an abnormal neurological exam, with spasticity, motor asymmetries, and developmental delay. Tonic spasms are the predominant seizure type. Additional seizures include focal motor seizures and hemiconvulsive seizures. Erratic myoclonus is absent in EIEE, which is in contrast with EME where it is an early characteristic, and tonic spasms occur late in the disease. Several different approaches have been implemented in the treatment of EIEE, including AEDs, steroids, ACTH, and vitamin B6. The outcome, however, is still poor, with approximately a 50% mortality during infancy, and survivors being severely affected and sometimes progressing to develop infantile spasms.

Differential Diagnosis

Normal behaviors of the newborn sometimes raise suspicion of seizures. Nonspecific random movements, including sucking, coughing, and gagging, are among these behaviors. Neonates may also experience normal myoclonus during REM as well as non-REM sleep. Jitteriness, a tremulous movement that is suppressible when holding the limb, is normal in newborns and is generally not a manifestation of seizure activity. Apnea, bradycardia, and tonic posturing can be seen from gastroesophageal reflux (Sandifer syndrome). A barium swallow or pH probe may be required to confirm this diagnosis. Hyperekplexia, an exaggerated startle response to an

unexpected stimulus, may resemble generalized myoclonus. However, hyperekplexia is non-fatigable, and can be elicited repeatedly by finger tap on the infant's glabella.

Treatment

The first step in treatment is to assess the general medical condition of the child, beginning with airway, breathing, and circulation. It is important to determine the underlying etiology of the seizures, since some conditions can result in brain injury if not treated promptly. Meningitis and hypoglycemia are two particularly important conditions to consider. After medically stabilizing the patient, antiseizure medications should be initiated to prevent recurrence. Pharmacotherapy is generally continued until the underlying cause has resolved, the seizures have subsided, and the patient is fully alert. Achieving these conditions often requires 1–3 months.

CNS Infection

Treatment of infection, if present, is of extreme importance in controlling seizures in the neonate. Broad spectrum antibiotics in high doses should be instituted after CSF has been obtained to evaluate for the presence of meningitis. In neonates, the first choice of antibiotics is ampicillin (100 mg/Kg/dose) and gentamycin (dose in accordance with gestational age).

Metabolic Abnormalities

Hypoglycemia, hypocalcemia, and hypomagnesemia are common electrolyte imbalances that should be corrected promptly. Pyridoxine dependency must also be considered in refractory seizures and can be diagnosed by administering intravenous pyridoxine (100 mg; the dose may be repeated four times to a total of 500 mg if needed) under EEG monitoring. If pyridoxine dependency is present, the seizures and epileptic changes on EEG will resolve within seconds of administration. Folinic acid–responsive seizures should also be considered in refractory cases, and may be combined with pyridoxine.

Institution of Antiseizure Medications

The acute treatment of neonatal seizures is not different from the management of any other emergency (see *Table 361.6*). After airway, breathing, and circulation have been addressed, and the above-mentioned causes of seizures have been investigated and treated, the physician is left with the decision of whether to institute antiseizure medications. In so doing, there are a few issues that need to be considered. Not all the clinical events in the neonate are seizures in origin, and may therefore not require treatment. Further, some benign causes of neonatal seizures are transient and resolve without associated morbidity. In these cases, instituting therapy will expose the neonate to medication side effects with limited benefit. More aggressive seizures, on the other hand, can be associated with severe neurological impairment and future morbidity. Such seizures therefore require treatment.

Table 361.5
Long-term outcome of neonatal seizures (From Tharp: neonatal seizures)

High mortality (30%) and morbidity (50% of survivors)
Approximately 30% of survivors develop epilepsy
Worst outcome in infants with hypoxic – ischemic encephalopathy, meningitis, and cerebral dysplasia
Better outcome with transient neonatal hypocalcemia, idiopathic and familial seizures, and stroke
Neonatal EEG, neurologic examination, and imaging results are best predictors of outcome

Phenobarbital

As stated above, this is the first drug of choice in the treatment of neonatal seizures. Phenobarbital is metabolized in the liver, and eliminated by the kidney. In infants with impaired function of these two organs, such as HIE patients, phenobarbital levels can be elevated and cause toxicity. Additionally, as the neonate matures, the metabolism of this drug augments, and the levels drop. This has the potential to cause breakthrough seizures. Phenobarbital levels should be monitored in neonates to avoid this phenomenon.

Phenytoin

This drug has variable pharmacokinetics in the developing neonate, with potential for subtherapeutic levels. Therefore, phenytoin levels should be monitored and its dose should be adjusted to each particular patient. In a randomized trial comparing phenobarbital and phenytoin, both drugs controlled seizures in less than 50% of patients.

Table 361.6

Doses of AEDs (Reproduced with permission from Mizrahi EM, Kellaway P (1998) Diagnosis and management of neonatal seizures. Lippincott-Raven, Philadelphia, p 181. Copyright © 1998 Lippincott Williams & Wilkins)

Drug	Loading	Maintenance	Average therapeutic range	Apparent half-life
Diazepam	0.25 mg/IV (bolus)	May be repeated 1–2 times		31–54 h
	0.5 mg/kg (rectal)			
Lorazepam	0.05 mg/kg (IV) (over 2–5 min)	May be repeated		31–54 h
Phenobarbital	20 mg/kg IV (up to 40 mg)	3–4 mg/kg in two doses	20–40 mcg/L	100 h after day 5–7
Phenytoin	20 mg/kg IV (over 30–45 min)	3–4 mg/kg in 2–4 doses	15–25 mcg/L	100 h (40–200)

Other Antiseizure Medications

Third-line antiseizure medications that have been tested include clonazepam, lidocaine, midazolam, and paraldehyde. Oral AEDs have also been employed including carbamazepine, primidone, valproate, vigabatrin, and lamotrigine. There is little known regarding the efficacy of these therapies, but some have shown promise in limited trials. In one study, 13 out of 13 newborns who failed to achieve seizure control on phenobarbital or phenytoin were seizure-free following the addition of midazolam. No adverse effects of the medication were reported and the patients demonstrated improved neurodevelopmental outcome. In a pilot study of levetiracetam monotherapy, six out of six neonates were seizure-free within 6 days of starting it. In a smaller case series, three infants, aged 2 days to 3 months, exhibited seizure freedom and had no side effects on levetiracetam. In a recent survey of child neurologists, 73% recommended treatment of neonatal seizures with either levetiracetam or topiramate, although adverse reactions were felt to occur more frequently from topiramate.

Prognosis

Neonatal seizures are mostly self-limited and disappear when the provoking insult resolves. Many infants, however, will experience seizure relapses after a seizure-free period. Other patients will continue to have seizures without a seizure-free interval. Epileptogenesis (the development of epilepsy) has been observed in several animal models of neonatal seizures. Rodent models of seizures and status epilepticus in the first 2–3 postnatal weeks generally cause very little cell death, and the synaptic sprouting associated with cell death in adult models of epilepsy are not observed in most neonatal models. Furthermore, neuronal death may not be observed even when epileptogenesis occurs. Initially, it was assumed that the lack of neuronal death indicated a relative absence of sequelae. More recently, however, the changes following neonatal seizures have come to be recognized as functional rather than structural. For example, limbic cognitive deficits are seen following neonatal seizures despite the absence of pathological abnormalities. Thus, a dissociation exists between pathological and functional deficits following neonatal seizures, and cell death may not be required for functional injury or subsequent epilepsy to occur within the hippocampal/limbic network. The long-term outcome of NS is illustrated in *Table 361.5*.

Prevention

Prevention of neonatal seizures centers on reducing known causes of brain injury. These include, but are not limited to, hypoxic-ischemic encephalopathy, intracranial hemorrhage, CNS infection, hypoglycemia, and stroke. Prompt recognition of hypoglycemia and infection are particularly important since these conditions worsen if not treated early. For causes of brain injury that are more difficult to avoid, neuroprotection may play a role in the future. A major development in the treatment of perinatal hypoxic-ischemic encephalopathy, the most common cause of neonatal seizures, is the administration of therapeutic hypothermia to prevent neuronal injury. In a recent meta-analysis that examined the 18-month outcome of newborns with HIE, therapeutic hypothermia significantly reduced the risk of death and neurodevelopmental disabilities, such as cerebral palsy and psychomotor retardation. In the largest study reviewed in that meta-analysis, there was a nonsignificant trend toward reduced rates of continued seizures in survivors (12/116 vs. 16/116, *P* value 0.42). A longer period of follow-up may be required to determine if epilepsy rates are truly improved in patients receiving hypothermia.

362 Epilepsy in Infancy and Childhood

John N. Gaitanis

Definitions

Seizures are self-limited clinical events resulting from an abnormal and excessive firing of cortical neurons (Table 362.1). They manifest as transient motor, sensory, autonomic, or psychic symptoms with or without an alteration of consciousness (Table 362.2). *Epilepsy*, on the other hand, is a condition characterized by recurrent, unprovoked seizures. Epilepsy does not constitute a single entity and is instead a heterogeneous group of disorders, with multiple etiologies and clinical manifestations. Subdivisions of epilepsy are based upon the etiology or the clinical features. The International League Against Epilepsy published a classification system for seizures in 1981, and for epilepsies in 1989. In it, epilepsy is categorized as either *localization-related* (focal onset beginning over one region of brain) or *generalized* (having a simultaneous onset over both hemispheres). Epilepsy is further subdivided as *idiopathic* (no underlying cause other than a possible hereditary predisposition), *symptomatic* (a consequence of a known or suspected disorder), or *cryptogenic* (presumed to be symptomatic, but the cause is unknown). This classification scheme is based largely on clinical and electroencephalographic data. Significant advances in molecular biology, neuroimaging, and genetics have since taken place and will likely play a role in the development of future classification schemes.

When seizures are so frequently repeated or so prolonged as to create a "fixed and enduring epileptic condition," they are termed status epilepticus (SE). The most commonly chosen duration for seizures to qualify as SE has been 30 min, based on the belief that seizures persisting longer than that result in brain injury. More recently, however, an "operational" definition of SE has been proposed as 5 min or more of continuous seizures or "two or more discrete seizures between which there is incomplete recovery of consciousness." This definition, which applies primarily to GCSE, may be used clinically to direct treatment and help avoid refractory SE.

Etiology

Epilepsy is a heterogeneous condition with a multitude of etiologies (Table 362.3). Idiopathic and cryptogenic etiologies account for 60–70% of cases while symptomatic causes account for 30–40%. These rates are similar in industrialized and developing countries. Idiopathic epilepsies have an underlying genetic basis. Many idiopathic cases result from channelopathies, which impair neurotransmission. Others involve genes that are important for broader aspects of development, which may also result in mental retardation, autism, or brain malformations. Symptomatic etiologies of epilepsy, on the other hand, develop following brain injury. In children, perinatal insults are important causes and include hypoxic-ischemic encephalopathy, stroke, intracranial hemorrhage, periventricular leukomalacia, and hypoglycemia. Later in childhood, head trauma, infections, and brain tumors are more common. In developing nations, neurocystercircosis is a particularly important cause and may account for as many as 60% of first-time seizures and one-third of symptomatic epilepsies.

Epidemiology

Epilepsy is estimated to affect 50 million people worldwide, and it accounts for 1% of the global burden of disease. In industrialized countries, its prevalence ranges between 4 and 10 active cases per 1,000 persons. Prevalence estimates are only slightly higher in the developing world, ranging between 3.8 and 15.4 per 1,000. The incidence of epilepsy, however, is noticeably higher in developing nations. It ranges between 114 and 190 per 100,000 in developing countries, but is only 24–53 per 100,000 in industrialized nations. Developing countries have higher mortality rates for epilepsy, accounting in part for the disparity in incidence and prevalence data.

The age of onset also differs between regions. In industrialized countries, the onset of epilepsy occurs at the extremes of life, whereas in developing nations, the onset

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_362,

Table 362.1
Seizure terminology

Seizure: A clinical event, displaying signs or symptoms, resulting from an abnormal and excessive discharge of cortical neurons
Epilepsy: Recurrent, unprovoked seizures
Generalized: The initial seizure discharge involves a large number of neurons throughout both hemispheres and the clinical manifestations indicate bilateral onset
Partial: The initial seizure discharge involves a limited number of neurons in just one hemisphere
Simple: A seizure that does not cause alteration in consciousness
Complex: A seizure involving alteration in consciousness
Idiopathic: Epilepsy with a genetic cause
Cryptogenic: Non-idiopathic epilepsy without a known cause
Symptomatic: Non-idiopathic epilepsy with a known cause (usually a brain insult or other lesion)
Tonic: Sustained posturing of a body part
Clonic: Rhythmic jerking of a body part
Myoclonic: Brief, irregular contractions of a body part
Atonic: An abrupt loss of muscle tone
Tonic-clonic: Tonic activity alternating with clonic movements
Absence: A transient discontinuation of activity with loss of awareness

is highest in young and middle-aged adults. Parasitic diseases, more endemic in the developing world, likely account for this difference.

The incidence of status epilepticus ranges between 18.1 and 41 per 100,000 patients per year. In the United States, this amounts to 102,000–152,000 cases and 22,000–42,000 deaths annually.

Pathogenesis

The pathogenesis of epilepsy is as varied as the etiologies. Idiopathic and symptomatic causes of epilepsy have entirely different mechanisms of disease. Symptomatic epilepsy results from brain injury, whereas idiopathic forms result from genetic alterations involving proteins necessary for normal neurotransmission. Idiopathic epilepsy is therefore less likely to reveal neuroimaging abnormalities and more likely to be associated with a family history of epilepsy. There is considerable genotype-phenotype heterogeneity within genetic causes of epilepsy, even within the same family.

For example, mutations of the sodium channel gene, SCN1A, result in six different phenotypes, ranging from generalized epilepsy with febrile seizures plus syndrome (GEFS+) on the milder end of the spectrum to severe myoclonic epilepsy of infancy at the severe end. SCN1A codes for the alpha subunit of the neuronal voltage-gated sodium channel. The alpha subunit forms the membrane pore of sodium channels. There is some correlation between genotype and phenotype. Mutations resulting in premature protein truncation are more likely to lead to a severe phenotype whereas missense mutations are associated with milder phenotypes.

Multiple ion channels are now known to play a role in epilepsy. They include the sodium channel genes SCN1A and SCN1B, potassium channel mutations of KCNQ2 and KCNQ3, chloride channel mutations in CLCN2, and calcium channel impairments of CACNB4. Genetic alterations of neurotransmitter receptors, such as the GABA receptor genes GABRD and GABRG2, also result in epilepsy. Just as mutations of a single gene result in varied phenotypes, mutations of two completely unrelated genes can lead to identical phenotypes. GEFS+, for example, can result from mutations of SCN1A, SCN1B, SCN2A, SCN9A, GABRG2, or GABRD. Confirmation of the specific genetic cause may be clinically useful when determining the correct treatment plan. Sodium channelopathies,

for example, may worsen with sodium channel–blocking agents such as carbamazepine and phenytoin. Genetic confirmation is also helpful when counseling families.

Symptomatic epilepsy, on the other hand, results from environmental rather than genetic causes. Traumatic, ischemic, and infectious insults all result in epilepsy. Epilepsy develops from different types of injury through common mechanisms. Breakdown of the blood-brain barrier (BBB) is observed in brain injury. When the BBB is disrupted, intravascular albumin leaks into the extracellular space, resulting in glial dysfunction. Without proper glial function, glutamate cannot be cleared from the extracellular space. Elevation of glutamate results in hyperexcitability and an influx of intracellular neuronal calcium, which in turn causes neuronal injury and seizures. The initial injury, caused in part by excessive glutamatergic activity, is followed by a latent period, during which time no seizure activity takes place. During that period, pathophysiological and structural alterations are occurring which will later culminate in epilepsy. Further understanding of how injury leads to epileptogenesis may provide targeted treatments, which can prevent the onset of epilepsy.

Excessive glutamatergic activity also plays a role in the development of status epilepticus. As an illustration of this, an outbreak of toxic encephalopathy caused by ingestion of mussels contaminated with domoic acid, a glutamate analogue, caused prolonged seizures in many of the affected patients. Excitatory amino acids, especially glutamate, also contribute to the neuronal injury caused by SE. As seizures persist, there is also downregulation of inhibitory mechanisms, further contributing to SE. GABA-A receptors become less susceptible to the GABA agonist effects of benzodiazepines. This causes refractoriness to treatment with the GABA-acting medications, benzodiazepines and barbiturates.

Pathology

Temporal lobe structures, particularly the hippocampus and amygdala, are the most susceptible regions to epileptogenesis following brain injury. The resulting

neuronal loss and fibrillary gliosis of the mesial temporal structures is termed mesial temporal sclerosis (MTS). MTS is the most common pathological finding in patients with temporal lobe epilepsy and is seen in 65% of temporal lobectomy specimens. In approximately one-third of patients with MTS, dual pathology is observed. Additional findings may include dysplastic neuroepithelial tumors, cavernous angiomas, caudate atrophy, inflammatory changes, and focal cortical dysplasia. The significance of dual pathology is not known, but it calls into question whether MTS is the cause or effect of active epilepsy. Neuronal migration disorders, for instance, may predispose the patient to febrile seizures, which later result in MTS. Alternatively, the pathological changes seen in MTS can mimic dysplastic tissue, erroneously pointing toward a dual diagnosis. A final possibility is that both dysplastic tissue and MTS share a common embryological origin, and that both act together in the development of epilepsy.

Clinical Manifestations

Epilepsy should be suspected whenever a patient reports transient, repetitive, and stereotyped symptoms. Seizure semiology, the signs and symptoms of how a seizure is expressed, differs depending on the seizure type. Partial seizures involve a localized region of the cerebral cortex, and their symptoms reflect the area of involvement. For example, occipital seizures result in visual hallucinations whereas frontal seizures are more likely to cause motor symptoms. There are two main subdivisions of partial-onset seizures: simple and complex. Simple partial seizures do not involve impairment of consciousness. The symptoms can include sensory, motor, autonomic, or psychic (emotional sensation, dream-like state, or déjà vu) changes. Complex partial seizures, on the other hand, involve impairment of consciousness. They typically manifest as behavioral arrest and may involve staring or automatisms (repetitive movements such as chewing, lip smacking, or fumbling with hands). The patient often has no memory for these behaviors. Simple and complex partial seizures can secondarily generalize into generalized tonic-clonic seizures. Distinguishing between a primary versus secondary generalized seizure can be difficult. Secondary generalized seizures are recognized by a preceding aura, which represents a simple partial seizure preceding generalization. Primary generalized seizures, on the other hand, are not associated with a preceding aura.

There are six major categories of generalized seizures: absence, tonic, clonic, myoclonic, tonic-clonic, and atonic (see *Table 362.2*). Absence seizures are often difficult to distinguish from complex partial seizures since both manifest as staring spells. When compared to complex partial seizures, absence seizures are shorter (under 20 s), occur more frequently (often multiple times daily), and are less likely to be associated with automatisms or a prolonged postictal state. Many patients with primary generalized epilepsy experience more than one generalized seizure type. In juvenile myoclonic epilepsy, for example, patients exhibit generalized tonic-clonic, myoclonic, and absence seizures.

Just as seizures can take multiple forms, status epilepticus also presents in varied ways. *Generalized Convulsive Status Epilepticus* is the most dramatic and life-threatening form of SE. Fortunately, it is readily recognizable. It may begin with a partial seizure (simple or complex) that generalizes secondarily, or it can start as a generalized convulsion. There may be tonic and clonic movements, typically bilateral and symmetric, although the onset may occur on just one side. Consciousness is always impaired from the time the seizure generalizes. Afterward, the patient is stuporous. If the patient does not recover from the postictal stupor within a reasonable time, the possibility of continuing epileptic brain activity must be considered. This sort of decoupling of the electrical and motor systems constitutes "subtle" nonconvulsive SE, sometimes with just twitching or blinking or even no movement at all. Electroencephalography (EEG) is often helpful in confirming this.

Diagnosis

The diagnosis of seizures begins with a careful history. A detailed description of the episode, focusing on its onset, progression, time course, and recovery, helps establish if seizures are a likely etiology. If parents have a video camera, recordings of the event are particularly helpful in determining its clinical characteristics. The physical examination looks for neurological dysfunction, as might be present in a symptomatic etiology. Laboratory evaluations search for items missed on the history and examination. Two studies are particularly valuable: electroencephalography (EEG) and magnetic resonance imaging (MRI). EEG measures the brain's electrical activity. Transient electrical disruptions (spike waves or slowing) can indicate a predisposition for seizures and help determine if the seizures are focal or generalized. In addition, the appearance of abnormalities can be specific for particular seizure types or epilepsy syndromes. EEG is far from a perfect test, and can be normal in as many as 50% of patients with known epilepsy. Similarly, patients without a history of

seizures can display EEG abnormalities. Thus, the study has to be interpreted within its clinical context. Prolonged inpatient or ambulatory EEG, both of which can be combined with video, is an effective way to capture an event and confidently diagnose epilepsy. MRI provides a structural assessment of the brain, helping to determine if an epileptic focus is present. It is particularly useful in patients with a focal seizure onset, localized exam, or lateralized EEG abnormalities.

Once a diagnosis of seizures has been established, it is incumbent upon the treating physician to establish whether the patient's seizure type and EEG characteristics fall within a well-described epilepsy syndrome. These are important to recognize since each syndrome exhibits a characteristic treatment response and prognosis.

Febrile Seizures are the most common form of childhood seizures, affecting between 2% and 4% of all children. They occur between 6 months and 5 years of age, but the peak incidence is 18 months. Febrile seizures can be divided into simple and complex types. Simple febrile seizures are generalized, last less than 15 min, and do not recur within a 24-h period. All others are considered complex. Overall, one-third of children with a first febrile seizure will experience a recurrence. Risk factors for recurrence include a family history of febrile seizures and an age of onset less than 18 months. In children with febrile seizures, the overall risk of later epilepsy is approximately 2%. This risk is higher in the presence of neurological or developmental abnormalities, complex febrile seizures, or a family history of epilepsy.

Severe myoclonic epilepsy of infancy (SMEI or Dravet Syndrome) can mimic febrile seizures early in its course. Seizures begin in the first year of life. They are often associated with a fever and can be prolonged. By age 2, multiple seizure types develop, including atypical absence, complex partial, and myoclonic. The child is initially developmentally appropriate, but a decline occurs between 1 and 4 years of age. By age 4, most children exhibit intractable seizures and developmental delays. In approximately 80% of patients, the condition occurs from mutations of SCN1A (see section on Pathogenesis). Mutations of SCN1A are also found in patients with febrile seizures and Generalized Epilepsy with Febrile Seizures Plus (GEFS+) syndrome.

Infantile spasms are one of the most worrisome epilepsy syndromes, since the seizures are subtle and the prognosis is often poor (*Fig. 362.1*). They typically develop during the first year, with a peak age of onset between 4 and 6 months. Brief (1–5 s), symmetric contractions of the trunk with extension and elevation of the arms and tonic extension of the legs characterize the typical spasm. They occur in clusters shortly after waking. During a cluster, the infant may appear irritable. The triad of infantile spasms, hypsarrhythmia (a chaotic EEG pattern), and developmental regression is termed West's syndrome. The *Lennox–Gastaut syndrome* will develop in as many as 50% of children with infantile spasms. This syndrome, which occurs between 1 and 7 years of age, is comprised of mixed seizure types, cognitive decline, and a slow spike and wave pattern on EEG (<3 Hz) (*Figs. 362.2* and *362.3*).

Absence seizures are common to three epilepsy syndromes: childhood absence epilepsy, juvenile absence epilepsy, and juvenile myoclonic epilepsy. *Childhood absence epilepsy* develops between 4 and 10 years of age and manifests with brief (5–15 s) periods of behavioral cessation or staring spells (*Fig. 362.4*). They can be exacerbated by hyperventilation. This can be a useful feature when diagnosing absence seizures in the office or EEG laboratory. The EEG reveals generalized 3 Hz spike and slow wave discharges in association with the clinical event. *Juvenile absence epilepsy* is similar, but has a later age of onset (6–10 years) and a greater frequency of generalized tonic-clonic seizures than childhood absence epilepsy. *Juvenile myoclonic epilepsy* has an onset between 12 and 18 years, and patients exhibit absence, generalized tonic-clonic, and myoclonic seizures. The myoclonic jerks typically occur in the early morning hours. The EEG displays fast (3.5–6 Hz), generalized spike and wave or polyspike and wave activity.

Benign childhood focal seizures account for 22% of children with epilepsy. These syndromes develop in school age and are outgrown in adolescence. They are characterized by their semiology, EEG features, and absence of neuroimaging abnormalities. The most common of these conditions is *benign epilepsy with centrotemporal spikes* (BECTS), which represents approximately 15% of all childhood epilepsies (*Fig. 362.5*). The most common seizure type is simple partial, involving motor or sensory symptoms of the hands or face. Generalized tonic-clonic seizures may also develop. Both seizure types commonly occur during sleep. The characteristic EEG pattern includes broad centrotemporal spikes that show an anterior-to-posterior dipole. In *Panayiotopoulos syndrome* (PS), children develop autonomic symptoms, with vomiting being the most common. Patients may appear restless or agitated during a seizure, and usually become confused or unresponsive over its course. Two-thirds of the seizures begin in sleep, and they are often prolonged (lasting greater than 30 min). EEG in PS reveals multifocal, high-amplitude, sharp slow wave complexes that shift between regions and hemispheres, but predominate in the occipital leads. *Idiopathic childhood occipital*

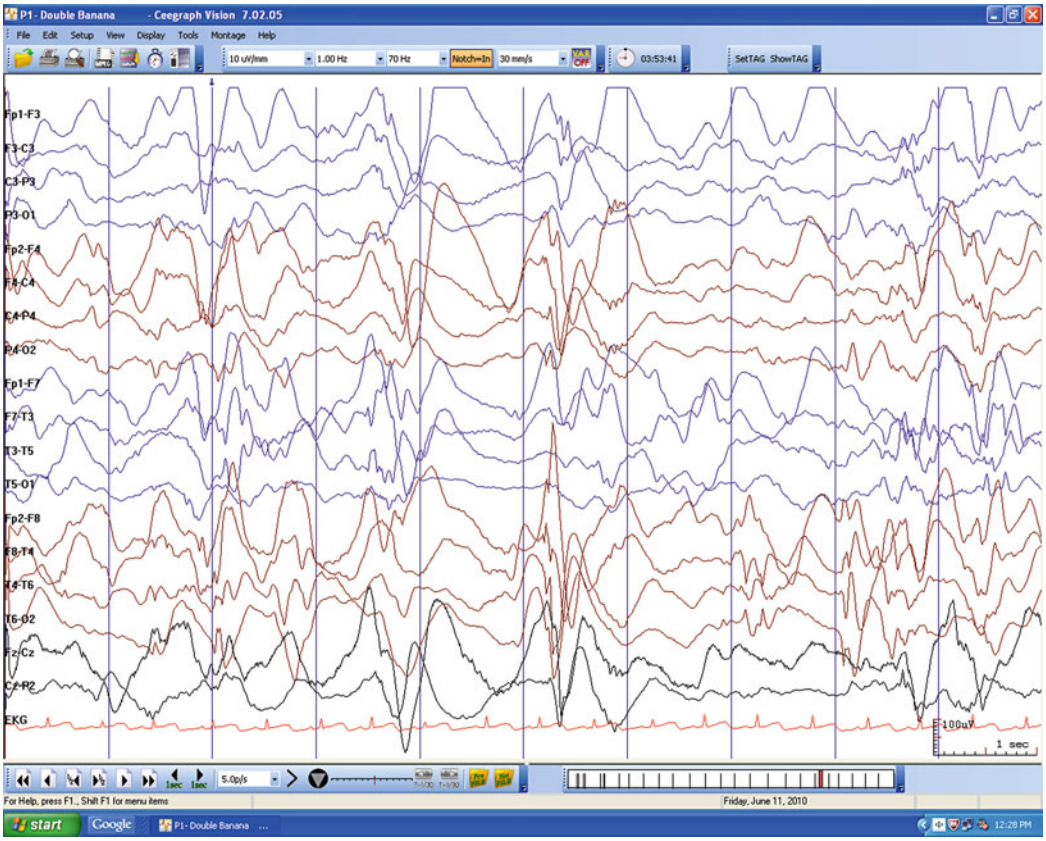

Figure 362.1

epilepsy of Gastaut (ICOE-G) is also characterized by occipital spike waves on EEG. They are sometimes observed only in sleep and may be intermixed with centrotemporal discharges. The semiology differs from PS and is characterized by visual hallucinations, blindness, or both. The seizures are short, lasting 1–3 min, and occur frequently (sometimes daily). They may be followed by a postictal headache which is indistinguishable from migraine. ICOE-G is outgrown later than the other benign focal epilepsies of childhood, and may sometimes evolve into atypical absence epilepsy (*Fig. 362.6*).

Differential Diagnosis

The first challenge in evaluating a patient with suspected seizures is to determine if the clinical events are epileptic or nonepileptic in etiology. There are several nonepileptic events (NEE) that resemble seizures, and the considerations change based on the patient's age.

The diagnosis of seizures is hardest to make in neonates, in whom subtle nonspecific clinical findings, such as eye deviation, apneas, bicycling, or buccolingual movements, may be the only manifestations. Many of these subtle signs are easily misdiagnosed. Suspected seizures are actually NEE in as many as 90% of neonates. The clinical event with the greatest specificity for epileptic seizures is focal clonic activity, which is epileptic in approximately 44% of newborns. Jitteriness, on the other hand, is nearly always a nonepileptic phenomenon. Because of the difficulty in confidently diagnosing seizures in the neonate, video EEG is often required.

In infancy, tonic posturing is a common event, and is often misdiagnosed. Without other associated signs or symptoms, tonic posturing is epileptic only 30% of the time. One common nonepileptic cause in infants is Sandifer syndrome. This refers to abnormal tonic posturing of the neck, trunk, or limbs, resulting from gastroesophageal reflux. There is often a temporal association with feeds, or there is a past history of spitting up or feeding intolerance. A gastrointestinal evaluation is needed to confirm this diagnosis.

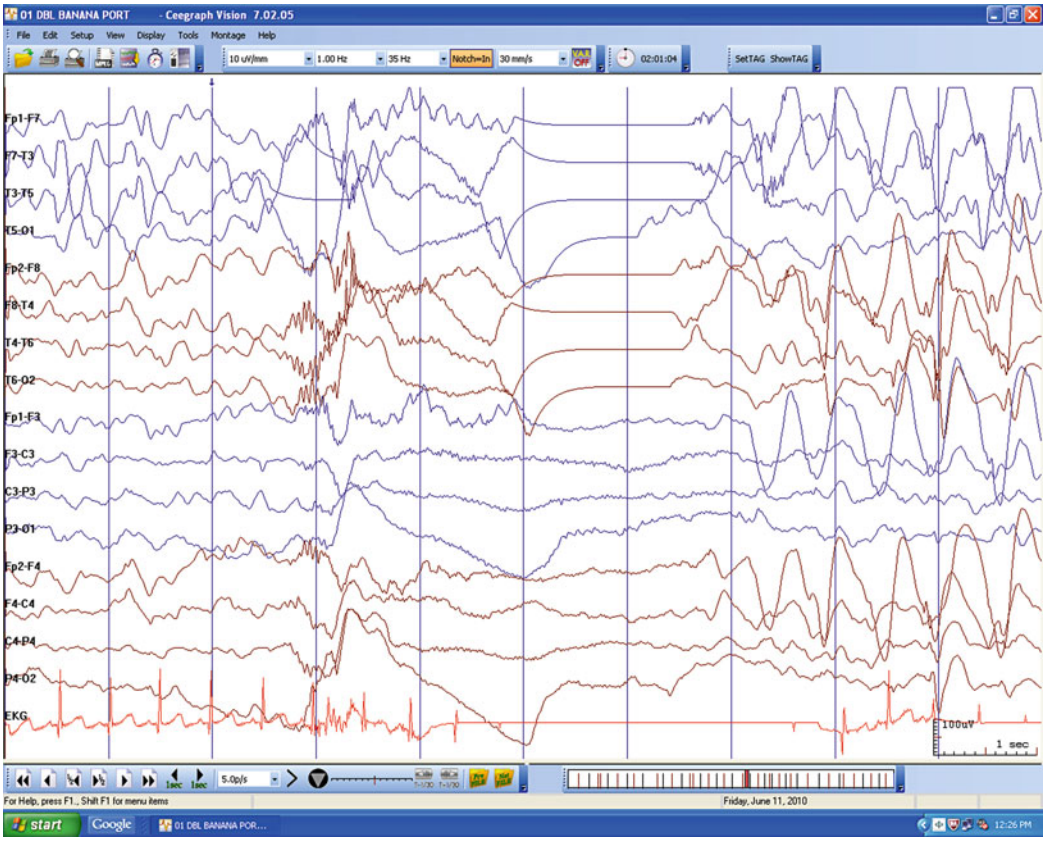

Figure 362.2

Twelve-month boy with infantile spasms. During his clinical spasms, there is a generalized decrement of the background activity with superimposed fast frequencies

Myoclonus is another event that is frequently misdiagnosed. Although myoclonic epilepsies can develop in infancy, there are two nonepileptic myoclonic syndromes that must be considered. These are benign neonatal sleep myoclonus and benign myoclonus of infancy. In benign neonatal sleep myoclonus, focal, multifocal, or generalized myclonic movements occur only during sleep. Each movement is brief, lasting a second or less, but the events may cluster. They end abruptly upon awakening. The movements usually begin in the first month and subside by 6 months of age, rarely persisting into childhood. The infant is otherwise neurologically normal. Benign myoclonus of infancy, on the other hand, begins at a later age (between 3 and 15 months) and involves tonic or myoclonic movements during wakefulness. The course is self-limited, and the events usually regress by age 2.

In early childhood, breath-holding spells are a common event. They may develop as early as infancy and will resolve prior to school age. Although most occur in response to an upsetting incident, the preceding cause is sometimes not observed by the parent. The child will display a color change, either pallor or cyanosis. Some children will have convulsive movements mimicking seizures and many are followed by a period of lethargy.

Later in childhood, most NEE can be distinguished from seizures based on a careful history or direct observation of the spells. Some include movement disorders such as motor tics, paroxysmal choreoathetosis, or focal dystonias. Narcolepsy, staring spells, complicated migraines, and syncope can also be difficult to distinguish from seizures. If all other causes have been excluded, psychogenic seizures must be considered. Many children with psychogenic seizure have epileptic seizures as well, so video EEG is often required for diagnosis.

Treatment

Once a correct diagnosis of epilepsy has been made, there are several reasons to consider treatment: (1) Reduce the risk of

Figure 362.3

Seven-year-old boy with a history of infantile spasms and profound global developmental delays. He has multiple seizure types including generalized tonic-clonic, atypical absence, and drop spells. His EEG shows prolonged runs of slow spike and slow waves (approximately 1–2 Hz) and frequent delta slowing

epilepsy-induced injury. (2) Lessen the risk of prolonged seizures (status epilepticus). (3) Prevent sudden unexplained death in epilepsy (which is fortunately a rare occurrence in children). (4) Lessen cognitive effects from frequent seizures. (5) Improve the patient's overall quality of life. As with any medical intervention, the benefits that the patient derives from treatment will need to outweigh potential risks. The decision to treat is individualized and based on both seizure (type, frequency, duration) and patient (age, compliance, level of activity) specific factors.

Because epilepsy treatment is aimed at prevention, a decision to treat cannot be made without first estimating the recurrence risk (see section on Prognosis). Once a decision has been made to treat, choosing the right antiepileptic drug (AED) becomes the next major consideration (*Table 362.4*). The optimal choice for a given patient depends on many factors, the two most important of which are efficacy and side effects. Efficacy differs based on the seizure type. For each seizure phenotype, there are first-, second-, and third-line treatments (*Table 362.5*). There is often more than one accepted first-line therapy. Deciding which therapy has the most favorable side-effect profile helps narrow this choice down to a single agent. Other important considerations include the frequency of dosing, ease of administration, and cost. In children, taste and the availability of a liquid or chewable preparation can be among the most important considerations since they impact greatly on compliance.

The seizure type is very important when choosing the correct AED. Generalized seizures respond best to broad-spectrum medications, and can be exacerbated by medications geared toward partial seizures, such as carbamazepine. Matching the correct treatment to the individual epilepsy syndrome is also important.

In febrile seizures, epidemiologic data indicate that the seizures are benign, so aggressive treatment measures are

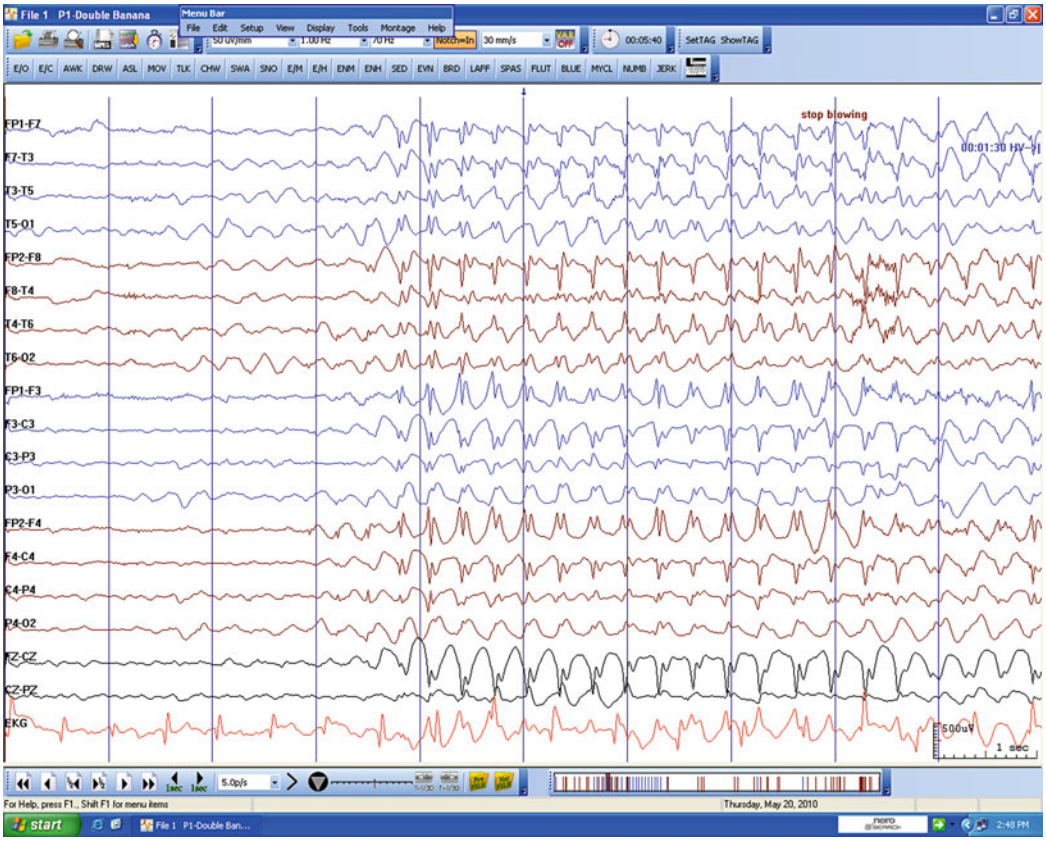

Figure 362.4

Eight-year-old girl with absence epilepsy. During her staring spells, bursts of generalized, 3 Hz spike and slow waves are seen on EEG

not required. The simplest preventative strategy is to use analgesics during febrile illnesses, although this approach has not demonstrated efficacy in clinical trials. Diazepam can also be given during febrile illnesses, but this results in only a modest reduction in recurrence. Additionally, rectal diazepam can be used acutely to abort a prolonged febrile seizure. Daily prophylaxis is rarely used in febrile seizures. Phenobarbital and valproic acid are effective for this purpose, but both have potential side effects. Treatment with a daily antiepileptic agent is therefore reserved for only the most severe cases.

Some patients initially diagnosed with febrile seizures go on to develop SMEI. Since this syndrome results from a mutation of voltage-gated sodium channel, sodium channel–blocking medications, such as carbamazepine and lamotrigine, can exacerbate seizures and should be avoided. Levetiracetam, topiramate, and stiripentol all offer better treatment success. The ketogenic diet can also be an effective option.

In infantile spasms, two treatment options are most effective: ACTH and vigabatrin. A course of pyridoxine may also be considered to exclude pyridoxine-dependent seizures. The Lennox–Gastaut syndrome may evolve from infantile spasms, and can be very refractory to treatment. Valproate and felbamate are two of the more effective options in this condition. The ketogenic diet can be effective in some patients, and vagus nerve stimulation may help prevent drop spells.

In absence seizures, ethosuximide is typically the first-line agent, but valproate and lamotrigine are also effective. In juvenile absence epilepsy and juvenile myoclonic epilepsy, valproate, levetiracetam, and lamotrigine are all effective options to consider.

For benign childhood focal seizures (PS, BECTS, and ICOE-G), treatment is optional since there is no evidence that the long-term prognosis is worse in untreated children. Daily prophylaxis depends largely on the presence of generalized convulsive seizures, since the simple partial seizures are typically not harmful. In ICOE-G, seizures can be

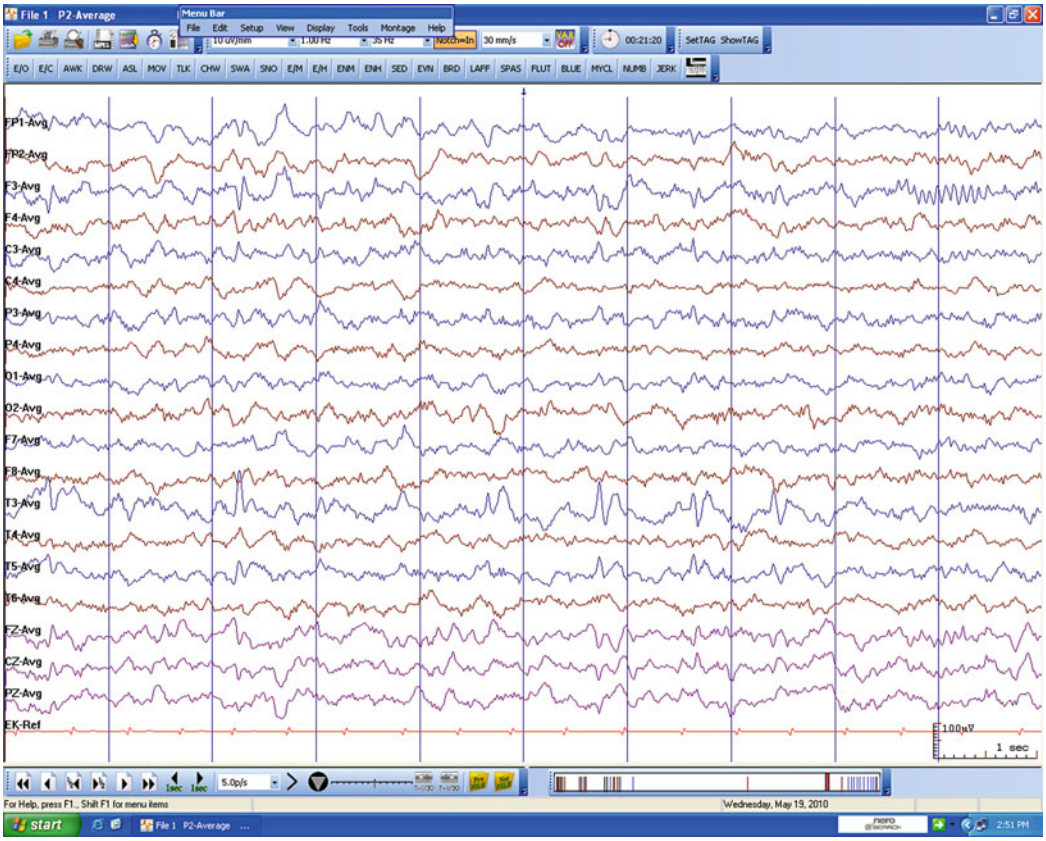

Figure 362.5

Seven-year-old boy with BECTS. His seizures are nocturnal and begin with a clicking sound of the throat followed by clonic activity of the face and hand. The involved side alternates between seizures. His EEG shows sleep-activated spike and slow waves over the left central and temporal regions (T3, T5, C3) which are accompanied by positive deflections over the frontal leads (F3) indicating a tangential dipole

frequent and may generalize, so continuous treatment is most needed more often in this syndrome than it is in PS and BECTS. If instituted, therapy consists of medications proven to be effective in partial seizures, and may include carbamazepine or valproic acid. In general, carbamazepine is preferred in the USA, and valproic acid has greater use in Europe. Newer medications, including gabapentin, lamotrigine, and levetiracetam, may also be effective. For BECTS, sulthiame is particularly effective and can normalize the EEG, but may result in cognitive impairment.

Regardless of which medication is chosen, the goal is the same – for the patient to be free of both seizures and side effects. With careful administration of the right medication, this goal can usually be achieved. In general, most AEDs are started at a low dose and increased gradually. This allows for early detection of side effects. If side effects occur, the dose is lowered. If seizures return, the dose is raised. If neither is present, no dose change is required. Unfortunately, some patients will have continued seizures and side effects, in which case, a medication change is generally needed.

Of patients who have never received an AED, approximately 47% will become seizure free with the first medication given. If a second drug is needed, only 13% will respond. If a third drug is used, the response rate is only 4%. A high initial seizure frequency before treatment, slowing on the EEG, and a symptomatic etiology are risk factors for developing medically intractable epilepsy.

After a patient has failed multiple AEDs, non-medication therapies must be considered. There are three non-medication options that are commonly used: the ketogenic diet, vagal nerve stimulator, and epilepsy surgery. All involve a multidisciplinary approach and require a comprehensive epilepsy center for their implementation and management.

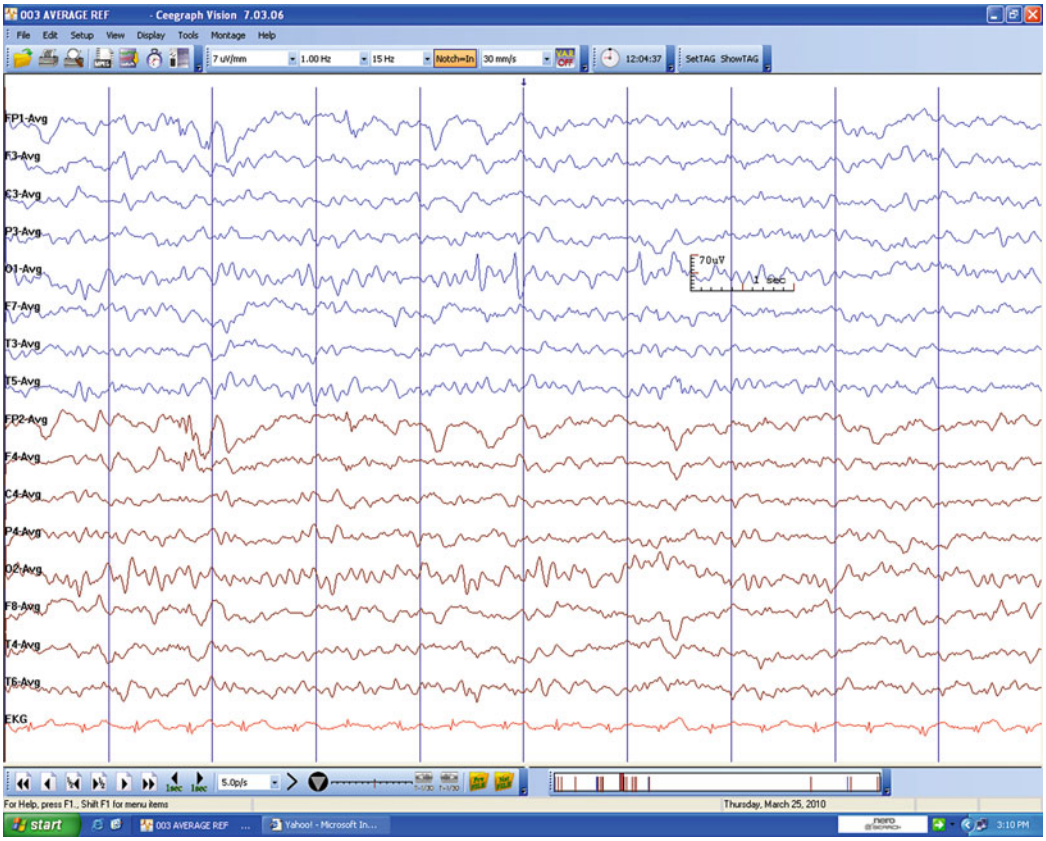

Figure 362.6

Nine-year-old boy with ICOE-G. His seizures cause him to wake from sleep with transient blindness followed by a headache. The EEG shows spike waves over the left occipital region (O1)

For status epilepticus, the ideal treatment acts rapidly, has long-lasting effects, produces little sedation, is easy to administer, safe, inexpensive, and can be pharmacologically reversed if needed. No single medication possesses all of these criteria, but the key requirements can usually be met.

In the largest prospective study on early treatment of SE, the Veterans Affairs Status Epilepticus Cooperative Study Group performed a randomized, double-blinded, multicenter trial using four i.v. treatments for status epilepticus: diazepam (0.15 mg/kg) followed by phenytoin (18 mg/kg), lorazepam (0.1 mg/kg), phenobarbital (15 mg/kg), and phenytoin (18 mg/kg). In patients with generalized convulsive status epilepticus, lorazepam had the best success rate, but this was statistically significant only when compared to phenytoin alone. No significant differences were observed among any of the four treatments with subtle SE. All of these trials lend support to intravenous lorazepam as initial therapy for SE.

An appropriate approach is to initiate therapy with lorazepam 0.1 mg/kg. If seizures persist, then phenytoin (20 mg/kg) or fosphenytoin (20 mg/kg phenytoin equivalents) should follow, with an additional 5–10 mg/kg of phenytoin/fosphenytoin if needed. In many cases, phenobarbital (20 mg/kg initially followed by an additional 5–10 mg/kg if needed) follows, with induction of anesthesia if the seizure persists beyond that. With the low success rate for subsequent drugs in the VA study, it is reasonable to consider moving on to definitive treatment with high-dose barbiturates, benzodiazepines, or propofol if SE remains refractory.

Prognosis

There are many ways to assess prognosis in patients with epilepsy. The most direct outcome measure is quantification of the seizures themselves. This includes an examination of seizure frequency, relapse rates following drug withdrawal, and the probability of outgrowing the condition. Assessment of comorbidities is also important, including developmental delays, intellectual impairment, and psychiatric disorders.

Table 362.4
Commonly used antiepileptic medications

Agent	Pediatric dose (mg/kg/day)	Half-life (h)[a]	Dosing schedule	Side effects
Carbamazepine (Tegretol)	10–35	25–65 (initial)	BID-QID	r, hep, bd, s,n

[a]Half-life is based on monotherapy and assumes normal renal function.

Other measures of clinical significance are quality of life and mortality risk in epilepsy patients. Some childhood epilepsy syndromes are labeled as "benign." The use of this term refers to the prognosis of the seizures themselves, and not to the severity of associated conditions. For example, BECTS is often associated with motor or language delay. These features can have profound effects on patients, yet the condition is still labeled as "benign" since the seizures are characteristically outgrown.

Overall, the recurrence risk following a first unprovoked seizure in childhood ranges between 44% and 64%. The recurrence risk is highest in patients with an abnormal neurological examination, an abnormal electroencephalogram, or a remote-symptomatic etiology. In patients with only a single non-symptomatic seizure who have a normal examination and EEG, the risk of recurrent seizures is low (approximately 25%), and observation off of antiepileptic medications is generally favored. Should a second seizure occur, the recurrence risk jumps to approximately 79%. Thus, treatment is often started following a second seizure.

When seizures remain in remission on antiepileptic medications, the question of when to end treatment arises. Of patients who have been seizure free for over 2 years, 60–75% will remain seizure free when medication is withdrawn. A remote-symptomatic etiology and an abnormal EEG portend a higher relapse risk. Moreover, some epilepsy syndromes, such as juvenile myoclonic epilepsy, have a high relapse rate requiring a prolonged treatment course whereas others, such as BECTS, have no chance of relapse once outgrown. The ultimate decision of withdrawing antiepileptic medications is therefore dependent on individual patient factors. Overall, following 2 years of seizure remission on medication, roughly two-thirds of children will remain seizure free following discontinuation of their antiseizure treatment. If seizures are to recur, they will do so within 1 year in 60–80% of patients. Late recurrences (greater than 2 years after stopping AEDs) can develop, but are rare.

Table 362.5
Which medications for which seizure types?

Seizure type	First-line therapy	Second-line	Third-line
Partial (all types)	CBZ, OXC	LTG, VPA, GBP	TGB, ZNS, PB, LAC
		TPM, PHT, LEV	
Generalized			
Tonic-clonic	VPA, LEV	LTG, TPM, PHT	PB, ZNS
Myoclonic	VPA, LEV	LTG, CZP	PB, ZNS

[a]Assuming no convulsive seizures.

Overall, the prognosis for most epilepsy patients is favorable. Approximately two-thirds will achieve long-term remission of greater than 5 years, and nearly half of those will do so off of medications. Positive predictors for remission include a rapid response to therapy (greater than a 75% seizure reduction within 3 months), and idiopathic epilepsy. Remission is less likely in patients with an underlying structural cause or abnormal EEG. When followed into adulthood, children with epilepsy are at greater risk of school dropout and unemployment, and are less likely to be married or have children.

Prevention

Strategies for epilepsy prevention differ depending on the etiology. In genetic epilepsies, the only form of prevention currently available is family counseling. The recurrence risk can be as high as 50% for autosomal-dominant inheritance or less than 1% for spontaneous mutations involving only a single child within the family. Diagnostic confirmation through genetic testing now makes it possible to provide an accurate risk assessment prior to family planning. As genetic causes are better understood, treatment strategies directed at the mechanisms of disease may offer potential for averting epilepsy onset.

Symptomatic causes of epilepsy offer the greatest prospects for prevention. Since symptomatic causes generally develop following known brain injury, the possibility exists of either averting the injury or disrupting epileptogenesis following the insult. In children, neonatal causes of brain injury, such as hypoxic-ischemic encephalopathy and complications from prematurity, are major preventable etiologies. In adults, stroke is the most common identifiable etiology, and can be avoided through lifestyle modifications and management of hypertension and hypercholesterolemia.

In the third world, cysticercosis remains a major cause of epilepsy and is potentially eradicable. Since the only animal reservoirs are humans and pigs, breaking the life cycle of *Taenia solium* is possible. Strategies include concomitant treatment of both human and porcine populations. In pigs, treatment with oxfendazole is effective and confers protection for at least 3 months. Other strategies include immunization of pigs and improved meat inspection.

If the injury itself cannot be prevented, perhaps the mechanisms of epileptogenesis, which follow the injury, can be. Presently, no such interventions are known to exist, but many are theorized. One possibility is to initiate antiseizure medications immediately following injury, and prior to the development of seizures. Current data for head trauma suggests that, although prophylactic treatment may reduce early seizures, it does not prevent late seizures or reduce neurological disability. Similar conclusions are observed following brain tumors and strokes. Given those results, antiseizure medications are not routinely started prior to the development of seizures, but more research is needed in this area. A different approach is to use neuroprotective agents immediately following injury in an effort to prevent epilepsy and improve neurological outcome. To date, no such agents have demonstrated proven clinical efficacy in reducing injury or preventing epilepsy. Stem cell therapy also offers potential. In a rat model of pilocarpine-induced epilepsy, intravenous transplantation of bone marrow mononuclear cells prevented the development of chronic seizures and reduced neuronal loss. One challenge to bringing such therapies to clinical use is the increased time and cost of studying epileptogenesis as the primary outcome. Since it can take years for epilepsy to develop, the use of biomarkers for epileptogenesis may be the best solution to making such trials feasible.

363 Movement Disorders

Yasser Awaad

Movement disorders in childhood have received little attention, especially when compared with such conditions as epilepsy or neuromuscular disorders. The information on movement disorders in childhood is scattered in multiple neurological and pediatric journals. This chapter attempts to put together information from these various sources in a form accessible to clinically oriented pediatricians.

Only disorders of children and adolescents under 18 years of age are dealt with. The differences in movement disorders between children and adults are striking. The clinical manifestations of extrapyramidal disease are profoundly influenced by the age of onset. A good example is the difference between Huntington disease in adults and children. Moreover, a number of disease processes occur almost exclusively in the pediatric age, for example, transient disorders. So the prevalence of the various movement disorders in children, their clinical presentation, course, prognosis, and management differ considerably from those in adults.

Movement disorders are syndromes characterized by impaired voluntarily movement, presence of involuntary movements, or both. There may be targeting and velocity of intended movements, abnormal involuntary movements, abnormal postures, or excessive normal-appearing movements at inappropriate or unintended times. Movement disorders in children include athetosis, chorea, dystonia, myoclonus, Parkinsonism, stereotypies, tics, and tremor. Movement disorders may be accompanied by weakness, spasticity, hypotonia, ataxia, apraxia, and other motor deficits, although many authors do not include these accompanying deficits among the movement disorders.

Movement disorders have been divided into hyperkinetic disorders in which there is excessive movement, and hypokinetic disorders in which there is a paucity of movement. Hyperkinetic disorders consist of abnormal, repetitive involuntary movements and include most of childhood movement disorders such as chorea, dystonia, myoclonus, stereotypies, tics, and tremor. Hypokinetic disorders are primarily akinetic or rigid. The primary syndrome in this category is Parkinsonism, occurring mostly in adulthood as Parkinson disease or one of the many forms of secondary Parkinsonism. In children, hypokinetic disorders are much less common than hyperkinetic disorders.

Abnormalities of movement that are presumed to be due to central nervous system disorders are typically divided into two primary categories: pyramidal and extrapyramidal. Many authors consider only the extrapyramidal symptoms to be movement disorders. "Extrapyramidal diseases" is the oldest but has fallen into disuse because of its lack of precision. The term includes other systems of control of movement that are not usually termed extrapyramidal, for example, the cerebellum. Pyramidal symptoms typically involve weakness, specific patterns of weakness, or spasticity. Pyramidal symptoms are thought to be due to injury to the pyramidal tract, including the corticospinal tract, and therefore to represent, to some extent, the effect of a denervated spinal cord. Extrapyramidal disorders are often described as everything that is not a pyramidal disorder. In particular, the term usually includes disorders of movement that are not due to weakness.

"Disorders of the basal ganglia" is also inadequate as not all abnormal movements are the result of involvement of these structures, and, conversely, lesions of the basal ganglia can manifest with cognitive deficit rather than with movement disorders. For these reasons, the term "movement disorders" seemed least inadequate, as it is merely descriptive and does not imply any hypothesis regarding the anatomical location of defects.

Movement disorder terminology has been well defined for adults but less so for children. Therefore, it is likely that movement disorders are underreported in children and that there is inconsistent terminology. Recently there have been attempts to provide specific definitions of childhood hypertonic disorders, including dystonia and rigidity. The prevalence in children of different types of hypertonic disorders, as well as other movement disorders, is not well known, although there have been studies investigating this in certain populations. Consistent definitions of non-hypertonic disorders in childhood are not yet available.

In adult movement disorders, it is frequently helpful to divide disorders into primary and secondary disorders, although there is no consistent definition of these terms. Many authors refer to disorders as primary if there is only a single dominant symptom and the underlying cause is presumably genetic or is due to an identified gene; however, the existence of a single symptom in childhood movement disorders is probably the exception rather than the rule.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_363,

Since Sydenham in 1686 identified the first disease characterized by a movement disorder, a long time has elapsed and, especially in the past 35 years, knowledge of the pathophysiology of abnormal movements has increased extraordinarily as a result of better understanding of neurotransmitter function, of modern neuroimaging techniques (especially MRI but also functional neuroimaging with MR spectroscopy, PET, and functional MR), and of the advent of molecular genetics. This last not only provides new bases for neurological classification, previously based exclusively on clinical/pathological data, but also raises the hope of prevention and possible cure of genetically determined movement disorders.

Although new disorders are being identified with such methods, progress in patient care has remained rather patchy, and much has to be done to improve the management of many movement disorders. Therapeutic difficulties are even greater where children are concerned. The consequences on learning and on the neurological and psychological development of children with chronic movement disorders are largely unknown. Even drug doses are often poorly established and extrapolated from adult practice, even though there are well-known differences in the handling of pharmacological agents between children and adults.

Movement disorders in children differ from those in adults in several important aspects. Perhaps the most important is that movement disorders in childhood are primarily symptoms of other diseases, rather than diseases by themselves. In adults, dystonia and Parkinsonism are usually due to primary dystonia or idiopathic Parkinson's disease, respectively. However, dystonia or Parkinsonism in children is more likely to be a feature of underlying static or progressive neurologic disorder. Diagnosis in children is complicated by the fact that many symptoms have more than one cause, and any particular underlying pathophysiology may lead to complex combinations of symptoms. The diagnostic evaluation in children is guided by symptoms, but the existence of a large class of diseases that can lead to the same set of symptoms often necessitates a broad etiologic evaluation. There may be specific etiologic treatments and symptomatic treatments, both of which may be beneficial in an individual child. In particular, many of the causes of childhood movement disorders do not yet have any specific treatment, yet symptomatic treatment for the resulting movement disorder can be extremely helpful and lead to improvement in quality of life.

Another distinction between movement disorders in adults and children is that many adult neurologic disorders can be attributed to anatomically localized injury, but childhood disorder frequently results from a global or multifocal injury that may affect particular cell types, receptor types, or metabolic pathways. Therefore in children, the injury is open sparse but global, with manifestations across multiple areas of function, including sensorimotor and cognitive functions.

The clinical manifestations of movement disorders will depend on the child's developmental stage. The same illness may present differently depending on the age at onset of symptoms. Detection of a progressive disorder may be complicated by superimposition of a progressive disorder on the natural improvement of function that is expected throughout childhood. Therefore, a child with a progressive movement disorder may continue to develop new skills despite falling further and further behind in age-appropriate behavior. The presence of a movement disorder may affect the current and continuing development of the child's normal motor and cognitive abilities. Therefore, an acute illness may have developmental consequences that outlast the duration of the injury itself.

Classification of the movement disorder based on temporal pattern is essential for diagnosis. It is also important to define the context in which the movements occur. Although it is often helpful to list the characteristics of the movements, the diagnosis relies on pattern recognition, and the clinician must see the movements. If the movements are not apparent during the neurologic examination, repeating the examination at another time or obtaining video recordings of the movements is essential. The widespread availability of video cameras has substantially improved diagnosis of movement disorders.

When approaching a patient with a movement disorder, it is helpful to determine the answers to some key questions:

1. Is the number of movements excessive (hyperkinetic) or diminished (hypokinetic)?
2. If hyperkinetic, do the individual movements appear normal or abnormal?
3. Is the movement paroxysmal (sudden onset and offset), continual (repeated again and again), or continuous (without stop)?
4. What is the developmental stage of the child, and has the development been normal?
5. How does voluntary movement affect the movement disorder? Are the symptoms and signs present at rest (body part supported against gravity), with maintained posture, with action, with approach to a target (intention), or a combination?
6. Has the movement disorder changed over time?
7. Do environmental stimuli or emotional states precipitate, exacerbate, or alleviate the movement disorder?
8. Is the patient aware of the movements?

9. Can the movements be suppressed voluntarily?
10. Are the movements heralded by a premonitory sensation or urge? (It may be helpful to ask the patient, "Why do you do that?")
11. Does the movement disorder abate with sleep?
12. Are there other findings on the examination suggestive of focal neurologic deficit or systemic disease?
13. Is there a family history of a similar or related condition?

Laboratory tests, imaging, and other diagnostic testing should be based on the specific movement disorder. There is no universal "movement disorder workup" because the causes are varied and some movement disorders (e.g., tics) are rarely symptomatic of an underlying disease (*Table 363.1*).

Movement disorders may be difficult to characterize unless other symptoms and behavioral context are taken into account. Chorea can resemble myoclonus. Dystonia can resemble spasticity. Paroxysmal movement disorders such as dystonia and tics may resemble seizure. Movements in some contexts may be normal and in others may indicate underlying pathology. For example, frequent eye blinking can be perfectly normal and appropriate in one setting, but excessive in another (tics). Movements that raise concern about a degenerative disorder in older children (progressive myoclonus) may be completely normal in an infant (benign neonatal myoclonus). Thus, it is important to view the movement disorder in the context of a complete history and neurologic examination.

The etiology of movement disorders in children is extensive and is discussed further below. The most common cause of secondary disorders is likely to be cerebral palsy, with a prevalence of 2 per 1,000. However, cerebral palsy itself represents a constellation of both injuries and symptoms (Surveillance of Cerebral Palsy in Europe, 2002). Cerebral palsy can be associated with almost all forms of childhood movement disorders, and despite the lack of an ongoing destructive process, the clinical picture may change during the development. The diagnosis and management of cerebral palsy is complex.

Specific types of movement disorders may represent injury to particular localized regions of the central nervous system. Ataxia most likely results from injury to the cerebellum or its inflow and outflow. Bradykinesia most likely occurs with injury to the substantia nigra or striatum of the basal ganglia leading to either presynaptic or postsynaptic failure of dopaminergic transmission. Chorea occurs in severe cortical injury or basal ganglia injury, particularly if the subthalamic nucleus is involved. Dystonia most likely involves injury to basal ganglia, but the possibility of cortical or cerebellar abnormalities cannot be excluded as contributors. Myoclonus most likely involves cortical, brainstem, or spinal injury to gray matter. The localization of tremor depends on the type, but some forms of tremor involve cerebellum or brainstem circuits. Tic disorders probably involve an abnormality of the basal ganglia, but cortical mechanisms may also contribute.

Treatment of childhood movement disorders is based primarily on symptomatology independent of the underlying cause. When a specific treatment for the underlying cause is available, certainly this should be applied, but in many cases such treatment is only partly effective. The goal of symptomatic treatment is to break the connection between the pathophysiology and the expression of clinical impairment.

It is essential to ask both the child and the parents for the most significant cause of disability. In some children, the impairment that is most evident to the clinician is not

Table 363.1
Phenomenologic classification of movement disorders

Movement disorder	Brief description
Athetosis	Slow, continuous writing movements of distal body parts, especially the fingers and hands
Chorea, ballism	Chaotic, random, repetitive, brief, purposeless movements. Rapid but not as rapid as myoclonus. When very large amplitude affecting proximal joints, choreic limb movements are often called *ballism*
Dystonia	Repetitive, sustained, abnormal postures typically have a twisting quality
Myoclonus	Sudden, brief, shock-like movements that may be repetitive or rhythmic
Parkinsonism	Hypokinetic syndrome characterized by a combination of reset tremor, slow movement (bradykinesia), rigidity, and postural instability
Stereotypy	Patterned, episodic, repetitive, purposeless, rhythmic movements
Tics	Stereotyped intermittent, sudden, discrete, repetitive, nonrhythmic movements, most frequently involving head and upper body
Tremor	Rhythmic oscillation around a central point or position involving any one body part or more than one

the primary cause of disability. Sometimes treatment of a disability is more effective, less time-consuming, and less risky than attempts to treat the underlying pathophysiology, and therefore it is essential to be certain that any treatment addresses the needs and goals of the child and family. In particular, it is usually neither necessary nor possible to treat all symptoms. It is most helpful to pick specific goals and to monitor progress toward those goals. In many cases, a team approach has been found to be helpful, particularly when there are multiple impairments leading to disability, and the team approach allows appropriate focusing and selection of interventions. In some individuals, a supportive environment and adaptive equipment are more effective than any medical intervention.

TIC Disorders and Tourette Syndrome

Tic disorders and related conditions are among the most common clinical conditions encountered by pediatric neurologists. The evaluation and management of these conditions is usually fairly straightforward and may follow predictable, relatively simple paradigms. On the other hand, more complex cases require considerable effort, numerous treatment strategies, and intensive management of patients and families. Gilles de la Tourette syndrome (TS) is a chronic neuropsychiatric disorder characterized by the presence of involuntary motor and phonic tics that wax and wane. Once considered a rare disorder, the prevalence of TS is estimated to be up to 1% of children and adolescents. In his late nineteenth-century description, Georges Gilles de la Tourette suggested a familial pattern and a psychogenic origin. Since then, there is further evidence for a genetic inheritance pattern, but accumulating data support a neurobiological disorder than emotional basis. In addition, those children with TS often suffer from a variety of concomitant psychopathologies, including obsessive–compulsive disorder, attention-deficit hyperactivity disorder, mood disorders, episodic outbursts, learning difficulties, sleep abnormalities, and other behavioral problems. Although the presence of neurobehavioral problems is not required for the diagnosis of TS, they are very common, and their clinical impact on the affected patient is often more significant than the impact of the tics themselves. The physician caring for a child with tics and complex psychopathologies must be able to recognize the various problems, understand their individual complexities, and develop an appropriate treatment plan.

Dystonia

Description

Dystonia is defined as a movement disorder in which involuntary sustained or intermittent muscle contractions cause twisting and repetitive movements, abnormal postures, or both.

Dystonia usually occurs only during voluntary movement or with voluntary maintenance of a posture of the limbs or body. For example, flexion of the fingers to hold a pen may lead to flexion of additional fingers, extension of the wrist, or movements of the opposite hand or the neck.

There is often no abnormal muscle tone in children with dystonia. A dystonic limb may or may not have increased resistance to movement, it may be either stiff or floppy, or change with time.

Focal dystonia is described if only one body part is involved, such as a hand, foot, or the neck. On the other hand, if two contiguous parts are involved, such as the face and neck, then it is termed a "segmental dystonia." If two noncontiguous parts of the body are involved, such as the face and one leg, it is termed a "multifocal dystonia." Hemidystonia involves one half of the body. If both legs, as well as one additional body part are involved, then it is termed "generalized dystonia." A focal dystonia that progresses to become generalized or generalized dystonia itself are the most common patterns observed in children.

Dystonia may occur at rest or with action and it may be triggered by the movement of other body parties. Task-specific dystonia occurs only rarely in children.

Primary dystonia includes the genetic dystonias, and some adult onset, focal dystonias, is not due to another disease. When dystonia is due to another identified disease, then it is called "secondary dystonia." Secondary dystonia is due to different causes, for example, cerebral palsy, metabolic disease, or head trauma.

The mechanism of dystonia is understood. Studies in humans and animals have not been able to find a good explanation that can relate particular injuries to the emergence of dystonic symptoms. Dystonia is frequently associated with injury to the basal ganglia, in particular the sensory-motor regions of the putamen. In children, dystonia may also occur with decreased dopamine as occurs in dopa-responsive dystonia (DRD). Low dopamine level can cause many childhood dystonias. Acute dystonic reactions in children and adults are caused by medications that selectively block the dopamine receptors in the indirect pathway. These reactions are treated with anticholinergic

medications that may increase the effectiveness of dopamine in both the direct and indirect pathways (Tables 363.2 and 363.3).

Examination

The child must be observed at rest, during the action of the parts of the body affected by dystonia, as well as actions unrelated to the dystonia. For example, a child with foot dystonia must be observed while sitting, standing, walking, and performing tasks with the hands. Mental distraction is helpful to elicit the dystonia. Distractions may help to determine the specific triggers for the dystonic movements and also assist in evaluating if other body parts are subtly affected. It is important to test the child during certain activities (reaching movements of the arms, speaking, and tongue movement).

When dystonia is present at rest, it is important to examine children when they are as relaxed as possible. Any stress or discomfort may worsen the symptoms.

Muscle tone is not usually increased in children with dystonia; it might be increased and there will be difficulty in differentiating dystonia from spasticity or rigidity. This will be difficult when dystonia and spasticity are simultaneously present (e.g., cerebral palsy). It is equally important to examine for other movement disorders, such as ataxia or myoclonus, which might lead to a specific diagnosis.

Dystonia is usually not present during sleep. Stiffness of the limbs during sleep suggests possible spasticity or fixed joint contractures. Dopa-responsive dystonia may improve

Table 363.2
Etiologic classification of dystonia

Primary: Dystonia is the only neurological sign and evaluation does not reveal an identifiable exogenous cause or other inherited or degenerative disease	*Secondary*: Variety of lesions, mostly involving the basal ganglia and/or dopamine synthesis
Childhood- and adolescent-onset	*Inherited non-degenerative* (*dystonia plus*)
• DYT1: Autosomal-dominant with reduced penetrance (approx. 30%), early limb-onset with predominant family phenotype	• Dopa-responsive dystonia (DRD): due to DYT5 and other genetic defects
• Other genes to be identified	• Myoclonus-dystonia: due to DYT11 and possibly other genetic defects
	• Rapid-onset dystonia-Parkinsonism due to DYT12
Adult onset	*Inherited degenerative*
• DYT7: Autosomal-dominant, cervical onset in adult life	Autosomal-dominant, autosomal-recessive, X-linked (DYT3), mitochondrial
• Other genes to be identified	
Mixed phenotype	*Degenerative disorders of unknown etiology*
• DYT6, DYT13: Autosomal-dominant, early- and late-onset, with possible cranial, cervical, and sometimes limb-onset and variable spread	• Parkinson's disease
• Other genes to be identified	• Progressive supranuclear palsy
	• Corticobasal ganglionic degeneration
	Acquired
	• Drugs (dopamine receptor blockers), other toxins
	• Head trauma
	• Stroke, hypoxia
	• Encephalitis, infectious, and post-infectious
	• Tumors
	• Peripheral injuries
	Other movement disorders with dystonic phenomenology
	• Tics, paroxysmal dyskinesias (DYT8, 9, 10)
	Psychogenic dystonia

Table 363.3
Classification of genetic loci associated with dystonia

Gene	Location	Inheritance	Phenotype	Gene Product
DYT1	9q34	AD	Early limb-onset PTD	Torsin A
DYT2	Not mapped	AR	Early onset	
DYT3	Xq13.1	XR	Lubag dystonia/Parkinsonism	Not identified
DYT4	Not mapped	AD	Whispering dysphonia	
DYT5	14q22.1	AD	DRD/Parkinsonism	GCHI
DYT6	8p21-p22	AD	"Mixed" cranial/cervical/limb-onset	Not identified
DYT7	18p	AD	Adult cervical	Not identified
DYT8	2q33-25	AD	PDC/PNKD	Not identified
DYT9	Ip21	AD	Episodic choreoathetosis/ataxia with spasticity	Not identified
DYT10	16	AD	PKC/PKD (EKDl & 2)	Not identified
DYT11	7q21	AD	Myoclonus-dystonia	Epsilon-sarcoglycan
DYT12	19q	AD	Rapid-onset dystonia-Parkinsonism	Not identified
DYT13	Ip36	AD	Cervical/cranial/brachial	Not identified
DYT14	14q13	AD	DRD	Not identified

Abbreviations: *AD* autosomal-dominant, *AR* autosomal-recessive, *XR* X-linked recessive, *PTD* primary torsion dystonia, *DRD* DOPA-responsive dystonia, *PDC* paroxysmal dystonic non-kinesigenic choreoathetosis, *PNKD* paroxysmal non-kinesigenic dystonia, *PKC* paroxysmal kinesigenic choreoathetosis, *PKD* paroxysmal kinesigenic dyskinesia, *GHC*1 GTP Cyclohydrolase 1

upon awakening in the morning or after a nap; but the symptoms worsen throughout the day. Other forms of dystonia may be worse upon morning awakening.

Dystonia has several genetic causes with autosomal-dominant inheritance. Therefore, a thorough family history of dystonia or other neurological diseases is very important. The onset of dystonia is important, but dystonia may start many years after the causative event. Toxin exposure and medications use (neuroleptics and psychiatric medications) must be investigated. Such medicines may cause dystonia even after they have been stopped. Autosomal-dominant inheritance is caused by too many different genes. The most common genes are DYT1 (9q34, encodes torsinA) and DYT5 (14q22.1-2, encodes GTP cyclohydrolase I, causing Dopa-responsive dystonia or Segawa's disease). DYT2 can cause an autosomal-recessive trait. DYT3 causes an X-linked dystonia-Parkinsonism syndrome of Lubag (Xq13). The familial rapid-onset dystonia-Parkinsonism is linked to chromosome 19.

Structural lesions like cerebral palsy, kernicterus, hypoxic injury, head trauma, encephalitis, tumors, basal ganglia stroke, Moyamoya disease, and congenital malformations can cause dystonia.

Different neurodegenerative diseases can cause dystonias like Fahr's disease (or basal ganglia calcification), pantothenate-kinase associated neurodegenerative disease (PKAN, formerly neurodegeneration with brain iron accumulation type I, formerly Hallervorden–Spatz disease, PANK2 gene at 20p12.3-p13), Huntington's disease (Westphal variant, IT15-4p16.3), spinocerebellar ataxias (SCAs), neuronal ceroid lipofuscinosis, Rett syndrome, Tay–Sachs disease, Sandhoff's disease, Niemann–Pick type C, metachromatic leukodystrophy, striatal necrosis, Leigh's disease, neuroacanthocytosis, vitamin E deficiency, HARP syndrome (hypoprebetalipoproteinemia, acanthocytosis, retinitis pigmentosa, and pallidal degeneration), Pelizaeus–Merzbacher disease, and ataxia telangiectasia (AT).

Other chemical and metabolic disorders like glutaric aciduria, acyl-CoA dehydrogenase deficiency dopa-responsive dystonia or DRD (biopterin metabolic defect DYT5 or tyrosine hydroxylase deficiency), dopamine agonist-responsive dystonia (or ALAD: aromatic L-amino acid decarboxylase deficiency), mitochondrial disorders, Wilson's disease, homocystinuria, GM1 gangliosidosis, metachromatic leukodystrophy, Lesch–Nyhan disease, methylmalonic aciduria, and tyrosinemia could lead to dystonia.

Different drugs and toxins can induce dystonia, for example, neuroleptic and antiemetic medications (haloperidol, Thorazine, olanzapine, risperidone, quetiapine, promethazine, prochlorperazine, etc.), calcium channel blockers, stimulants (amphetamine, cocaine, ergot alkaloids, etc.), anticonvulsants (carbamazepine, phenytoin, etc.), thallium, manganese, carbon monoxide, ethylene glycol, cyanide, methanol, and wasp sting. Drug- or

toxin-induced dystonia may occur while taking the drug or months after stopping the drug. Other paroxysmal disorders could induce dystonia, paroxysmal kinesogenic choreoathetosis (PKC), paroxysmal non-kinesogenic choreoathetosis (PNKC), familial periodic paralysis, exercise-induced dystonia, complex migraine, alternating hemiplegia, and paroxysmal torticollis of infancy.

There are some disorders that misdiagnosed as dystonia, like tonic seizures (including paroxysmal nocturnal dystonia caused by nocturnal frontal lobe seizures); syringomyelia; Arnold–Chiari malformation type II; atlantoaxial subluxation; posterior fossa mass; cervical spine malformation (including Klippel–Feil anomaly); ocular skew deviation with vertical double vision causing neck twisting, juvenile rheumatoid arthritis; Sandifer's syndrome (gastrointestinal disorder associated with hiatus hernia in infants); spasmus nutans; tics; self-stimulation; spasticity; myotonia; rigidity; stiff-person syndrome; Isaac's syndrome; startle disease (hyperexplexia); neuroleptic malignant syndrome; and psychogenic disorders.

The investigation of dystonia depends on the specific type of dystonia. In hemidystonia MRI will show a localized injury to the brain, often at or before birth.

In many cases, dystonia will start before early adulthood without obvious cause, and then become progressively worse. In these cases, there may be a genetic mutation in the *DYT1* gene. The child should be tested for the presence of this gene, particularly if symptoms began in the foot and progressed to other areas of the body.

Metabolic causes for dystonia are treatable and should be excluded. Dopa-responsive dystonia (DRD) is a rare disorder of the enzyme pathway responsible for synthesizing dopamine. DRD is tested by measuring chemicals in the CSF and in the blood, following an oral dose of phenylalanine (known as the phenylalanine loading test).

Metabolic disorders, such as Wilson's disease, amino acid or organic acid disorders, and lysosomal storage diseases may be tested for in certain children. An MRI is helpful during the workup for many metabolic diseases.

Treatment

It is recommended that any child with unexplained dystonia should receive a trial of L-dopa therapy (*Table 363.4*). If the child does have DRD, the response is often dramatic and further testing may be arranged. L-dopa may also be helpful in some children with dystonia due to cerebral palsy, or perhaps in other metabolic disorders or structural abnormalities.

Table 363.4
Treatment Options for Dystonia

Oral Medication
1. L-dopa therapy
2. Trihexyphenidyl (Artane®)
3. Diazepam (Valium®)
4. Clonazepam (Klonopin®)
5. Valproate (Depakote®)
6. Baclofen
7. Carbamazepine (Tegretol®)
8. Reserpine or tetrabenazine (Nitoman®, not available in the USA)
Choice of the best regimen is usually by trial and error. It is difficult to predict which medicine will be most effective for a particular child
Botulinum toxin injections
For focal dystonias
Deep brain stimulation (DBS)
Particularly in children who have a mutation in the *DYT1* gene
Intrathecal baclofen pump (ITB therapy)
A very promising treatment
Other surgical procedures
1. Tendons lengthening or cutting muscles
2. Dorsal rhizotomy

Trihexyphenidyl (Artane®) is the most commonly used medication for children with dystonia. Sometimes requires very high doses of 50 mg or 100 mg per day, or even more in some children. Slow titration will help to tolerate the medicine with relatively few side effects. Other medicines that have used include diazepam (Valium®), clonazepam (Klonopin®), valproate (Depakote®), baclofen, carbamazepine (Tegretol®), reserpine, or tetrabenazine (Nitoman®, not available in the USA). Choice of the best regimen is usually by trial and error. It is difficult to predict which medicine will be most effective for a particular child.

Focal dystonias can be treated with botulinum toxin injections into those specific muscles. The goal of the injections is to reduce the symptoms of dystonia, without causing significant muscle weakness. Toxin injections usually need to be repeated every 3–6 months.

Deep brain stimulation (DBS) has been used to improve dystonia particularly in children who have a mutation in the *DYT1* gene. Implantation of the stimulator electrode in the globus pallidus led to gradual resolution of symptoms over 2–12 months.

Intrathecal baclofen pump (ITB therapy) is a very promising treatment. Although originally developed as a treatment for spasticity, recent results suggest that there may be benefit in dystonia as well.

Other surgical procedures like tendons lengthening or cutting muscles help to reduce the effect of the dystonic muscles. Dorsal rhizotomy, cutting the sensory nerves from muscles where they enter the spine is helpful; however, this procedure is more likely to improve spasticity, rather than dystonia.

Dopa-Responsive Dystonia

Other names for dopa-responsive dystonia *(DYTS)* include *dystonia-Parkinsonism syndrome*, *dystonia with diurnal variation*, and *Segawa disease.* The cause of the syndrome is either of two different genetic abnormalities. The inheritance of one type is as an autosomal-dominant trait and the other is as an autosomal-recessive trait. The dominant type is due to mutations in the gene for guanosine triphosphate cyclohydrolase 1, the cofactor for tyrosine hydroxylase, and the recessive form is due to mutations in the tyrosine hydroxylase gene. Most reported cases of "juvenile Parkinsonism" are probably variants of dopa-responsive dystonia.

Clinical Features

Marked variation in expressivity occurs between affected members of the same kindred and even between monozygotic twins. Age at onset is usually between 4 and 8 years but ranges from infancy to 12 years. Incorrect diagnosis of early onset cases is common; cerebral palsy is the common misdiagnosis. The initial feature is nearly always a gait disturbance caused by leg dystonia. Flexion at the hip and knee and plantar flexion of the foot cause toe walking. Flexor and extensor posturing of the arms develop. Finally, Parkinsonian features, such as cogwheel rigidity, masklike faces, and bradykinesia, appear. The disease reaches a plateau in adolescence. Postural or intention tremor occurs in almost half of patients, but typical Parkinsonian tremor is unusual.

Diurnal fluctuation in symptoms occurs in more than half of patients. Symptoms improve considerably on awakening and worsen later in the day. Movement and exercise exacerbate dystonia in some patients. Other disorders with exercise-induced dystonia as the main or only clinical feature may be expressions of the same genetic error.

Diagnosis

Dopa-responsive dystonia may be difficult to differentiate from other genetic disorders with dystonia because of phenotypic variation among family members. Diagnosis by mutation analysis is available. Important clues to diagnosis are features of Parkinsonism without other neurological signs, diurnal variation in severity of symptoms, exacerbation of symptoms with exercise, and response to levodopa.

Management

A small dose of levodopa usually provides immediate and complete relief in most patients, even when initiating treatment long after symptoms begin. No other dystonia responds so well. Initiate carbidopa-levodopa therapy at the lowest possible dose, and slowly increase the dose until a response is established. Long-term therapy is beneficial and required; symptoms return after discontinuing the drug. Trihexyphenidyl, in doses lower than ordinarily needed to treat also idiopathic torsion dystonia, and bromocriptine are partially effective.

Chorea

Chorea is a hyperkinetic movement disorder characterized by frequent, brief, and purposeless movements that tend to flow from one body part to another body part in an unpredictable manner. The affected child often appears fidgety or restless and unable to sit still. The word "chorea" comes from the Greek word for dance. The jerky movements of the feet or hands are often similar to dancing or piano playing. Chorea and ballismus are a spectrum sharing the same differential diagnosis. When chorea is severe, the movements may cause flailing motions of the arms or legs that results in throwing whatever is in the hand or falling to the ground. This form of severe chorea is referred to as "ballism." Akathisia can appear as chorea, but it is the result of a sense of a need to move, whereas chorea refers to involuntary movements. Choreaic movements can be sudden and jerky or can be more continuous and flow-in. Choreiform is often used to describe the benign piano-playing movements seen in normal young children when arms are extended during the neurologic exam. When chorea is the primary manifestation, a substantial differential diagnosis can be obtained. Athetosis is a slower writhing and twisting movement. Choreoathetosis is a movement of intermediate speed, between the quick, flitting movements

of chorea and the slower, writhing movements of athetosis. Choreoathetosis is the most common form in children. Choreoathetosis tends to worsen with attempts at movement and often occurs only while the child is attempting to move. Chorea may affect the hands, feet, trunk, neck, and face. In the face, they often lead to nose wrinkling, continual flitting eye movements, and mouth or tongue movements. These disorders may be distinguished from tics, as tics tend to repeat the same set of movements. In addition, the child often describes a "buildup" in the need to make the tic, with a sense of release afterward. There is no such sense of release following chorea; the movements are continually changing and flowing from one body part to another.

Etiologies

Chorea can be classified into primary (inherited) and secondary (acquired) disorders. Primary causes include essential chorea and benign familial (hereditary) chorea. Autosomal-dominant, recessive, and X-linked inheritances have been described. Huntington's disease is the most famous inherited cause of chorea; the autosomal-dominant transmission of a triplet repeat (CAG) at the Huntington site on chromosome 4. Huntington's disease rarely presents in childhood with chorea. Juvenile-onset Huntington's disease (also known as the Westphal variant) is characterized by Parkinsonism (bradykinesia and rigidity) and dystonia. The number of CAG triplet repeats predicts the onset of Huntington's disease. The normal repeat number is <35. When the number is >70, onset of symptoms occurs at less than 18 years of age. The majority of chorea in childhood is secondary or acquired. Many causes of secondary chorea have been identified, but for most patients chorea is not the only sign or symptom. The most common cause of chorea in childhood is acute rheumatic fever (ARF). Other causes include metabolic disorder (hypo- or hypernatremia, hypocalcemia, hyperthyroid, pregnancy, or hypo- or hyperglycemia), perinatal brain injury (cerebral palsy), infectious or peri- or post-infectious disease (acute disseminated encephalomyelitis, viral encephalitis, and celiac disease), other autoimmune disease (systemic lupus erythematosus [SLE] or antiphospholipid antibody [APLA] syndrome), vascular disorders (Moyamoya syndrome, or basal ganglia stroke), toxins (methanol, carbon monoxide, manganese), other heredodegenerative disorders (Wilson's disease, ataxia telangiectasia, Niemann–Pick type C disease, Friedreich's ataxia, Machado–Joseph disease, gangliosidoses, other lysosomal storage diseases), and disorders of intermediary metabolism (glutaricaciduria, Lesch–Nyhan syndrome). Chorea can be the manifestation of conversion. It is very important to note that because behavioral changes are often observed as part of rheumatic chorea, one must avoid misconstruing the chorea of Sydenham's chorea as psychogenic. Common iatrogenic causes of chorea or exacerbations of extant chorea include dopamimetics, antiepileptics (e.g., phenytoin), antidepressants (e.g., selective serotonin reuptake inhibitors), methylphenidate (and other stimulants), antihistamines, anticholinergics, calcium channel blockers, digoxin, and oral estrogens.

Diagnostic Evaluation

A diagnostic test for treatable causes includes: throat culture with rapid group A ®-hemolytic streptococcal (GABHS) testing, serum antistreptolysin O and antideooxyribonuclease (AntiDNase) B titers, electrocardiogram, echocardiogram, thyroid function tests, complete blood count (for acanthocytes), antinuclear antibody test, erythrocyte sedimentation rate, electrolytes (i.e., sodium, potassium, chloride, bicarbonate), magnesium, calcium, serum ceruloplasmin, APLAs (including lupus anticoagulant, anticardiolipin, and anti-®2 glycoprotein 1), urine drug screen, and urine pregnancy test, uric acid, quantitative immunoglobulin (ataxia telangiectasia), α-fetoprotein, serum amino acid, urine organic acid, and arterial (or cerebrospinal fluid) lactate and pyruvate testing, Epstein–Barr virus titers, Lyme disease titers, human immunodeficiency virus, serum calcium, and genetic testing for Friedreich's ataxia, spinocerebellar ataxia type 3 (Machado–Joseph disease), and possibly dentatorubropallidoluysian atrophy (DRPLA). Brain magnetic resonance imaging (MRI) with and without contrast is recommended in order to look for structural abnormalities, such as those related to a tumor, stroke, metabolic or degenerative disorders, or a previous injury due to low oxygen.

Sydenham's (Rheumatic) Chorea

Chorea is one of the major Jones criteria for the diagnosis of ARF. The revised Jones criteria indicate the presence of chorea without any other criteria is sufficient to make the diagnosis of ARF. The development of ARF after a GABHS infection is thought to occur in only 1–2% of those infected. Only a fraction of those patients with ARF will develop Sydenham's chorea. Sydenham's chorea is most common in children aged 5–15 years old. There is enough evidence that suggests individuals who develop ARF have a genetic susceptibility. There is a roughly 2:1 female

predominance after age 10. Typically, the clinical manifestations of Sydenham's chorea begin several weeks to several months after a GABHS infection

The onset is insidious, with gradually progressive clumsiness and behavior and personality change, usually with emotional labiality, aggression, impulsivity, and obsessive–compulsive behaviors. The emotional labiality and personality change presents the most salient morbidity. The typical natural history of Sydenham's chorea is weeks to months of a waxing and waning course, with ultimate resolution of the chorea. Some individuals have behavioral changes that persist for months. Relapse of chorea can occur with or without subsequent GABHS infection. Therefore, it can be very difficult to distinguish between recurrences and relapse. There is a recognized increased risk of relapse associated with pregnancy (chorea gravidarum), oral contraceptives, and probably with intercurrent infection other than GABHS. Ten to twenty percent of patients, and perhaps as many as 50%, have a relapsing course. Recurrence and relapse provoke consideration of whether prophylactic penicillin is effective and whether follow-up investigations of cardiac function are needed. An additional confounding factor is that pharyngeal carriage of GABHS is common and is not necessarily eradicated by antibiotic prophylaxis. Therefore, surveillance testing for GABHS may produce false-positives. Certainly, signs, such as new murmur or abnormal rhythm, and symptoms, such as fatigue, palpitations, and shortness of breath, demand cardiac reassessment.

The diagnosis of Sydenham's chorea is made on the basis of clinical history and can be supported by laboratory data. However, laboratory data should be viewed as ancillary, not confirmatory. Most children with Sydenham's chorea have positive serology (antistreptolysin O and AntiDNase B antibodies) for GABHS, but over 25% are serologically negative. Most children with Sydenham's chorea have negative throat cultures for GABHS. MRI scans occasionally show signal abnormalities in the basal ganglia, but a clear clinical-radiographic linkage has not been seen. Therefore, structural imaging is neither diagnostically sensitive nor specific for Sydenham's chorea. Presence of carditis or valvitis or other manifestations of ARF supports the diagnosis of Sydenham's chorea. Every child thought to have Sydenham's chorea should be evaluated for rheumatic heart disease. Cerebrospinal fluid parameters in Sydenham's chorea have not been well studied. ARF remains a quintessential example of post-infectious or peri-infectious autoimmune disease. Although anti-brain antibodies have been recognized in a proportion of Sydenham's chorea patients for 30 years, the nature of the pathogenic mechanism has only recently been elucidated. Specifically, sera from patients with active Sydenham's chorea contain antibodies directed at brain lysoganglioside and GABHS glucosamine. Thus, there appears to be a direct effect of antibody on neuronal cell signaling, perhaps leading to inappropriate release of striatal dopamine.

SLE and APLA Syndrome

Chorea is an uncommon sign of SLE. When it is the only sign of SLE, it remains so for years. Less than 10% of children will have chorea, 50% are younger than 16 years of age. Usually it will have a poor prognosis. Chorea of SLE is clinically identical to that seen in ARF. Treatment of the underlying SLE is indicated. Chorea in SLE may be iatrogenic (drug-induced). Haloperidol may be effective for SLE chorea, but the other treatments for Sydenham's chorea may also be effective. The chorea of APLA syndrome is indistinguishable from that of SLE. Autoimmune mechanisms for chorea should include investigations for (antiphospholipid antibodies lupus anticoagulant, anticardiolipin, and anti-®2 glycoprotein 1), even if recurrent venous or arterial thrombosis have not occurred.

Chorea Associated with Viral Encephalitis

Post- or peri-infectious chorea is common and is very difficult to treat. There might be an MRI signal abnormalities in deep gray matter brain structures, such as basal ganglia and thalamus, as part of an aseptic meningitis or meningoencephalitis as well as in acute disseminated encephalomyelitis.

Wilson's Disease

Wilson's disease (hepatolenticular degeneration) is rare, but it has to be ruled out because it is treatable. It is an autosomal-recessive disease on chromosome 13, resulting in deficient ceruloplasmin; it leads to an intracellular accumulation of copper in the brain (particularly the basal ganglia) and liver. When Wilson's disease presents with chorea, hepatic function is already compromised. Slit-lamp examination often reveals copper deposits in the margin of the iris (Kayser–Fleischer ring). Although abnormal copper accumulation begins at birth, the symptoms of Wilson's disease may not become apparent until late childhood or adolescence. In all patients, copper initially accumulates in the liver. This may cause acute or chronic hepatitis or liver cirrhosis. The degree of liver involvement is variable and may range from mild elevations of certain

liver enzymes to complete liver failure. Associated symptoms may include fatigue, anorexia, weight loss, generalized weakness, ascites and abdominal swelling, or jaundice. Other findings may include hepatomegaly, splenomegaly, or both (hepatosplenomegaly). In general, the younger the age at symptom onset, the greater the degree of liver involvement. In patients with Wilson's disease, neurologic symptoms seem to be predominant after age 20.

Many individuals with Wilson's disease experience symptoms associated with damage to the nervous system. These symptoms usually become apparent during the second decade of life or, in some patients, during the third decade; however, such findings have been known to appear as late as age 50. Neurologic abnormalities rarely occur in patients younger than age 10. These neurologic symptoms may include tremor of the head, arms, or legs; generalized dystonia; and bradykinesia, particularly those of the tongue, lips, and jaw. Patients may also experience clumsiness, ataxia, or slowness of finger movements and loss of fine motor skills. Tremor or trembling may be present in one hand or leg and gradually progress to involve all four limbs. Speech may become increasingly slurred or slowed (dysarthria). The voice may also have a hoarse or "whispering" quality (whispering dysphonia). In some patients, swallowing may become increasingly difficult (dysphagia).

Psychiatric problems also occur in some individuals with Wilson's disease. These may include increasing agitation and irritability, mood swings, hysteria, neurotic anxiety, bizarre behaviors, or depression accompanied by thoughts of suicide. A relatively small percentage of people with Wilson's disease may experience dementia or, in severe cases, psychosis (e.g., manic-depressive disease, schizoaffective disorder, or schizophrenia).

The goal of drug therapy in individuals with Wilson's disease is to remove excess copper from the body and prevent ongoing copper accumulation and deposition. Therefore, drug therapy must be continued throughout life. Inadequate treatment or disruption of drug therapy may result in life-threatening complications or irreversible organ damage. The initial approach is the removal of excessive copper with chelating agents. The most common agent used for this purpose is D-penicillamine (Cuprimine®, Depen®). D-penicillamine depletes pyridoxine or Vitamin B6 from the body. Therefore, dietary supplementation with pyridoxine is required. The side effects of D-penicillamine range from minor disturbances to severe or life-threatening complications, such as aplastic anemia, immune complex nephritis, systemic lupus erythematosus, or myasthenia gravis. In some individuals, neurologic symptoms may worsen during penicillamine therapy. Other chelating agents used are trientine (Syprine) as well as a drug known as tetrathiomolybdate. There are indications that neurologic symptoms may not worsen during tetrathiomolybdate therapy. Ongoing maintenance therapy usually involves use of zinc acetate (Galzin®), which blocks the absorption of copper in the intestines and promotes the elimination of copper in the stool. Patients with Wilson's disease must avoid copper-rich foods such as cocoa, chocolate, liver, mushrooms, nuts, and shellfish and ensure that their copper intake is restricted to less than 1 mg/day. Liver transplantation may be considered in patients with severe, overwhelming (fulminant) liver disease. Other treatment is symptomatic and supportive.

Chorea of Hyperthyroidism

Hyperthyroidism must be ruled out in any patient with chorea or hyperkinesis. Treatment of hyperthyroidism is dictated by the etiology. The chorea secondary to hyperthyroidism is indistinguishable from that of other causes. Manifestations of hyperthyroid disease, such as weight loss, anxiety, and altered thermoregulation, may be helpful in diagnosis.

Treatment

The decision to treat the Chorea should be granted if symptoms bother the child or interfere with activities of daily living. If chorea is secondary to a treatable etiology, such as hyperthyroidism, SLE, or drug reaction, treatment of the underlying disease may alleviate the chorea. If the child is taking any medications that can cause or worsen chorea, these should be tapered and discontinued, if possible. Dopamine blockers (such as neuroleptics) and presynaptic depleters for neurotransmitters (such as reserpine and tetrabenazine) have been used to treat Chorea. These drugs selectively enhance the function of the indirect pathway by blocking the inhibitory effect of dopamine on this pathway. However, the incidence of side effects in children from neuroleptics has been reported to be as high as 20%. Therefore, it is often safer to start with an alternative medication, such as a benzodiazepine, particularly clonazepam, diazepam, or clobazam. Hypotension is a side effect of the presynaptic depleters. Neuroleptics have significant side effects (tardive dyskinesia, weight gain, prolongation of the QT interval). Tetrabenazine is a very effective medication for chorea, but it is not available in the USA. The antiepileptic drug valproate is considered to be an effective treatment for chorea, but reports vary.

Its mechanism of action is not known but may be through nonspecific − aminobutyric acid (GABA) potentiation. Other GABA-mimetic medications, such as baclofen and clonazepam, appear to have efficacy as well.

Treatment of Syndeham's chorea depends on the disability associated with the chorea. In many cases, the chorea causes only mild disability and symptomatic treatment is not required, because Syndeham's chorea is usually self-limited. When treatment is acquired, antiepileptics like valproate can be effective and are usually associated with fewer side effects than phenothiazines or butyrophenones. Benzodiazepines may be used. Symptomatic treatment for 2–4 months is usually sufficient. Corticosteroids, intravenous immunoglobulin, or plasma exchange have been used on the basis of the presumptive autoimmune mechanism. Antibiotic prophylaxis to prevent GABHS recurrence is recommended to prevent carditis or valvitis, not to prevent chorea. The cardiac manifestations of ARF cause a great deal of morbidity (and mortality) and are irreversible. Penicillin still is the first-line treatment for prevention. Penicillin intramuscular injection of 1.2 million units of benzathine G. can be administered as a monthly, oral form (e.g., Pen V®) and can be given at 250 mg twice daily. The antibiotic sulfadiazine is another option. Patients allergic to penicillin and sulfadiazine, erythromycin can be administered at 250 mg orally bid. The duration of treatment has not been determined, but the American Heart Association recommendations are available. Patients with carditis or valvitis, but no persistent cardiac or valve disease, prophylaxis should continue for 10 years from diagnosis, or "well into adulthood" (whichever is longer). For patients with cardiac disease, the duration of prophylaxis should be for at least 10 years subsequent to the prior episode and until the patient is older than 40 years of age. For patients without cardiac disease (the most common scenario), prophylaxis should continue for 5 years or until 21 years of age.

Pediatric Movement Disorders: Myoclonus

Description

Myoclonus is "sudden, brief, jerky, shock-like, involuntary movements." The movements are quite rapid and may be triggered by attempts at voluntary movement, sensory stimulation, or startle. Myoclonus may cause rhythmic jerks, in which case, it is termed a "myoclonic tremor." Myoclonus is categorized based upon the likely source of movement. Such sources include cortical or subcortical areas or the spinal cord.

Cortical myoclonus is thought to be due to a lack of inhibition in the sensory or motor cortex. Subcortical myoclonus is often due to abnormalities in the brainstem; spinal myoclonus is presumed to be due to abnormalities in spinal inhibitory circuits. Myoclonus may be severely disabling, particularly when it is triggered by movement. In some cases, it may also be very mild. The most common example of a mild myoclonus is sleep myoclonus. In this form of myoclonus, children or adults have occasional brief jerks of an arm or a leg; these "jerks" occur while the individual is falling asleep. Negative myoclonus is a sudden involuntary relaxation of a muscle, rather than a contraction; this is thought to be due to mechanisms similar to those of sleep myoclonus. Cortical reflex myoclonus is triggered by attempts to obtain a knee jerk or other tendon reflex. Epilepsia partialis continua is a type of focal epilepsy that causes myoclonic tremor. Myoclonus is often associated with epilepsy; there is a particular class of degenerative disorders called "progressive myoclonus epilepsies (PME)" in which the association of myoclonus and epilepsy is common.

Examination

As with other movement disorders, it is important to determine which parts of the body are affected by myoclonus. It may occur in a single limb, the neck, the back, or the face. In other cases, it may affect the entire body. When severe, myoclonus may cause the child to fall. It is important to determine whether symptoms improve or worsen with voluntary activity. This is often tested by observing the child attempting to drink from a cup. In some cases, a myoclonic jerk may be caused by an unexpected, loud noise or a gentle tap on the tip of the nose or on the forehead.

To test for negative myoclonus, also known as asterixis, children are asked to extend their arms with the wrists back or to perform some other movement that requires holding the limb against gravity. In this way, a sudden loss of muscle contraction causes the hand or the arm to fall in a downward direction. Since myoclonus may occur along with other movement disorders, it is important to look for evidence of dystonia, tremor, ataxia, or spasticity. It is also important to look for opsoclonus, which is a random, dance-like jerking of the eyes in all directions. This eye movement occurs in the opsoclonus-myoclonus-ataxia syndrome.

Mechanism

The mechanism of myoclonus is not well understood. Cortical myoclonus is possibly a disorder of decreased inhibition in the cortex. The frequent association with seizure disorders suggests that there may be a common cause for myoclonus and some types of epilepsy. However, the reason for the reduced inhibition is not known. The mechanism of subcortical and spinal myoclonus is even less well understood. A group of disorders called "startle syndromes" probably involves hyperexcitability of the normal brainstem startle circuits and decreased inhibition in spinal circuits. This may be due to a mutation in the receptor for the neurotransmitter glycine.

Etiology

Etiological Classification of Myoclonus

Physiological
- Anxiety-induced
- Exercise-induced
- Sleep jerks and nocturnal myoclonus

Essential

Epileptic

Symptomatic
- Postcentral nervous system injury
  - Hypoxia
  - Trauma
  - Stroke
- Basal ganglia degenerations
- Idiopathic torsion dystonia
- Hallervorden–Spatz disease
- Hepatolenticular degeneration (Wilson's disease)
- Huntington disease
- Drug-induced
- Carbamazepine
- Levodopa
- Tricyclic antidepressants
- Lysosomal storage diseases
- Metabolic encephalopathies
- Dialysis syndromes
- Disorders of osmolality
- Hepatic failure
- Renal failure
- Myoclonic encephalopathy
- Idiopathic
- Neuroblastoma
- Spinal cord tumor
- Spinocerebellar degenerations
- Toxic encephalopathies
- Viral encephalitis

Physiological

Sleep myoclonus, benign myoclonus of infancy

Essential Myoclonus

Familial essential myoclonus, essential myoclonus-dystonia, stimulus-sensitive myoclonus

Epileptic

Juvenile myoclonic epilepsy, progressive myoclonic epilepsies, epilepsia partialis continua, Rasmussen's encephalitis, early infantile myoclonic encephalopathy, infantile spasms (West syndrome), Lennox–Gastaut syndrome, benign familial myoclonic epilepsy, Angelman syndrome.

Idiopathic epilepsy without any other neurological problem may have myoclonus as a major clinical expression. This includes entities such as benign myoclonus of infancy, myoclonic absences, juvenile myoclonic epilepsy of Janz, and photosensitive epileptic myoclonus. In such instances, the jerks are usually generalized and occur spontaneously, are frequently facilitated by lack of sleep, alcohol, etc., and may be triggered by visual stimuli.

Myoclonus may also be present in patients with generalized tonic-clonic epilepsy in the setting of a progressive encephalopathy (progressive myoclonic epilepsy), which will be discussed in another section.

Symptomatic

- *Fixed injury*: Carbon-monoxide poisoning, hypoxic injury or near-drowning (Lance-Adams syndrome), heatstroke, trauma, stroke, and electrocution
- *Storage/degenerative*: Sialidoses (cherry-red-spot myoclonus), lipidosis, lysosomal storage disease (Niemann–Pick type C, Tay–Sachs, Sandhoff's), other storage disorders (neuronal ceroid lipofuscinosis), pantothenate-kinase associated neurodegenerative disease (PKAN, formerly neuronal brain iron accumulation

type 1, formerly Hallervorden–Spatz disease), Wilson's disease, Lafora body disease, Rett syndrome, Baltic myoclonus, spinocerebellar ataxias (SCAs), dentatorubropallidoluysian atrophy (DRPLA), multiple sclerosis, and mitochondrial disorders (e.g., myoclonic epilepsy with ragged-red fibers [MERRF] and others)
- *Infections/para-infectious*: New-variant Creutzfeldt–Jacob disease (nvCJD), subacute sclerosing panencephalitis (SSPE), viral encephalitis, and *Streptococcus*
- *Endocrine*: Hyperthyroidism, hyponatremia, and hypoglycemia
- *Structural*: Tumors that irritate the brain in a direct manner, tumors that release chemicals into the blood (as in abdominal or thoracic neuroblastoma [which causes the opsoclonus-myoclonus-ataxia syndrome]), and palatal myoclonus (with injury to the Guillain–Mollaret triangle in the brainstem or cerebellum)
- *Drug-induced/toxins*: Antiseizure medications (valproate, carbamazepine, etc.), antidepressants (amitryptaline, nortryptaline, desipramine, fluoxetine, sertraline, lithium, etc.), stimulants (amphetamine, dexedrine, methylphenidate, some asthma inhalers, caffeine, etc.), liver toxic medications, respiratory depressants, corticosteroids, amiodarone, acyclovir, bismuth, thallium, and L-dopa
- *Associated with systemic illness*: Dialysis, renal failure, liver failure, pulmonary disease, and carbon dioxide intoxication

Workup

Myoclonus may be tested by looking at the electrical activities in brain and affected muscle(s). Electromyography (EMG) of the muscles typically shows the duration and frequency of the myoclonic bursts, and whether these bursts spread to other spinal segments (as is seen in propriospinal myoclonus). It may also be helpful in determining whether jerking movements occur simultaneously in more than one limb, or whether they flow gradually down the body. In cortical myoclonus, there may be an excessively large brain electrical response to electrical stimulation of the hands or feet. This response is tested by using somatosensory-evoked potentials (SSEPs). In some cases, it is also possible to demonstrate the myoclonic electrical signal in muscle following a tendon tap. This may be helpful in diagnosing cortical reflex myoclonus.

In any form of myoclonus, it is important to look for a cause. Any medication or toxin that could produce the symptoms should be removed if possible. Family history needs to be investigated and metabolic studies may be appropriate, particularly if there are other symptoms or if symptoms become progressively worse. Metabolic tests may include screening for treatable disorders such as Wilson's disease. Since myoclonus may be a symptom of general systemic illness, including liver failure and some types of tumors, it is important to screen for general health problems. In particular, in the opsoclonus-myoclonus syndrome, the child should have a CT or nuclear medicine scan of the chest and abdomen as well as blood and urine tests. These tests look for evidence of a neuroblastoma tumor. If there is a suspicion of an epilepsy syndrome, an electroencephalogram (EEG) is recommended. Brain MRI is important to look for tumors, stroke, malformations, or other structural lesions near the cortex, brainstem, or cerebellum. This is particularly true if the myoclonus is focal or if the child is suspected of having the syndrome of epilepsia partialis continua. Since certain viral infections can cause myoclonus, a spinal tap is sometimes needed for this diagnosis.

Many cases of essential myoclonus or essential myoclonus-dystonia will improve with small amounts of alcohol. Although this is useful for diagnosis, it is not helpful for long-term treatment.

Treatment

- If a specific cause can be found, then the myoclonus will usually resolve if treatment of the underlying disease is effective. Immune-mediated myoclonus (such as occurs in opsoclonus-myoclonus) usually requires treatment with oral steroids such as prednisone, in addition to removal of the tumor if one is found.
- Intravenous immunoglobulin and plasmapheresis has also been attempted in some cases. Juvenile myoclonus epilepsy usually responds to valproate, and may require lifelong treatment. Symptomatic treatment usually includes benzodiazepines such as clonazepam or diazepam. Cortical myoclonus may respond to valproate, piracetam, or lamotrigine. There are reports of myoclonus due to a hypoxic event responding to 5-hydroxy-tryptophan (5HT), and this may be helpful in other causes as well. Carbamazepine may worsen myoclonus and should be avoided.

Startle Disease or Hyperekplexia

Excessive startle or complex motor reactions in response to sudden unexpected stimuli occur in startle disease or hyperekplexia. When severe, there may be generalized muscle contraction resulting in postural instability and falls. After the fall, there is recovery of normal tone and control. The attacks are worsened by stress and fatigue and ameliorated by central nervous system (CNS) depressants. Hyperekplexia may be sporadic or familial with dominant inheritance (chromosome 5q). Disorders such as the Jumping Frenchmen of Maine, Latah, and Myriachit probably represent variants of startle disease. Abnormal startle and hyperekplexia have also been described in brainstem lesions. In the neonatal variety of startle disease, slight stimuli induce a nonepileptic convulsion that may be tonic or clonic or a mixture of the two. A quivering vocalization precedes the silence when a profound syncope ensues, with subsequent anoxic seizure. The clinical diagnosis is made by the nose-tap test: percussion of the tip of the nose induces an obvious startle. Ictal treatment is by repeatedly flexing the baby (face to knee); further episodes are prevented by clonazepam or clobazam.

Benign Nocturnal Myoclonus

Sudden jerking movements of the limbs during sleep occur in normal people of all ages. They appear primarily during the early stages of sleep as repeated flexion movements of the fingers, wrists, and elbows. The jerks do not localize consistently, stop with gentle restraint, and end abruptly with arousal. When prolonged, the usual misdiagnosis is focal clonic or myoclonic seizures. The distinction between nocturnal myoclonus and seizures or jitteriness is that it occurs solely during sleep, it is not activated by a stimulus, and the EEG is normal. Treatment is not required. Anticonvulsant drugs may increase the frequency of benign nocturnal myoclonus by causing sedation.

Benign Myoclonus of Infancy

Many series of patients with infantile spasms include a few with normal EEG results. These infants cannot be distinguished from others with infantile spasms by clinical features because the age at onset and the appearance of the movements are the same. The spasms occur in clusters, frequently at mealtime. Clusters increase in intensity and severity over weeks or months, and then abate spontaneously. After 3 months, the spasms usually stop altogether, and although they may recur occasionally, no spasms occur after 2 years of age. Affected infants are normal neurologically and developmentally and remain so afterward. The term "benign myoclonus" suggests that the spasms are an involuntary movement rather than a seizure. A normal EEG result distinguishes this condition from other types of myoclonus in infancy. No other tests are required. Treatment is not required.

Tremor

Tremor is a rhythmic, involuntary back-and-forth oscillation of part of the body. Tremor in children may be caused by many disorders including familial essential tremor, focal epilepsy, or a psychogenic movement disorder. Tremor is often seen with ataxia, dystonia, or myoclonus. Physiologic tremor is the normal shaking that occurs when people attempt to exert large forces or lift heavy objects. If a child has weakness, this type of tremor may be accentuated. Ataxia may lead to tremor when the inaccurate movements are corrected and then repeatedly over corrected.

Tremor may occur at rest, while maintaining a fixed arm position or posture (postural tremor) or with movement or kinetic, action, or intention tremor.

Tremor may occur in the hands, feet, back, neck, face, voice, or other parts of the body. The frequency of the tremor may be described by the number of cycles per second, or Hertz (Hz). Tremor may appear suddenly, or worsen gradually over months or years. Most types of tremor disappear during sleep, only to return the next day upon awakening. Tremor is often associated with other neurological disorders; therefore, it is important to look for the cause of tremor.

In familial essential tremor, the onset may occur at any age. Once started, this type of tremor often continues or becomes slowly worse with time. Some family members may notice that the tremor improves briefly after drinking alcohol. This type of tremor is usually postural, and may be particularly evident while the child attempts to eat or drink from an open cup.

Types of Tremor

There are still many controversial issues with regard to tremor. The Movement Disorder Society has suggested

definitions as well as clinical and syndromic classifications of tremors. Because of the numerous etiologies for tremor, a practical etiologic classification or a valid physiologic classification is not available.

Tremor is a rhythmic, involuntary, oscillatory movement of a body part. The amplitude and frequency of tremor is not crucial to this definition. For practical purposes, the following categories are presented.

Resting Tremor

Resting tremor occurs in a body part that is supported in such a way that skeletal muscle activation is neither necessary nor intended. Resting tremor is mostly found in Parkinson's disease and other basal ganglia disorders. This is a rarity in childhood and will not be considered further here.

Action Tremor

Tremors not occurring at rest are categorized as action tremor. This occurs during any voluntary contraction of skeletal muscle. The most relevant forms of action tremor are postural tremor, kinetic tremor, and intention tremor.

Postural Tremor

Postural tremor occurs during an attempt to hold a body part motionless against the force of gravity.

Kinetic Tremor

These are tremors occurring during any voluntary movement.

Tremor During Target-Directed Movements (Intention Tremor)

Classic intention tremor is present when amplitude increases during visually guided movements toward a target at the determination of the movement. It can be inferred that a disturbance of the cerebellum and its afferent or efferent pathway is present. The type and distribution of the tremors in hyperthyroidism and due to sympathomimetic drugs correspond to those of physiologic tremor; most drug-induced tremors are a mixture of postural and kinetic tremors.

Essential Tremor

Essential tremor (ET) is the most frequent movement disorder. Patients exhibit a mixed postural and kinetic tremor without other neurologic abnormalities. The upper limbs are predominantly involved. Other body parts are less commonly involved. Many patients with ET inherit the disease through an autosomal-dominant gene; however, the ratio of hereditary versus sporadic ET is unknown. This diagnosis can be made on clinical grounds if this tremor type is of long duration. The "red flags" are rapid onset, unilateral tremor, rest tremor, and gait disturbance.

Examination

The child is examined to determine which body parts are affected, as well as the frequency and amplitude of the tremor. The tremor is observed while the child is at rest, while holding a posture against gravity (e.g., as with the arms outstretched), and while reaching for targets. Tremor may be accentuated by attempting to drink from a nearly full cup of water. It may be difficult to distinguish myoclonic or dystonic tremor from "true" tremor. Frequently, the distinction depends upon whether or not other symptoms are present, such as dystonic posturing or stimulus sensitivity. In dystonic tremor, there is often a "null point" or a position of the joint at which the tremor disappears, and then reverses direction as the joint is moved farther. The child's strength must be assessed, as enhanced physiologic tremor may become more apparent if there is muscle weakness. Family history of tremor is important, as several types of tremor, myoclonus, or dystonia may be inherited. It is also important to look for medications or toxins that are known to cause tremor (such as valproate, sympathomimetics, or centrally acting substances). The following information should also be obtained in the history taking and examination: past history of neurologic disorders, type of tremor, onset, asymmetry, evidence of systemic disease (e.g., hyperthyroidism), and evidence of additional neurologic symptoms (such as dystonia, gait disturbance).

Mechanisms

There are probably many mechanisms that may cause tremor. In some cases, there is alternating muscle activity in the flexors and extensors about a joint. This suggests the

presence of an oscillatory signal in the nervous system. In other cases, there is rhythmic contraction or relaxation of a single muscle or group of muscles. Tremor may be generated in muscles, when they are strongly contracted, the spinal cord, the brainstem, the basal ganglia, as in Parkinson's disease, and the cortex. Occasionally, anxiety and hyperthyroidism might increase tremors in children.

Workup

The workup of tremor depends upon the specific type of tremor and its possible cause. Any medications that may worsen tremor should be avoided, if possible. If the constellation is typical for ET, no additional investigations (neuroimaging) are mandatory. If the tremor had sudden onset, an MRI of the head may be able to show a stroke, multiple sclerosis, or other lesion. Treatable conditions, in particular hyperthyroidism and Wilson's disease, should be considered. Wilson's disease may present in the first decade as hemolytic anemia or as a hepatic problem; a neurologic presentation is not encountered before the second decade and not as an isolated tremor. Electroencephalogram (EEG), which measures electrical activity in the brain, is important if there is a suspicion that the tremor is due to focal seizures. If there has been gradual onset, it is important to check electrolytes, including glucose, calcium and magnesium, thyroid function, copper in the urine (for Wilson's disease), and possibly the amount of adrenaline metabolites (for pheochromocytoma). If Parkinsonian features are present, a trial of L-DOPA may be helpful. Rarely, an EMG may help to determine if the tremor is more likely to be due to dystonia or myoclonus. Tests for myoclonus, including EEG with back-averaging and SEP (somatosensory-evoked potentials), may help to confirm the presence of dystonia or myoclonus. If there is a family history of tremor, it may be helpful to try the use of alcohol. This is often tried with an adult family member, rather than the child. If the tremor improves with alcohol, this suggests that it will also improve with other medications such as primidone.

Treatment

There is no general treatment for tremor per se. Mild tremor does not require treatment. If there is a specific illness such as Parkinson's or Wilson's disease, tremor will improve with appropriate therapy. For the underlying condition ET may be improved with propranolol (0.5–1.5 mg/kg bodyweight) and primidone. However, most children and adults with ET are not functionally impaired and manage without drug treatment. Medication can be limited to particular (stressful) events. In all cases, the child should start with a very small dose. The dose should be increased gradually in order to avoid side effects. Long-term use of primidone, which is metabolized, in part, to phenobarbital, is probably not desirable. If the tremor is felt to be psychogenic, then psychotherapy may be helpful in determining and avoiding any psychiatric triggers for the movement. Patients especially adolescents have to avoid certain dietary products like caffeine, recreational drugs, and alcohol.

Non-movement Disorders of Infancy and Childhood

Movement disorders can be classified as transient, paroxysmal, and chronic. Transient movement disorders (TMDs) are simply defined as those that stop over time. In a review by Fernandez-Alvarez (1998), 19% of 356 children under the age of 18 with movement disorders had a TMD. Most common in infancy, TMDs are readily recognized with experience. The generally benign and transient nature of these disorders has resulted in a lack of understanding (but no shortage of theories) as to the underlying cause in most cases. The following discussion approaches the TMDs on the basis of their age of presentation. The aim is to provide a practical approach to the recognition of the more common TMDs. There is insufficient space to discuss the possible theoretical basis of most of these conditions.

The differentiation between a transient and a paroxysmal movement disorder is clearly somewhat artificial as many of the latter diminish or stop with time.

Benign Neonatal Sleep Myoclonus

Benign neonatal sleep myoclonus (BNSM) was described by Coulter and Allen in 1982. Myoclonic jerks confined to sleep start in the neonatal period. They abruptly stop with arousal and are never seen in the awake state. The jerks are most frequent during NREM sleep but may appear during all stages. They may be unilateral or bilateral and often appear in short clusters and shift sides. The severity of individual jerks and duration of clusters may vary considerably. The EEG is normal both during the jerks and interictally. Detailed neurophysiological studies with back-averaging have not been performed.

Rocking the basinet or crib, touch and simple restraint do not abolish the jerks and may actually induce them. Neurological examination and metabolic investigations

are normal. BNSM is more common in preterm newborns. Usually the jerks cease by 2–7 months of age. A recent report described completely normal follow-up in five siblings with BNSM seen 3–10 years after remission. The relationship between BNSM and benign myoclonus of early infancy (BMEI) is not clear, although in one series 2/21 patients with BNSM were reported to have developed BMEI on follow-up.

Benign Myoclonus of Early Infancy

Benign myoclonus of early infancy (BMEI) was described by Lombroso and Fejerman in 1977. The usual age of presentation is between 3 and 15 months. The history is suggestive of infantile spasms with episodes of limb stiffening occurring in clusters. However, unlike infantile spasms the episodes usually occur in the awake state rather than in drowsiness and are often provoked by excitement or frustration.

There are rarely more than 10 events in a cluster, whereas with established infantile spasms many more episodes can be seen. There is no developmental delay or regression and the neurological examination is normal. Interictal EEG is normal.

Typically there were tonic spasms of the limbs with associated shuddering-like movements of the trunk. EMG of the tonic limb spasms revealed durations as long as 2 s. The EEG was normal during the spasms. Therefore the term "myoclonus" is probably not appropriate for these events. There was a close similarity between BMEI and "nonepileptic reflex tonic seizures," a condition described by the same group where sustained tonic contractions occur only when the infant is held in someone's arms.

The jerking episodes become more prominent for a few weeks or months after onset but, within an average of 3 months, decrease considerably in most infants. They disappear spontaneously by 2 years of age. Antiepileptic drugs do not stop the episodes.

Most of the cases have been sporadic; however familial occurrence has been reported.

As well as infantile spasms, the differential diagnosis includes benign myoclonic epilepsy of infancy, when there are generalized ictal and interictal EEG abnormalities.

Transient Idiopathic Dystonia of Infancy

This condition was first reported by Willemse in 1986 and other reports followed. Onset is usually in the first 6 months. There is dystonic posturing of an upper limb and sometimes the trunk or a leg. The typical arm posture is forearm pronation with hyperflexion of the wrist. When prone, the affected arm often rests on the dorsum of the hand. Typically, the posture disappears with intentional movement, for example, when reaching out to grab an object. Motor and mental development is usually normal. The posturing usually stops before the age of 2 years. Some cases seem to have more prominent dystonia and a more prolonged clinical course. Genetic factors may have a role.

Symptomatic forms of dystonia are not uncommon in the first year of life and investigations are usually required, but the normal development and the lack of functional abnormality suggest idiopathic dystonia. Investigations have been reported to be normal, including imaging and tests for metabolic disorders. However, one report has documented a decreased perfusion of the basal ganglia and left temporomesial cortex using SPECT and decreased glucose metabolism in the basal ganglia and cerebellum in one patient. Worsening of the dystonic posturing apparently induced by cisapride, a 5-HT receptor antagonist, has been described in two patients.

Beltran and Coker described transient dystonia beginning in the newborn period to 3 months of age in four infants exposed to cocaine in *utero*. Torticollis was a particular feature. Angelini described nine patients with paroxysmal episodes of dystonia involving limbs and trunk. The episodes lasted minutes to hours. It is not clear if this is the same condition.

Benign Paroxysmal Torticollis

Snyder first reported this condition in 1969. Drigo et al. have recently reported a large series of 22 patients. It is characterized by recurrent episodes of torticollis without persistent or obligatory head tilt, followed by subsequent spontaneous resolution. Onset is usually in the first year often between 2 and 8 months of age but sometimes as early as in the first week of life or as late as 30 months. Attacks tend to occur frequently at the onset (1–2 months) and sometimes with a striking regularity.

Truncal posturing (retrocollis and tortipelvis) may also be seen. A few cases have been familial. The episodes last from 10 min to 14 days, may recur two or three times a month, and involve either side. Drigo et al. have suggested the attacks can be subdivided into the more common "periodic torticollis" lasting hours or days and a "paroxysmal" form lasting only minutes and accompanied by ptosis and mydriasis. Many episodes appear in the morning and may be precipitated by

postural changes, for example, changing from the upright to the supine position. There may be a prodrome of irritability, pallor, ataxia, distress, or vomiting prior to the attack. Ataxia may be a dominant feature. Neurological examination between attacks is normal. In most cases the attacks stop by 2–3 years of age without treatment. EEG and neuroimaging are normal. The pathophysiology of benign paroxysmal torticollis is subject to speculation. The observation of eye rolling or deviation in some cases suggests labyrinthine involvement. Abnormal oculo-vestibular function has also been suggested. Some believe that benign paroxysmal torticollis is related to benign paroxysmal vertigo and is a migraine equivalent and may precede these conditions. In a recent report, two of four patients belonged to kindred with familial hemiplegic migraine and linked to the CACNA I A mutation giving further support that BPT may be a "migraine equivalent" or a channelopathy.

Children with apparent benign paroxysmal torticollis need to be carefully investigated. The differential diagnosis includes seizures, vertigo, gastroesophageal reflux, and Sandifer's syndrome, dystonic reaction to drugs, posterior fossa, and craniocervical junction abnormalities (basilar impression, platybasia, atlantoaxial instability, Arnold–Chiari malformation, and Klippel–Feil syndrome). Vestibular testing may be difficult to perform and interpret in young children. EEG during the paroxysms is normal. Neuroimaging studies are necessary to exclude congenital and acquired lesions involving the craniocervical region.

Treatment with dimenhydrinate. Meclizine and chlorpromazine has not been successful. The prognosis, however, is favorable and follow-up studies suggest spontaneous resolution in most cases.

Shuddering Attacks

Shuddering attacks are benign paroxysmal spells of childhood that can mimic epileptic seizures. They may superficially resemble several seizure types, including tonic, absence (typical and atypical), and myoclonic seizures. The pathophysiology is unknown, although a relationship with essential tremor has been postulated. The origin is unclear, but shuddering attacks are not epileptic in nature. Incidence is unknown, but shuddering attacks are relatively uncommon. These episodes are usually benign and non-disabling. They are not associated with increased morbidity or mortality and tend to remit spontaneously. No sex predilection is reported. The condition is seen in older infants and young children.

Parents describe the paroxysmal episodes of shuddering attacks as a sudden flexion of the neck and trunk and adduction of the arms. A shiver-like movement of the trunk ("like a chill") occurs, and the body may stiffen. Consciousness does not seem to be altered, but this can be difficult to confirm. The episode usually lasts 5–15 s. Unlike epileptic seizures, shuddering attacks do not occur during sleep. General and neurological examination findings are normal. The cause is unknown. A relationship with essential tremor has been postulated because there may be an increased frequency of essential tremor in the families of these children.

Absence seizures, benign childhood epilepsy, complex partial seizures, dizziness, vertigo and imbalance, epilepsy, juvenile myoclonic, essential tremor, febrile seizures, frontal lobe epilepsy, psychogenic nonepileptic seizures, seizures, and epilepsy: overview and classification, simple partial seizures, syncope and related paroxysmal spells and tonic-clonic seizures. No laboratory studies are helpful for the diagnosis of shuddering attacks. EEG, brain CT scan, or MRI may be performed because epileptic seizures are in the differential diagnosis. However, the results of these studies are normal.

Reviewing the appearance of a typical episode as captured on video camera by the parents is helpful in suggesting the diagnosis; however, prolonged electroencephalography (EEG) video monitoring to record a typical episode definitively differentiates shuddering attacks from epileptic seizures. Recordings of the spells confirm that typical characteristics of an episode are 5–10 s of shiver-like movements of the trunk and limbs with no impairment of consciousness and no EEG discharge during the episode. A normal EEG result helps to rule out an epileptic origin. Ambulatory EEG without video recording is useful for diagnosis because it records the EEG, but not the clinical event, although eyewitnesses marking the event with a pushbutton can vouch that the event was the kind in question. Routine EEG results are typically normal. In most cases, no treatment is necessary for shuddering attacks. Occasionally, if the episodes are unusually frequent or disabling, treatment may be attempted. However, there is no consistently effective treatment. Antiepileptic drugs are ineffective. Propranolol can be helpful in isolated cases, although pediatric dosages are not established. Infants and children with shuddering attacks are typically referred to a neurologist to check for possible seizures. Shuddering attack episodes tend to remit. A relationship to essential tremor occurring later in life has not been definitively established. The primary care physician should educate the family concerning the benign nature of this condition and the excellent long-term prognosis.

Sandifer Syndrome

Sandifer syndrome involves spasmodic torsional dystonia with arching of the back and rigid opisthotonic, posturing, mainly involving the neck, back, and upper extremities, associated with symptomatic gastro esophageal reflux, esophagitis, or the presence of hiatal hernia. Pediatric neurologists may be the first to see patients with Sandifer syndrome because the primary care provider and the parents may believe that the spasms represent seizures. Pediatric emergency department physicians, pediatric neurologists, and gastroenterologists see patients with this complex with some frequency. The syndrome is most certainly under recognized, and delays in diagnosis are due to atypical presentations or cases in which the diagnosis is not part of the differential. The true pathophysiological mechanisms of this condition remain unclear. The incidence is unknown, although there is some suggestion that in clinical practice, it occurs in less than 1% of children with gastroesophageal reflux. Mortality is not typically associated with Sandifer syndrome. Morbidity consists of the discomfort associated with this syndrome. Infants may lose weight if persistent or severe gastroesophageal reflux disease (GERD) is present. Associated morbidities may also include the presence of a hiatal hernia and esophagitis. Race does not seem to influence incidence. No sex predilection is recognized. Typically, Sandifer syndrome is observed from infancy to early childhood. Peak prevalence is in individuals younger than 24 months. Children with mental impairment or spasticity may experience Sandifer syndrome into adolescence. Sandifer syndrome is most commonly mistaken for seizures. The child typically appears to have an alteration in mental status associated with the tonic posturing. A relationship with feeding may suggest a diagnosis of Sandifer syndrome, which commonly occurs after feeding. The child may have a sudden rotation of the head and neck to one side and the legs to the opposite side with a stretched out appearance. Typically, the back is arched posteriorly with hyperextension of the spine and elbows may be flexed and held posteriorly with hyperextended hips. Torticollis may be present. Although the intermittent stiff tonic posture and periods of crying and apparent discomfort may suggest seizures, in many cases the rhythmic clonic component, which may be present in seizures, is not described. Various stiff, bizarre postures can be observed.

- Typically, the duration of the posture is 1–3 min.
- This brief, paroxysmal pattern of posturing accounts for the fact that the movement observed in Sandifer syndrome may be mistaken for seizures.
- During the posture, the infant may become very quiet or, less commonly, become very fussy. Fussiness and evident discomfort is most commonly observed as the posture abates.
- If a significant volume of gastroesophageal reflux is observed, even without actual vomitus, some infants and children may manifest evidence of respiratory tract irritation as well, including cough, wheezing, and stridor, depending on the degree and volume of reflux.

In children with Sandifer syndrome without mental impairment, the examination findings are normal. Children with Sandifer syndrome with mental impairment often have evidence of spasticity and may be diagnosed with cerebral palsy. Sandifer syndrome in infants is most commonly associated with normal examination findings. Sandifer syndrome in older children may be associated with mental impairment. Dysfunction of the lower esophagus is thought to be the most common precipitating factor. In some children, a cause cannot be found. Gastroesophageal reflux disease (GERD) with varying degrees of esophageal inflammation is common. Esophageal dysmotility, characterized by low-amplitude waves, lack of normal propagation, and low lower esophageal sphincter (LES) pressure, is not the cause but most likely the consequence of esophagitis: gastroesophageal reflux, seizure, infantile spasms, tonic seizures, torticollis, and dystonia. In patients with Sandifer syndrome, pH monitoring is useful in demonstrating gastroesophageal reflux and in clarifying any temporal association of reflux and posturing. Barium swallow studies are used less frequently, although they may be useful in documenting anatomy and the possible association with hiatal hernia. Cranial MRI is helpful in defining the nature of the neurologic deficits in children with mental impairment. Video-EEG monitoring helps differentiate seizures from posturing related to reflux and can be combined with a pH probe study to demonstrate the nature of the spells. Endoscopy may confirm anatomy via visualization and allows biopsy samples to be obtained to confirm mucosal changes due to esophagitis.

Sandifer syndrome does not require treatment unless the spasms are the result of gastroesophageal disease significant enough to interfere with growth and feeding. In the latter case, therapy should be directed toward the specific cause (see Chap. 178, "Gastroesophageal Reflux"). The American Gastroenterological Association has issued recent guidelines for the management of gastroesophageal reflux disease (GERD). The primary aim of medical care is to identify Sandifer syndrome. This can be accomplished most often by soliciting a careful history of

the times of day the spasms occur and the precipitating causes. If recognizing the complex is difficult, then video-EEG monitoring may be of value. Often, parent education and explanation regarding the nature of the spasms are all that is required in treatment of this condition. If the patient does have pathologic gastroesophageal reflux or complications from gastroesophageal reflux such as esophagitis, then therapy for gastroesophageal reflux, or specifically for esophageal peptic disease, is indicated. Muscle relaxants could be used in patients with Sandifer syndrome in whom a GI cause has been excluded and seizure-like postures are causing distress and discomfort for the patient or their family. However, muscle relaxants have not been demonstrated to relieve the seizure-like manifestations of Sandifer syndrome.

In cases with severe, confirmed gastroesophageal disease that is interfering with growth and development, some evidence suggests that fundoplication may alleviate symptoms (Fig. 363. 1).

Primary consultations should be with a gastroenterologist. If any doubt surrounds the nature of the seizure-like activity or if the child has underlying neurological impairment, a consultation with a pediatric neurologist could be beneficial. When gastroesophageal reflux is discovered, treatment must be directed at the reflux.

Therapeutic response for the treatment of gastroesophageal reflux disease may take as long as 2 weeks. If treatment is successful, weight increases and vomiting episodes decrease. Prokinetic agents are used to augment cholinergic activity. Prokinetic pharmacotherapy is often used before acid suppression therapy in children without evidence of esophagitis because of the predominance of motility-related problems over increased acid (and regurgitation over pain) in the pathogenesis and presentation. Different medications have been used to treat this disorder. Dopaminergic antagonist (Metoclopramide (*Reglan*)) that works by increasing LES tone gastric emptying stimulates muscular activity, leading to decrease in reflux. *Antacids* are agents used as diagnostic tools in providing symptomatic relief in infants. Associated benefits include symptomatic alleviation of constipation (aluminum antacids) or loose stools (magnesium antacids). *H2 receptor antagonists* like antacids are agents that do not reduce the frequency of reflux, but they decrease the amount of acid in the refluxate by inhibiting acid production. All are equipotent when used in equivalent doses. They work best in patients with nonerosive esophagitis. Because of proton pump inhibitor (PPI) superiority, H2 blockers are reserved for use in patients unable to tolerate PPIs. *Ranitidine* (*Zantac*) inhibits histamine stimulation of the H2 receptor in gastric parietal cells, which reduces gastric acid secretion, gastric volume, and hydrogen ion concentrations. *Famotidine* (*Pepcid*) competitively inhibits histamine at H2 receptor of gastric parietal cells, resulting in reduced gastric acid secretion, gastric volume, and hydrogen ion concentrations. *Proton pump inhibitors* are agents indicated in patients who need complete acid suppression (e.g., infants with chronic respiratory disease or neurological disabilities). Administer with the first meal of the day (children with nasogastric or gastrostomy tubes may have granules mixed with an acidic juice, then flush tubes to prevent blockage). *Omeprazole* (*Prilosec*) decreases gastric acid secretion by inhibiting the parietal cell H^+/K^+ -ATP pump. It is used for the short-term treatment (4–8 weeks) of GERD. Lansoprazole (*Previcid*) *suppresses* gastric acid secretion by specific inhibition of the (H+, K+)-ATPase enzyme system (i.e., proton pump) at the secretory surface of the gastric parietal cell. It blocks the final step of acid production. The effect is dose-related and inhibits both basal and stimulated gastric acid secretion, thus increasing gastric pH. *Esomeprazole magnesium* (*Nexium*), S-isomer of omeprazole, inhibits gastric acid secretion by inhibiting H^+/K^+-ATPase enzyme system at secretory surface of gastric parietal cells. Used in severe cases of and patients not responding to H2 antagonist therapy. Sandifer syndrome is not life threatening. Many patients with the condition eventually outgrow the spasms in later childhood. The diagnosis of Sandifer syndrome should not be made without

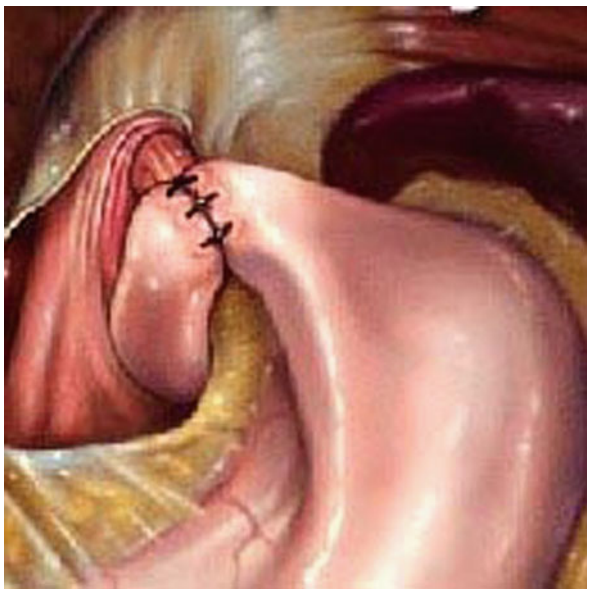

Figure 363. 1

adequate study. It is important to exclude infantile spasms, require relatively rapid treatment and management. In infantile spasms, a hypsarrhythmia pattern is observed on EEG.

Stereotypies in Normal Children

A wide variety of repetitive movements is readily recognized by parents as part of normal development and these are not considered as TMDs. Body rocking occurs in 6–19% of normal young children, thumb-sucking in 21%, nail-biting in around 12% of preschool children, and hair twisting in approximately16% of normal children.

Stereotypic movements are well recognized among neurologically impaired children, for example, in autism and Rett syndrome. However, they are also commonly seen in children without major neurological impairment. They are the most common movement disorder of childhood after tics. Tan et al. defined stereotypies as "involuntary coordinated, patterned, repetitive, rhythmic, non-reflex non-goal directed motor activity that is carried out in exactly the same way during each repetition." They described ten normal children with stereotypies.

Seven were boys. Only two of the ten children seemed to be completely normal, the others had mild learning difficulties, speech problems, and attention-deficit disorder.

The onset of the stereotypies was at 12 months or younger in five of the children. The oldest age of onset was 6 years. A large variety of movements were seen. The commonest were arm flapping and leg shaking. The movements appeared when the child was excited, stressed, bored, or unoccupied. Follow-up was available to a maximum age of 11 years in nine children and the stereotypies had completely stopped in only two.

Stereotypies usually appear earlier than tics. Typically, the same basic movement persists over time although often with elaboration. This is in contrast to tics, where there is usually a constant changing, with one tic dominating for a while and then another taking over. The phenomenology of a stereotypic movement may be identical to that of a complex tic or a compulsion. The child's description of the event may help in the differentiation. There may be a sense of pleasure obtained from performing the stereotypy. This is in contrast to the feeling of physical discomfort and need to perform a tic to relieve the discomfort. Older children may report the association of obsessive thoughts with a compulsion.

Stereotypies may superficially resemble seizures but calling the child or interacting with them, for example, by tickling, can immediately stop the movements. There is generally no need to attempt treatment. Even if the movements persist for a number of years, over time, the child tends to restrict the movements to times when they are not observed by others, for example, when they are alone in their bedroom.

Self-stimulation (Infant Masturbation)

Infant masturbation is usually only a diagnostic problem in young girls as it is readily recognized in boys. Infant masturbation can be mistaken for epileptic seizures, abdominal pain, and paroxysmal dystonia. Typically, the legs are tightly opposed and the feet crossed at the ankles.

There may also be mechanical pressure over the suprapubic or pubic area. Pelvic thrusting may be prominent. Irregular breathing, facial flushing sweating, irritable cries, and grunting give an impression that the child is in pain. The episodes can last minutes to several hours. A fixed and glazed look may give the impression of altered consciousness but the episode can usually be stopped immediately by picking up the child. This may produce annoyance and resumption of the activity as soon as the child is put down again. Multiple observers have suggested that the infant experiences orgasm and this is often followed by exhaustion, or sleep giving the impression of a postictal state.

Still and many others, since, postulated that the behavior begins after an episode of local vulval irritation, which sensitizes the child to pleasurable sensations arising from genital stimulation. Some young girls persist in the activity for many hours a day (so-called malignant masturbators). Sexual abuse, family stress, deprivation of affectionate parental physical contact, parental feelings of guilt, anger, shame, or perception of the child as vulnerable have all been suggested as underlying causes with very limited proof.

There are few follow-up studies. Bakwin described three girls. One continued to perform the movements at 4 years of age. Another stopped at 6–7 months and there had been no recurrence up to age 8 years. The third child, at 12 months carried a large rag doll with her constantly and repeatedly threw it to the floor and would rhythmically press her body against it "as in the sexual act." By 4 years, she rarely exhibited the behavior and when last seen was a medical student.

No treatment is necessary. It is important to explain to the parents that this is a normal behavior, more pronounced in some children. Self-stimulation is a better term than masturbation, which carries with it thousands of years of both moral and medical prejudice. Considerable

explanation may be required to prevent the use of unsuccessful coercive measures to try to stop this benign activity.

Midazolam Withdrawal Syndrome

Midazolam infusions have been increasingly used in intensive care units to provide sedation and analgesia for critically ill children. Sudden cessation of the midazolam can result in a withdrawal syndrome characterized by altered state of consciousness, restlessness, irritability, vomiting, tremors, and choreoathetoid and dystonic movements. This may occur more frequently when the midazolam is combined with fentanyl. In this setting, investigations are required to exclude metabolic disorders and nonconvulsive status epilepticus, but the possibility of a withdrawal syndrome should be kept in mind as it may be more common than is generally recognized.

Conclusion

The transient movement disorders of childhood are a distinctive group of disorders that are not rare. Over a number of years of practice, most general pediatric neurologists become familiar with them. They are usually seen in infants. Most require some investigation but recognition allows a limitation of what otherwise could be a very expensive diagnostic workup. They are a satisfying group of disorders to deal with, as most need no specific treatment and settle with time. The long-term neurological outcome is generally good, although some children subsequently are found to have learning and attention problems.

364 Sleep and Its Disorders in Childhood

Jonathan Lipton · Sanjeev Kothare

Introduction

Sleep disorders are common in pediatrics and a major cause of both child and parental morbidity. It is estimated that approximately 25% of children experience a sleep problem during childhood. Epidemiologic data increasingly suggest that children in the United States do not get the adequate sleep for optimum academic, physiological, psychological, and social functioning. Insufficient sleep can have profound, potentially detrimental physiological and metabolic effects, and associate with an increase in symptoms of anxiety or depression, impairment of attention mechanisms, and behavioral problems. Even modest sleep loss in school-age children results in an increased risk of obesity consistent with sleep deprivation experiments in healthy young adults that result in the metabolic syndrome. It has been estimated that there is a 226% increase in health care utilization in children with obstructive sleep apnea. This represents a significant financial burden further underscoring the importance of childhood sleep disorders as a public health problem.

Sleep Structure and Physiology

Sleep can operationally be defined as a *reversible* behavioral state of quiescence characterized by a relative lack of motor activity, decreased level of consciousness, and an increased arousal threshold as an adoption of species-specific, state-dependent postures. Sleep is not a single "offline" physiological condition but rather a dynamic series of connected, yet distinct, behavioral and physiological states (*Table 364.1*). Sleep is divided between rapid eye movement (REM) sleep and non-REM (NREM) sleep. NREM is further subdivided into N1, N2, and N3 manifest as progressive slowing and synchronization of the electroencephalogram. REM sleep, in contrast, is characterized by a relative activation of the cortex with reemergence of certain waking EEG frequencies, eponymic, rapid, phasic, eye movements, fluctuations in heart rate and respirations, and a decrease muscle tone on EMG. A night's sleep has a remarkably stable, developmentally specific architecture.

Sleep Architecture from Birth to Adolescence

Sleep is the primary activity of the brain during early development, and also to a large extent during childhood and adolescence, accounting for about 40% of an average day's behavior. Significant changes in sleep architecture occur throughout early childhood. While changes occur across the entire lifespan, the most significant changes occur within the first few years (*Figs. 364.1* and *364.2*).

Newborn (0–3 months). The normal newborn sleeps 16–20 h per day. Sleep generally occurs in 1–4 h periods, followed by 1–2 h wake periods. Classic EEG patterns are not present in the first months of life, and sleep staging is divided equally into active sleep and quiet sleep.

Infants (3–12 months). NREM stages 1 through 3/4 can be identified, and sleep is entered through one of these stages. The proportion of REM sleep begins to decline around 3 months of age (*Figs. 364.1* and *364.2*). Throughout the first 12 months of life, total sleep time (TST) decreases to about 14 h per day. Sleep consolidation into a 6–8 h nighttime period occurs in about 75% by age 9 months and in nearly all children by 12 months. Naps persist about twice a day in 2–4 h blocks.

Toddlers (1–3 years). TST decreases to about 12 h per day with one nap per day, but the duration of the nap decreases to 1–3 h. Up to 25% of toddlers have sleep problems with bedtime resistance and frequent night awakenings. Behavioral insomnia of childhood is the primary sleep disorder in this age group.

Preschool (3–6 years). TST may decrease slightly and generally is 11–12 h per day. Most children stop taking naps by age 5. Bedtime resistance, nightmares, and nighttime fears are common in this age group. Obstructive sleep apnea syndrome (OSAS) and arousal parasomnias peak during this stage.

School-aged children (6–12 years). Children still require 10–11 h of sleep, with rare naps. Sleep problems in this group include insufficient sleep, bedtime resistance, OSAS, and poor sleep hygiene. Sleep restriction in this age group has been related to behavioral problems.

Adolescence (13–18 years). Sleep requirements are 8–9 h (*Fig. 364.3*), however most adolescents are sleep deprived due to social and school activities. Delayed

Table 364.1
Sleep stages

Stage	Polysomnographic characteristics	Behavioral characteristics
Wake	Alpha rhythm (8–13 Hz) over occipital region with eye closure attenuating with eye opening, rapid eye blinks, EMG variable	Variable
NREM 1 (N1)	Low amplitude theta (4–7 Hz), vertex waves, slow conjugate eye movements	Light sleep
NREM 2 (N2)	K complexes, sleep spindles	Limb movements commonly seen
NREM 3/4 (N3)	Slow high amplitude delta frequency (0.5–2 Hz) adopts at least 20% of 30 s epoch	Highest arousal threshold
REM	Variable low amplitude mixed frequency, runs of central theta (e.g., sawtooth waves), alpha, rapid phasic eye movements, decreased muscle tone, variability heart rate and respirations	Dreaming, paralysis of extremities

NREM non-rapid eye movement, *REM* rapid eye movement

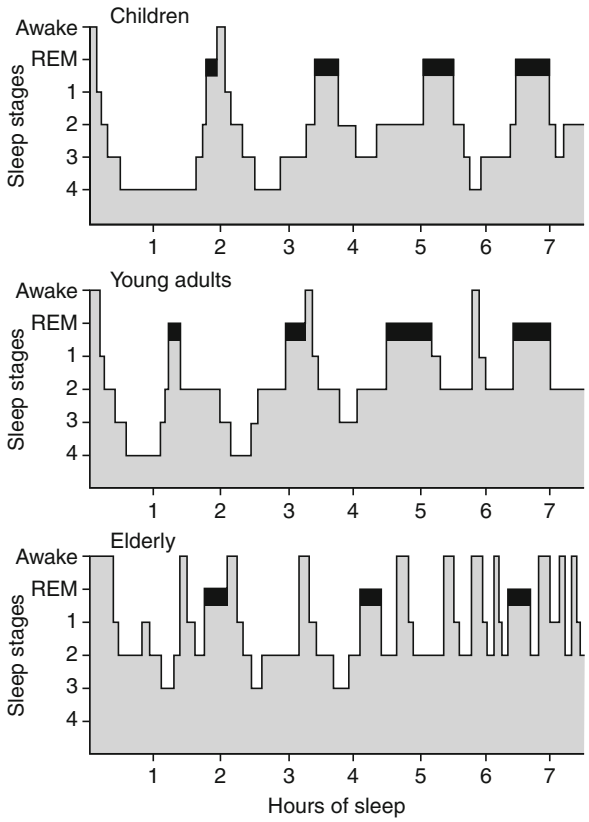

Figure 364.1
Sleep architecture changes with age **(Modified from Mindell JA, Owens JA (2003) A clinical guide to pediatric sleep: diagnosis and management of sleep problems in children and adolescents. Lippincott Williams and Wilkins, Philadelphia)**

sleep phase syndrome, OSAS, insufficient sleep, insomnia, restless legs syndrome (RLS), periodic limb movements of sleep (PLMS), and narcolepsy are seen in this age group (see below).

Mechanisms of Sleep

The biological mechanisms that govern sleep are still largely mysterious. A "two-process" model has been widely adopted that predicts the interaction between homeostatic sleep drive ("Process S") and the circadian timing system ("Process C") (*Fig. 364.3*). Process S is manifest as sleep drive (or sleep "pressure") that accrues proportionally to the duration of wakefulness and dissipates rapidly during sleep. Thus, sleep drive is predicted to be greatest just before sleep and least just after sleep. Process C refers to the 24-h (circadian) periodic oscillations of sleep propensity regulated by the endogenous and autonomous circadian timing mechanism. The core circadian clock comprises an evolutionarily conserved transcriptional, translational, and posttranslational feedback loop that is chiefly orchestrated by the master circadian regulator in the suprachiasmatic nucleus (SCN) of the hypothalamus (*Fig. 364.4*). The SCN is both necessary and sufficient to synchronize the biological clock. The endogenous clock is precisely entrained to the geophysical world by various *zeitgebers* ("time-givers"), including the light-dark cycle, feeding cues, and social interactions. Importantly, the circadian clock appears to be ubiquitous, present in most if not all tissues. The mechanisms by which the central timekeeper in the SCN conveys synchronizing information to peripheral tissues remain obscure.

Neuroanatomy and Neurochemistry of Sleep

The neuroanatomical substrates of arousal comprise monoaminergic nuclei in the brainstem including

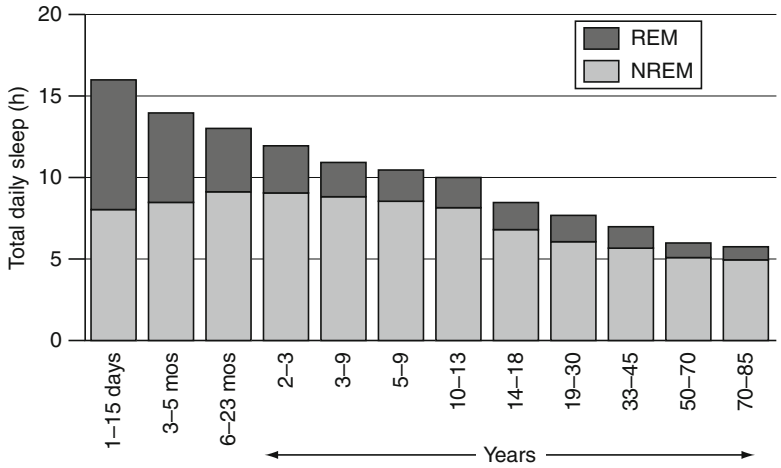

Figure 364.2
Ontogeny of REM/NREM sleep **(Modified from Roffwarg HP, Muzzio JN, Dement WC (1966) Ontogenic development of the human sleep–dream cycle. Science 152:604–619)**

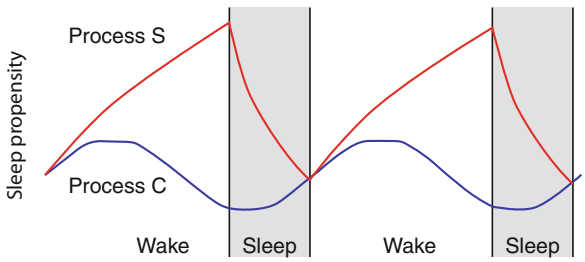

Figure 364.3
The two process model of regulation in sleep propensity. **Shown is the relationship of the circadian timing mechanism (Process C) to homeostatic sleep drive (Process S). Note that homeostatic drive is always greatest just before sleep and least just after sleep. Importantly, in the hours before sleep note opposite effects of Process C and Process S on sleep propensity; this can result in significant insomnia in the hours prior to the appropriate bedtime**

the locus coeruleus (noradrenergic), dorsal raphe (serotonergic), tuberomamillary nucleus (histaminergic), ventral periaqueductal gray (dopaminergic), and pedunculopontine nucleus (cholinergic) that project toward the basal forebrain and thalamus (*Fig. 364.5*). The ventro-lateral preoptic nucleus (VLPO), containing GABA-ergic and galanin-ergic nuclei appears to be a final common pathway in the stimulation of sleep as lesions in this region result in profound insomnia. The stability of state transitions between sleep and wake is modulated by the orexin/hypocretin system that originates in the lateral hypothalamic nucleus. Dysfunction of this system results in narcolepsy. Several sleep-promoting factors have been identified including adenosine, tumor necrosis factor-α, and interleukin-1. The precise mechanism by which the experience of clinical sleepiness arises, however, remains poorly understood.

Physiological Correlates of Sleep States

Sleep influences most major physiologic systems including breathing, cardiovascular function, the endocrine system, and muscle tone. Heart rate, blood pressure, and respiratory rate decrease dramatically during NREM sleep but extraordinary variability in both pulse and respirations are seen in phasic REM sleep. There is an increase in hypoxic ventilatory response during REM sleep as well as a modification of the hypocapnic control of respiration. These phenomena may contribute to the physiological instability associated with REM–NREM transitions as well as sleep–wake transitions.

Core body temperature (Tb) shows a circadian variation independent of sleep. The amplitude of temperature variation is about one degree. Secondly, there is a reduction in the body's thermal set point (the result of increased heat dissipation and decreased heat generation). In REM sleep, there is an absence

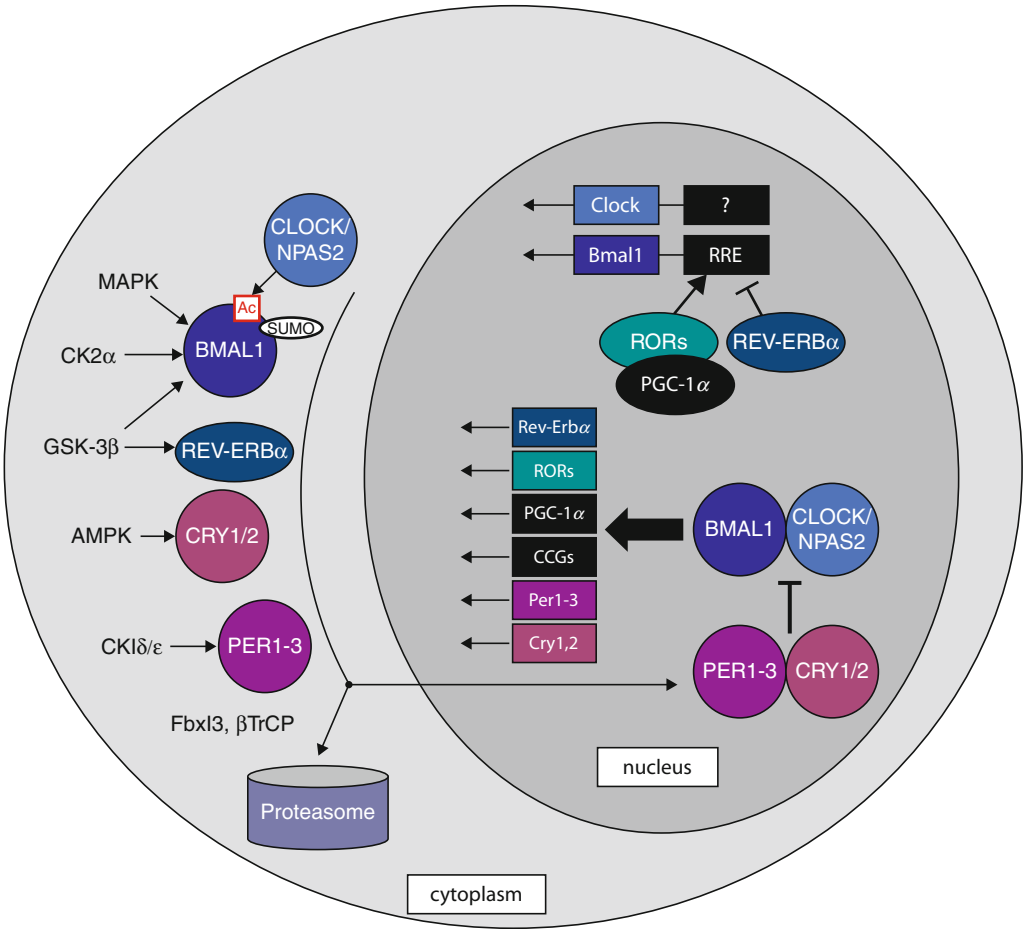

Figure 364.4

Schematic of the molecular clock transcriptional-transalational feedback loop. The "positive limb" is initiated by binding of BMAL1:CLOCK/NPAS2 heterodimers in the nucleus that activate the transcription of clock-controlled genes (CCGs). Upon translation in the cytoplasm, several of these CCGs, including the PERs and CRYs re-enter the nucleus, and inhibit the activity of the BMAL1:CLOCK complex, closing the feedback loop. Note that clock proteins undergo extensive post-translational modification that contribute importantly to their dynamics

of thermoregulatory response, resulting in effective poikilothermy and a drifting of Tb toward environmental temperature.

Slow-wave sleep is associated with secretion of growth hormone independent of circadian time. Sleep onset (and possibly slow-wave sleep) is associated with inhibition of thyroid-stimulating hormone and of the adrenocorticotropic hormone–cortisol axis, an effect that is superimposed on the prominent circadian rhythms in the two systems.

The pineal hormone melatonin is under direct modulation by the circadian pacemaker via a complex neuroanatomical pathway starting with the retinohypothalamic tract and traversing the SCN and cervical sympathetic chain. Melatonin is predominantly secreted at night independently of sleep and thus may represent a biological signature of circadian time. Exogenous melatonin increases sleepiness and sleep duration when administered in adults attempting to sleep during daylight hours (when endogenous melatonin is low). Melatonin has been used for sleep-onset and sleep maintenance insomnia in children, however neither effectiveness nor safety of long-term use have been established.

Evaluation of Sleep Disorders in Children

Studies have shown that despite recognizing the importance of sleep, most pediatricians do not feel comfortable identifying and treating sleep disorders.

Assessment of sleep disorders should include:

Sleep history – difficulty going to bed, initiating or maintaining sleep, excessive daytime sleepiness and nocturnal awakenings, unusual behaviors at night, snoring and difficulty breathing, schedules on weekdays and weekends, and napping. Validated questionnaires such as the "BEARS" algorithm, Pediatric Daytime Sleepiness Score (PDSS), and the Pediatric Sleep Questionnaire (PSQ) can be useful for assessment of age-specific subjective sleep parameters.

Medical and psychiatric history – asthma, allergies, gastroesophageal reflux disease (GERD), chronic lung disease, sickle cell disease, epilepsy, headaches, cerebral palsy, developmental delay, ADHD, autism, depression, bipolar disorder, and anxiety.

Family history – sleep-disordered breathing, narcolepsy, sleep-related movement disorders.

Developmental screen and assessment of school functioning and behavioral assessment.

Physical examination, especially:

Growth parameters: height, weight, BMI

ENT exam: looking for deviated septum, adenotonsillar hypertrophy, adenoid facies, or oropharyngeal crowding.

Neurologic exam: especially in children with excessive sleepiness and seizures.

Polysomnography (PSG)

A PSG is a continuous recording of EEG, EKG, EOG (electro-oculogram), respiratory effort using chest and abdominal belts, airflow, gas exchange and end tidal CO2, electromyogram, snore microphone, and pH probe (Fig. 364.6).

A PSG is warranted to investigate causes of excessive daytime sleepiness such as sleep-disordered breathing, sleep fragmentation due to frequent nocturnal arousals from PLMS, bruxism, GERD, the etiology of episodic nocturnal phenomena (e.g., parasomnias versus nocturnal seizures), or as a screening tool prior to a test for excessive daytime sleepiness such as the multiple sleep latency test (MSLT).

Sleep logs. Sleep logs give an estimate of the number, duration, and timing of daily episodes of nocturnal sleep, daytime naps, and wake periods.

Actigraphy. Actigraphy has been widely recognized as a low-cost, home-based tool for screening of sleep disorders, especially circadian rhythm disorders or behavioral insomnias. Actigraphy data is limited by the confounding of influences of immobility during wakefulness or, conversely, sleep-related movements.

Multiple Sleep Latency Test (MSLT)

The MSLT is a validated objective measure of the ability or tendency to fall asleep. It is indicated as part of the evaluation of patients with suspected narcolepsy and idiopathic hypersomnia. This test involves five 20-min opportunities to nap during the day with each nap being separated by 2 h. The sleep onset for each nap is determined as sleep latency. A sleep latency between 5 and 10 min indicates mild/moderate daytime sleepiness, whereas <5 min indicates severe daytime sleepiness). Onset of REM sleep within 15 min of sleep onset is determined as SOREMP (sleep onset REM period) (Fig. 364.7).

Disorders of Sleep Onset and Maintenance in Children

Insomnia

Insomnia is defined by repeated difficulty with sleep initiation, duration, consolidation, or quality despite adequate time and opportunity for sleep that results in some form of daytime impairment (defined as at least one of the following: fatigue, attention or concentration impairment, poor school performance, vocational dysfunction, mood disturbance or irritability, daytime sleepiness, decreased motivation or initiative, proneness for errors, tension, headaches, or gastrointestinal symptoms in response to sleep loss, or concerns or worry about sleep). Insomnia can be difficult to assess in young children because signs and symptoms are expressed by caregivers with limited accuracy and reliability. Population-wide studies suggest that there is a high prevalence of children getting inadequate sleep. Parental or child self-reported problems with sleep initiation or maintenance in school-age children varies from 30% to 41%. Finally, insomnia can have a profound effect on family dynamics and, conversely, familial distress can be a risk factor for development of insomnia, even into adulthood.

The Primary Insomnias

Infants and toddlers. The most common cause of sleeplessness in the youngest children – with estimated prevalence of 10–30% – is behavioral insomnia of childhood (BIC). BIC can been subdivided into two: (1) sleep-onset association type characterized by a child's dependency on stimulation or objects for return to sleep (e.g., parental touch, coddling, co-sleeping, or pacifier) and (2) learned-onset type typically characterized by stalling at bedtime secondary to inadequate limit setting.

Preschool-aged children (3–5 years). Bedtime resistance and sleep onset insomnia are common in preschool children as an expanding communicative palette results in further limit-testing behavior. Differential diagnosis for insomnia includes anxiety disorder, post-traumatic stress disorder (PTSD), child abuse, and use or acute disuse of medications that interfere with REM sleep such as clonidine or selective serotonin reuptake inhibitors (SSRIs).

Problems with sleep hygiene are a common cause of insomnia in this age group frequently secondary to duration of time in bed that exceeds the child's sleep requirement. This frequent phenomenon results in varying constellations of sleep fragmentation with nocturnal

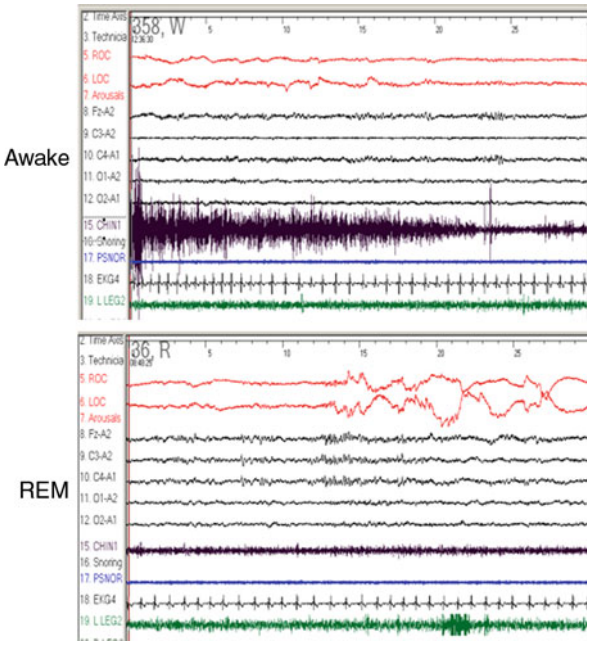

Figure 364.7
MSLT montage comparing appearance of wake to REM sleep

arousals, sleep onset insomnia, and an exacerbation of behavioral difficulties associated with sleep.

School-age children (6–11 years). Inadequate sleep and poor sleep hygiene are common in school-age children as the increased social, educational, and parental demands are made of them. Bedtime resistance, shortened sleep duration, and sleep-onset delay are common in this age group.

Adolescents (12–18 years). Hormonal changes that accompany adolescence have been hypothesized to result in the prominent changes in adolescent sleep patterns that include reduced daytime alertness, delayed sleep phase syndrome (DSPS) with delayed bedtimes, and reduced sleep timing (see below). A combination of increased autonomy and the psychosocial, familial, and educational demands of adolescent life also promote poor sleep hygiene.

Psychophysiological insomnia. Characterized by a heightened level of arousal in bed, psychophysiological insomnia often manifests as excessive anxiety about sleep, heightened inability to relax in bed, or an ability to sleep better away from home can also present in adolescents.

Idiopathic insomnia. The term idiopathic insomnia refers to a relatively rare uncommon condition characterized by lifelong insomnia without identifiable cause, with usual onset in childhood or adolescence, and strong family history. In children, it must be distinguished from behavioral insomnia and should always remain a diagnosis of exclusion. Patients with idiopathic insomnia can be distinguished from normal short sleepers because the latter are not distressed by relatively reduced total sleep time.

Secondary or Comorbid Insomnia

Medical and Psychiatric Conditions. Several medical conditions may impair sleep onset or maintenance including pain, colic, otitis media, asthma, allergies, gastroesophageal reflux, sickle cell disease, fibromyalgia, and cancer. It can be particularly difficult to distinguish sleep dysfunction as a contributing cause as opposed to a symptom of an underlying psychiatric disorder. Anxiety disorders, major depression, and post-traumatic stress disorder should always be considered in the differential diagnosis of insomnia. In older children and adolescents, use of alcohol and other recreational drugs should be explored as possible causes for insomnia.

Neurological Conditions. Children with neurological conditions are at particular risk of insomnia. Attention-deficit disorder (ADD) with or without hyperactivity has been repeatedly identified as either the cause or a symptom of sleep onset and/or sleep maintenance insomnia. Low ferritin levels (less than 50 ng/mL) have been associated with both ADD and sleep-related movement disorders (see below). Sleep and epilepsy have a mutual relationship with sleep quality strongly affecting seizure control. Many anti-convulsants alter sleep macroarchitecture and can also contribute to both sleep initiation and maintenance difficulties. For unknown reasons, insomnia is common in children with autistic spectrum disorders (ASD). Insomnia is common in children with cerebral palsy (CP) and those with severe visual impairment are especially affected. Sleep maintenance is extremely disrupted in Angelman syndrome and Rett syndrome; however, little is known about the underlying pathophysiology. Finally, children with the rare Smith–Magenis syndrome demonstrate circadian cycle inversion and may suffer from significant insomnia.

Circadian Rhythm Sleep Disorders (CSRD)

Circadian oscillations are the manifestation of an endogenously working clock that has, in each individual, a genetically specified period. Yet, the circadian system is extraordinarily plastic and responds to environmental cues – so-called zeitgebers (or "time-givers") including light, food, and social interactions – that serve to synchronize the clock with geophysical and sociobiological time.

CSRDs result from a misalignment of the endogenous clock with the socially mandated schedule and can result from: (1) environmentally imposed behavior or cues such as shift work, jet lag, or a dearth of normal light/dark cues; (2) decreased sensitivity to synchronizing cues such as light (e.g., with blindness); and (3) genetic variability in the biological clock itself that renders a relatively short or long period or inappropriate responsiveness to *zeitgebers*.

Delayed Sleep Phase Syndrome (DSPS). DSPS is the most common CSRD in the pediatric population, especially adolescents (prevalence ~7%), and is characterized by a delay in the phase of circadian clock mechanism relative to local time. DSPS presents with sleep-onset insomnia, daytime sleepiness, and sleep deprivation until the restrictions on the mandated schedule are relieved (e.g., during the weekend) and the circadian phase is "expressed." When patients with DSPS are permitted to sleep without restriction, sleep is normal, differentiating it from psychophysiological insomnia. Delays in melatonin secretion, changes in core body temperature, and sleep/wake cycle have been demonstrated in DSPS patients. Treatment has focused on resetting the circadian clock (chronotherapy) by advancing sleep times and/or light therapy in which subjects are exposed to bright light at the same time every morning after the normal physiological temperature nadir. Pharmacologically, exogenous melatonin administered prior to desired sleep time has been shown to have efficacious hypnotic and phase-shifting effects.

Advanced Sleep Phase Syndrome (ASPS). ASPS refers to a condition in which an individual falls asleep and wakes early relative to local time. A tendency toward relative phase advancement occurs with normal aging. True ASPS is uncommon however, and may have a strong genetic basis. Mutations in two regulators of the "negative limb" of the circadian feedback loop – *Per2* and *CK-1ε* – have been identified in familial cohorts (◉ *Fig. 364.2*).

Blindness. Because blind individuals do not benefit from the entraining influences of light on the endogenous circadian clock, they may exhibit a "free-running" rhythm in which the circadian phase cycles independently of local time often resulting in severe insomnia. Melatonin has proven valuable as an exogenous entraining signal in these patients. A free-running circadian rhythm is extremely rare in sighted individuals.

Jet Lag Disorder and Shift Work Disorder. Children are not frequently exposed to jet lag or regular shift work. Both can result in chronic sleep disruption secondary to misalignment of internal clock with local time.

Hypersomnias in Childhood

Narcolepsy

Narcolepsy is a disabling disorder of sleep characterized by excessive daytime sleepiness for at least 3 months duration in the absence of another primary sleep disorder and/or episodes of emotionally triggered cataplexy. The presence of cataplexy (i.e., a paroxysmal, bilateral decrease of muscle tone) with excessive daytime sleepiness is sufficient to make a diagnosis. Narcolepsy has other features that vary in prevalence including hypnagogic (occurring with falling sleep) or hypnopompic (occurring with waking) hallucinations, sleep paralysis, and an urge to sleep that is often uncontrollable.

Narcolepsy has an estimated prevalence in the United States of 0.8 per 100,000; however, the prevalence is higher in Japan and lower in Europe. It is more common in women and has a bimodal age of diagnosis: the first peak occurs at about 15 years and the second, smaller peak, at about 36 years. Narcolepsy with cataplexy can be familial. Interestingly, about 85–95% of patients with narcolepsy with cataplexy carry the HLA DQ1B*0602 haplotype, suggesting a genetic predisposition to the disease (importantly however, 99% of individuals with this haplotype do not have narcolepsy).

Elegant genetic studies in narcoleptic dogs in conjunction with molecular studies in mouse models have identified the orexin/hypocretin system as the culprit signaling defect in narcolepsy. The orexins are a family of neuropeptides produced exclusively in the lateral nucleus of the hypothalamus. These orexinergic neurons make extensive projections both caudally into the brainstem arousal system and rostrally into the basal forebrain (◉ *Fig. 364.5*). In *postmortem* brains from patients with narcolepsy with cataplexy, an absence of orexin-expressing neurons has been noted. It has been hypothesized that orexins stabilize the transitions between REM and NREM sleep. Thus, loss of orexinergic signaling results in sleep-state instability with frequent and abrupt wake/REM transitions, sleep fragmentation, and the other associated symptoms of the disease. The underlying mechanisms of cataplexy remain controversial. Orexin levels in the cerebrospinal fluid (CSF) of patients with narcolepsy with cataplexy are severely reduced or undetectable. Importantly, individuals with narcolepsy *without* cataplexy have normal CSF orexin levels.

The diagnosis of narcolepsy is made on clinical grounds. Supporting tests of sleepiness such as the MSLT are recommended. A mean sleep latency of less

than 8 min and presence of two or more sleep-onset REM periods on an MSLT is supportive of a diagnosis of narcolepsy. These values are not validated for children. Diagnosis can be difficult in the pediatric population, especially in young children. Misdiagnoses include laziness, attention-deficit, epilepsy, opposition-defiant disorder, depression, tics, and even psychosis.

Consolidation of nocturnal sleep and control of cataplexy are the treatment goals of narcolepsy therapy. Optimization of sleep hygiene is a required first step. Scheduled daytime naps can be remarkably helpful. Sleep-stabilizing medication such as sodium oxybate is increasingly used. Stimulants such as modafinil or amphetamine derivatives (e.g., methylphenidate or dextroamphetamine) can effectively offset daytime sleepiness and limit unwanted diurnal sleep bouts. Sodium oxybate (or g-hydroxybutyrate), a GABA-B receptor agonist, is approved for treatment of cataplexy and is also beneficial in sleep consolidation, daytime fatigue, and possibly hypnagogic hallucinations. Sodium oxybate is not approved for children; however, it has been used off-label. Cataplexy can be controlled with selective serotonin/noradrenaline reuptake transporters and their derivatives (e.g., venlafaxine) or with second-generation tricyclic antidepressants (e.g., clomipramine or desipramine).

Other causes of cataplexy. Niemann–Pick disease C, Prader–Willi Syndrome, and myotonic dystrophy can present with cataplexy and should be differentiated from idiopathic narcolepsy with cataplexy.

Other Hypersomnias

Idiopathic hypersomnia. Idiopathic hypersomnia is an incompletely defined disorder reserved for daytime sleepiness in the absence of cataplexy or identifiable cause; it is always a diagnosis of exclusion.

Kleine–Levin syndrome. This rare disorder is characterized by relapsing–remitting episodes of hypersomnia, cognitive disturbances, and behavioral disturbances usually of primal functions including hyperphagia and hypersexuality. Between episodes, sleep and wake behavior are normal. Hypersomnia episodes may last for a few days to several weeks. The cause of this syndrome remains obscure. Symptomatic cases of Kleine–Levin syndrome associated with structural brain lesions have been reported, but most cases are idiopathic. The syndrome is often linked to an antecedent respiratory illness of presumed viral origin.

Pediatric Parasomnias

Definitions

Parasomnias are defined as undesirable physical events or experiences that occur during entry into sleep, during sleep, or during arousals from sleep. They are classified as (1) disorders of arousals from non-rapid eye movement (NREM) sleep, (2) parasomnias associated with rapid eye movement (REM) sleep, and (3) other parasomnias.

Disorders of Arousal from NREM Sleep

Most disorders of arousals occur during slow wave sleep (SWS) during incomplete transitions into wakefulness, and are characterized by automatic behavior, altered perception of the environment, and variable degree of amnesia for the event. They tend to occur in the first third of the night when SWS is more prominent. The EEG during the episodes demonstrates an admixture of theta, delta, and alpha frequencies. They are felt to be due to a faulty switch that prevents normal sleep cycle progression. They are brought out by sleep deprivation, medications, noisy or stimulating environments, stress, fever, and sleep fragmentation due to obstructive sleep apnea (OSA) or periodic limb movements of sleep (PLMS). Several studies suggest a genetic predisposition to some of the arousal parasomnias.

Evaluation should include a complete description of the event, time of night when they happen, frequency of episodes, recollection of the event by the child, and presence during daytime naps. Information regarding whether the movements are rhythmic and stereotypical, associated with eye deviation, and focal tonic clonic activity may support an epileptic origin to the events. Examination should focus on looking for evidence of upper airway obstruction such as adeno-tonsillar hypertrophy, midfacial hypoplasia, and retrognathia. In appropriate cases, a video-EEG may be indicated to rule out seizures. Overnight polysomnography is indicated when there is concern for an intrinsic sleep disorder like OSA or PLMS, rather than to document the parasomnia per se.

Management usually includes reassurance, securing the environment, voidance of known precipitants such as sleep deprivation, caffeinated drinks, and avoiding any attempts of restraining or awakening the child during the episode which may actually be counterproductive. Medications should be reserved for protracted cases with no associated sleep disorders, frequent

events or those associated with a threat for injury. Low-dose clonazepam or tricyclic antidepressants for a short duration have been used with good success in such cases.

Sleep walking (somnambulism): Occurs in up to 17% of children, highest at 12–13 years of age, and with equal frequencies amongst males and females. It is further classified as calm or agitated subtype, with the former more common in children. The major concern during these benign behaviors is risk for injury.

Confusional arousals: Occur mainly in infants and toddlers, in up to 17.3% of the population. A typical event begins with moaning, evolving to confusion, and agitated behavior lasting 5–15 min. Attempts to wake up the child fully are unsuccessful.

Sleep Terrors: Occurs in 1–6% of children with peak frequency between 4 and 8 years of age. The child may sit up suddenly and scream with a blood-curdling battle cry. There is an expression of intense fear on the face and is accompanied with autonomic activation including mydriasis, tachycardia, and diaphoresis. Some children may report indistinct recollections of threat such as monsters, spiders, and snakes from which they have to defend themselves. In most cases, however, there is no recollection of the event. The event may last from a few minutes up to 20 min. Most cases go into a natural remission by adolescence.

Nocturnal seizures: Parasomnias must be differentiated from nocturnal seizures. Frontal lobe seizures are especially important since they occur predominantly in sleep, sometimes many times per night, and are characterized by stereotypical movements, thrashing of entire body, vocalizations, and dystonic posturing lasting 20 s to a few minutes with minimal postictal drowsiness or confusion. Paroxysmal nocturnal dystonia, which is now considered to be a frontal lobe seizure, is characterized by an arousal from NREM sleep, accompanied with dystonic posturing, bizarre movements of the extremities, and vocalization, with minimal EEG correlation due to a deep-seated focus of seizure onset in the mesial frontal region.

REM Parasomnias

Nightmares. These are characterized by vivid dreams in the second half of the night with intense feelings of terror or dread that typically awaken the child from sleep. The child can be easily aroused, with good recollection of the event. They are frequently seen between the ages of 3 and 6 years. Prevalence ranges from 30% to 90% for occasional and 5–30% for frequent episodes. In children, psychiatric disorders are seen more often in those experiencing nightmares than those without nightmares. They may also be a marker for a history of sexual abuse in children and adolescents.

REM sleep behavior disorder (RBD). This disorder is characterized by enacting of unpleasant and combative dreams with complex movements that can be vigorous and violent due to lack of REM sleep atonia. The disorder occurs more often in the sixth or seventh decade in males, and may precede onset of Parkinson's disease, or progressive supra-nuclear palsy. The disorder is uncommon in children, but may be seen in association with use of selective serotonin reuptake inhibitors like fluoxetine, or accompanying narcolepsy, and Tourette's syndrome. RBD responds very well to clonazepam given at bedtime.

Recurrent isolated sleep paralysis. This is characterized by a generalized inability to speak, or to move the trunk, head, and limbs that occur during the transitional period between sleep and wakefulness. The episodes are brief and transient, but may be accompanied with vivid hallucinations which make them very distressing. Usually seen with narcolepsy, they may be seen as an isolated form in otherwise healthy individuals, with a strong family history in some cases.

Sleep-related hallucinations. These are characterized as vivid dreams, or perceptions not based in reality, that occur at sleep onset (hypnagogic hallucinations) or on awakening (hypnopompic hallucinations) that occur in otherwise healthy individuals, but are frequent seen as part of the symptoms of narcolepsy. They may be visual, tactile, auditory, or kinetic in nature. They probably represent brief intrusion of REM sleep into NREM sleep or wakefulness.

Sleep-related enuresis. Nocturnal enuresis (bedwetting) refers to involuntary passage of urine while asleep. It occurs in almost 15–25% of children at 5 years of age, more often in boys, and in almost 1–3% of adolescents. It may be classified as primary (when present from birth) or secondary (with periods of at least 6 months of dryness prior to recurrence of enuresis) and nocturnal or diurnal. Three major pathological factors have been considered as possible etiologies: Group 1, volume dependent with polyuria; Group 2, detrussor dependent, with involuntary detrussor contractions, and small urinary bladder; Group 3, with decreased arousability. There are strong associations of enuresis with genetic and familial factors, and high prevalence of secondary enuresis in children with OSA. Treatment involves removal of inciting factors, reassurance, behavioral programs, and use of nasal desmopressin, or oral tricyclics like imipramine.

Exploding head syndrome. It is a harmless but potentially terrifying situation usually occurring while a patient is falling asleep, and is characterized by a terrifying loud

noise, accompanied by myoclonic jerks, or the perception of a flash of light. Events are very brief. There is no headache or pain accompanying these episodes; and they can begin in childhood. No treatment is needed.

Sleep-related eating disorder. Usually seen accompanying sleep walking and daytime eating disorder, it is characterized by out-of-control eating binges, predominantly of carbohydrate-containing diets, 2–3 h after sleep onset, with no recall of the event subsequently. They can be seen to begin in childhood, but are more often seen in teenage years and adulthood. These behaviors have recently been described in association with use of hypnotics like zolpidem.

Catathrenia. Also called nocturnal groaning, this can occur in REM or NREM sleep during expiration in clusters of 2 min to an hour, ending with a snort, and accompanied with changes in heart rate. The onset may begin during childhood or adolescence. The exact etiology is unknown, and no specific therapy has been found to be effective.

Sleep starts. Also called hypnic jerks, these are sudden whole body jerks experienced by individuals during sleep–wake transition. Variations include sensory; auditory, including exploding tinnitus; and visual sensations, which may occur without the motor jerks. No treatment other than reassurance is necessary for them.

Sleep-sex disorders. Inappropriate sexual behavior occurring during sleep without conscious awareness has been reported in adults, with onset around adolescence in some cases.

Sleep-talking. Is very common in the general population, and can occur in REM or NREM sleep with a strong familial and genetic propensity.

Hypnic headaches. This is characterized by diffuse headache occurring 4–6 h after sleep onset at a consistent time, lasting 30–60 min, seen in older adults accompanied by nausea but no other autonomic features.

Rhythmic Movement Disorders of Sleep

Restless Legs Syndrome (RLS) and Periodic Limb Movements of Sleep (PLMS)

RLS is a common sensorimotor disorder of unclear cause characterized by (1) an urge to move the limbs often in association with an unpleasant sensation, (2) the urge to move is worse at night or occurs only at night, (3) the urge to move is present while at rest, and (4) the urge to move or unpleasant sensation is relieved by movement. Diagnosis can be extremely challenging in children. Periodic limb movements of sleep (PLMS), a related disorder, is diagnosed almost exclusively by 0.5–5 Hz limb movements seen during polysomnography and thus, most patients with PLMS are unaware of the presence of the movements (*Fig. 364.8*). When PLMS is associated with sleep disturbance and daytime sleepiness, it is referred to as periodic limb movement disorder (PLMD). RLS and PLMS, like other disorders that potentially alter sleep quality and duration can have demonstrable impact on cognitive function, mood, neurological status, and quality of life. Primary RLS is idiopathic whereas secondary RLS has been associated with iron deficiency, pregnancy, end-stage renal disease, neuropathy, and certain medications.

Epidemiology. The prevalence in the pediatric population has been estimated at about 2% in 8–17 year olds in the United States and United Kingdom. Thus, RLS affects an estimated 984,000 of the school-age pediatric population in the United States. The prevalence of PLMS in children is unknown. While RLS and PLMS can exist independently of one another in the same individual, many patients with RLS also have PLMS.

Diagnosis. For children over the age of 12, adult definitions of RLS apply. Because of the difficulty of expressing sensory symptoms in younger children, modifications to the adult diagnostic criteria have been adopted (*Table 364.2*).

Etiology and Associations. In children with confirmed RLS, a history of RLS in a biological parent can be found in more than 70%, suggesting that genetic factors may play a prominent causative role. Polymorphisms in at least four independent loci have been identified that confer increased risk of PLMS and/or RLS. Whether these polymorphisms will provide insight into the etiology and neuropathology of RLS is unclear. Both RLS and PLMS are associated with attention-deficit hyperactivity disorder (ADHD) and interestingly, all three disorders have been associated with iron deficiency, suggesting that iron metabolism may represent a common pathophysiological pathway. The prevalence of ADHD or ADHD symptoms in patients with RLS symptoms is 18–26% whereas the converse prevalence of RLS (or RLS symptoms) in patients with ADHD is 10.5–44%, again supportive of mechanistic overlap between these disorders.

Treatment. The primary treatment of RLS and PLMS are the dopaminergic agonists ropinirole and pramipexole; however, neither has been approved for use in children. Serum ferritin below 50 ng/mL has been associated with increased severity of RLS; furthermore, supplemental iron administration has demonstrated benefit in RLS.

Head banging. Also called *jactatio capitis nocturna*, it is now classified as a rhythmic movement disorder of sleep

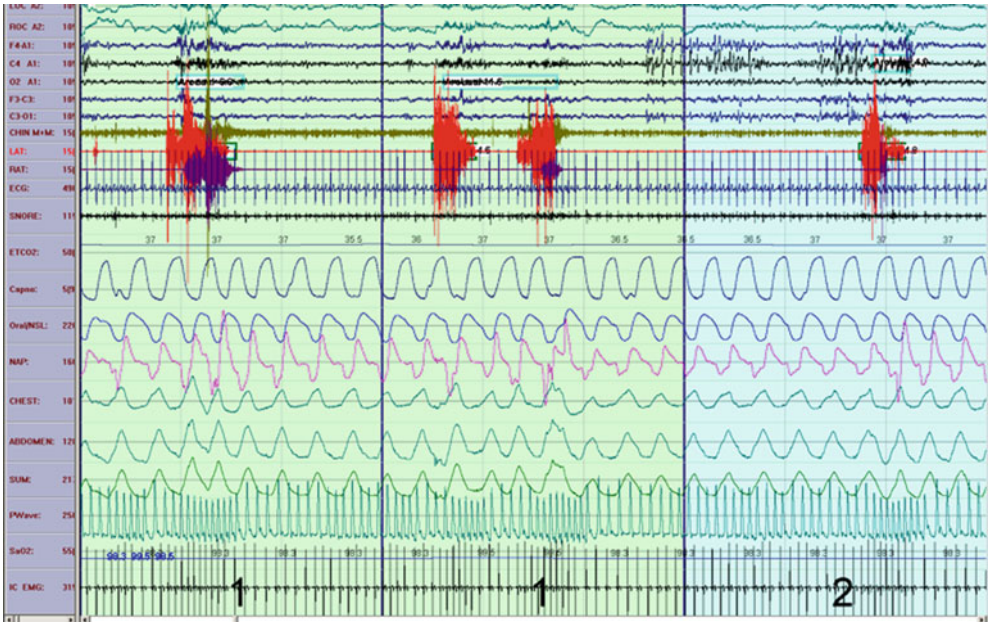

Figure 364.8
***Polysomnographic characteristics of periodic limb movements of sleep*. Note high amplitude paroxysmal activity of both legs lasting 1–2 s per movement**

Table 364.2
Criteria for making the diagnosis of definite RLS in children

1. The child meets all four essential adult criteria for RLS (the urge to move the legs, is worse during rest, relived by movement and worse during the evening and at night)
2. The child relates a description in his or her own words that is consistent with leg discomfort (the child may use terms such as "oowies," "tickle," "spiders," "boo-boos," "want to run," and "a lot of energy in my legs" to describe the symptoms. Age-appropriate descriptors are encouraged)
Or
1. The child meets all four essential adult criteria for RLS
2. Two of the three following supportive criteria are present
(a) Sleep disturbance for age
(b) A biologic parent or sibling has definite RLS
(c) The child has a polysomnographically documented periodic limb movement index of 5 or more per hour of sleep

and is characterized by rhythmic movements of head and body at sleep onset in infants and toddlers. It is seen more often in children with developmental disability and autism, but may be seen in normal children. No specific treatment other than reassurance is indicated.

Bruxism. The prevalence of bruxism (teeth grinding) is 14–17% in childhood, decreasing over the lifespan. Sleep-related bruxism without clear cause is termed primary, whereas secondary sleep-related bruxism may be associated with the use of psychoactive medications, recreational drugs or a variety of medical disorders. It can lead to abnormal wear of teeth, jaw muscle pain, or temporal headache. Dental examination and oral appliance may be indicated. The cause of bruxism is unknown; however, it may represent a motor manifestation of sleep-disordered breathing.

Sleep-Disordered Breathing: Obstructive Sleep Apnea

Obstructive sleep apnea syndrome (OSAS) was first reported in children over 30 years ago; however, it remains underdiagnosed despite strong evidence of increasing incidence. OSAS is a form of sleep-disordered breathing (SDB) that comprises one end of a spectrum of sleep-associated changes in upper airway resistance that in its most severe form constitutes recurrent hypoxia and subsequent arousals from sleep. OSAS is diagnosed on polysomnography by the presence of obstructive apneas (absence of airflow for at least two breaths) or hypopneas

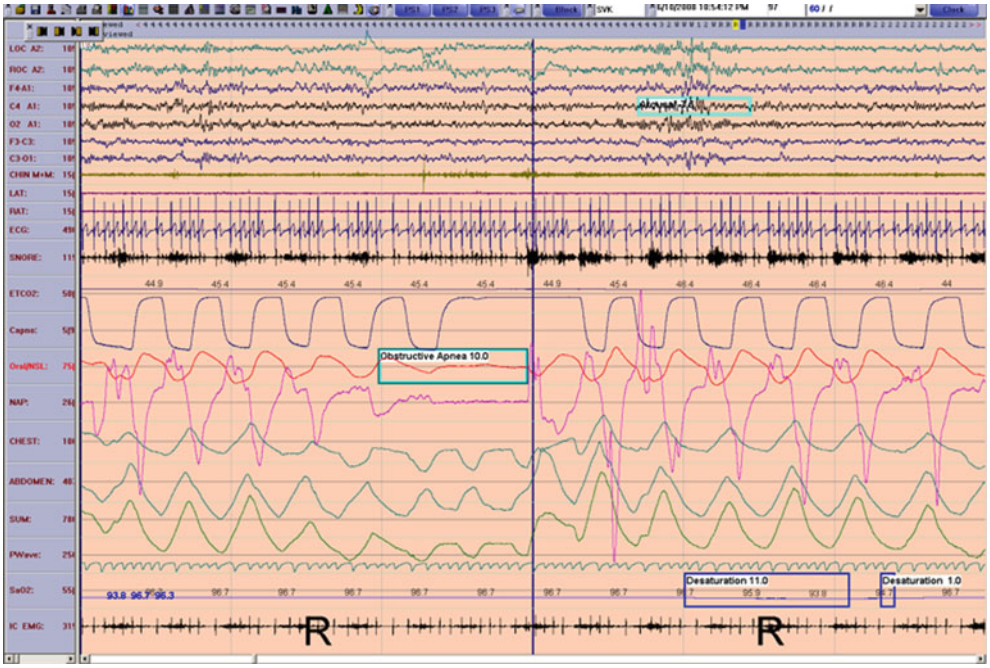

Figure 364.9
Polysomnographic characteristics of obstructive sleep apnea. Note diminution and then absence of oral thermistor (oral) and nasal air pressure (NAP) followed by an EEG arousal, brisk recovery breath, and delay of desaturation

(a greater than 30% reduction in baseline nasal airflow with an associated decrease in oxyhemoglobin saturation of at least 3%) and in children, an apnea-hypopnea index (AHI = (number of apneas + number of hypopneas)/total sleep time) of greater than one per hour (Fig. 364.9). Recurrent respiratory effort–related arousals (RERAs; defined as a decrease in airflow without associated desaturation) occurring in the absence of frank hypopnea, apnea, or gas exchange abnormalities is referred to as upper airway resistance syndrome (UARS). UARS has been hypothesized to result from a decreased arousal threshold in relation to respiratory fluctuations during sleep.

Epidemiology. OSAS affects 2–3% of middle school children and as many as 13% of children aged 3–6 years. Importantly, the prevalence may be two- to fourfold higher in vulnerable populations: children with adenotonsillar hypertrophy, craniofacial anomalies, African-American race, preterm birth, and relatively low household income may have increased odds of having OSAS. In children, OSAS has been associated with adverse cardiovascular and metabolic outcomes: higher blood pressure, left ventricular hypertrophy, higher C-reactive protein, and increased insulin resistance. Whether these associations translate into increased risk of disease in adulthood remains unknown.

Symptoms. Symptoms of OSAS include snoring, mouth breathing, daytime sleepiness, frequent nocturnal arousals, and cognitive-behavior problems, especially attention-deficit, mood impairment, and poor school performance.

Pathophysiology. The pathophysiology of pediatric OSA includes neurophysiological, anatomical, and mechanical factors that conspire to increase upper airway resistance during sleep. Studies have demonstrated a correlation between the degree of airway narrowing and apnea-hypopnea index (AHI). Anatomic causes of upper airway narrowing such as adenotonsillar hypertrophy are the most common cause of pediatric OSA. Increased airway collapsibility during inspiration has been described in children with OSA suggesting either increased airway compliance or abnormal neuromuscular compensatory changes in pressure oscillation during sleep-associated breathing.

Obesity. Body mass index is among the strongest predictors of both presence and severity of OSAS in adults. Several studies have demonstrated that incremental increases in AHI correlate with increases in body mass index (BMI). Childhood overweight (>95% of BMI for age) and obesity are rising at an alarming rate with prevalence tripling over the past two decades. The Cleveland Family Study demonstrated a 4.6-fold increase in OSA in

overweight children compared to normal weight children. This odds ratio may increase even further when adolescents age 13–16 years are considered as a separate cohort. The mechanisms by which obesity increases OSAS risk are likely multiple and may include impairment of airway and lung mechanics or velopalatal insufficiency and do not, in contrast to adults, appear to be related to parapharyngeal fat deposition.

Association with metabolic syndrome. Adolescents with obesity and SDB are 6.5 times as likely to have metabolic syndrome (a constellation of insulin resistance, dyslipidemia, hypertension, and obesity) when compared to those without SDB and controlled for age, sex, preterm status, and race.

Treatment. The initial therapy for OSA in both obese and non-obese children is surgical tonsillectomy and adenoidectomy (T&A). The success rate of T&A is about 85%; however, efficacy is markedly reduced in obese children suggesting that obesity itself independently contributes to sleep-related airway resistance. For patients in whom T&A do not resolve symptoms, continuous positive airway pressure (CPAP) delivered via a mask interface is extremely effective in stenting the airway. CPAP initiation can be difficult in certain children, especially those with neurodevelopmental disorders. Other therapies include oral appliances that advance the mandible, rapid maxillary expansion, and reconstructive surgeries such as maxillary mandibular advancement and uvulo-palato-pharyngioplasty.

Central sleep apnea. Central sleep apnea (CSA) is defined as the absence of airflow accompanied by a lack of effort to breath. CSA likely results from abnormal neurological control of breathing. CSA after the postnatal period should prompt investigation of central nervous system (CNS) causes including congenital causes (i.e., central alveolar hypoventilation syndrome), infection, structural lesions (e.g., Arnold–Chiari malformation, midline tumors, holoprosencephaly), or peripheral disorders such as myasthenia gravis or motor neuron disease (e.g., spinal muscular atrophy).

365 Coma

David J. Michelson · Stephen Ashwal

Case History

A woman left her house at 1:45 pm to go shopping, leaving her 11-month-old son in the care of her two teenaged children. An hour later her 16-year-old son called her in a panic, crying that his "little brother is dead." Paramedics were called and arrived within 4 min to find the little boy pulseless and apneic. The boy's 15-year-old sister explained that she had found him with his head in a bucket she had been using to mop the floors. The paramedics started chest compressions and mask ventilation with 100% oxygen. They transported the boy to a nearby emergency room, where he was intubated and given three successive intravenous doses of epinephrine. A spontaneous pulse was first recovered after 35 min of resuscitation. His temperature was 90°F (32°C), his pupils were fixed and dilated, and he had no corneal or gag reflex or facial grimace to pain. His first arterial blood gas showed a pH of 6.72 and a base deficit of 31 mEq/L, and he was given multiple boluses of normal saline and bicarbonate. He had episodes of body stiffening that were concerning for seizures and was given an intravenous loading dose of phenobarbital and transferred to a tertiary care center for further management. His initial head CT showed mild cerebral edema (*Fig. 365.1*). He was weaned off of mechanical ventilation and from all sedating medications, but he continued to lie in bed with his eyes closed, unresponsive to voice, with only flexion of the right arm with noxious compression of the sternum. His pupils were minimally reactive to light, and he had brisk oculocephalic reflexes, but his eyes were disconjugate at rest, and he demonstrated no visual tracking. Magnetic resonance imaging of the brain done on the fifth day of hospitalization showed brightness on diffusion and T-2 weighted images bilaterally in the thalami, basal ganglia, and subcortical white matter (*Figs. 365.2–365.4*). Magnetic resonance spectroscopy showed N-acetyl aspartate to creatine ratios more than four standard deviations below the mean for age in cortical and subcortical gray matter and a small amount of lactate in the occipital gray matter (*Figs. 365.5* and *365.6*). At the parents' request, the boy had a gastrostomy tube placed, and he was discharged 2 months later to their care in a condition best described as a coma due to a severe global hypoxic-ischemic brain injury.

Definition/Classification

Coma is a disease state of persistent unconsciousness that derives from the ancient Greek word for deep sleep. Patients may *awaken* from coma into normal consciousness or into other pathological states of altered or depressed consciousness, but this awakening does not occur in response to external stimuli of any kind. In coma, dysfunction of the brain prevents the generation of arousal and awareness, the two necessary components of full consciousness. The severe metabolic and structural injuries capable of causing coma carry a high risk of death and severe long-term neurological disability.

A patient who is fully conscious demonstrates both arousal or wakefulness and awareness of both their internal states, such as hunger, thirst, and pain, and their external world, such as it comes to them through visual, auditory, tactile, olfactory, or gustatory stimulation. Patients who are said to be *falling into* a coma show gradually decreasing levels of awareness, attention, and arousal, such that increasingly intense stimulation is required for them to show any response as they become lethargic, stuporous, and obtunded, and finally, comatose.

Most patients are only comatose for a short time, typically a period of several days to weeks, before either dying from their medical problems or beginning to show signs of improvement. When improvement occurs in arousal alone, with patients regaining spontaneous eye-opening and sleep–wake cycles but lacking clear signs of awareness of their internal or external state, purposeful action, or communicative ability, the condition is described as a *vegetative state*. If awareness partially recovers but is insufficient for consistent communication, a patient may be described as being in a *minimally conscious state*. Some patients recover from coma dramatically, passing quickly from lower to higher levels of function. Other patients remain in a prolonged or *permanent* vegetative or minimally conscious state.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_365,

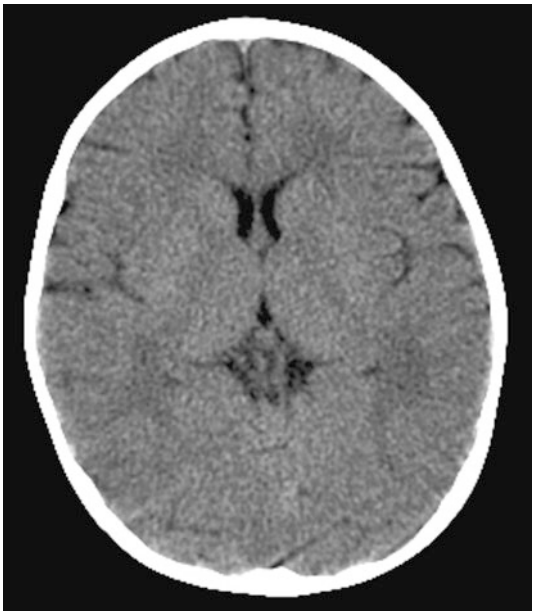

Figure 365.1
Eight hours after an 11-month-old boy suffered cardiopulmonary arrest, computed tomography showed loss of the distinction between the cortical gray and subcortical white matter with relative hypodensity of the supratentorial structures, suggesting bihemispheric cerebral edema

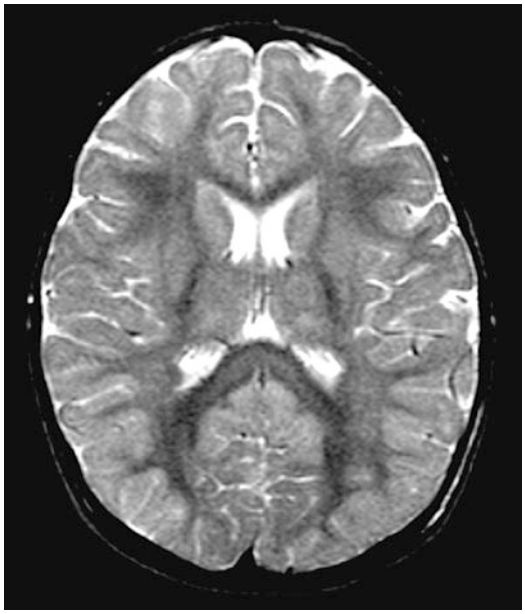

Figure 365.2
Five days after an 11-month-old boy suffered cardiopulmonary arrest, magnetic resonance imaging showed brightness on T2 weighted (Fig. 365.2) and diffusion weighted (Fig. 365.2) axial sequences and darkness on the apparent diffusion coefficient map (Fig. 365.3) within the bilateral subcortical white matter, corpus callosum, basal ganglia, and thalami, consistent with diffuse hypoxic-ischemic injury

Other disorders of consciousness include *delirium*, in which arousal may be heightened or depressed but in which attention and awareness fluctuate rapidly, and *akinetic-mutism*, in which arousal may be normal, but patients demonstrate minimal signs of attention and awareness only intermittently. The *locked-in syndrome* is often discussed with disorders of consciousness because it can mimic coma in many ways. Patients in a locked-in state are fully awake and aware but have motor impairments that make it difficult or impossible for them to demonstrate this on examination. Patients with psychiatric illnesses such as depression and schizophrenia may present with *catatonia* or *pseudocoma*, demonstrating dramatically reduced voluntary behavior and responsiveness, although they maintain normal consciousness and lack any structural or metabolic disturbance of brain function.

Brain death is also frequently discussed in association with coma. It was initially described by French physicians as a *state beyond coma* in which all signs of consciousness and all brainstem reflexes, including the respiratory drive, are irrevocably destroyed by injury. In most countries, this has come to be accepted as an alternative to cardiorespiratory arrest for defining the end of life. The major distinctions between the disorders of consciousness are outlined in *Table 365.1* and the differences between the vegetative and minimally conscious states are outlined in *Table 365.2*.

Etiology

Arousal is initiated and sustained by a complex neuronal network that widely distributes multiple sensory and circadian inputs to the cerebral cortex. Awareness and full consciousness likely arise from the integrated processing of this input in the polymodal association areas of the cortex. Coma can occur with relatively small structural injuries to the brainstem, more widespread cortical or subcortical injuries to both cerebral hemispheres, or diffuse metabolic disturbances that cause generalized impairment of neuronal function.

There are four main anatomical structures involved in the generation of arousal: the brainstem, thalamus, basal forebrain, and hypothalamus. Within the brainstem, the

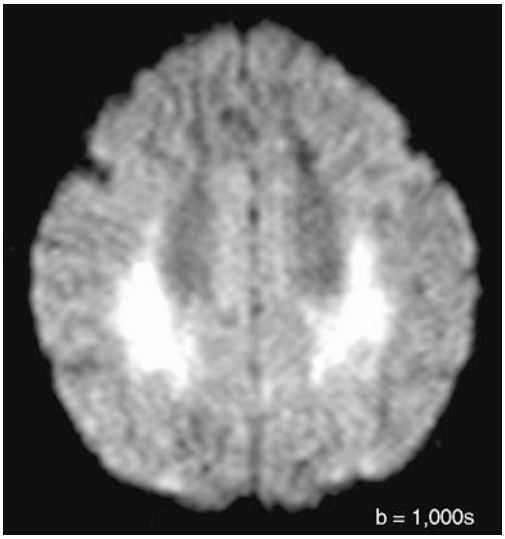

Figure 365.3
Five days after an 11-month-old boy suffered cardiopulmonary arrest, magnetic resonance imaging showed brightness on T2 weighted (Fig. 365.2) and diffusion weighted (Fig. 365.2) axial sequences and darkness on the apparent diffusion coefficient map (Fig. 365.3) within the bilateral subcortical white matter, corpus callosum, basal ganglia, and thalami, consistent with diffuse hypoxic-ischemic injury

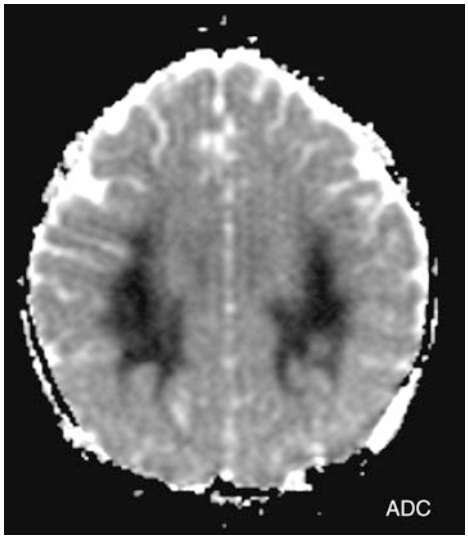

Figure 365.4
Five days after an 11-month-old boy suffered cardiopulmonary arrest, magnetic resonance imaging showed brightness on T2 weighted (Fig. 365.2) and diffusion weighted (Fig. 365.2) axial sequences and darkness on the apparent diffusion coefficient map (Fig. 365.3) within the bilateral subcortical white matter, corpus callosum, basal ganglia, and thalami, consistent with diffuse hypoxic-ischemic injury

ascending activating system (AAS) composed of excitatory glutamatergic neurons within the upper pontine and lower midbrain tectum relays a variety of stimuli along two pathways, the first to the thalamus and the second to the basal forebrain. Other structures and neurotransmitters from the brainstem, the pedunculopontine tegmental and laterodorsal nuclei (acetylcholine), locus ceruleus (noradrenaline), midline raphe nuclei (serotonin), and substantia nigra pars compacta (dopamine) modify arousal through both cortical and subcortical (thalamus, basal forebrain, and striatum) connections.

The thalamus participates in the generation of arousal through circuits which relay specific sensory inputs to the cortex and through nonspecific output from midline, medial, and intralaminar nuclei. The basal forebrain arousal system consists of the nucleus basalis of Maynert, the substantia innominata, the diagonal band of Broca, the magnocellular preoptic nucleus, the medium septum, and the globus pallidus. These structures receive input from the brainstem and hypothalamus and assist in the maintenance of the waking state via cholinergic excitation of the thalamus and cortex.

The hypothalamus contains histaminergic nuclei, predominantly in the tuberomammilary and posterior regions, which influence the activity of basal forebrain and thalamocortical neurons. The perifornicеal and lateral areas of the hypothalamus contain neurons that secrete orexins (hypocretins), which not only influence nearby histaminergic, noradrenergic, and serotonergic neurons but also have widespread arousal-promoting connections throughout the cerebral cortex.

The functional correlates of altered consciousness have been examined through advanced imaging studies of cerebral metabolism in conditions of physiologic (sleep), pharmacologic (anesthesia), and pathologic unconsciousness. The most consistent change across etiologies is the deactivation of the polymodal association cortices, including the bilateral lateral frontal, medial frontal, parietotemporal, posterior parietal, precuneal, and posterior cingulate areas. The posterior cingulate in particular shows early and dramatically decreased metabolism in unconsciousness, even beyond that seen in the thalamus, and it has the highest basal metabolism in normal conscious wakefulness.

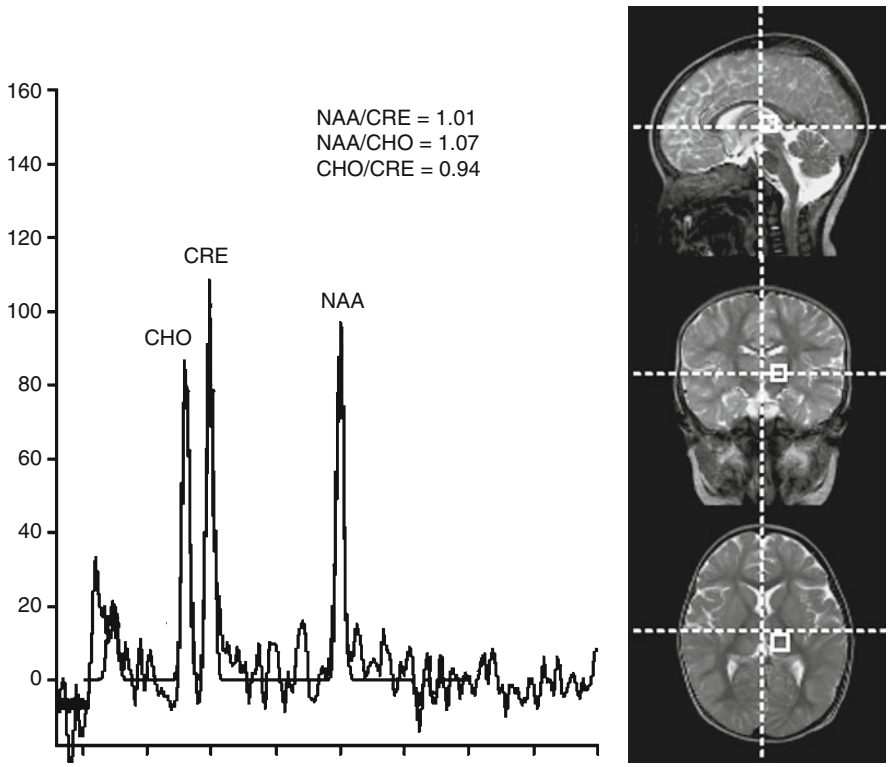

Figure 365.5

Five days after an 11-month-old boy suffered cardiopulmonary arrest, magnetic resonance spectroscopy showed NAA/Cr ratios more than four standard deviations below the mean in the occipital gray matter (*Fig. 365.5*) and left thalamus (*Fig. 365.6*). A small lactate peak was also discernible in the occipital cortex, consistent with the injury being due to ischemia

In most cases of coma, such as those resulting from severe traumatic brain injury, global hypoxic ischemic injury, or the progression of a previously known disease state, the etiology is clear from the initial history and physical examination. An unexplained coma is a true medical emergency and such patients require immediate testing for treatable causes. A listing of broad categories for the etiology of coma, along with subcategories and specific examples, is given in *Table 365.3*.

Epidemiology

In the United States, coma has a yearly incidence of approximately 60 per 100,000 children, and cases are fairly evenly divided between traumatic and non-traumatic causes of brain injury. A prospective, population-based study of non-traumatic coma in the United States from 2001 found that infection was responsible for 38% of pediatric cases, with *Neiserria meningitidis* being the most commonly identified organism. Toxic ingestions, both accidental and non-accidental, were responsible for 10% of all cases and for 35% of cases among adolescents. Seizures, congenital heart disease, brain malformations, accidental drowning, diabetes, and inborn errors of metabolism were among the other common etiologies of non-traumatic coma in children. A smaller but more recent study from India also found infection to be the most common cause of pediatric non-traumatic coma. Sixty percent of cases were attributed to infections and *Mycobacterium tuberculosis* was the most commonly identified organism.

In their now landmark study from 1984 of 500 adults with coma of initially unknown cause, Plum and Posner found that 65% had diffuse metabolic causes, usually from poisonings and intoxications. They also found that 20% had supratentorial mass lesions, including 77 hemorrhages and 9 infarctions, and that 13% had infratentorial lesions, which were mainly brainstem infarctions. Eight of their patients had psychiatric pseudocoma.

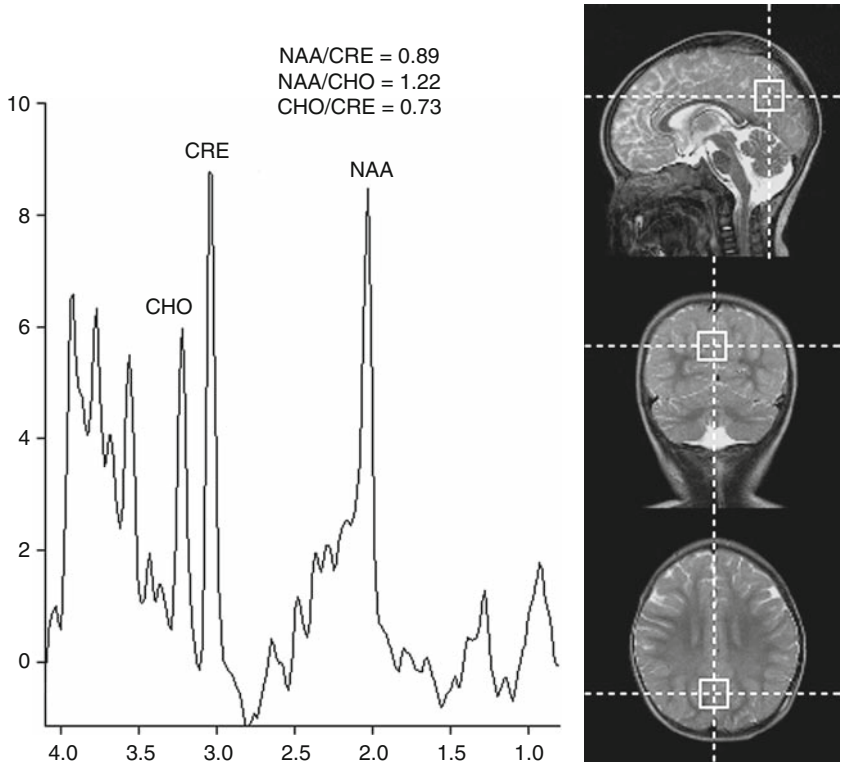

Figure 365.6

Five days after an 11-month-old boy suffered cardiopulmonary arrest, magnetic resonance spectroscopy showed NAA/Cr ratios more than four standard deviations below the mean in the occipital gray matter (*Fig. 365.5*) and left thalamus (*Fig. 365.6*). A small lactate peak was also discernible in the occipital cortex, consistent with the injury being due to ischemia

Table 365.1

Disorders of consciousness. The disorders of consciousness discussed in the text are differentiated from normal by the degree to which arousal, awareness, and motor function are impaired

Condition	Arousal	Awareness	Motor function
Normal consciousness	Normal	Normal	Normal
Locked-in syndrome	Normal	Normal	Low to absent
Akinetic-mutism	Normal	Low	Intermittent
Delirium	High or low	Low	High or low
Lethargy	Mildly low	Mildly low	Mildly low
Stupor	Moderately low	Moderately low	Moderately low
Obtundation	Severely low	Severely low	Severely low
Coma	Absent	Absent	Low
Vegetative state	Variable	Absent	Low
Minimal consciousness	Variable	Low	Low
Brain death	Absent	Absent	Absent

Table 365.2

Vegetative and minimally conscious states. The diagnostic criteria for these disorders of consciousness have been put forward by the American Academy of Neurology

Vegetative state	Minimally conscious state
No evidence of self- or environmental awareness, with demonstration of all of the following: • No evidence of sustained, reproducible, purposeful, or voluntary behavioral responses to visual, auditory, tactile, or noxious stimuli • No evidence of language comprehension or expression • Intermittent wakefulness occurring with sleep–wake cycles • Sufficiently preserved autonomic function to survive with supportive care	Limited but reproducible evidence of self- or environmental awareness, demonstrated by one of the following: • Purposeful movements or affect expressions in response to relevant environmental stimuli that are not purely reflexive • Simple command following, gestural or verbal yes/no responses (regardless of accuracy), or intelligible verbalization

Table 365.3

Etiologies for coma. Broadly defined etiologic categories for coma, along with subcategories and specific examples

Category	Subcategory	Examples
Non-structural	External toxins	Carbon monoxide, cyanide, ethylene glycol, lead, methanol, mushrooms, thallium
	Medications	Alcohol, amphetamines, anticholinergics, antipsychotics, barbituates, bromides, lithium, monoamine oxidase inhibitors, opioids, paraldehyde, phencyclidine, salicylates, sedative hypnotics
	Organ failure	Hyper- or hypocalcemia, cortisolism, glycemia, natremia, tension, thermia, or thyroidism; hyperammonemia, hypercapnea, hypoxia, ketoacidosis, porphyria, uremia, Wernicke encephalopathy
	Infections	Cerebral malaria, encephalitis, meningitis, post-infectious encephalitis, sepsis, syphilis, typhoid fever
	Other	Postictal state
Structural – symmetrical	Supratentorial	Bilateral anterior cerebral or carotid artery occlusion, hydrocephalus, thalamic hemorrhages, traumatic brain injury
	Infratentorial	Basilar artery occlusion, midline brainstem tumor, pontine hemorrhage
Structural – asymmetrical	Supratentorial	Acute disseminated encephalomyelitis, adrenoleukodystrophy, cerebral abscess, cerebral vasculitis, chemotherapy-related leukoencephalopathy, Creutzfeldt–Jakob disease, disseminated intravascular coagulation, fat embolization, hemispheric mass (tumor, bleed, and abscess) with herniation, intracerebral bleeds, massive or bilateral infarctions, progressive multifocal leukoencephalopathy, multiple sclerosis, nonbacterial thrombotic (marantic) endocarditis, pituitary apoplexy, subacute bacterial endocarditis, thrombophlebitis, thrombotic thrombocytopenic purpura
	Infratentorial	Brainstem hemorrhage, brainstem infarction

Clinical Evaluation

The initial assessment and management of a comatose patient should address the adequacy of basic life support functions, ensuring that the patient has a patent airway and adequate respiration, oxygenation, and circulation.

Patients with an altered level of consciousness can aspirate oral secretions and thus may require

prophylactic intubation and ventilation even when the underlying cause of their coma has not otherwise compromised their respiratory function. Patients with a traumatic or unknown cause of coma should be assumed to have a spinal cord injury until proven otherwise and treated with appropriate spinal precautions. Initial measurement of blood sugar as well as repeated measurements of the vital signs, including temperature, arterial blood gas determination (hypoxia, hypercarbia), blood pressure, heart rate, and respiratory rate, aid in the diagnosis and avoidance of correctable causes of further injury. Some patients will require urgent medical or surgical interventions before they are stable enough for a detailed neurodiagnostic evaluation.

All patients should be given high concentrations of supplemental oxygen until continuous oxygen saturation monitoring is possible. In patients with known diabetes, coma of unknown etiology, or measured hypoglycemia (less than 60 mg/dL), treatment with supplemental glucose is warranted. A 0.5 g/kg intravenous bolus of dextrose should be given using a 10% solution in neonates, a 25% solution in children under 30 kg, and a 50% solution in larger children. Unlike adult patients, who may have unrecognized chronic malnutrition, children do not require intravenous thiamine prior to receiving intravenous dextrose to prevent Wernicke encephalopathy. The benefits of treating coma due to hypoglycemia outweigh any theoretical drawback of giving supplemental glucose to patients with anoxic or ischemic brain injury. Diabetics with hypoglycemia should also be given a 0.1 mg/kg (maximum 1 mg) intravenous dose of glucagon.

Intravenous naloxone hydrochloride should be given to patients with coma of unknown etiology at a dose of 0.1 mg/kg (maximum 2 mg) to reverse possible accidental or intentional opioid toxicity. Most children are at little risk for the severe withdrawal effects, which can be precipitated by naloxone use in patients with established opioid dependence.

A detailed and systematic general physical examination, done once the patient has been stabilized, can help determine the underlying cause of coma. The sections that follow review some of the more important considerations.

Vital Signs

Hypotension will cause loss of consciousness when the mean arterial blood pressure drops below levels for which cerebral autoregulation can maintain adequate cerebral blood flow. Hypotension may result from shock, poisoning, or damage to the medullary pressor center. Hypotension due to hypovolemia, whether from dehydration or hemorrhage, is associated with peripheral vasoconstriction and cool extremities. Hypotension due to septic shock and Addisonian crisis is associated with peripheral vasodilation and warm extremities.

Severe hypertension will overwhelm the autoregulatory capacity of cerebral blood vessels and lead to vasogenic edema and hemorrhagic infarction. Hypertension may be seen with renal disease, poisoning, or as an adaptive response to any cause of increased intracranial pressure (ICP). The Kocher–Cushing reflex response to increased ICP, frequently referred to as *Cushing's triad*, consists of hypertension, bradycardia, and irregular respirations and is caused by compression or ischemia of the medullary pressor center.

Bradycardia can also be seen with myocardial injury and with poisonings, such as with beta-blockers or cholinergic agonists. Tachycardia may result from hypotension, hyperthyroid storm, fever, anemia, hypoxia, and poisoning with stimulants and anticholinergics.

Respiratory depression can be seen with poisonings and with carbon dioxide retention from impaired pulmonary gas exchange. Tachypnea can be seen with hypoxia, fever, and various causes of metabolic acidosis, including sepsis, diabetic ketoacidosis, renal failure, hepatic failure, and poisonings with such substances as methanol, ethylene glycol, paraldehyde, and salicylates. Damage to the basal forebrain, thalami, or hypothalamus may result in *Cheyne-Stokes respirations*, with slowly alternating hypoventilation and hyperventilation. The emergence of such a respiratory pattern in a comatose patient may be an early sign of central herniation.

Other abnormal respiratory patterns can be seen with brainstem injuries and can be seen sequentially during central herniation. Damage to the low midbrain ventral to the aqueduct of Sylvius or of the upper pons ventral to the fourth ventricle can cause *central neurogenic hyperventilation*. Hyperventilation in comatose patients is far more commonly caused by compensation for metabolic acidosis or hypoxia. Metabolic acidosis, such as with diabetic ketoacidosis, can cause *Kussmaul breathing*, with deep, regular respirations. Lesions of the dorsolateral tegmentum of the middle and caudal pons medulla may cause *apneustic breathing*, in which the patient breathes inward quickly, pausing at full inspiration. *Cluster breathing* shows great variability in the pauses between breaths and can be seen with lower pontine tegmental lesions. Progressively irregular respiratory rate and rhythm may be referred to as *ataxic or agonal breathing*, seen with damage to the reticular formation of the dorsomedial medulla, at times immediately prior to the onset of complete apnea.

Fever may occur as a result of subarachnoid hemorrhage, intraparenchymal hemorrhage, or hypothalamic injury. Fever can also result from heatstroke, thyroid storm, and from poisonings such as with anticholinergic toxicity, neuroleptic malignant syndrome, or serotonin syndrome. Shivering without sweating is suggestive of fever of neurologic or toxic etiology. However, fever is usually a sign of infection and, in a comatose patient, it should prompt consideration of a diagnosis of meningitis or encephalitis, whether or not meningismus is present. Fever may be absent when infection occurs in young infants or in the setting of renal failure, hypothyroidism, or immunocompromise. Empirical use of broad spectrum intravenous antibiotics at meningitic doses is preferable to waiting for the results of cerebrospinal fluid (CSF) testing by lumbar puncture. In patients with altered consciousness or any focal neurological disturbance, use of computed tomography (CT) of the brain is favored, if available, to look a supratentorial mass lesion that might lead to the lumbar puncture precipitating downward transtentorial herniation and brainstem compression.

Hypothermia is usually due to cold exposure but can also be caused by sepsis, hypothyroid coma, hypopituitarism, Wernicke encephalopathy, lesions of the posterior hypothalamus, and poisonings such as with barbiturate overdose. Hypothermia is more likely to be due to a neurological cause in patients who are sweating but not shivering. Several well-described toxidromes are summarized in *Table 365.4*.

Head, Eyes, Ears, Nose, Throat, and Neck

The head and neck examination may reveal occult signs of trauma, such as scalp laceration, scalp edema or hematoma, or depressed skull fracture. Anterior basal skull fracture may cause bruising around the orbits (*raccoon eyes*) and temporal bone fracture may cause bruising over the mastoid portion of the bone (*Battle's sign*) but these findings may first appear several days after injury. Signs of meningismus, including nuchal rigidity, may be masked by coma but generally indicate meningeal irritation, which can occur with meningitis, inflammation of surrounding structures (e.g., retropharyngeal abscess), carcinomatosis, subarachnoid hemorrhage, or transtentorial herniation. Patients with hypothyroidism or hyperthyroidism may have a generally enlarged, asymmetrical, or nodular thyroid gland.

Edema of the conjunctiva or eyelids suggests fluid overload, as occurs in congestive heart failure, or reduced osmotic pressure, as occurs with hypoalbuminemia or nephrotic syndrome. Sunken orbits would suggest severe (>10%) dehydration. Conjunctival petechiae can be seen with thrombophilia as well as with fat embolism, as may occur after long bone fracture from trauma or surgery. The sclerae may become icteric with hyperbilirubinemia and liver disease. The lenses may show band keratopathy with hypercalcemia or cataracts with hypocalcemia. Brown Kayser–Fleischer rings at the margin of the iris are seen with copper deposition in patients with Wilson's disease.

The funduscopic examination may show the chronic effects of long-standing medical conditions, such as hypertension or diabetes, or reveal acute changes such as papilledema due to increased ICP, retinal hemorrhages from trauma, retinal edema from methyl alcohol poisoning, or grayish retinal deposits from lead poisoning.

The otoscopic exam may reveal a middle ear infection or evidence of a fracture through the temporal bone with evidence of hemotympanum or CSF otorrhea. Clear or serosanguinous drainage from the ear canal or nose can be tested for glucose or, more specifically, beta trace protein (prostaglandin B synthase) or beta-2-transferrin, to identify CSF leakage.

The patient's breath may suggest alcohol intoxication, diabetic ketoacidosis, or acetone, phenol, or salicylate ingestion (fruity acetone odor); uremia (ammonia odor); hepatic encephalopathy (musty odor or *fetor hepaticus*); arsenic, phosphorus, organophosphate, or thallium poisoning (garlic odor); cyanide poisoning (bitter almond odor); or oral, pharyngeal, or sinus infection (foul odor). Examination of the oral cavity may find lacerations of the tongue to suggest convulsions or blue-black gingival staining to suggest bismuth, mercury, or lead poisoning.

Skin

A comprehensive head-to-toe and back-to-front inspection of the skin, hair, and nails may show signs of dehydration, drug exposure, trauma, or infection. The skin may be hot and dry in the setting of heatstroke or anticholinergic poisoning or hot and sweaty as part of the sympathetic response to hypotension or hypoglycemia. The relevance of various skin findings to the etiology of coma is reviewed in *Table 365.5*.

Other General Examination

Cardiac auscultation can reveal arrhythmias and murmurs associated with structural heart disease, cardiomyopathy,

Table 365.4

Toxidromes with coma. The characteristic changes associated with various categories of poisonings

Toxidrome	Pupils	Cardiovascular --- Respiratory	Temperature --- Skin	Other	Examples
Anticholinergics	Dilated	Tachycardia, hypertension --- Tachypnea	Hyperthermia --- Dry and flushed	Dry mucous membranes, quiet bowel sounds, urinary retention, myoclonus and seizures	Antihistamines, tricyclic antidepressants, cyclobenzaprine, orphenadrine, antiparkinson agents, antispasmodics, phenothiazines, atropine, scopolamine, belladonna alkaloids (Jimson Weed)
Sympatho-mimetics	Dilated	Tachycardia, hypertension, widened pulse pressure --- Tachypnea, Hyperpnea	Normal --- Diaphoresis	Tremors, hyperreflexia, seizures	Cocaine, amphetamines, ephedrine, pseudoephedrine, phenylpropanolamine, theophylline, caffeine
Hallucinogens	Dilated	Tachycardia, hypertension --- Tachypnea	Hyperthermia --- Normal		PCP, LSD, mescaline, psilocybin, MDMA, MDEA
Opioids	Small	Bradycardia, hypotension --- Bradypnea, pulmonary edema	Hypothermia --- Needle marks		Opioids (heroin, morphine, methadone, oxycodone, hydromorphone), diphenoxylate
Sedative-hypnotics	Small	Bradycardia, hypotension --- Bradypnea, hypopnea	Hypothermia --- Normal	Hyporeflexia	Benzodiazepines, barbiturates, carisoprodol, meprobamate, glutethimide, alcohols, zolpidem
Cholinergics	Small	Bradycardia, hypertension or hypotension --- Tachypnea or bradypnea	Normal --- Diaphoresis	Salivation, urinary and fecal incontinence, diarrhea, emesis, lacrimation, GI cramps, bronchoconstriction, fasciculations, seizures	Organophosphate and carbamate insecticides, nerve agents, nicotine, pilocarpine, physostigmine, bethanecol, urecholine
Serotonin syndrome	Dilated	Tachycardia, hypertension --- Tachypnea	Hyperthermia --- Diaphoresis and flushing	Tremor, myoclonus, hyperreflexia, trismus, rigidity, diarrhea	MAOIs, SSRIs, meperidine, dextro-methorphan, TCAs, L-tryptophan
Tricyclics	Dilated	Tachycardia, hypertension then hypotension, arrhythmias and cardiac conduction disturbances --- Hypopnea	Hyperthermia --- Normal	Seizures, myoclonus, choreoathetosis	Amitriptyline, nortriptyline, imipramine, clomipramine, desipramine, doxepin

Table 365.5

Skin changes in coma. Various skin findings which may be seen in association with unexplained coma and examples of the underlying causes

Skin change	Underlying cause
Antecubital needle marks	Opioid abuse
Pale skin	Anemia or hemorrhage
Sallow, puffy appearance	Hypopituitarism
Hypermelanosis	Porphyria, Addison's disease, chronic nutritional deficiency, disseminated malignant melanoma, chemotherapy
Generalized cyanosis	Hypoxemia, carbon dioxide poisoning
Grayish-blue cyanosis	Methemoglobin (aniline or nitrobenzene) intoxication
Localized cyanosis	Arterial emboli, vasculitis
Cherry-red skin	Carbon monoxide poisoning
Icterus	Hepatic dysfunction, hemolytic anemia
Petechiae	Disseminated intravascular coagulation, thrombotic thrombocytopenic purpura, drugs
Ecchymosis	Trauma, corticosteroid use, abnormal coagulation from liver disease or anticoagulants
Telangiectasia	Chronic alcoholism, vascular malformations of the brain
Vesicular rash	Herpes simplex, varicella, Behcet's disease, drugs
Petechial-purpuric rash	Meningococcemia, gonococcemia, staphylococcemia, *pseudomonas* infection, subacute bacterial endocarditis, allergic vasculitis, purpura fulminans, Rocky Mountain spotted fever, typhus, fat emboli
Macular-papular rash	Typhus, *Candida* infection, *Cryptococcus* infection, toxoplasmosis, subacute bacterial endocarditis, staphylococcal toxic shock, typhoid, leptospirosis, *Pseudomonas* sepsis, immunological disorders, systemic lupus erythematosus, dermatomyositis, serum sickness
Ecthyma gangrenosum	*Pseudomonas* sepsis
Splinter hemorrhages, Osler's nodes, gangrene of digits	Subacute bacterial endocarditis, anemia, leukemia, sepsis

and valvular disease associated with endocarditis. Peritoneal lavage may be required to exclude hemorrhagic abdominal injury in a comatose patient with known or suspected trauma. Bowel sounds are hypoactive in many acute abdominal conditions and with anticholinergic poisoning. Hyperactive bowel sounds are seen with acetylcholinesterase inhibitor toxicity.

Hepatomegaly is seen with right heart failure, lysosomal and glycogen storage disorders, and hepatic tumors. A nodular or hard liver edge can be seen with hepatic tumors and with cirrhosis. Splenomegaly can be seen with portal hypertension, hematological malignancies, infections, and collagen vascular diseases. Ascites can be seen in association with liver disease, right heart failure, and ovarian cancer.

Breast, testicular, and rectal examination may reveal primary tumors. Stool testing for occult gastrointestinal bleeding may indicate a bowel carcinoma. Gastrointestinal bleeding can precipitate hyperammonemic encephalopathy in patients with cirrhotic liver failure. Generalized lymphadenopathy can be seen with hematologic malignancy, infections, immunodeficiency states, collagen vascular diseases, hyperthyroidism, Addison disease, and drug reactions. Localized adenopathy suggests a nearby malignancy or infection.

Level of Consciousness

The state of consciousness should be described in detail to avoid ambiguity. The patient should be tested with cues of increasing intensity, with stimulation progressing from verbal to visual to noxious, and the maximal response should be recorded. Voluntary eyelid and vertical eye

movements are sometimes preserved in locked-in syndromes due to anterior brainstem injuries and should be tested for in all patients with apparent coma.

The Glasgow Coma Scale (GCS) records the best eye opening, motor, and verbal response of the patient and is in widespread use in emergency rooms and intensive care units around the world. The verbal response scale has been modified for preverbal children in the Pediatric Coma Scale (PCS) (*Table 365.6*). The GCS and PCS correlate with long-term morbidity and mortality but have low predictive value as single measures of the severity of injury. One significant drawback of these scales is that patients who are intubated or who have suffered severe facial trauma will necessarily score lower in the eye opening and verbal subscales. Another is that neither of the scales directly records brainstem reflexes, such as the pupillary light reflex, that are strongly predictive of the outcome.

Pupillary Reflexes

Normal pupillary dilation in dim light depends on intact sympathetic efferents which arise in the hypothalamus, synapse in the thoracic level of the spinal cord, synapse again in the superior cervical sympathetic ganglion, and then travel along with the internal carotid arteries to the ciliary ganglia and the pupillodilator muscles of the iris. Constriction of the pupils in response to light depends on the afferents from the optic nerves reaching their projections to the parasympathetic Edinger–Westphal nuclei of the midbrain tectum and on the efferent nerves arising there and traveling along the surface of the oculomotor nerves to the ciliary ganglia and the pupillosphincter muscles of the iris.

Thalamic lesions, pontine lesions, and toxic-metabolic causes of coma that impair sympathetic inputs to the pupils leave them small, even pinpoint, but reactive. The reaction to light may be so slight as to require magnification, such as through an otoscope, to observe. Lesions along the sympathetic pathway can also cause *Horner syndrome*, a triad of ipsilateral miosis, mild ptosis due to denervation of the superior and inferior tarsal muscles of the eyelids, and anhydrosis of the face, neck, and arm. Midbrain lesions that interrupt both sympathetic and parasympathetic pathways result in fixed and irregular midposition pupils which may be unequal. An injury to the midbrain or to the third nerve that only affects parasympathetic function causes the ipsilateral pupil to be large and unresponsive to light. A sluggishly reactive pupil may be due to partial compression of the oculomotor nerve and occurs early during uncal herniation, prior to pupillary dilation and oculomotor palsy. Pupillary abnormalities can be of a fixed nature due to prior ocular or neurological injury or may be transient due to seizures

Table 365.6
Coma scales. The components and scores for the Glasgow Coma Scale and Pediatric Coma Scale are outlined

Sign	GCS	PCS	Score
Eye opening	Spontaneous	Spontaneous	4
	To command	To sound	3
	To pain	To pain	2
	None	None	1
Verbal response	Oriented	Age-appropriate vocalization, smile, or orientation to sound	5
	Confused, disoriented	Irritable, consolable, uncooperative, aware of the environment	4
	Inappropriate words	Irritable, inconsistently consolable	3
	Incomprehensible sounds	Inconsolable, unaware of the environment, restless, agitated	2
	None	None	1
Motor response	Obeys commands	Obeys commands, spontaneous movements	6
	Localizes pain	Localizes pain	5
	Withdraws	Withdraws	4
	Abnormal flexion to pain	Abnormal flexion to pain	3
	Abnormal extension to pain	Abnormal extension to pain	2
	None	None	1
Best total score			15

or ophthalmic or systemic medications with effects on the autonomic nervous system.

Ocular Movements

Normal conjugate ocular motility, whether spontaneous or reflexive, requires intact function of the brainstem from the vestibular nuclei at the pontomedullary junction to the oculomotor nuclei in the midbrain. Its presence helps to reduce suspicion for a brainstem injury as a primary cause of coma. The resting position of the eyes when the patient is maximally stimulated may show a discrepancy in eye position, representing weakness of one of the extraocular muscles. Oculomotor or third nerve palsy from a midbrain lesion or from compression of the nerve results in severe ptosis and downward and lateral deviation of the eye. Abducens or sixth nerve palsy results in inward deviation of the eye and can result from an injury to the nucleus in the pons or to compression of the nerve anywhere along its extensive course, which can be due to increased ICP. Trochlear or fourth nerve palsies are inapparent in comatose patients. Conjugate eye deviations at rest are usually due to lesions that disrupt the input to the lateral gaze centers adjacent to the abducens nuclei (parapontine reticular formations) from the contralateral frontal eye fields in the premotor cortex. Downward deviation of the eyes is seen not only in midbrain injury, particularly compression of the midbrain tectum but also in hepatic failure and some other metabolic causes of coma. Downward and inward deviation of the eyes, such that patients appear to be looking at their nose, can occur with thalamic or subthalamic lesions. Conjugate upward deviation of the eyes is not a particularly helpful sign for the localization of lesions causing coma.

Nystagmus can be a sign of an irritative or epileptogenic cause of coma, which can occur in isolation or with other subtle motor signs of seizure activity such as twitching movements of the eye, eyelid, face, jaw, or tongue. Vertical *ocular bobbing*, whether upward or downward, generally indicates diffuse and severe brain injury. When the bobbing involves rapid downward jerking and a slow return to midposition, in association with lateral gaze paralysis, it is typically due to an acute pontine injury. *Ocular flutter*, with conjugate horizontal saccades, is reflective of dysfunction of the cerebellum.

Reflexive ocular movements can be elicited by sudden, rapid head turning (oculocephalic reflex), or by cold water irrigation of the ear canals (vestibuloocular reflex). The oculocephalic reflex clearly cannot be tested in patients with a known or possible cervical spine injury. When the oculocephalic reflex is preserved, the eyes move conjugately in a direction opposite to the direction the head turns, as would be required to maintain gaze fixation. This is sometimes referred to as the *doll's eye* reflex or phenomenon being positive, but due to ambiguity regarding these terms the ocular response should simply be described. Caloric testing is done with the patient supine, with the head raised 30° from horizontal to maximally stimulate convection currents in the endolymph of the lateral semicircular canal. The ear canal is visualized to ensure that it is unobstructed, and that the tympanic membrane is intact, and 10 mL of ice-cold water is slowly instilled. When the vestibuloocular reflex is intact, the eyes will show conjugate deviation toward the cold ear canal. Corrective nystagmus away from the slow deviation and back to a point of visual fixation is seen only in conscious subjects. Irrigation of the ear canals with warm water causes slow conjugate eye deviation away from the warmed canal in the comatose patient and additional nystagmus back toward the point of visual fixation in the conscious patient. The mnemonic COWS (cold opposite, warm same) refers to the fast phase of the nystagmus seen in conscious patients. Simultaneous bilateral cold water irrigation would result in slow downward eye deviation and simultaneous bilateral warm water irrigation would cause slow upward eye deviation. Oculocephalic and caloric testing can be abnormal due to diffuse brainstem lesions, individual cranial nerve palsies, restrictive eye disease, including severe globe and eyelid edema, or vestibular dysfunction due to ototoxic, sedative, paralytic, or anticholinergic medications.

Motor Exam

The purposeful and reflexive movements of the limbs are helpful localizing signs in the examination of the comatose patient. Flaccid hemiparesis with conjugate gaze toward the paralysis indicates a pontine lesion affecting the contralateral pyramidal tract and the ispilateral abducens nucleus. Flaccid hemiparesis with conjugate gaze away from the paralysis can occur with a supratentorial lesion disrupting the contralateral pyramidal tract and corticobulbar tract to the parapontine reticular formation. Generalized flaccidity can be seen early with any cause of coma, including diffuse supratentorial injuries, brainstem injuries, or metabolic encephalopathies. Hypertonicity of the limb muscles due to injury to the motor system, whether unilateral or generalized, usually takes time to develop.

Decorticate posturing is flexion at the elbow and wrist, adduction of the shoulder, and extension of knee and

ankle. Its presence indicates disruption of corticospinal tracts above the rubrospinal pathway from the midbrain (upper limb flexion) and the vestibulospinal pathway from the pontomedullary junction (upper and lower limb extension). *Decerebrate posturing* is extension at the elbow and wrist, adduction and internal rotation of the shoulder, and extension of the knee and ankle. Bilateral decerebrate posturing is usually due to bilateral midbrain or pontine lesions that disrupt the corticospinal and rubrospinal tracts, leaving the vestibulospinal pathways unopposed. Bilateral decerebrate posturing is a far more ominous sign than decorticate posturing or unilateral posturing of either kind, which can be seen with transient injuries anywhere along the motor system.

Posturing may sometimes be mistaken for tonic or clonic seizure activity but it needs to be recognized because it may indicate progressive brainstem compression due to an expanding posterior fossa mass lesion or to transtentorial herniation. Convulsive movements due to seizures may be overt but also can be quite subtle, particularly in established refractory status epilepticus. Myoclonus that is non-rhythmic and not generalized can occur with many metabolic causes of coma, including global hypoxic-ischemic encephalopathy or hepatic encephalopathy. Myoclonus that is rhythmic and generalized can occur with anoxic injury and is predictive of a dismal outcome when caused by myoclonic status epilepticus. Rhythmic myoclonus due to a brainstem injury and tonic posturing due to hypocalcemia can also mimic epileptic convulsions.

Limb movements in response to local pain should be tested and recorded, although many such responses are mediated by spinal reflexes that can easily be mistaken for purposeful withdrawal and are generally unhelpful for defining the cause or severity of coma. Withdrawal of an arm from a painful stimulus that includes abduction at the shoulder is reliably non-reflexive and indicates some preservation of the spinothalamic and corticospinal tracts. Purely reflexive withdrawal of the arm can be as complex as to include adduction of the shoulder, flexion of the elbow, and pronation of the arm. The complex but purely reflexive withdrawal of the leg known as the *triple flexion response* includes flexion of the hip, flexion of the knee, and dorsiflexion of the ankle. The extensor plantar reflex of the foot or *Babinski sign* is nonlocalizing and can be seen in coma from any cause.

Brain Herniation

The Monroe–Kellie hypothesis states that because the volume of the skull is fixed, when there is an increase in the volume of any one of the intracranial contents (brain, blood, CSF), there must be a compensatory decrease in the volume of the others. This will hold true for an infant with unfused sutures if the changes in volume and pressure are too great or rapid for suture widening to accommodate. In the setting of an expanding intracranial mass lesion such as a subdural hematoma, for example, there will initially be a compensatory decrease in CSF volume due to the compression of lateral ventricles and arachnoid cisterns, and a decrease in cerebral blood volume due to the compression of cerebral veins and sinuses. When the hematoma is small, these compressible spaces allow increases in volume to have little effect on the ICP and the system is described as compliant. When these spaces are maximally compressed, however, the system loses its compliance. Further and relatively small increases in hematoma volume will cause more dramatic increases in ICP and dangerous displacements of arterial blood and brain tissue.

Caudal displacements of brain tissue include *uncal herniation* of the medial temporal lobe beneath the tentorium and *central herniation* of the diencephalon through the tentorium and of the brainstem through the foramen magnum. Comatose patients with known or suspected increased ICP must be watched carefully for signs of these forms of life-threatening herniation. In most, in the setting of an expanding lateral mass lesion, there is a lateral shift of the diencephalon away from the mass and compression of the third nerves against the tentorium. Typically, this involves the third nerve ipsilateral to the mass lesion, but the contralateral third nerve can be affected first, or both nerves can be affected simultaneously. Early compression leads to dysfunction of the more superficially located parasympathetic fibers to the eye and to a dilated and nonreactive pupil. Further compression of the third nerve leads to ptosis and a fixed lateral and downward gaze. With further lateral displacement of the diencephalon and midbrain, there is a compression of the cerebral peduncles of the midbrain against the tentorium, causing signs of pyramidal tract dysfunction such as hemiplegia or decorticate posturing. This may occur on either side but usually occurs first in the contralateral cerebral peduncle, causing the *Kernohan's notch phenomenon*, with pyramidal dysfunction in the limbs ipsilateral to the mass lesion. Loss of the sympathetic input to the eye from the diencephalon will cause a previously dilated pupil to become midposition but remain nonreactive. Severe lateral displacement will finally lead to actual herniation of the most medial portion of the temporal lobe (uncus) through the tentorium and to caudal displacement of the brainstem through the foramen magnum or central herniation.

Central herniation can also occur directly with the downward displacement of the diencephalon, such as might be caused by bilateral mass lesions, including obstructive hydrocephalus. The signs of central herniation may evolve in a rostrocaudal fashion, with loss of midbrain function being followed by loss of pontine and then medullary function. Early signs of midbrain dysfunction include deepening coma, loss of sympathetic inputs to the eyes that leave them small but reactive to light, loss of reflexive vertical gaze, and bilateral corticospinal tract dysfunction with weakness or posturing. Lower midbrain injury can cause further loss of parasympathetic inputs to the eyes that leave them midpositioned and nonreactive to light, more complete loss of eye movements mediated by the third nerve nuclei, and loss of the rubrospinal tract that causes posturing to become decerebrate. Central neurogenic hyperventilation is sometimes, but infrequently, seen with midbrain compression. Diencephalic and midbrain injuries in an unventilated patient are more likely to present with a Cheyne-Stokes pattern of respiration.

Involvement of the pons and midbrain will lead to a loss of virtually all cranial nerve reflexes, flaccid paralysis with loss of all posturing, and increasingly dysfunctional respiratory patterns described as apneustic, ataxic, and, finally, agonal. Central herniation does not always progress in a slow or stepwise fashion, and medullary signs of severe autonomic dysfunction may be present early. Herniation may progress precipitously soon after the first signs of increased ICP are noted and the structural injuries associated with the brainstem signs outlined above may be irreversible. Close monitoring and early intervention are needed to manage increases in ICP. The measures available for decreasing ICP are outlined in *Table 365.7*.

Table 365.7
Interventions to decrease ICP

Decrease cerebral blood volume
30° head elevation in neutral position
Hyperventilation to a pCO_2 of 25–30 mmHg
Anesthetic agents (barbiturates, propofol) to reduce $CMRO_2$
Paralytic agents to reduce resistance to ventilation
Analgesic agents to reduce agitation
Prevention of hyperthermia with aggressive cooling measures
Decrease extracellular fluid and CSF volume
Osmotic diuretics (mannitol, 3% saline)
Loop diuretics (furosemide)
Corticosteroids (dexamethasone)
Carbonic anhydrase inhibitors (acetazolamide)
Intraventricular drainage of CSF
Decrease/ameliorate intracranial brain tissue volume
Decompressive lesionectomy
Decompressive resection of adjacent brain tissue
Decompressive craniectomy and dural expansion

History

Ideally, a clinical history will be obtained concurrently by the physician or other team members while the patient is being transported, stabilized, and put through initial examinations and laboratory tests. Attempts should be made to contact those who may know about the patient's past medical history or who may have witnessed the events leading up to the patient's loss of consciousness. A family member or bystander may have witnessed trauma or seizures. Others caring for the child may be aware of a past history of disease predisposing to loss of consciousness or be aware of the presence and time course of any prodromal symptoms. Complaints from the child suggestive of increased ICP or meningeal irritation, such as headache, nausea, vomiting, photophobia, or nuchal rigidity, would suggest subarachnoid hemorrhage, meningitis, or hydrocephalus. Symptoms such as dyspnea or chest pain would suggest a respiratory, cardiac, or neuromuscular disorder. Symptoms of cranial nerve dysfunction such as diplopia, dysphagia, dysarthria, and dizziness would suggest direct brainstem injury or compression from a posterior fossa mass.

If the loss of consciousness remains unexplained, the child's environment should be evaluated for the presence of illicit drugs or prescription medications that may have been accidentally or intentionally ingested. Children failing to emerge from anesthesia after surgery should be investigated for such surgical complications as fat embolism, adrenal insufficiency, hypothyroid coma, and opioid overdose.

Pseudocoma

There are several findings on examination of the eyes inconsistent with unconsciousness that are helpful in identifying patients who are either purposefully feigning coma or appear unarousable as a manifestation of psychiatric illness. A history of prior psychiatric illness or of precipitation of the apparent coma by a stressful event should be taken into account but do not exclude medical causes of coma. In true coma, passive eyelid opening will

not induce movement of the eyes and the eyelids will close slowly and gradually when released. In pseudocoma, patients will often actively resist eye opening, either forcefully, attempting to keep their eyes tightly shut, or subtly, inducing a Bell's phenomenon of upward eye rolling during eyelid opening. When released, the eyelids will close quickly or hesitantly. Nystagmus with the vestibuloocular reflex test is not seen in true coma. The severe vertigo and nausea induced by cold caloric testing may *awaken* a patient with pseudocoma.

Diagnostic Testing

Laboratory Testing

The testing that should be done for all patients with unexplained coma should begin with a bedside test of blood glucose, followed by formal laboratory testing of serum glucose as well as a complete blood cell count (CBC), a chemistry panel that measures serum electrolytes (Na, K, Cl, HCO3, Ca, Mg, Phos) and renal function (BUN, Cr) and liver function tests (ALT, AST, Alk Phos, Tbili, Albumin, Ammonia, PT, PTT). Tests for accidental and intentional toxic ingestions should include a screening urine test for common drugs of abuse and serum tests for alcohol, salicylates, acetaminophen, and tricyclic antidepressants. These tests will identify around 80% of all toxic overdoses. Additional testing can be ordered through urine thin layer chromatography or specific serum tests when there is a suspicion that a patient had access to other potentially toxic compounds.

An arterial blood gas will help in the identification and differentiation of metabolic and respiratory disturbances associated with altered consciousness (Table 365.8).

Inborn errors of metabolism may be hinted at by abnormalities in the screening laboratory tests such as hypoglycemia, metabolic acidosis, or hyperammonemia but will require more detailed testing for identification. Small amounts of plasma, serum, and urine should be collected, frozen, and saved for later analysis when a child presents with a possible inborn error of metabolism, as testing after the child has been stabilized may be less diagnostic. Secondary analysis can include measures of urine ketones, amino acids, and organic acids, plasma lactate and pyruvate, plasma amino acids, and serum acylcarnitine profiles.

Other tests can be ordered depending on clinical suspicion or when the cause of coma remains obscure after other assessments are done. These tests include blood cultures, urine cultures, and lumbar puncture for CSF culture regarding possible infection and thyroid function and cortisol studies regarding possible endocrine disorders. Neuroimaging should be performed prior to lumbar puncture to look for any evidence that the procedure could precipitate herniation, such as midline shift, a posterior fossa mass, or loss of any of the cisternal spaces (suprachiasmatic, basilar, superior cerebellar, quadrigeminal plate). Lumbar puncture should also be deferred in the presence of an uncorrected coagulopathy. The serum cortisol level should be elevated in the stressful setting of coma and a low to normal value should prompt further laboratory testing for adrenal insufficiency. Patients who have suffered generalized trauma or who

Table 365.8
Arterial blood gas and respiratory rate evaluation. Interpretation of the respiratory rate and arterial blood gas results

Respiratory rate	Metabolic pattern	ABG results	Causes
Increased	Metabolic acidosis	pH < 7.35 $PaCO_2$ < 30 mmHg HCO_3 < 17 mmol/L	Uremia, diabetic ketoacidosis,lactic acidosis, poisoning with salicylates, methanol, and ethylene glycol
Increased	Respiratory alkalosis	pH > 7.45 $PaCO_2$ < 30 mmHg HCO_3 > 17 mmol/L	Hepatic failure, acute sepsis, acute salicylate poisoning, cardiopulmonary disease with hypoxemia, psychogenic hyperventilation
Decreased	Respiratory acidosis	pH < 7.35 (acutely) $PaCO_2$ > 90 mmHg HCO_3 > 17 mmol/L	Respiratory failure due to CNS disease, neuromuscular disease, or cardiopulmonary disease
Decreased	Metabolic alkalosis	pH > 7.45 $PaCO_2$ > 45 mmHg HCO_3 > 30 mmol/L	Vomiting, alkali ingestion

remain immobile for a prolonged period of time should be monitored for elevated serum creatine kinase levels indicating rhabdomyolysis.

Electrocardiography

In addition to continuous monitoring of the heart rate, comatose patients should undergo electrocardiography to identify myocardial infarction, arrhythmia, or conduction disturbance that may indicate an electrolyte abnormality or toxidrome prior to confirmation by blood tests.

Computed Tomography and Magnetic Resonance Imaging

Following stabilization, the patient with unexplained coma should undergo neuroimaging. A CT scan of the brain without contrast can be obtained rapidly in most medical centers and visualizes most abnormalities that would require immediate intervention, including intracranial hemorrhage, hydrocephalus, cerebral edema, and impending herniation. MRI is superior to CT in identifying acute stroke, diffuse axonal injury, and lesions of the posterior fossa but its use is limited by the longer image acquisition times, need for patient immobility, and patient inaccessibility within the scanner. MRI done with special sequences, including diffusion weighted imaging, diffusion tensor imaging, and proton spectroscopy can identify abnormalities in patients with unexplained coma and can contribute to the assessment of a child's prognosis for recovery, as discussed below.

Electroencephalography

An electroencephalogram (EEG) can identify seizure activity in patients suspected to be unconscious due to status epilepticus, including those who have prolonged depressed consciousness following a witnessed seizure. The presence of focal epileptiform discharges, slowing, or suppression on EEG suggests an underlying focal lesion as may occur with hemorrhage, infection, or stroke. Temporal lobe periodic lateralized epileptiform discharges (PLEDs) are frequently seen with herpes simplex encephalitis but are nonspecific. Metabolic encephalopathies associated with hepatic or renal failure are often associated with frontally predominant triphasic, high-amplitude slow waves. EEG activity that is generally slow or suppressed is a nonspecific indicator of brain dysfunction but does exclude pseudocoma; such patients will typically have EEG findings consistent with normal wakefulness.

Prognosis

The diagnostic evaluation of a patient in coma will often result in sufficient information to provide an estimate of the degree of brain injury that has occurred and of the level of recovery that can be expected. Other than patients who meet the clinical criteria for brain death, however, there are rarely situations in which the neurologist can have certainty regarding either survival or neurological prognosis. Nevertheless, giving families early estimates of the likelihood of a good recovery will help to prepare them to understand later, more definitive declarations regarding prognosis and to make decisions about the appropriateness of future resuscitative efforts.

Many academic reports of outcomes in children use qualitative terms such as good or poor without tying them to quantitative measures that would be comparable between studies. The majority of studies of brain injury in adults report overall long-term outcomes using the simple five-category Glasgow Outcome Scale (GOS), describing patients as either dead, vegetative and unresponsive, severely disabled and dependent on others, moderately disabled but able to live independently, or doing well enough to return to work or school. When the GOS is used, the upper two categories are often considered good outcomes. An eight-category version, the GOS Extended, subdivides each of the three higher categories into halves to further distinguish levels of disability. Other measures that are frequently reported in adults include the 8-item Disability Rating Scale, the 12-item Functional Independence Measure (FIM), and the 8-category Rancho Los Amigos Scale of cognitive function. Scales of global outcome developed for children include the six-category Pediatric Cerebral Performance Category Scale Score, the WeeFIM, and the KOSCHI (King's Outcome Scale for Childhood Head Injury) score.

There is a considerable difference in the general prognosis for coma that is drug induced, otherwise non-traumatic, or traumatic in origin. For drug-induced coma, a good recovery can usually be expected for patients identified early and provided with good supportive care. Brain injury is usually secondary to at least potentially avoidable metabolic or systemic derangements such as hypotension, hypoxia, or hypoglycemia. For non-traumatic coma due to hypoxic-ischemic injury and for traumatic coma, the clinical features present during the initial

resuscitation may not be highly predictive of outcome, but a number of clinical, laboratory, and radiological findings in subsequent days have been found to help predict a favorable or unfavorable outcome.

Non-traumatic Coma

The prognosis for patients in coma secondary to non-traumatic and non-drug-induced reasons is generally poor, with only 15% of patients recovering independent function. The outcome for children with coma due to hypoxic-ischemic encephalopathy, as might occur following cardiopulmonary arrest, is significantly worse than for those with potentially reversible metabolic encephalopathies, as might be seen with hepatic or renal failure. Naturally, more extensive structural brain injury is correlated with poorer outcome, as is the length of time of coma before some degree of recovery is seen. A child's age does not predict the degree of recovery in most analyses.

A practice parameter published by the AAN regarding the prognosis of comatose adults following resuscitation for cardiac arrest identified a number of clinical and laboratory findings that show evidence of being very highly predictive of a poor outcome, including (1) absent pupillary or corneal reflexes or absent or extensor motor responses to stimulation after 3 days, (2) myoclonic status epilepticus within the first day, (3) bilaterally absent cortical somatosensory evoked potentials (SSEP) in the first 3 days, and (4) a serum neuron-specific enolase level greater than 33 ng/L. There was evidence to suggest that the presence of burst-suppression, generalized suppression, or generalized epileptiform discharges on EEG was associated with a poor prognosis but was not specific enough to be used for outcome prediction.

Studies of the outcomes of resuscitation for cardiopulmonary arrest in children have shown that a number of clinical factors are associated with a poorer prognosis. Mortality and morbidity is generally higher in patients with cardiac arrest rather than respiratory arrest. In one study, 57% of 21 children with pure respiratory arrest died before leaving the hospital and 10% were severely impaired or dead a year later, while 92% of 80 children suffering cardiac arrest died prior to leaving the hospital and another 4% were in a vegetative state or had died a year later. Another study of 599 children with out-of-hospital combined cardiopulmonary arrest showed that only 8.6% survived to hospital discharge and that few of them had good neurological outcomes.

Cardiac and cardiopulmonary arrests that occur in hospital have a better rate of survival and of good neurologic outcome. One study of 880 children found that 27% survived to discharge and that the majority of survivors had good neurologic function at the time of discharge. Cardiopulmonary resuscitation that continues for more than 10–15 min or requires more than one bolus of epinephrine suggests a poor prognosis, but there have been cases with good outcomes despite 60 min of resuscitation for children with in-hospital arrest or ice-water submersion.

Few findings on the initial physical examination have been found to be as predictive of outcome from hypoxic-ischemic coma as those seen after 24 h. Poor outcomes were seen in all children with absent pupillary responses after 24 h in one study and in all children without purposeful movement or normal brainstem reflexes in another, but there have also been reports of children with better outcomes despite these findings. Along these lines, while lower GCS scores are associated with poorer outcomes, with one study finding that none of the children who had a GCS of 3 or 4 after the first 24 h had a good recovery, there are reported exceptions and predicting outcomes using a child's GCS score at the scene, or on admission is even less accurate. The effect of paralytic or sedative medications must be taken into account when assessing these physical findings.

Several studies have suggested that somatosensory evoked potential (SSEP) testing in children with severe hypoxic-ischemic brain injury is as useful as in adults with cardiac arrest for accurately predicting poor outcome when there is no cortical response. However, other studies have shown this finding to have a specificity of 92–95% and sensitivity of 61–75% for poor outcomes, making its clinical use far more problematic in children than in adults. Other electrophysiologic studies, including EEG, brainstem auditory evoked potentials, and visual evoked potentials, are all even more prone to error in predicting outcome, although severe abnormalities show a correlation with poorer outcomes. Conversely, initial or follow-up EEGs showing little to no slowing or suppression, normal reactivity to stimuli, or normal sleep rhythms in comatose survivors of hypoxic-ischemic injury have been correlated with favorable outcomes, suggesting a potential prognostic value to repeated or continuous monitoring.

Studies of the use of MRI for predicting outcomes for children in coma from hypoxic-ischemic injury have found that there is a greater sensitivity and specificity to abnormal findings 3–4 days after the injury, with one showing universally poor outcomes (vegetative state or death) for children with T2 hyperintensity within the brainstem or within both the cortex and basal ganglia. Studies of magnetic resonance spectroscopy have found

that severely depressed N-acetylaspartate levels and elevated lactate levels are also associated with poorer neurological outcomes.

Traumatic Coma

Children with traumatic coma can have a good outcome despite prolonged coma and generally do better than children with non-traumatic coma, but this makes predicting long-term prognosis even more difficult.

The most accurate predictors in early research studies were age, the GCS score on presentation and within the first week, and the presence or absence of pupillary reactivity. A recent study of 309 children compared the predictive value of the GCS score, other clinical variables including injuries to other organs, and the results of head CT scans and found that the GCS score was the best predictor of survival, with few children with an initial GCS score of 3 or 4 showing better than moderate disability. CT findings of cerebral edema and intracranial hemorrhage were also associated with poorer outcomes.

One study of children with severe traumatic brain injury showed continued clinical improvement after hospital discharge with the number of children who were independent in all areas of function increasing over an average of 2 years from 37% to 65%. Another study found that cognitive impairments in children who had survived for more than 1 year after suffering severe TBI were better predicted by the duration of coma measured as the time to follow commands, than by the initial GCS score. Other studies have shown that the duration of posttraumatic amnesia is also a better predictor than the GCS score for long-term cognitive impairment.

Additional predictors of poorer recovery include open head injuries, multiple skull fractures, deeper, more diffuse and more severe brain injury on neuroimaging, increased ICP, fever, seizures, and unstable blood pressure. For infants, a non-accidental etiology of the head trauma is often associated with signs of secondary ischemic brain injury and is predictive of greater morbidity and mortality.

Persistent Vegetative State

Children who awaken from coma into a vegetative state have some chance to regain consciousness; most who do will do so early in their recovery and will continue to have severe disability. When the vegetative state persists for more than 1 month following non-traumatic coma, or for more than 3 months after traumatic coma, improvements are very unlikely. Survival in the vegetative state is precarious and requires meticulous medical and nursing care, but recovery to a state of independence is almost unheard of for patients in such a state for more than a year and has never been reported for patients in a persistent vegetative state for 3 years. There are a significant number of patients who are initially misdiagnosed as being vegetative but later reclassified as being in a minimally conscious state following repeated and more detailed evaluations that consider the possibility of fluctuating levels of consciousness and limitations on interactions due to sensory deficits. Most of the older reports of patients making surprisingly good recoveries from the vegetative state were likely minimally conscious patients who had been misdiagnosed as vegetative. However, there have been more recent reports of the use of functional brain imaging to identify vegetative patients with preserved receptive language function who did make exceptional late recoveries.

Brain Death

The clinical requirements on physicians for declaring a child as having died from brain death are fairly consistent across most regions of the world, although, when surveyed, knowledge of these requirements and documentation of the examinations performed is often incomplete. The difficulties that physicians face in presenting a diagnosis of brain death to a child's family are universal. Although brain death has been used in clinical practice since the 1970s, families are likely to have little familiarity with the concept and to see ambiguity in the ongoing use of cardiopulmonary support systems, especially when physicians persist in referring to them as providing *life support*.

The diagnosis of brain death requires that there be an irreversible cause of injury to the brain that precludes any chance for recovery of consciousness. In a few countries, including the United Kingdom, it is sufficient for the injury to involve only the brainstem, although in most countries, including the United States, there is a requirement for *whole brain* death that involves both the brainstem and the cerebral hemispheres.

With the loss of all brainstem function, there should be no spontaneous movements, postures, or convulsions, no movements in response to stimulation other than those mediated by spinal reflexes, no brainstem reflexes including pupillary, corneal, oculocephalic, vestibuloocular, or gag reflexes, and no spontaneous respiration despite elevation of the partial pressure of CO_2 from at or below 40

mmHg to above 60 mmHg on arterial blood gas testing, or a 20 mmHg elevation from an initial level above 40 mmHg. For a purely clinical diagnosis to be accurate, the examination cannot be confounded by factors that interfere with the examination, such as facial trauma, or that might induce unresponsiveness, such as significant hypothermia, hypotension, metabolic disturbance, or significantly elevated serum levels of sedating or paralyzing medications. When the clinical examination is limited in any way, confirmation can be obtained using a radionucleotide scan that shows absent cerebral blood flow. Confirmatory testing with EEG to show electrocerebral silence has been recommended for children under 1 year of age but this test is prone to being influenced by metabolic derangements and is less helpful in the setting of confounding circumstances.

Following brain death, patients frequently develop cardiac and cardiovascular instability despite intensive supportive care. Continuous intravenous infusion of vasopressin has been found helpful in preventing the severe diuresis and hypotension resulting from the loss of pituitary function. Patients whose organs are not being maintained for donation can be withdrawn from artificial support, with intravenous drips, ventilators, and all monitors turned off to allow families a period of time with their child before the absence of a heartbeat is confirmed by a physician through auscultation and palpation and the absence of cardiac activity is documented by an electrocardiogram. In rare instances when there have been reasons to continue supportive care indefinitely, organ failure usually occurs in less than a week, although there are bodies that have been maintained following brain death for months or years.

366 Acute, Subacute, and Chronic Progressive Encephalopathies

Generoso Gutierrez-Gascón

Introduction

Definitions and Exclusions

For purposes of this chapter, "encephalopathy" will mean *a disorder in which there is an altered mental state, which, depending on the type and severity, can include loss of cognitive function, personality changes, inability to concentrate, confusion, delirium, stupor, or coma.* It does not refer to a single disease, but to a syndrome of global brain dysfunction, which can be caused by many different illnesses, both systemic, secondarily affecting the brain, and primary in the brain itself. The onset may be acute, subacute, chronically progressive, or static. This chapter will not discuss the static or nonprogressive encephalopathies such as the mental retardation or cerebral palsy syndromes, nor will it discuss neuropsychiatric disorders such as the autistic spectrum disorders (See Dr. Pamela High's section on ❯ Developmental and Behavioral Disorders). Furthermore, it will exclude traditional acute infectious etiologies such as viral encephalitis (e.g., Herpes Simplex encephalitis), bacterial and fungal meningitis, toxic encephalopathies from ingested heavy metals like lead, accidental poisoning, drug ingestion in suicide attempts, or inhaled toxins, such as carbon monoxide.

Encephalopathies discussed in this chapter are likely to be seen by pediatricians and primary care practitioners throughout the world, although some are seen in some parts of the world more than others. For example, HIV encephalopathy (AIDS) is not uncommon in Africa and south Asia, and subacute sclerosing panencephalitis (SSPE) in Turkey and India, but early cases of the encephalopathy associated with the H1N1 influenza pandemic, though first described in Mexico and southern California, have been seen throughout the world.

Classification

This chapter will arbitrarily discuss encephalopathies by age group (infancy and early childhood, mid-childhood, and late childhood/adolescence), with stratification by clinical course (acute, subacute, chronic progressive) (See ❯ *Tables 366.1* and ❯ *366.3*).

Etiology and Clinical Presentation

Etiologies discussed in this chapter include inborn errors of metabolism, lysosomal storage disorders, epileptic encephalopathies, infection-related such as acute toxic encephalopathy and Reye syndrome, immune-mediated, slow virus infections, and progressive encephalopathic degenerative diseases. Because there are many different etiologies, the disturbance in mental status may be accompanied by other neurological symptoms or signs, such as seizures, ataxia, weakness, movement disorders or visual loss, depending on the part of the brain affected. The mental status change, especially in the progressive encephalopathies, may also be expressed as specific higher cortical dysfunction, such as aphasia, apraxia, or agnosia, before progression to a dementia. Dementia is defined as a loss of previously acquired cognitive and/or behavioral function and is central to the neurodegenerative diseases.

Management

Adopting a mind set of searching for treatable and reversible etiologies can focus the diagnostic and treatment approach. The neuropathologic substrate, particularly in the acute toxic-metabolic encephalopathies, is usually cerebral edema. This can be indicated by CT brain findings of decreased attenuation periventricularly and in subcortical white matter or increased T2 signal intensity on brain MRI. Functional techniques such as magnetic resonance spectroscopy (MRS) and positron emission tomography (PET), single photon emission computerized tomography (SPECT) show the pathophysiology better, but are not widely available in non-tertiary care centers and in the developing world. CSF findings may show increased

opening pressure, no pleocytosis, and normal protein. Electroencephalography (EEG) reveals diffuse slow background activity of low or high voltage, indicating depressed brain functioning. If an inborn error of metabolism is suspected, blood for amino acid determination by gas-liquid chromatography (GLC), urine for organic acid determination by gas chromatography-mass spectroscopy (GCMS), or better yet, a blood spot on filter paper to be sent to a regional or national laboratory for tandem mass spectroscopy (tandem MS) should be obtained. Also, samples for blood pH, electrolytes, lactate, pyruvate, ammonia, glucose, carnitine, liver function tests, and CSF for lactate and pyruvate should be obtained. For possible future studies, samples of the following should be stored frozen: 3 ml of CSF for future possible studies such as neurotransmitter metabolites, polymerase chain reaction (PCR) amplification for viral DNA fragments, immunoglobulins, oligoclonal bands, myelin basic protein, and measles-specific antibody titers; 5 ml of urine; and 5 ml of blood (−20°C), 1 ml in a fluoride tube and the rest in a heparinized tube. Until a specific diagnosis is made, if the initial tests suggest an organic aciduria, broad spectrum cofactor supplementation for possible treatable and reversible acute encephalopathies can be given without risk of adverse reactions. A starting combination is thiamine (300 mg plus per day), biotin (50 mg twice a day), riboflavin (100 mg/kg/day), and L-carnitine (100 mg/kg/day in three divided doses). If a mitochondrial disease of

oxidative phosphorylation is suspected, one can add vitamin K, vitamin C, and coenzyme Q. Specific therapy can then await specific diagnosis (See ❯ Chap. 38, "Disorders of Organic Acid and Amino Acid Metabolism" by Ozand and Al-Essa).

The specific etiology, pathogenesis, genetics, neuropathology, clinical manifestations, diagnostic investigations, differential diagnosis, and treatment will be discussed, when appropriate, for the individual diseases that are not otherwise discussed elsewhere in this book, such as in the section on ❯ Inborn Errors of Metabolism (Pinar Ozand), ❯ Chap. 360, "Neonatal Neurology" (William Brown and Mara Coyle), or ❯ Chap. 362, "Epilepsy" (John Gaitanis). For single gene disorders, prenatal diagnosis is possible through amniocentesis or chorionic villus sampling. If the single gene mutation in a progressive debilitating or fatal disease is already known in a family, having been identified in a previously affected child, and abortion is not an option, preimplantation genetic diagnosis (PIGD), using in vitro fertilization (IVF) techniques, can be utilized as preventive treatment, in IVF centers with technically qualified obstetricians and geneticists.

Web-Based Resources for Physicians

For readers who desire in-depth information beyond this chapter, web-based resources are the quickest way to access information at the point of service, since computers and internet access are now available almost everywhere, except in the most remote locations. For diagnostically puzzling patients whose presentations suggest some kind of chromosomal, genetic or unrecognized syndrome, www.simulconsult.com can be helpful in narrowing down differential diagnostic possibilities. For more detailed descriptions of genetic diseases with Mendelian inheritance, consult OMIM (Online Mendelian Inheritance in Man) at www.ncbi.nlm.nih.gov/omim. For succinct information on clinical presentation and management of any genetic disease, click on "Gene Reviews" in www.genetests.org. For information on availability of molecular genetic testing, on a clinical or research basis, for any of the genetic diseases discussed in this chapter, click on "Laboratory Directory" in www.genetests.org. For information on ongoing clinical trials, consult www.clinicaltrials.gov. For evidence-based

Infancy and Early Childhood

Acute Encephalopathies

Hypoxic-ischemic encephalopathy (HIE)
Inborn errors of metabolism
- Aminoacidurias
- Organic acidurias
- Urea cycle disorders
- Vitamin-dependent disorders
- Fatty acid oxidation (FAO) disorders
- Neurotransmitter-related disorders

Neonatal encephalopathy describes an obtunded newborn with abnormal pediatric Glasgow Coma Scale, often experiencing seizures and exhibiting hypotonia. In developed countries, 2–3 per 1,000 live term birth infants develop acute, moderate to severe encephalopathy. Rates are 10 times that in less developed nations (See *Table 366.1*).

Most commonly *hypoxic-ischemic encephalopathy (HIE)* is the cause. Neonatal encephalopathy and HIE are covered in the Chap. 360, "Neonatal Neurology" by William Brown and Mara Coyle Brown, and in the Neonatology section.

It is in this age group that *the inborn errors of metabolism (IEM)* are most likely to present. The devastating metabolic diseases of the newborn are discussed in the chapter by P. Ozand and M Al-Essa, on Disorders of Amino and Organic Acidurias. The aminoacidurias, such as non-ketotic hyperglycinemia, organic aciduras such as methylmalonic and propionic acidemia, fatty acid oxidation disorders and vitamin-dependent disorders, such as pyridoxine dependency present as neonatal encephalopathies in developed countries, but are much more common in populations where there are large families and a high rate of consanguineous marriages.

Moammar et al. report that in the Eastern Province of Saudi Arabia, over 25 years, IEM had a cumulative incidence of 150/100,00 live births. Small-molecule disorders were diagnosed in 134/248 patients (54%). Organic acidurias were the most common (48/248 patients; 19%), methylmalonic aciduria being the most frequently observed (13/48 patients; 27%). Lysosomal storage diseases were diagnosed in 74/248 patients (30%), of which mucopolysaccharidosis was the most frequently observed (28/74; 38%).

Fatty Acid Oxidation Disorders (FAO)

Medium-chain acyl Co-A dehydrogenase deficiency (MCAD)
Very long chain acyl Co-A dehydrogenase deficiency (VLCFA)
Multiple acyl Co-A dehydrogenase deficiency (Glutaric aciduria Type 2)

Medium-, long-, and short-chain acyl-CoA dehydrogenase deficiencies (MCAD, LCAD, SCAD) are due to defects of the β-oxidation spiral. The encephalopathic presentations are acute toxic encephalopathy with nonketotic hypoglycemia in infancy and toddlerhood provoked by fasting (primarily MCAD), the syndrome of nonketotic hypoglycemia plus very low plasma carnitine and absent dicarboxylicaciduria (carnitine transport defects), and sudden infant death (SIDS). MCAD is the most common mitochondrial β-oxidation disorder, occurring in 1/10,000 to 1/20,000. Children usually present between ages 3 and 15 months. A common presentation is vomiting, lethargy, followed by fasting and associated with a preceding viral gastrointestinal or respiratory infection. In the emergency room, it presents as an acute toxic encephalopathy or coma, with hypoketotic hypoglycemia, hyperammonemia, and abnormal liver function tests. Serum carnitine is low, urine acycarnitines are increased. The differential diagnosis includes other fatty acid oxidation disorders, exogenous toxin ingestion, and true Reye syndrome. Management utilizes10% dextrose intravenously, L-carnitine 100 mg/kg/day orally in divided doses, frequent short feeds. Prognosis: the risk of death with first episode is about 20%. If treatment is delayed, developmental retardation, behavioral problems, seizures, and failure to thrive may result. Preventive treatment: living siblings should be screened with acylcarnitine profiles and subsequent siblings should be screened in the neonatal period.

For further discussion of MCAD, as well as other FAOs – very long chain acyl-CoA dehydrogenase deficiency, multiple acyl-CoA dehydrogenase deficiency (glutaric aciduria Type 2), see chapter by Ozand and Al-Essa, Chap. 38, "Disorders of Organic Acid and Amino Acid Metabolism".

Neurotransmitter-Related Disorders

These disorders are due to a relative deficiency or excess of a neurotransmitter. Two of these disorders present as encephalopathy in the neonatal period – biopterin-dependent PKU and non-ketotic hyperglycinemia. In biopterin-dependent PKU, the etiology causing encephalopathy *is 6-PTS deficiency (6-pyruvoyltetrahydropterin synthase). In non-ketotic hyperglycinemia*, it is the excessive glycine (a CNS neurotransmitter), due to defects in various components of the mitochondrial glycine cleavage enzyme system, that causes the seizures and encephalopathy in the acute neonatal presentation. Clinical presentation and treatment are discussed in the chapter by Ozand and Al-Essa, Chap. 38, "Disorders of Organic Acid and Amino Acid Metabolism".

Other

Other rare miscellaneous acute encephalopathies to be mentioned but not discussed here are acute chemotherapy-related leukoencephalopathy, usually in leukemia patients treated with methotrexate, and bronchiolitis-associated encephalopathy in critically ill infants, seen in pediatric intensive care units.

Subacute Encephalopathies

Biotinidase deficiency
Epileptic encephalopathies
  Early myoclonic encephalopathy
  Early infantile epileptic encephalopathy (Ohtahara syndrome)
  Febrile infection-related epilepsy syndromes (FIRES)
Mitochondrial disorders (of oxidative phosphorylation)
  Subacute necrotizing encephalomyelopathy (Leigh's disease)
  Mitochondrial encephalomyopathy, lactic acidosis, stroke-like episodes (MELAS)
  Myoclonic epilepsy with ragged red fibers (MERRF)

Biotinidase Deficiency

This subacute to progressive encephalopathy is mentioned because it is eminently treatable, by giving biotin, L-carnitine, and Polycitra. In areas of the world where neonatal metabolic screening is done, the encephalopathy can be prevented because of early diagnosis and treatment. The disorder is described in the chapter by Ozand and Al-Essa, Chap. 38, "Disorders of Organic Acid and Amino Acid Metabolism".

Epileptic Encephalopathies

The epileptic encephalopathies are disorders that present as seizures of various kinds that are refractory to

medication treatment and are accompanied by developmental behavioral arrest or regression. In infancy, these are the infantile spasms or West syndrome, in early childhood, the Lennox Gastaut syndrome and Severe Myoclonic Epilepsy (Dravet syndrome). These are discussed in the Chap. 362, "Epilepsy" (John Gaitanis). Two epileptic encephalopathies appear in the neonatal period – early myoclonic encephalopathy and early infantile epileptic encephalopathy with burst-suppression, or Ohtahara syndrome.

Other Selected Epileptic Encephalopathies

Early Myoclonic Encephalopathy (Neonatal Myoclonic Encephalopathy). This clinical-EEG syndrome presents in the neonatal period with partial or fragmentary erratic myoclonus, massive myoclonias, and frequent partial motor seizures. The EEG displays complex spike bursts, sharp waves, and slow waves, separated by flattening of the background and localized discharges, so-called suppression bursts. These become more apparent in sleep and may persist into late childhood, after a transient hypsarrhythmia in late infancy. The etiology is usually nonstructural/ metabolic, for example, non-ketotic hyperglycinemia. Treatment is directed at the etiology. Symptomatic suppression of seizures with antiepileptic drugs is rarely successful in this refractory epileptic encephalopathy. Prognosis is severe, with early death, or severe and profound psychomotor retardation.

Early Infantile Epileptic Encephalopathy with Burst-Suppression (Ohtahara Syndrome). Tonic spasms are the main seizures, often appearing in clusters. Suppression bursts appear in both wake and sleep. They evolve into hypsarrhythmia at 3–4 months of age and West syndrome, then eventually to diffuse slow spike waves and the Lennox–Gastaut syndrome. The etiology most commonly is structural brain lesions such as prenatal cerebral dysgenesis. Prognosis is dire, with early death or marked psychomotor retardation and seizure intractability, despite treatment with ACTH, corticosteroids, vigabatrin, or ketogenic diet.

Febrile Infection-Related Epilepsy Syndrome (FIRES), A Nonencephalitic Epileptic Encephalopathy. Previously healthy children develop prolonged or recurring seizures lasting days after fever onset, usually with respiratory or nonspecific infections. CSF shows no pleocytosis and no pathogens. EEG usually reveals diffuse slowing or multifocal discharges. Neuroimaging is normal and no inflammation is seen on brain biopsies, when done. The course is dire. A.van Baalen reported only two recovered in a series of 22 children in Germany. Two died, two had behavioral disturbances, eight continued with impaired consciousness, and eight developed medically refractory epilepsy. The pathogenesis is likely neuronal hyperexcitation rather than inflammatory cerebral damage.

Mitochondrial Disorders: Disorders of Oxidative Phosphorylation

Leigh's disease
MELAS (mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes)
MERRF (myoclonic epilepsy associated with ragged red fibers)

Leigh's Disease (Subacute Necrotizing Encephalomyelopathy)

Leigh syndrome is a relatively common disease. About one-half are diagnosed before the age of 6 months. A previously healthy infant begins with brain stem signs such as poor feeding, sucking, and swallowing, and supranuclear ophthalmoplegia. A central hypoventilation syndrome is prominent early. Seizures may occur early, movement disorders late. Developmental arrest and then deterioration follows. Diagnosis is made by noting the typical course, elevated CSF lactate and pyruvate, and a typical distribution on brain MRI of paramedian T2 increased intensity lesions in brainstem, cerebellum, and basal ganglia. Magnetic resonance spectroscopy (MRS) reveals elevated lactate peaks in these lesions. The differential diagnosis includes the organic acidurias presenting as progressive encephalopathy like glutaric aciduria type 1, biotinidase deficiency, and biopterin-dependent PKU, the primary lactic acidoses, atypical peroxisomal disorder, and infantile neuraxonal dystrophy. Leigh's disease is caused by mitochondrial DNA as well as autosomal recessive, nuclear coded DNA mutations. Although several enzyme complexes of the respiratory chain, primarily in Complex IV, are involved, the most commonly reported defect is in the ATPase6 gene at mtDNA position 8993, causing defective ATP production. The pathology consists of spongy degeneration, demyelination, gliosis, necrosis, with relative sparing of neurons, and capillary proliferation. Treatment is primarily supportive and symptomatic. Metabolic treatment using mitochondrial "cocktails" have been used, with inconclusive results. These usually include biotin 50 mg/day or more, thiamine 300 mg/day or more, coenzyme Q10, vitamin K, and vitamin C. Dichloroacetate has been used to lower serum lactate levels. Patients with pyruvate dehydrogenase complex deficiency may respond to the ketogenic diet. The prognosis is grave, this being a fatal disease, although there may be periods of arrest of progression.

MELAS – Mitochondrial Encephalomyopathy, Lactic Acidosis, and Stroke

MELAS (mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes) is a multisystem disorder typically beginning usually between 2 and 10 years of age. Development is usually normal, though stature may be short. The most common initial symptoms are generalized tonic-clonic seizures, recurrent headaches, anorexia, and recurrent vomiting. Exercise intolerance or proximal limb weakness can present early. Sensorineural hearing loss is common. Stroke-like episodes of recurrent transient hemiparesis or cortical blindness may be associated with altered consciousness. Motor abilities, vision, and mentation are impaired by adolescence.

The diagnosis rests on a combination of clinical findings and molecular genetic testing. Mutations in the mitochondrial DNA (mtDNA) gene *MT-TL1* encoding $tRNA^{Leu(UUR)}$ are causative. The most common mutation, present in over 80%, is an A-to-G transition at nucleotide 3243. Mutations can usually be detected in mtDNA from leukocytes. However, because of heteroplasmy in mitochondrial disorders, the pathogenic mutation may be undetectable in leukocytes but can be detected in other tissues, such as cultured skin fibroblasts grown from skin biopsies or, most reliably, skeletal muscle obtained from muscle biopsy.

No specific treatment for MELAS exists. Sensorineural hearing loss has been treated with cochlear implantation. Seizures respond to antiepileptics. Coenzyme Q10 and L-carnitine have been beneficial in some individuals.

MELAS is transmitted by usually asymptomatic mothers. A male with a mtDNA mutation cannot transmit it to any of his offspring. A female (affected or unaffected) transmits the mutation to all of her offspring. Prenatal diagnosis for MELAS is available if a mtDNA mutation has previously been detected in the mother.

MERRF – Myoclonic Epilepsy, Ragged Red Fiber Syndrome

MERRF is a multisystem disorder characterized by myoclonus, which is often the first symptom, followed by generalized epilepsy, ataxia, weakness, and dementia. Onset is usually in childhood, occurring after normal early development. Common findings are hearing loss, short stature, optic atrophy, and cardiomyopathy with Wolff–Parkinson–White (WPW) syndrome. Less common are pigmentary retinopathy and lipomatosis.

The clinical diagnosis of MERRF is based on the clinical history and exam of myoclonus, generalized epilepsy, ataxia, and ragged red fibers (RRF) in the muscle biopsy. The mitochondrial DNA (mtDNA) gene *MT-TK* encoding $tRNA^{Lys}$ is the gene most commonly associated with MERRF. The most common mutation, present in over 80% of affected individuals with typical findings, is an A-to-G transition at nucleotide 8344 (m.8344A>G). Mutations are usually present in all tissues and can be detected in mtDNA from blood leukocytes. However, because of "heteroplasmy" in mitochondrial disorders, the pathogenic mutation may be undetectable in mtDNA from leukocytes and may only be detected in other tissues, such as cultured skin fibroblasts from skin biopsy or, most reliably, skeletal muscle obtained by muscle biopsy.

Levetiracetam, clonazepam, zonisamide, and valproic acid (VPA) have been used to treat the myoclonic epilepsy. However, VPA may cause secondary carnitine deficiency and should be avoided or if used, L-carnitine must be added. Coenzyme Q_{10} (100 mg 3 × /day) and L-carnitine (1,000 mg 3 × /day) are often used in hope of improving mitochondrial function.

Mitochondrial genetics dictates that the mother of an affected child usually has the mtDNA mutation and may or may not have symptoms. The father is not at risk for having the disease-causing mtDNA mutation. If a male has an mtDNA mutation, he cannot transmit it to his children. A female with the mutation (whether affected or unaffected) transmits the mutation to all of her offspring. Prenatal diagnosis for MERRF is possible if an mtDNA mutation from the mother has been identified.

Progressive Encephalopathies

Incidence

Progressive encephalopathy (PE) in children is a heterogeneous group of diseases mainly composed of metabolic diseases, but consists also of neurodegenerative disorders where neither metabolic nor other causes are found. In an epidemiologic study from Norway by Stromme P et al. from 1985 to 2003, 84 PE cases were registered in Oslo, with 28 different diagnoses. The age-specific incidence rates per 100,000 were 79.89 (<1 year), 8.64 (1–2 years), 1.90 (2–5 years), and 0.65 (>5 years). Furthermore, 66% (55/84) of the cases were metabolic, 32% (27/54) were neurodegenerative, and 2% (2/84) had HIV encephalopathy. In regard to presentations by age group, 71% (60/84) of the cases presented at <1 year, 24% (20/84) were late infantile presentations, and 5% (4/84) were juvenile presentations. Neonatal onset was more common in the metabolic (46%) (25/55) compared to the neurodegenerative group (7%) (2/27). Unspecified neurodegenerative disease occurred in 20% (17/84) of all cases. Overall two-thirds of the cases were metabolic, of which almost half presented in the neonatal period.

One way to conceptualize the progressive genetic encephalopathies in infancy and early childhood is to consider whether progressive degeneration at the onset occurs primarily in the gray matter or in the white matter (See *Table 366.2*, Progressive Genetic Encephalopathies).

Although the disturbance in mental status, usually heralded by developmental arrest and then deterioration, may seem similar, early accompanying neurological symptoms/signs differ. Most of the lysosomal storage diseases are primarily gray matter diseases, because symptoms are due to abnormal storage of metabolic products in neurons. Seizures present early in the course. These are best exemplified by the GM2 gangliosidoses (Tay–Sachs, Sandhoff) and the neuronal ceroid lipofuscinoses. In the white matter diseases (leukodystrophies or leukoencephalopathies), there is progressive degeneration, or hypomyelination, of myelin, and present with long tract (pyramidal) signs early in the course.

Lysosomal Storage Diseases

GM2 gangliosidoses (Tay–Sachs, Sandhoff)
GM1 ganlgiosidoses
Neuronal ceroid lipofuscinosis, Infantile Form (Santavuori), Late Infantile (Jansky–Bielslchowsky), juvenile (Batten–Spielmeyer–Vogt)
Mucolipidoses
Mucopolysaccharidoses (Hurler, Hunter, San Filippo)
Leukodystrophies
- Globoid Cell leukodystrophy (Krabbe disease)
- Metachromatic Leukodystrophy
- Multiple Sulfatase Deficiency (Austin's disease)

These disorders, all presenting in the neonatal and early childhood period, are discussed in the Chap. 39, "Lysosomal Storage Diseases", by Ozand and Al-Essa.

Other Leukodystrophies, Leukoencephalopathies

The term leukoencephalopathies is a broad one which includes any disorder which primarily affects brain white matter or myelin, and so includes disorders of hypomyelination or dysmyelination. The leukodystrophies are inherited disorders characterized by progressive degeneration of the white matter of the brain.

Ozand and Al-Essa (Chap. 39, "Lysosomal Storage Diseases" chapter) discuss the traditional leukodystrophies:
- Globoid cell leukodystophy (Krabbe's disease)
- Metachromatic leukodystrophy (MLD)
- Multiple sulfatase deficiency (Austin's disease)

Other leukodystrophies discussed here are:
- Pelizaeus–Merzbacher disease
- Canavan's disease
- Alexander's disease

Two relatively recently described leukoencephalopathies are:
- Vanishing white matter disease
- Megalencephalic leukoencephalopathy with subcortical cysts

Pelizaeus–Merzbacher Disease (PMD)

PMD is an x-linked leukodystrophy secondary to mutations in the proteolipid protein (PLP) gene, which presents in infancy or early childhood, with "wheeling" nystagmus, hypotonia, and impaired cognition. Hypotonia evolves into spasticity, the nystagmus disappears but cerebellar ataxia, choreoathetosis may appear, as well as optic atrophy. Death occurs in the second to third decade. A connatal form presenting in the first 3 months of life has a much more severe course, with laryngeal stridor, and early death. The clinical diagnosis is based on clinical signs and symptoms, diffuse T2 hyperintensity of the brain MRI, an x-linked inheritance pattern, and finding mutations of the PLP1 gene. Abnormalities of the PLP gene also cause a phenotypically different entity, spastic paraplegia type 2 (SPG 2), which presents at a later age. Treatment is symptomatic and supportive, aimed at preventing secondary complications with multidisciplinary surveillance. Although *PLP*1-related disorders are inherited in an x-linked manner, *de novo* mutations have been reported. Males with the PMD phenotype do not reproduce; males with the SPG2 phenotype may have children. All daughters of a male proband will be carriers; no sons will inherit the mutation. All sons of a female carrier are at a 50% risk of inheriting the mutation and having the disease; all daughters are at a 50% risk of being carriers. Carrier testing for at-risk relatives and prenatal testing for pregnancies at increased risk are possible in families in which the disease-causing *PLP*1 mutation has been identified.

Canavan Disease (CD)

In CD, macrocephaly begins in the first year of life, with failure to sit and marked hypotonia, which eventually evolves into spasticity. In CD, there is diffuse T2 hyperintensity of the white matter which on magnetic resonance spectroscopy shows markedly elevated NAA (n-acetylaspartic acid). Urine shows acetylaspartic aciduria. ASPA is the only gene associated with CD. Three common mutations account for

approximately 99% of the disease-causing alleles in Ashkenazi Jewish patients and approximately 50–55% of disease-causing alleles in non-Jewish patients. There is a later presenting rare juvenile form of CD. CD is inherited as an autosomal recessive. This disease is the next targeted disease for prevention by genetic screening of the population at risk, Ashkenazi Jews, following the decreasing incidence of Tay–Sachs disease because of genetic screening.

Alexander Disease (AD)

The classical presentation, the infantile form, affects 51% of patients with AD. It presents in the first 2 years of life with megalencephaly, frontal bossing, psychomotor deterioration, seizures, pyramidal signs, and hydrocephalus due to aqueductal stenosis. There is also a neonatal form, a juvenile form, onset 4–10 years, affects about 23%, and an adult form (about 24%) with wide variability of symptoms. Children with the infantile form survive from weeks to years; with the juvenile form, to the 20s and 30s. In AD, increased T2 hyperintensity predominates in the frontal lobes. Brain biopsy shows inclusion bodies (Rosenthal fibers) in astrocytes. *GFAP*, which encodes glial fibrillary acidic protein, is the only gene currently known to be associated with AD. Molecular genetic testing has eliminated the need for diagnostic brain biopsy. Treatment is symptomatic and supportive.

Vanishing White Matter Disease (Childhood Ataxia with Central Hypomyelination)

Vanishing white matter (VWM) is one of the most prevalent inherited childhood leukoencephalopathies, but this may affect people of all ages, including neonates and adults. It is a progressive disorder clinically dominated by cerebellar ataxia and in which minor stress conditions, such as fever or mild trauma, provoke major episodes of neurologic deterioration. Typical pathological findings include increasing white matter rarefaction and cystic degeneration, oligodendrocytosis with highly characteristic foamy oligodendrocytes, meager astrogliosis with dysmorphic astrocytes, and loss of oligodendrocytes by apoptosis. Vanishing white matter is caused by mutations in any of the genes encoding the five subunits of the eukaryotic translation initiation factor 2B (eIF2B), EIF2B1 through EIF2B5. eIF2B is an ubiquitously expressed protein complex that plays a crucial role in regulating the rate of protein synthesis. Vanishing white matter mutations reduce the activity of eIF2B and impair its function to couple protein synthesis to the cellular demands in basal conditions and during stress. Reduced eIF2B activity leads to sustained improper activation of the unfolded protein response, resulting in concomitant expression of proliferation, prosurvival, and proapoptotic downstream effectors. Consequently, VWM cells are constitutively predisposed and hyperreactive to stress. VWM genes are housekeeping genes, so it is surprising that the disease is primarily a leukoencephalopathy. The pathophysiology of selective glial vulnerability in VWM remains poorly understood.

Megalencephalic Leukoencephalopathy with Subcortical Cysts (MLC)

MLC is an autosomal recessive disease characterized by infantile-onset macrocephaly, often in combination with mild gross motor developmental delay and seizures, gradual onset of ataxia, spasticity, and sometimes extrapyramidal findings. Mental deterioration is late and mild. Some die in the second and third decades of life, others are alive in their forties.

Magnetic resonance imaging (MRI) shows diffusely abnormal and swollen cerebral white matter and subcortical cysts in the anterior temporal or frontoparietal areas. On follow-up, atrophy ensues. Approximately 80% of MLC patients have mutations in MLC1, the only gene associated with MLC. Sequence analysis detects mutations in approximately 60–70% of affected individuals. Two phenotypes can be distinguished among the non-MLC1 mutated MLC patients: a classical and a benign phenotype. Management utilizes antiepileptic drugs for seizures, physical therapy for motor dysfunction, and special education.

The differential diagnosis is essentially that of white matter diseases that present with a large head, namely, Canavan's disease (CD), due to aspartoacylase deficiency, and Alexander's disease. Both present in the first year of life and are inherited in an autosomal recessive fashion. Neuroimaging differentiates these from each other and from MLC.

POLG (DNA Polymerase Gamma) – Related Disorders

POLG-related disorders comprise a continuum of overlapping phenotypes that were clinically defined long before their molecular basis was known. Mitochondrial DNA is replicated by DNA polymerase gamma. Onset of the *POLG*-related disorders ranges from early childhood to late adulthood. Diagnostic criteria do not exist. Two POLG-related diseases that occur in early childhood with encephalopathy are Alpers–Huttenlocher syndrome (AHS) and childhood myocerebrohepatopathy spectrum (MCHS). Establishing the diagnosis requires identification

of two disease-causing *POLG* mutations, for each of these syndromes.

Alpers–Huttenlocher Syndrome (AHS)

AHS affects approximately one of every 51,000 and is characterized by childhood-onset progressive severe encephalopathy with intractable epilepsy and hepatic failure. As the illness progresses, neuroimaging shows gliosis initially in occipital areas and generalized brain atrophy. Molecular genetic testing consists of targeted mutation analysis and sequence analysis. The p.Ala467Thr mutation is the most common *POLG* mutation associated with AHS and is found in almost half of all affected individuals. Two other specific mutations tested are p.Trp748Ser and p.Gly848Ser. These are found in 70% of AHS patients. The rest require full-sequence analysis of both POLG alleles.

Depletion of mitochondrial DNA (mtDNA) develops in clinically affected tissues causing a mitochondrial oxidative-phosphorylation defect. The central nervous system regions affected in AHS are the same as those affected by Leigh syndrome but typically evolve in the reverse order. In AHS, the gliosis is most severe and occurs earliest in the cerebral cortex, followed by the cerebellum, basal ganglia, and brain stem.

Treatment is symptomatic and supportive. Valproic acid (Depakene®) and sodium divalproex (Depakote®) should be avoided. Because other anticonvulsants have also been implicated in accelerating liver deterioration, liver enzymes should be monitored every 2 to 4 weeks after introducing any new antiepileptic medications.

Childhood Myocerebrohepatopathy Spectrum (MCHS)

MCHS presents between the first few months of life up to about age 3 years with developmental delay or dementia, lactic acidosis, and a myopathy with failure to thrive. Other features of a mitochondrial disorder that may be present include liver failure, renal tubular acidosis, pancreatitis, cyclic vomiting, and hearing loss. Seizures are not present, at least early in the disease course.

Aicardi–Goutieres Syndrome (AGS)

AGS is an early-onset encephalopathy that results in severe mental and physical handicap. A subgroup of infants with AGS presents at birth with abnormal neurologic findings, hepatosplenomegaly, elevated liver enzymes, and thrombocytopenia, a picture similar to congenital infection. Otherwise, affected infants present at variable times after the first few days of life, frequently after a period of apparently normal development. Typically, they demonstrate the subacute onset of a severe encephalopathy characterized by extreme irritability, intermittent fevers, loss of skills, and slowing of head growth. Between 20% and 50% of affected individuals have generalized tonic-clonic or focal tonic seizures. As many as 40% have chilblain skin lesions on the fingers, toes, and ears.

The most important clinical laboratory tests are CSF examination for number of white cells and concentrations of interferon alpha and neopterin. These are most likely to be informative early in the disease and are frequently normal after the first few years of life. CSF IFN-α concentration is greater than 2 IU/mL (normal: <2 IU/mL). Lymphocytosis is defined as more than 5 lymphocytes/mm^3 CSF. Typical values range from 5 to 100 lymphocytes/mm^3. CSF concentrations of neopterin (and less so biopterin) are frequently raised in molecularly proven AGS. Levels of the neurotransmitter metabolites 5HIAA, HVA, and 5MTHF are normal.

The diagnosis can be confirmed in children with typical clinical findings, calcification of the basal ganglia and white matter on CT brain scan and leukodystrophic changes in brain MRI, and identifiable mutations in one of the four known causal mutations. Mutations in *TREX1*, *RNASEH2A*, *RNASEH2B*, and *RNASEH2C* are identified in approximately 80% of individuals.

Management includes chest physiotherapy and treatment of respiratory complications; attention to diet and feeding methods to assure adequate caloric intake and avoid aspiration; and seizure control. Infants should be monitored with repeat ophthalmologic examinations in the first few months for glaucoma. Older children should be followed for evidence of scoliosis, insulin-dependent diabetes mellitus, and hypothyroidism.

Most AGS is inherited in an autosomal recessive manner. Most individuals with AGS do not reproduce. Prenatal testing is possible for pregnancies at increased risk if the disease-causing mutation(s) in the family have been identified. Rarely, AGS can be caused by *de novo* autosomal dominant mutations in *TREX1*.

Neuronal Ceroid Lipofuscinoses (NCLs)

The neuronal ceroid-lipofuscinoses (NCLs) are the most common hereditary progressive neurodegenerative

diseases. The prevalence is about 1.5–9 per million population. The incidence ranges from 1.3 to 7 per 100,000 live births, depending on the country.

The NCLs are inherited lysosomal storage disorders presenting early with seizures, then intellectual and motor deterioration, progressive blindness, and death. They are to be differentiated from other disorders called in old terminology "the familial amaurotic idiocies," of which Tay–Sachs, Sandhoff's diseases (the GM2 gangliosidoses) are the prototype. NCLs and GM2 gangliosidoses commonly present in infancy or late infancy, with seizures and visual loss. However, the blindness in GM2 gangliosidoses is due to macular degeneration with a cherry red spot (cerebromacular degeneration) on opthalmoscopic examination, while in the NCL's, progressive blindness is due to retinitis pigmentosa (cerebroretinal degeneration).

Phenotypes have been characterized clinically by age of onset and order of appearance of the clinical features: infantile neuronal ceroid-lipofuscinosis (INCL, Santavuori), late-infantile (LINCL, Jansky–Bielschowsky), juvenile (JNCL, Batten–Spielmeyer–Vogt), adult (ANCL, Kuf's disease), and Northern epilepsy (NE, progressive epilepsy with intellectual disability). The clinical presentations of INCL, LINCL, and JNCL are discussed in the Chap. 39, "Lysosomal Storage Disorders" chapter by Ozand and Al-Essa. The differential diagnosis, genetics, diagnostic tests, and management are discussed here.

Differential Diagnosis

For INCL, Santavuori type (infantile onset):

Tay–Sachs and Sandhoff diseases, Leigh syndrome, Rett syndrome, the infantile peroxisomal disorders (infantile Rhefsum's, neonatal adrenoleukodystrophy), subacute presentations of non-ketotic hypoglycinemia, pyridoxine dependency, CSF glucose transporter deficiency (Devivo syndrome), Niemann–Pick disease types A and B. The distinguishing feature usually is lack of retinal degeneration in these disorders. The differential diagnoses are as follows:

For LINCL, Jansky–Bielschowsky type (late infantile onset):

The epileptic encephalopathies, particularly Severe Myoclonic Epilepsy of Infancy (Dravet syndrome) and Lennox-Gastaut syndrome, and other lysosomal storage disorders.

For JNCL, Batten–Spielmeyer–Vogt type (juvenile onset):

MELAS, MERRF, juvenile onset GM2 gangliosidoses.

The retinal degeneration of JNCL differs from classic retinitis pigmentosa in that in JCNL there is loss of central vision first, not peripheral, and rapidly progresses, with total blindness in 1–2 years.

Genetics

All are inherited as autosomal recessive.

For INCL, Santavuori type: Age of onset 6–24 months. Major gene involved is PPT1.
For LINCL: Classic Jansky–Bielshcowsky type: Onset 2–4 years, major gene is TPP1.
But, there are less common variants:
Finnish variant: Onset 4–7 years. Gene is CLN5.
Early juvenile variant: Onset 18 months to 8 years. Gene is CLN6.
Other variants: Onset 3–7.5 years. Genes are MFSD8, CLN8, CTSD, PPT1.
For JNCL: Batten–Spielmeyer–Vogt: Classic presentation, gene is CLN3.
Rarer variants: Genes are PPOT1, TPP1, CLN9.

Diagnosis

With a good pediatric hematopathologist, diagnosis can be made clinically by electron microscope analysis of lymphocytes in the buffy coat, achieved by centrifuging a sample of blood, which reveal curvilinear or fingerprint bodies or granular osmophilic deposits typical of NCL. Such storage material can also be seen by obtaining ganglion cells through rectal biopsy or conjunctival biopsy, although analyzable samples are technically difficult to obtain. Skin biopsies can also be sampled. White blood cells and cultured skin fibroblasts can be examined for three enzymes: PPT1 (palmitoyl-protein thioesterase 1), TPP-1 (tripeptidyl peptidase 1), and CTSD (cathepsin D). Molecular genetic testing utilizes targeted mutation analysis or sequence analysis.

Management

Treatment is symptomatic and supportive. Drugs used may be antiepileptics, anti-dystonia drugs such as trihexyphenidyl, benzodiazepines for spasticity, antidepressants, and antipsychotics. Phenytoin and carbamazepine need to be avoided because they may activate seizures and and increase rate of deterioration. Lamotrigine can exacerbate myoclonus and seizures, particularly in the late infantile form.

Mid-Childhood

Acute Encephalopathies

Infection-related encephalopathies
- Acute toxic encephalopathy
- Reye–Johnson syndrome
- Influenza-associated encephalopathy
  - Acute necrotizing encephalopathy
- ADEM
- AHLE
- Metabolic encephalopathies
  - Hepatic encephalopathy
  - Uremic encephalopathy
  - Hypertensive encephalopathy (PRES, posterior reversible encephalopathy syndrome)
  - Hypoglycemic encephalopathy

Infection-Related Encephalopathies

Acute Toxic Encephalopathy

Acute toxic encephalopathy results from bacterial toxins from a number of agents: *Bordetella pertussis*, *Shigella*, *Campylobacter jejunum*, *Salmonella*, *Bartonella henseke*. It presents with acute change in mental status, but is not due to infectious encephalitis or meningitis. The treatment is antibiotics directed at the infectious agents.

Reye–Johnson Syndrome

Reye–Johnson syndrome (See Chap. 217, "Hepatopathies and Reye Syndrome") presents 3–5 days after a viral infection, often influenza, as an acute change in mental status associated with hypoglycemia, hyperammonemia, fatty infiltration of the liver, and cerebral edema. Four clinical and EEG stages have been postulated in the past, with patients recovering if in Stage 1 or 2, equivocal in Stage 3, almost always progressing to death in Stage 4. The association of aspirin and Reye syndrome is now considered spurious, and the rise and fall in the incidence of Reye syndrome remains unexplained.

The biochemical explanation for Reye-like symptoms is a generalized disturbance in mitochondrial metabolism, eventually resulting in metabolic failure in the liver and other tissues. The etiology of "classical" Reye syndrome is unknown. Hypothetically, the syndrome may result from an unusual response to the preceding viral infection, which is determined by host genetic factors but can be modified by a variety of exogenous agents.

For the past decade or so, reported cases of Reye or Reye-like syndromes have usually had a biochemical explanation, usually the fatty acid oxidation disorders. The treatment of Reye syndrome was always supportive, with the therapeutic aim of reducing cerebral edema.

Influenza-Associated Encephalopathy

Influenza-associated encephalitis/encephalopathy is an uncommon but potentially more serious complication widely reported in Japanese populations, although cases from other East Asian countries, North America, and Europe have been described. Clinical manifestations are diverse, and typically involve febrile seizures and abnormal behaviors in mild cases, with rapid evolution through decreased consciousness to coma in severe forms. Influenza is also a known trigger for a number of rarely encountered, yet often serious, CNS diseases, including Reye–Johnson syndrome. In cases of serious disease, the prognosis is often poor, with outcomes including death or severe neurological sequelae.

Acute necrotizing Encephalopathy (ANE). First described by Mizuguchi et al., ANE occurs early after influenza A and H1N1 infection and presents with encephalopathy and seizures, no CSF pleocytosis, no elevated blood ammonia, and symmetrical multifocal brain lesions and hypoxia, intoxication, hemolytic uremic syndrome, metabolic and neurodegenerative disorders have been ruled out. Most cases occurred in children younger than 5 years of age of Asian origin. Sporadic cases have been reported in Europe and North America. Brain MRI using T2 weighted images, diffusion-weighted imaging (DWI), and apparent diffusion coefficient (ADC) maps show symmetrical lesions in the pons, thalami and geniculate bodies, with swelling. Pathology shows necrosis with petechiae in thalamus and tegmentum of the pons and myelin pallor in cerebellar and cerebral subcortical white matter.

Pathogenesis of IAE is not fully understood but may involve viral invasion of the CNS, proinflammatory cytokines, metabolic disorders, or genetic susceptibility. An autosomal dominant viral acute necrotizing encephalopathy (ANE) was recently found to have missense mutations in the gene Ran-binding 2 (RANBP2).

Acute Disseminated Encephalomyelomyelitis (ADEM)

Acute disseminated encephalomyelitis (ADEM) is a diffuse, monophasic demyelinating disease that follows either a viral infection or, rarely, a viral immunization. Symptoms typically develop a week or two after the antecedent infection and include headache, lethargy, and coma. The clinical course is rapid, and as many as 20% of those affected die; the remaining patients recover completely. ADEM

is discussed in detail, and AHLE briefly, by Tanuja Chitnis, ❯ Chap. 375, "Parainfectious and Autoimmune Disorders".

Acute Hemorrhagic Leukoencephalomyelitis (AHLE)

Acute hemorrhagic leukoencephalomyelitis of Weston Hurst is a rare fulminant disorder typically affecting young adults and children and is thought to be a hyperacute form of ADEM. AHLE often presents with abrupt onset of fever, neck stiffness, seizure, and/or focal neurologic signs several days following a viral illness or vaccination. The illness is preceded by a recent episode of upper respiratory infection, most often of unknown cause. The differential diagnosis considers a direct central nervous system infection or a toxic ingestion. Pathology shows lesions much more severe than those of ADEM and includes destruction of small blood vessels, disseminated necrosis of white and gray matter with acute hemorrhage, fibrin deposition, and abundant neutrophils. Scattered lymphocytes are seen in foci of demyelination. An autoimmune pathophysiology is likely, with immune cross-reactivity between myelin basic protein moieties and various infectious agent antigens. Although treatment is not well-established; some authors report that a combination of immunosuppressant medications and/or therapeutic plasma exchange may be of benefit. Prognosis is severe, with death in days to a week after symptom onset. Significant residuals remain in the few who survive.

Hepatic Encephalopathy (See chapter on ❯ Liver Failure). Specific neurologic features in *hepatic encephalopathy* are asterixis, and an EEG pattern of triphasic waves upon a slow background, although the latter is nonspecific and may be seen in other encephalopathies. The toxin most implicated is ammonia. The most important component of managing a child with hepatic encephalopathy is basic intensive care with regulation of fluid status, glucose, and electrolyte homeostasis. Specific management includes measures to reduce serum ammonia concentrations, and the prevention and prompt treatment of complications. Methods to reduce ammonia target various steps in its metabolism. This includes reducing its production in and absorption from the intestine and promoting its metabolism in the liver. Specific pediatric care issues, approaches to treatment of fulminant hepatic failure, the role of artificial liver support devices, and decision for liver transplantation are beyond the scope of this chapter.

Uremic Encephalopathy. In *uremic encephalopathy* (See chapter on ❯ Chronic Renal Failure), hypertension is often associated (see chapter on ❯ Hypertension in Children), and the syndrome of posterior reversible encephalopathy (PRES) is seen. Pavlakis, et al. assert that PRES is just a new name for hypertensive encephalopathy. Clinical presentation is usually with seizures, headache, visual disturbances including cortical blindness, and encephalopathy. PRES is a clinical-neuroradiological syndrome, with bilateral posterior parietal-occipital increased T2 and FLAIR signal intensities, which resolve over time. PRES has been reported with a number of different conditions in normotensive children – cancer chemotherapy, usually leukemia, systemic lupus erythematosus, measles vaccination, glomerulonephritis, vasculitis, immunosuppressive treatment, renal failure and eclampsia, but it is likely that a comorbid acute hypertensive episode has occurred. The rise in blood pressure is probably rapid, and may be brief, so that it may not have been clinically observed before the clinical/radiological picture emerges. Jones BV et al. postulate that children develop hypertensive encephalopathy at lower absolute pressures than adults owing to the relative "left shift" of their range of cerebral blood flow autoregulation. Neuroradiological perfusion techniques that were applied in their patients support vasodilatation, rather than vasoconstriction and edema, as the primary pathogenic event, with breakdown of blood-brain barrier, and extravasation of protein and fluid. Arterioles situated a short distance from the cortical surface are most affected, and sympathetic nervous activity affords protection from these effects. The posterior circulation has significantly less sympathetic innervation than the carotid circulation, which may explain why the majority of lesions in hypertensive encephalopathy are found in the vascular territory of the posterior circulation. The syndrome is reversible, if secondary complications, such as hemorrhage into the leukoencephalopathic areas, do not occur.

Hypoglycemic Encephalopathy. The multiple different causes of hypoglycemia in infants, children, and adolescents are discussed in the chapter on ❯ Hypoglycemia. Encephalopathic presentations of hypoglycemia vary in different ages. Neonates may be asymptomatic. Older children may show palpitations, perspiration, and pallor, with a feeling of weakness and hunger if hypoglycemia is rapid, which usually precede encephalopathic manifestations like disorientation, confusion, headache, inability to concentrate, somnolence, and seizures. If blood glucose levels dip to 10 mg/dL or less, coma ensues, with pupillary dilatation, bradycardia, hypotonia, and shallow breathing. The pathogenesis may involve energy depletion, accumulation of metabolites from nonglucose metabolism, and changes in levels of neurotransmitters. Pathologically, laminar necrosis of the cerebral cortex has long been described, the hippocampus being particularly sensitive.

Recent studies have also reported extensive lesions in cerebral white matter and reversible lesions in the splenium of the corpus callosum (Gallucci M), thought to be due to cytotoxic edema. The management requires prompt glucose replacement, whatever the etiology, with thiamine supplementation. In malnourished patients, niacin, to prevent pellagra, should also be given.

Subacute Encephalopathies

Two parasitic diseases are worth discussing here, since their presentations are essentially with encephalopathy.

Cerebral malaria
Trypanosomiasis (African sleeping sickness)
Epileptic encephalopathies
- Electrical status epilepticus in slow-wave sleep (ESESS)
- Landau–Kleffner syndrome
- Continuous spike waves in slow-wave sleep (CSWS)

Cerebral Malaria (See chapter on Malaria)

Cerebral malaria is a rapidly progressive encephalopathy with a 20% mortality in the pediatric population. This means 80% of children survive, but often with neurological residuals. Although rare relative to the total number of infections, cerebral malaria significantly contributes to approximately 1,000,000 deaths per year and disproportionately affects children less than 6 years of age in sub-Saharan Africa.

A cardinal feature of the pathology is the massing of red cells containing *Plasmodium falciparum* toward the end of its life cycle within the cerebral capillaries. Adhesion of these parasitised red cells to endothelium, an event which may initiate cerebral malaria, is being studied at the molecular level. Basic pathogenesis in mouse models and human studies focus on cytokines, inflammation, cytoadherence, and endothelial activation. Coagulation is variably important, but it is most likely the end point of a series of processes.

One model of pathogenesis is cytokine storm and TNF activation. Lessons from the mouse model and in vitro tissue culture have definitely demonstrated that the endothelium must be stimulated via inflammatory/activation agents before the ligands on the surface are sufficient for sequestration to occur. The correlation of retinal and cerebral pathology suggests that those pediatric patients with features of malarial retinopathy who survive must have had similar changes in the brain including ring hemorrhages. However, anti-TNF agents applied when patients are in coma have not proven effective. They probably have to be given before the TNF cascade begins.

Low levels of nitric oxide, and its precursor arginine, have been found, in cerebral malaria, suggesting that less localized nitric oxide is available to provide for vascular dilatation, which subsequently leads to endothelial activation, upregulation of proadherent molecules, and damage of alternative pathways, including activation of superoxide dismutase. This suggests the possibility of L-arginine as a treatment.

Clinical presentation is a diffuse, febrile encephalopathy, with nonfocal signs, in a *P. falciparum* endemic area (or in travelers who have recently been in such an area). The incubation period is usually 10–18 days. The fever may be intermittent, irregular, or continuous. Generalized seizures occur in 50%, nuchal rigidity rarely occurs, and bilateral pyramidal tract signs when severe, which may proceed to decorticate and decerebrate posturing. Most important is examination of the fundus. Ophthalmoscopic examination to evaluate the retinas in comatose children greatly increases the accuracy of diagnosis of cerebral malaria. It is also a measure of prognosis in patients with evidence of retinopathy with or without papilledema and is a tool for stratifying or triaging patients into treatment or further diagnostic workup. The pediatric retinal findings are peripheral whitening, orange and white vessels, hemorrhages, and papilledema.

Regarding treatment, chloroquin is used for non-*falciparum* malaria. But there is now widespread resistance in endemic areas. All cases *of falciparum* malaria must be admitted for therapy owing to the high mortality of the disease. Falciparum malaria is treated with atovaquone-proguanil (Malarone) or quinine sulfate plus doxycycline, tetracycline, or clindamycin. Cerebral malaria is treated with intravenous quinidine. Since 1991, quinidine gluconate has been the only parenterally administered antimalarial drug available in the United States. A loading dose of 6.25 mg base/kg (10 mg salt/kg) of quinidine gluconate is infused intravenously over 1–2 h, followed by a continuous infusion of 0.0125 mg base/kg/min (0.02 mg salt/kg/min). At least 24 h of quinidine infusion is recommended. Once the patient can take oral medication, and the parasite density is less than 10%, the treatment course is completed with oral quinine at a dosage of 10 mg salt/kg every 8 h. The combined treatment course of quinidine/quinine is 7 days, if the disease was acquired in Southeast Asia, and for 3 days if from South America and Africa. The availability of artemisinin combination therapy in adults across most of Africa produces more

rapid cures with no definitive drug failures at present. However, the resistance and delayed clearance patterns seen in Southeast Asia and Africa are worrying for emerging resistance. Clinical trials with artemisinin compounds have shown decreased mortality in adults with severe disease after 48 h of treatment, compared to quinine. No such studies in pediatric patients have been published and almost all mortality in children with cerebral malaria occurs within the first 48 h. Regarding prevention, the RTS,S vaccine trials ongoing in multiple African nations are showing positive results with decreases in both disease incidence and severe disease.

African Trypanosomiasis (Sleeping Sickness)

Sleeping sickness is caused by two organisms: in East Africa, *Trypanosoma brucei rhodesiense,* which causes the more severe form, and in West Africa, *Trypanosomoa brucei gambiense.* They are transmitted by tsetse flies, who feed primarily on wild animals, causing a painful, red swelling at the site of the bite. The infection then spreads through the blood circulation, causing episodes of fever, headache, sweating, and swelling of the lymph nodes. When it reaches the brain, behavioral changes such as fear and mood swings occur, followed by headache, fever, delirium, and asthenia. Patients experience drowsiness during the day, but nighttime insomnia. Symptoms may include anxiety, headache, mood changes, and an uncontrollable urge to sleep. West African trypanosomiasis is primarily a problem in rural populations, and tourists rarely become infected with *T. b. gambiense.* East African trypanosomiasis is an occupational hazard for persons such as game wardens who work in areas where infected wild animals and vectors are present, and in occasional tourists who visit game parks.

Patients without CNS involvement are treated with suramin. The protocol is available through the Centers for Disease Control (CDC). Patients who have positive lumbar punctures should be treated with melarsoprol, a trivalent arsenic compound which, however, has significant toxicity. It can cause hepatotoxicity, cardiac arrhythmias, albuminuria, vomiting, abdominal pain, peripheral neuropathy, and paraplegia. Arsenic encephalopathy occurs in as many as 10% of treated patients and is frequently fatal. The 5–10% risk of mortality from the therapy is outweighed by the risk of the disease. The mortality of CNS African trypanosomiasis is 100%. As is true for suramin, melarsoprol is only available in the United States through the CDC.

Other regimens being explored include a combination chemotherapy, eflornithine alongside nifurtimox, to decrease the time frame and overall dosing of eflornithine, in order to reduce the risk of emerging drug resistance. A nitroheterocycle, fexinidazole, whose trypanocidal activity was first shown nearly 30 years ago, has entered clinical trials. The World Health Organization has declared a campaign to eradicate human African trypanosomiasis.

Epileptic Encephalopathies

Electrical status epilepticus in slow-wave sleep (ESESS)
Landau–Kleffner syndrome (LKS)
Continuous Spike Wave in Sleep (CSWS)

ESESS is an EEG finding and is defined as epileptiform discharges occurring in 80–85% of nocturnal slow-wave sleep. The terms continuous spike wave in slow-wave sleep (CSWS) and Landau–Kleffner syndrome (LKS) describe the clinical epileptic syndromes, among others, that can be seen with ESESS.

LKS is a disorder of uncertain etiology, presenting usually in early childhood, with subacute loss of both comprehension and production of language over weeks to months, where seizures occur concurrently or after language loss begins, and a behavioral change occurs with hyperactive, impulsive, and inattentive behavior. Seizures are usually mild and easy to control, but suppression of seizures does not necessarily herald recovery of language function. The initial language loss often appears as an auditory verbal agnosia, but other childhood aphasia syndromes may occur. Although anecdotal papers have reported remarkable reversal of seizures and language loss with IV or oral steroids, IV IgG, high-dose diazepam, ketogenic diet, or multiple subpial transaction, no controlled studies have been done, and many children with LKS have long-standing language and learning disabilities lasting into adulthood. The reacquisition of oral language is aided by use of visual systems, such as signing.

Although there is an overlap between LKS and CSWS, children with CSWS present with a more global regression, have more problematic epilepsy, and have EEG foci located predominantly in frontotemporal or frontocentral regions. In contrast, children with LKS present with language, not cognitive, loss, have fewer seizures, and the EEG foci are said to be predominantly in the posterotemporal regions. Reports from Japan tout high-dose valproic acid or a combination of valproic acid and ethosuximide as causing remission of CSWS in 2/3 of their patients. Other reports from Europe report levetiracetam as being the most effective AED, causing remission in 40% of patients. Most reports agree that early age of onset and longer duration of ESESS in CSWS bode for poor prognosis.

Chronic Encephalopathies

Adrenoleukodystrophy
Niemann–Pick Type C (see Ozand and Al-Essa chapter on Lysosomal Storage Diseases)
Juvenile Huntington's disease

Adrenoleukodsystrophy (ALD)

ALD is a disorder where a defective enzyme, lignoceroyl-coenzyme A interrupts the normal β-oxidation of very long chain fatty acids (VLCFAs) in the peroxisomes, resulting in the accumulation of the C-26 and above VLCFAs, a main component of myelin. Excess VLCFAs stimulate adjacent astrocytes and macrophages, which initiate a tumor necrosis factor cytokine cascade which results in demyelination. ALD is an x-linked disorder, the gene *ABCD1* being mapped to Xq28. In neuroimaging studies, increased T2 and FLAIR intensity is primarily in bilateral occipito-parietal areas.

Although there is a neonatal form and an adult form, adrenomyeloneuropathy, which presents as a progressive spastic diplegia, the most common childhood presentation is between the ages of 4 and 8 years. Initial presentations are a decline in school work and ADHD-like symptoms, then early visual agnosia, cortical blindness, progressive dementia, upper motor neuron dysfunction, with adrenal insufficiency, which often predates neurological symptoms and may manifest over time as progressive darkening of the skin and requires ACTH stimulation tests for confirmation.

There is another phenotype, Addison's disease only, presenting with adrenal insufficiency usually by age 7–8 years, with no neurologic signs, but who, in about 10%, later in life usually develop adrenomyeloneuropathy. About 20% of female carriers develop mild neurological signs later in life, usually after age 35.

Diagnosis is made by the typical history, clinical neurological signs, the brain MRI, and elevated serum levels of VLCFAs. Molecular genetic testing of *ABCD1*, the only gene known to be associated with X-ALD, is clinically available.

Differential diagnosis includes other leukodystrophies like metachromatic and globoid cell leukodystrophies, other childhood dementing disorders such as NCL, the juvenile or Batten–Spielmeyer–Vogt presentation, and subacute sclerosing panencephalitis (SSPE).

Management includes replacement steroid therapy for the adrenal insufficiency, psychological, supportive, and educational support. Bone marrow transplantation is an option available for boys with the typical childhood form, who have brain MRI abnormalities, but with still preserved cognitive function (performance I.Q.>80) and a normal neurological examination. An investigational therapy is Lorenzo's oil, a 4:1 mixture of the triglycerides of oleic and erucic acid, prepared from olive oil and rapeseed oil, given to presymptomatic boys treated with Lorenzo's oil who had reduction of C26, and resulted in reduced risk of later brain MRI abnormalities. However, some still developed ALD. Lorenzo's oil remains an investigational therapy.

Juvenile Huntington's Disease

The prevalence of Huntington's disease is 3–7/100,000 in people of western European ancestry. It is much less in African blacks, Chinese, and Japanese. The highest prevalence in the world is probably in the Lake Maracaibo region of Venezuela. It is an autosomal dominant progressive degenerative disease that usually presents in midlife with chorea and slowly progressive dementia. It is due to an expansion of 36 or more CAG trinucleotide triple repeats in the Huntington gene HTT (See Movement Disorders chapter, by Yasser Awaad). In any triple repeat disease, there is the phenomenon of anticipation; that is, the disease expresses itself at younger and younger ages in subsequent generations. *Juvenile Huntington's Disease* is defined as presenting before the age of 20 years and occurs primarily through paternal transmission of HTT. In adolescents, it presents with rigidity rather than chorea, and with mental status changes such as attention and concentration problems, cognitive slowness, and impaired executive functioning, so it should be in the differential diagnosis of decrease in school performance. There may be depression, personality changes, intermittent explosiveness, and even psychosis. Seizures occur in up to 50% of children presenting before the age of 10 years. The pathology shows selective degeneration of neurons in the corpus striatum – the caudate and putamen. Brain MRI can show striatal atrophy 10 years before clinical symptoms appear. Treatment is supportive and symptomatic. Antiparkinsonian agents containing L-DOPA aimed at decreasing rigidity risk increasing chorea. Haloperidol, tetrabenazine, or benzodiazepines may suppress chorea. Psychiatric disorders can be treated with appropriate psychotropic medications. Genetic counseling is mandatory for at-risk, presymptomatic children under age 18 years. The consensus at present is not to gene-test these children because of the psychosocial, legal, and ethical implications of genetic testing of children and adolescents for a disease that has no definitive treatment.

Late Childhood – Adolescence

Acute Encephalopathies

Acute confusional migraine
Immune-mediated encephalopathies
- Hashimoto's encephalopathy
- Rassmussen's encephalitis

Other immune mediated epileptic encephalopathies
- Acute encephalitis with refractory, repetitive partial seizures (AERRPS)
- Devastating epileptic encephalopathy in school-aged children (DESC)
- New onset refractory status epilepticus (NORSE)

Acute Confusional Migraine (ACM)

Gascon and Barlow first described pubertal and early adolescent children who presented to emergency rooms with the acute onset of confusion, disorientation, and short-term memory loss lasting hours. If an EEG was done during this period, it showed high-voltage diffuse delta slowing, most prominent posteriorly. After an overnight sleep, they recovered and returned to normal. In retrospect, the presence of mild headache was elicited. Some neurologists consider these episodes similar to, if not identical with, the syndrome of transient global amnesia in adults. The differential diagnosis includes nonconvulsive status epilepticus, drug ingestion, concussion, encephalitis, or acute posychosis. Brain MRIs and CSF studies are normal. A history of migraine headaches preceding the confusional episode can be obtained, or subsequently, conventional migraine with or without aura develops (See chapter on ❯ Headache by Mack and Matarese). No treatment is necessary, since the episodes resolve spontaneously after sleep (See ❯ *Table 366.3*).

Immune-Mediated Encephalopathies

Hashimoto's encephalopathy
Rassmussen's encephalitis

Hashimoto's Encephalopathy

Hashimoto's encephalopathy is of presumed autoimmune origin and is characterized by high titers of antithyroid peroxidase antibodies. It is more common in women than in men and has been reported in pediatric, adult, and elderly populations throughout the world.

The clinical presentation may be relapsing and remitting and include seizures, stroke-like episodes, cognitive decline, neuropsychiatric symptoms, and myoclonus. Thyroid function tests are normal. Diagnosis is made first, by excluding other toxic, metabolic, and infectious causes of encephalopathy, and secondly, finding elevated titers of antithryoid antibodies. Pathological findings can suggest an inflammatory process, but features of a severe vasculitis are absent. It may be that Hashimoto's encephalopathy will be subsumed into a group of nonvasculitic autoimmune inflammatory meningoencephalopathies, such as paraneoplastic limbic encephalitis, which usually occurs in women with ovarian teratomas, who have elevated NMDA receptor antibodies. Treatment with corticosteroids is almost always successful, although relapse may occur if treatment is abruptly terminated. Intravenous immune-globulin and plasma exchange may also be effective.

Rassmussen's Encephalitis

This is a rare, disabling disease of childhood, presenting first as epilepsia partialis continua, may progress to refractory focal seizures and focal status epilepticus, hemiplegia, and dementia. Neuroimaging studies show progressive hemiatrophy of the brain. Anti Glu-R3 antibodies (against the glutamate receptor subunit 3) have been reported in some, but not all, patients. The pathology shows inflammation, with cytotoxic T cell reactions against neurons. Immunotherapy using corticosteroids, IV IgG, tacrolimus, and intraventricular alpha interferon, and plasmapheresis have temporarily arrested the course of the disease, all of which supports an autoimmune pathogenesis. Eventually, however, the patients are candidates for hemispherectomy for refractory seizures.

Other Immune-Mediated Epileptic Encephalopathies

Acute encephalitis with refractory, repetitive partial seizures (AERRPS)
Devastating epileptic encephalopathy in school-aged children (DESC)
New onset refractory status epilepticus (NORSE)

What these epileptic encephalopathies with different acronyms all have in common is an acute or subacute onset of status epilepticus after a febrile illness, with no evidence of encephalitic infection, followed by

drug-resistant partial epilepsy, reported from Japan, France, the United Kingdom, and Singapore. They appear like a more acute, rapidly evolving Rassmussen's encephalitis, but not limited to a hemisyndrome. AERRPS was defined as a prolonged acute phase of more than 2 weeks, partial seizures frequently evolving into convulsive status, drug resistance, with viral encephalitis and metabolic disorders excluded. DESC was described as status epilepticus and fever at onset, later occurrence of drug-resistant epilepsy and neuropsychological deficits. Response to steroid treatment in DESC patients was unsuccessful. Specchio et al. described eight cases which overlapped with AERRPS and DESC. In two AERRPS cases, antibodies against Glu ε2 were found. In Specchio's eight cases, two had anti-GAD (glutamic acid decarboxylase), one had a CL (anti-cardiolipin) and anti-B2-GPI (anti-beta 2 glycoproteinI autoantibody), and one had ASMA (anti smooth muscle) auto-antibodies. Only one patient recovered; the rest had chronic epilepsy. Response to steroid treatment in DESC patients was unsuccessful.

Subacute Encephalopathies

Non-convulsive status epilepticus (NCSE)
- Absence status
- Psychomotor status (complex partial status epilepticus)
- Comatose patients

Nonconvulsive status epilepticus (NCSE) is defined as a state of altered mental status that can vary from confusion to obtundation to coma for at least 30 min, where an EEG records continuous or frequent electrographic seizures. It constitutes about 25% of all cases of status epilepticus, 8% in subarachnoid hemorrhage, and 8–10% in coma. In *absence status epilepticus*, the child may constantly blink the eyes or may stare blankly, and the EEG shows continuous three cycles per second spike-wave complexes. *In psychomotor status, also called complex partial status epilepticus,* in addition to an altered mental status, there may be automatisms. The EEG shows repetitive high-voltage theta waves in temporal areas. The diagnosis is verified by return to a normal state of consciousness concomitant with suppression of the EEG discharges by intravenous AEDs, usually diazepam or lorazepam. Both of these forms of NCSE present in a patient who is ambulatory, and where the differential diagnosis includes acute confusional migraine, drug ingestion, or psychosis. For primary generalized absences, if benzodiazepines do not stop the status, intravenous valproate (Depacon) is most appropriate. For psychomotor status, if benzodiazepines do not stop it, intravenous phenobarbital or phenytoin (or IM fosphenytoin) would be appropriate. General anesthesia with agents like short-acting barbiturates, propofol, or ketamine, which are options in refractory convulsive status epilepticus (CSE), are not usually necessary in NCSE.

Then there is the critically ill patient, where it occurs in 8–10% of patients in coma. There is a bimodal distribution of NCSE in critically ill patients, affecting children (age <1 year) and the elderly. It is commonly detected in an intensive care unit, after a patient has been hospitalized for overt CSE. After successful suppression of clinically observed seizures, the patient fails to wake up and this is not accounted for by medication-induced drowsiness. The estimated incidence is 15–40% after CSE. It may also occur in any patient who fails to awaken after any acute brain illness, whether an acute stroke, subarachnoid hemorrhage (incidence 8%), head injury, acute encephalitis, hypoxic-ischemic encephalopathy, or postoperatively, for example, after surgery for correction of congenital cardiac anomalies. In this setting, NCSE is diagnosed by a high index of suspicion and by continuous EEG monitoring.

The presence of NCSE is a risk for clinical deterioration and poor prognosis, independent of the original acute brain insult. Not enough studies have been done yet to determine whether early recognition and prompt suppression of electrographic seizures significantly improves outcome.

Chronic Encephalopathies

Slow virus diseases
- Subacute sclerosing panencephalitis (SSPE)
- HIV encephalopathy (See chapter on Human Immunodeficiency Virus)
- Progressive multifocal leukoencephalopathy (PMFL)

Progressive genetic encephalopathies
- Wilson's disease (see Movement Disorder chapter, Yasser Awaad)
- Juvenile Huntington's disease (See previous section in this chapter)
- Neurodegeneration with brain iron deposition (PANK2)
  - Formerly called Hallervorden–Spatz disease
- Progressive myoclonic encephalopathies
  - Unverricht
  - Lafora
  - MERRF (See previous section in this chapter)

Slow Virus Diseases

Subacute Sclerosing Panencepalitis (SSPE)
Human immunodeficiency virus (AIDS encephalopathy)
See chapter on Human Immunodeficiency Virus
Progressive multifocal leukoencephalopathy

What these all have in common is the persistence over years of a virus, in mutated form, after an initial infection, either from long known common viruses like measles, or viruses that were previously unknown but emerged in the late twentieth century, human immunodeficiency virus and papova virus. Recovery from the initial systemic infection occurs, but after a prolonged latent period, symptoms of brain dysfunction appear, and slowly progress.

Subacute Sclerosing Panencephalitis (SSPE)

SSPE is a progressive degenerative encephalopathy due to persistence in the CNS of a mutated form of the measles virus (MV). (See chapter on Measles) It is now extremely rare in the developed world, where countries have reached or exceeded 80% of the population being immunized with the measles vaccine, but still endemic in the developing world where that standard of immunization has not been reached. The viral genome consists of biased hypermutations affecting principally the matrix (M) gene. There are high CSF titers of antibodies to measles virus, with infiltrations of B and T cells into the CNS. The pathogenesis starts with measles infection at a critical stage of maturation of the CNS and immune system, usually before the age of 2 years. The infection is not contained, despite what seems like initial recovery from childhood systemic measles. There is no major histocompatibility complex in neurons. The mutations of the MV genome affect viral epitopes that are critical for recognition of infected cells. Therefore, there is a defective cytotoxic lymphocyte response and lack of viral clearance. The mutated virus lies dormant in the CNS for years until it becomes activated. What triggers the activation is not known. The pathology reveals nuclear inclusions in neurons that contain the viral antigens. Neurofibrillary tangles can be seen in neurons and oligodendrocytes. Perivascular cells are predominantly CD4+ T cells, with B cells seen more in parenchymal inflammatory infiltrates.

The typical clinical presentation usually starts with cognitive and behavioral deterioration, often mimicking the symptoms of attention deficit hyperactivity disorder, with decline in school performance, over weeks to months. Periodic myoclonus then reveals itself as sudden falls or uncontrolled periodic movements, which in the beginning may be as subtle as eye blinks or slight postural changes, but then proceed to falls. If not treated at this stage, motor and mental deterioration inexorably proceed, until a neurovegetative state or death. The stages of deterioration were first proposed by Jabbour and modified by Gascon et al. (See *Table 366.4*.)

The typical presentation discussed above can occur anywhere from mid-childhood through adolescence, and presents subacutely, followed by a chronic, progressive course.

Atypical presentations have been reported in infancy as an encephalopathy without the typical myoclonus, in childhood as an acute fulminant encephalopathy, as an ADEM presentation, and in adulthood.

The following drugs have been used in anecdotal reports: amantadine, cimetidine, corticosteroids, intravenous immunoglobulin, interferon beta, inosiplex, alpha interferon, and ribavarin. In the only published randomized, controlled treatment study, which compared oral inosiplex to combination inosiplex and intraventricular alpha interferon, carried out by the International Consortium on SSPE in Ankara, Mumbai, and Manila, there was no statistically significant difference between the two treatments. However, there was a satisfactory treatment outcome, meaning improvement or stabilization, in 34% of those treated with inosiplex alone, and 35% in those who had combined treatment. These are higher than the spontaneous remission rates of 5–10% reported in the literature. The conclusion is that neither treatment is

Table 366.4
SSPE stages

IA	Behavioral, cognitive, personality changes
IB	Myoclonic spasms – aperiodic, focal, subtle, infrequent
IIA	Myoclonic spasms – periodic, generalized, synchronous, frequent. EEG relatively normal background activity, but with PSWCs
IIB	Apraxias, agnosias, speech/language, spasticity, ataxia. Ambulatory with assistance
IIIA	Sits independently, may stand, no walking, no ADLs. Speaks less, visual difficulties. Spasms frequent, multifocal
IIIB	Bedridden, no spontaneous speech, poor comprehension, may be blind, dysphagia, chorea-ballismus-athetosis. EEG delta background; PSWCs obscured
IV	No myoclonic spasms, neurovegetative state. EEG background attenuation, no PSWCs

PSWC's periodic slow-wave complexes, ADLs activities of daily living (Modified from Gascon et al. 1993)

Table 366.5
CSF IgG synthesis index

Total intrathecal IgG synthesis (mg/day) = [(IgGCSF – IgGserum/615)–(AlbCSF-Albserum/291) × (IgGserum/Albserum)(0.43)] × 5

Concentrations in mg/dL, 615 and 291 are the average normal serum/CSF ratios for IgG and albumin, 0.43 the molecular mass ratio of albumin to IgG, and 5 the average daily production of CSF in deciliters (From Conrad AJ et al. 1994)

statistically superior to the other, but treatment is superior to no treatment. The critical laboratory value to follow for treatment response is the CSF IgG Synthesis Index, the best indication of immune response activation. (See *Table 366.5*.)

At this writing, although inosiplex has been available throughout the world, it has recently been approved by the FDA for restricted use in the USA. Clinical trials using ribavarin are being carried out in Japan and the Philippines.

Progressive Multifocal Leukoencephalopathy (PMFL)

PMFL is a rare slow virus infection of the brain caused by the JC virus, a common papova virus often acquired during childhood. The virus remains dormant unless certain circumstances, such as an immunosuppressive state, foster viral reactivation. Once reactivated, the virus may infect the brain and cause PML. It is a demyelinating disease caused by direct infection of oligodendrocytes by the JC virus.

It was first recognized through post-mortem examination in patients with severe illnesses, usually lymphomas or Hodgkins disease, who were immuno-compromised. Later, it was recognized as one of the superinfections in acquired immunodeficiency syndrome (AIDS) due to human immunodeficiency virus (HIV). With the advent of antiretroviral therapy, all the superinfections in AIDS have been decreasing in incidence. With the advent of neuroimaging, PML can be recognized in life through brain MRI. Recently, it has been recognized to occur in association with a drug used to treat multiple sclerosis, natalizumab, if there are multiple treatments.

The symptoms of PML may begin gradually, usually worsen rapidly, and vary depending on which part of the brain is infected. These may include difficulty with walking and other movements, decline in mental function, speech and visual difficulties. Rarely, headaches and seizures occur. Symptoms of PML are similar to the presenting symptoms of multiple sclerosis. A diagnosis of PML is made on the basis of results from magnetic resonance imaging of the brain, which shows T2-hyperintense, small to large, sometimes confluent lesions in the white matter, sparing the subcortical U-fibers. The diagnosis is confirmed by polymerase chain reaction (PCR) for JC virus in cerebrospinal fluid. The treatment is either cessation of immunosuppressive therapy in cancer patients or successful restoration of the immune system in HIV infection.

Pantothenate Kinase-Associated Neurodegeneration (PKAN)

Also called neurodegeneration with brain iron deposition (NBIA)
Formerly called Hallervorden–Spatz disease
(See also, Movement Disorders chapter by Yasser Awaad)

PKAN usually presents with dystonia, rigidity, and retinitis pigmentosa before age 10 years, and is due to progressive deposition of iron in astrocytes, microglia, and neurons of the globus pallidus. About one-fourth of patients present in adolescence, with slower progression, psychiatric symptoms, and intellectual decline.

The diagnosis is made by noting a progressive dystonia coupled with the "eye of the tiger" sign on brain MRI, a small region of hyperintensity surrounded by a rim of hypointensity in the globus pallidus, which, on coronal or transverse T2-weighted images, appears like a tiger's eye. Sequence analysis detects the mutations in PANK2, the only gene abnormality found in this disease.

Iron chelation therapy has not proven effective. The parkinsonian signs may respond to levodopa and bromocriptine, but not to anticholinergics. Botulinus toxin injections may help muscle rigidity or spasticity, as well as oral or intrathecal baclofen with a baclofen pump. Surgical approaches are ablative pallidotomy or deep brain stimulation.

Genetic counseling for the family is the same as for any autosomal recessive disease. Carrier testing for relatives at risk and prenatal testing for pregnancies at risk are possible if the disease-causing mutations have already been identified in an affected family member. The prognosis is dire, with death by age 20 years in about half of patients.

Progressive Myoclonic Epileptic Encephalopathies

Unverricht–Lundborg disease
Lafora disease

Unverricht–Lundborg Disease

Unverricht–Lundborg disease (EPM1) is an autosomal recessive neurodegenerative disease with onset from age

6–15 years, stimulus-sensitive myoclonus, action myoclonus, myoclonic seizures, and generalized convulsions. Some years after the onset, ataxia, incoordination, intentional tremor, and dysarthria develop. Individuals with EPM1 are initially mentally alert but show emotional lability, then mild cognitive decline over time. EPM1 results from defective function of cystatin B, a cysteine protease inhibitor, due to mutations in the *CSTB* gene. Brain MRI is normal. EEG shows generalized spike and polyspike/slow-wave discharges upon a slow background, and photic activation. The diagnosis can be confirmed by identifying disease-causing mutations in *CSTB* through targeted mutation analysis or sequence analysis. The differential diagnosis includes myoclonic epilepsy with ragged red fibers (MERRF) (See previous section on ❯ MERRF in this chapter), neuronal ceroid-lipofuscinosis (Kufs type), and Lafora disease. The drug of choice is valproic acid, to which clonazepam can be added. High-dose piracetam suppresses the myoclonus. Levetiracetam can suppress myoclonus and myoclonic seizures. Sodium channel blockers (carbamazepine, oxcarbazepine), GABAergic drugs (tiagabine, vigabatrin), and gabapentin and pregabalin may aggravate myoclonus and myoclonic seizures. Phenytoin aggravates neurologic symptoms and can accelerate cerebellar degeneration.

Lafora Disease

Lafora disease (LD) is a progressive degenerative disease which begins in adolescents between 12 and 17 years with symmetrical, multifocal, or generalized myoclonus and/or generalized tonic-clonic seizures. Emotional disturbance and confusion are common soon after seizures begin and are followed by dementia. Dysarthria and ataxia appear early; spasticity late. Death results a decade later from status epilepticus or complications of nervous system degeneration.

Diagnosis is usually based on the history, clinical course, and detection of mutations in the genes known to be associated with LD: *EPM2A* or *NHLRC1(EPM2B)*. Skin biopsy to detect pathognomonic Lafora bodies is sometimes necessary to confirm the diagnosis.

Of the antiepileptic drugs, phenytoin, and possibly lamotrigine, carbamazepine, and oxcarbazepine exacerbate seizures. Piracetam has been reported to be particularly effective, but is not available in the USA. Levetiracetam is the closest related drug. Treatment is otherwise supportive and aimed at preventing complications.

LD is inherited through autosomal recessive transmission. Carriers (heterozygotes) are asymptomatic. DNA testing for at-risk relatives and prenatal diagnosis for at-risk pregnancies are possible if the disease-causing mutations in the family are known.

367 Ataxias

S. H. Subramony

Ataxia: Definition

Ataxia refers to a syndrome of neurological dysfunction characterized by problems with balance and poor coordination of movements. Typically, it results from pathology in the cerebellum and its connecting pathways. It leads to difficulties with gait and stance, poor dexterity of limb movements, often a dysarthric speech and changes in eye movements that can produce visual symptoms such as blurry vision or a sense of oscillation of the environment called oscillopsia. Occasionally, a similar poor coordination of limb movements and imbalance can result from lesions that affect sensory input to the central nervous system, especially proprioceptive input. This is called sensory ataxia. Patients with cerebellar ataxia present with gait and balance in the absence of any demonstrable muscle weakness. Tasks requiring fine coordination such as writing, handling tools and utensils become difficult, and in the case of lower limbs, activities like biking and skating can suffer before regular walking becomes abnormal. Speech becomes slurred and appears to have abrupt changes in pitch and volume.

Neurological examination of patients with cerebellar ataxia reveals many abnormalities. Gaze-evoked nystagmus is usually seen and primary position nystagmus can also occur. For example, downbeat nystagmus in primary position is considered to be a pathognomonic sign of a lesion at the cranio-vertebral junction. Visual pursuit is abnormal and becomes jerky because pursuit of visual objects is achieved using small saccades (saccadic pursuit). Sacccades (quick, targeted eye movements) usually have normal speed with cerebellar lesions but are not accurate; they can over- or undershoot the target with subsequent corrective saccades to cancel the error (hypermetric and hypometric saccades). The dysarthria of cerebellar disease is characterized by unnecessary changes in pitch and volume and wrong emphasis on various syllables ("scanning dysarthria"). Limb motility and posture can be disturbed in several ways. There can be an action tremor that appears when a limb is maintained in sustained posture such as when the fingers are pointed at each other with elbows up. This type of tremor becomes even more overt when the limbs are moved in a purposeful, target-oriented fashion such as touching the examiner's finger and patient's nose repeatedly (finger to nose test) or the heel is slid along the shin from the knee to the ankle (heel to shin test). The oscillation of limbs in these situations is a form of kinetic tremor. A tremor of the head and trunk can occur (titubation). Also, fast movements that require accuracy result in either over- or under-reaching the target (hypermetric or hypometric movements). This can be shown by the finger chase test in which the patient is asked to touch the examiner's finger tip again and again as the latter is moved to a new location in a rapid manner. Multi-jointed movements become decomposed; the rapid pronation and supination of the forearm over the thigh is an example (dysdiadochokinesis). With increasing cerebellar dysfunction, patients have increasing sway of the body when placed in the feet together position of stance (such maneuvers as tandem stance and one foot stance become abnormal even earlier, but may not be specific). Eventually, patients tend to have a broad-based stance in their natural position. Tandem gait (heel to toe walking) becomes abnormal early with cerebellar ataxia. Later, regular gait becomes broad based, lurching and veering in quality.

With sensory ataxia, patients can have stance and gait problems and limb incoordination, but do not have speech or eye movement difficulties. The ataxia results from sensory loss (especially position and kinesthetic sense). Patients may admit to numbness, but this is not always the case. The deep tendon reflexes are lost or diminished because of the sensory fiber dysfunction. In many of the inherited types of ataxias, both sensory and cerebellar components are present. This chapter will give an outline of the various ataxic disorders with an emphasis on the genetic forms of the disease. An approach to a patient presenting with ataxia will be presented.

Etiological Classification of Ataxias

Ataxias are broadly grouped into acquired and inherited forms. Any overt structural lesions in the cerebellum and connecting pathways can lead to ataxia. These can usually be diagnosed readily when imaging studies are obtained,

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_367,

especially MRI scans of the brain. In these cases, signs of cerebellar disease are often accompanied by signs related to damage to contiguous structures being affected by the structural lesion. Signs and symptoms may be asymmetric depending on the location of the lesion. However, there are many acquired lesions of the cerebellum in which an evident lesion of the cerebellum may be lacking. *Table 367.1* lists acquired causes of cerebellar ataxia that are common in pediatric age groups.

A more difficult diagnostic situation occurs when progressive ataxia is related to an atrophic or degenerative process in the cerebellum, brainstem, and other connecting pathways. In childhood, almost all of these are related to genetic disorders. Information on the mutations and genes involved is available in many but not all of these diseases. The majority of inherited ataxias in childhood have autosomal recessive (AR) inheritance; thus the parents (who are carriers) are asymptomatic, but siblings may be affected. With small family sizes, most of these cases present as singletons. Consanguinity may be a clue to AR inheritance. Other inherited ataxias of childhood have mitochondrial or X-linked inheritance. The analysis of the pedigree may point to the mode of such inheritance, though many of these patients are also singletons. Lastly, autosomal dominant (AD) ataxias may occasionally present in childhood, though commonly they are of adult onset. The diagnostic process in childhood is particularly difficult because many inherited diseases, not usually grouped as primarily ataxic in character, can present with ataxia (in addition to other signs) in this age group. *Table 367.2* lists the inherited diseases which are conventionally classified as an ataxia. *Table 367.3* is a list of disorders usually with childhood onset in which ataxia can be a major feature, but these are not typically classified as ataxias. Lastly, a special group of ataxic diseases have onset in the neonatal period. These are classified as congenital ataxias.

Table 367.1
Acquired ataxias seen in pediatric age groups

Entities with overt structural lesions on imaging	Entities in which an overt structural abnormality is not universally seen
Tumors in the posterior fossa	Infections
	Acute cerebellar ataxia of childhood
	Post-infectious
Cranio-vertebral junction anomalies	Toxic disorders
	Chemotherapy (5FU, Ara C)
	Anticonvulsants (DPH)
Vascular disease	Sequel to hypoxic encephalopathy
Demyelinating disease	Hypothyrodism
Infections (cerebellar abscess, Bickerstaff encephalitis)	Autoimmune
	Paraneoplastic (e.g. opsoclonus-myoclonus syndrome)

Epidemiology

Ataxias are rare disorders. Epidemiological studies generally have tried to estimate prevalence of degenerative ataxias and the usual figures range up to 9.3 per 100,000. There are interesting variations in the occurrence of genetic ataxias among various geographic and ethnic groups. Thus, Friedreich's ataxia, the most common recessive ataxia is confined to Indo-European populations. There are pockets of high prevalence of certain SCAs, likely the result of isolated population kinetics: examples include high prevalence of SCA 1 among the Iakut in Siberia, SCA 2 in the Eastern provinces of Cuba, and SCA 3 in the Portuguese Azores.

In the following sections, different types of acquired and inherited ataxias are described, including their pathogenesis, clinical features, therapy, and prognosis.

Acquired Ataxias in Childhood

A number of disorders in which imaging studies can be diagnostic can have an ataxic presentation in childhood. These include posterior fossa tumors such as cerebellar astrocytomas and pontine gliomas, congenital malformations at the cranio-vertebral junction, and bacterial infections such as a cerebellar abscess. The term brainstem or Bickerstaff encephalitis is used for an acute clinical picture that includes ataxia and oculomotor palsy with added clinical signs such as obtundation and Babinski sign that distinguish the disease from Miller-Fisher variant of Guillain–Barre Syndrome (GBS). MRI often shows signal density changes in the brainstem. Vascular lesions, including ischemic strokes and malformation, can occur in the pediatric age group, but again can be diagnosed readily be imaging. Demyelinating diseases like multiple sclerosis can present with lesions in the cerebellum and connecting pathways. Ataxia in these situations usually develops fairly rapidly, and correct diagnosis leads to appropriate intervention. Other ataxias of nongenetic origin such as those related to hypothyroidism and previous hypoxic

Table 367.2
Inherited ataxias

Autosomal recessive ataxias	Autosomal dominant ataxias	X-linked ataxias	Mitochondrial ataxias
1. Friedreich ataxia (FA)	1. Spinocerebellar ataxias types 1 through 31 (There is no SCA 9 or 24)	1. Fragile X tremor ataxia syndrome (FXTAS)	1. Neurogenic weakness, ataxia, retinitis pigmentosa (NARP)
2. Ataxia with oculomotor apraxia (AOA) type 1 and 2	2. Machado–Joseph disease (MJD also known as SCA 3)	2. Other X-linked ataxias	2. Other mtDNA diseases such as MERRF, MELAS, and KSS can have ataxia as a feature
3. Ataxia telangiectasia (AT)	3. Dentatorubral-pallidoluysian atrophy (DRPLA)		
4. Ataxia with vitamin E deficiency (AVED)	4. Episodic ataxias types 1 through 6		
5. Autosomal recessive ataxia of Charlevoix-Saguenay (ARSACS)			
6. Polymerase gamma related ataxias: mitochondrial recessive ataxia syndrome (MIRAS), sensory ataxic neuropathy, dysarthria and ophthalmoplegia (SANDO), myoclonic epilepsy myopathy sensory ataxia (MEMSA)			
7. Autosomal recessive cerebellar ataxia 1 (ARCA 1)			
8. Ataxia Telangiectasia–like disorder (ATLD)			
9. Spinocerebellar ataxia with axonal neuropathy (SCAN 1)			
10. Marinesco–Sjogren syndrome			

Table 367.3
Autosomal recessive or X-linked syndromes with ataxia and other features

1. Amino acid disorders: Hartnup disease, urea cycle diseases, triple H syndrome
2. Carbohydrate disorders: pyruvate dehydrogenase complex (PDHC) deficiency
3. Storage disorders: late-onset Tay–Sachs (LOTS); Ceroid lipofuscinosis; Neimann–Pick disease, type C
4. Aceruloplasminemia
5. Eukaryotic initiation factor 2 gene related diseases (vanishing white matter disease)
6. Congenital disorders of glycosylation (CDG's)
7. Others: proteolipid protein (PLP) mutations; cerebrotendinous xanthomatosis; Regsum diseases; Giant axonal neuropathy

encephalopathy are rare, but may have cerebellar atrophy on imaging studies. The following section deals with some special types of acquired ataxias seen in children.

Acute Cerebellar Ataxia of Childhood and Post-Infectious Ataxia

Acute cerebellar ataxia (ACA) of childhood refers to a problem of involving only the cerebellum that occurs in children, usually in the setting of a preceding viral infection. Post-infectious encephalomyelitis can have ataxia as a major feature, but usually evidence for a more diffuse affliction of the nervous system including the hemispheres and spinal cord can be found. Some authors use the term acute cerebellitis (AC) to refer to a more severe disorder with associated cerebellar edema and features of increased intracranial pressure.

Pathogenesis: The speculation has been made that ACA may be a post-infectious immune phenomenon whereas AC may be the result of a direct infection.

Clinical features and diagnosis: The antecedents can be a nonspecific viral syndrome, but varicella is a trigger in many, with a peak incidence at the age of 5–6 years. A similar syndrome following Epstein–Barr virus or vaccinations has been reported in teenage years. Children with ACA develop an acute ataxic disorder that is not associated with a more diffuse process reflected by seizures, meningismus, or obtundation. CSF may show some elevation of protein, and a modest mononuclear pleocytosis and PCR may allow identification of a specific etiology such as EBV. Edema, hydrocephalus, and herniation have been described in some and may require decompressive surgery. Some authors refer to this as acute cerebellitis (AC) in which additional features of headache, menigismus, fever, and obtundation can occur. Patients with AC usually have prominent MRI abnormalities in the form of cerebellar edema and diffuse T2 hyperintensity in the cerebellar cortex, and secondary features of compression are often seen with hydrocephalus and tonsillar herniation. In contrast, MR imaging in acute cerebellar ataxia may be normal or show spotty changes in the cerebellum and its peduncles (◉ *Fig. 367.1*).

Differential diagnosis: Other types of acute cerebellar or balance disorders such as tumors, demyelinating disease, toxic diseases, and inborn metabolic errors need to be considered in the acute situation. Acute labyrinthitis and migraine can present with associated balance problems.

Treatment: Patients with evolving features of intracranial hypertension obviously need careful monitoring and decompressive procedures such as posterior fossa decompression and ventriculostomy. These authors in their review also note that occasionally a direct infective agent can be identified by PCR and this may need an appropriate antibiotic. Steroids have been suggested to reduce swelling.

Prognosis: In the majority of children, the prognosis is excellent with full recovery over a few weeks to months. A minority may have residual neurological problems.

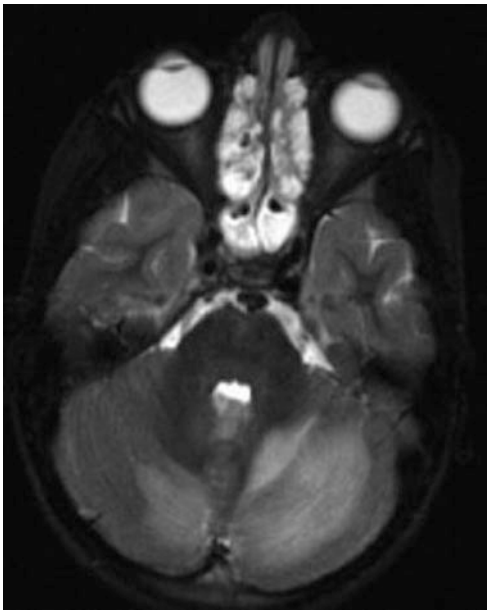

Figure 367.1
Signal density changes in cerebellar cortex in acute cerebellar ataxia of childhood (From Bruecker Y, Claus F, Demaerel P et al (2004) MRI findings in acute cerebellitis. Eur J Radiol 14:1478–1483. With permission)

Toxic Causes of Ataxia

Alcohol which is a common cause of ataxia among adults (both acute intoxication and chronic alcoholic cerebellar degeneration) is not of particular concern in young children. However, iatrogenic ataxia related to pharmacological agents is not uncommon. Antiepileptics are particularly prone to cause ataxia when their levels are supratheraputic, though there is considerable individual variation as to the level that is cerebello-toxic. History of chronic antiepileptic use, together with inappropriate dosing or introduction of another drug that may result in an interaction, is often obtained. It is well recognized that older antiepileptics such as diphenylhydantoin and carbamazepine can produce gait ataxia and other cerebellar disturbances at toxic levels. In a meta-analysis of second generation antiepileptics (gabapentin, lamotrigine, levetiracetam, oxcarbazepine, pregabalin, tiagabine, topiramate, or zonisamide) used as adjunct therapy, all of them were found to increase the risk of imbalance with the exception of gabapentin and levetiracetam. A dose-response relation was seen with almost all of the drugs. Zacarra et al. reported that gabapentin, lamotrigine, pregabalin, topiramate, oxcarbazepine, and zonisamide were all found to produce ataxia or dizziness. Measuring drug levels may be useful to diagnose antiepileptic induced ataxia.

Some cancer chemotherapeutic agents such as 5 fluorouracil and cytosine arabinoside produce ataxia as a side effect. An acute cerebellar dysarthria has been reported with infusions of the agent irinotecan.

Opsoclonus-Myoclonus Syndrome(OMS)

This syndrome is characterized by the acute or subacute onset of imbalance and ataxia, soon followed by opsoclonus, a chaotic, irregular, and involuntary movement of the eyes ("dancing eyes").

Pathogenesis: It is likely a result of an autoimmune phenomenon triggered by an underlying neoplasm, but can be idiopathic. It has been postulated that in OMS associated with neuroblastomas, there is an immune reaction against the tumor that has cross reactivity with neuronal tissue. Antibodies against cerebellar Purkinje cell antigens have been noted in the sera of OMS patients, and some have antibodies to neurofilament and the Hu antigen.

Clinical features and diagnosis: Opsoclonic eye movements are conjugate, fast, and multidirectional and can be often precipitated by changes in fixation. This is associated with myoclonic movements and behavioral changes including usually extreme irritability, sleep disturbance, developmental regression, and sometimes loss of speech. In young children, about 50% of cases have an associated neuroblastoma, but this figure may be higher if high-resolution imaging of abdomen is obtained. In older children and adults, OMS can be associated with a direct infection such as with West Nile virus or parainfectious process or other types of malignancies such as lymphomas, lung cancer, and breast cancer. All young patients with OMS require a thorough search for neuroblastoma with high-resolution scans through the adrenals, measurement of catecholamine metabolites in urine, and metaiodobenzylguanidine (MIBG) scan.

Treatment: Apart from treatment of any neoplasm found, a number of immunomodulatory therapies such as corticosteroids and ACTH have shown benefit in many of the motor aspects of this disorder. IVIG, other immunosuppressants such as azathioprine, and plasma exchange have also been used in an anecdotal fashion. Any neuroblastoma needs to be removed. Neuroblastomas associated with OMS tend to be small and localized.

Prognosis: Opsoclonus tends to resolve even with no treatment, and the ataxic disturbance also improves, though not completely. Recovery in speech and language, as well as behavioral abnormalities, tends to be incomplete, and children often require long-term therapy for relapses. As adolescents, these children can exhibit poor school performance and behavioral difficulties such as impulse control and mood disorders. Adults with OMS tend to recover after a monophasic illness.

Cerebral Folate Deficiency

This disorder is characterized by insomnia, agitation, declining head growth, and cognitive decline. There is associated gait ataxia, speech changes, and epilepsy. Serum and RBC folate levels are normal, but CSF 5-methyl tetrahydrofolate levels are decreased. The disorder has been linked to folate receptor antibodies and defective folate transport.

Congenital Ataxias

The concept of congenital ataxia may not have an exact definition. However, these rare syndromes are characterized by onset very early in life, usually in the neonatal period, the presence of cerebellar hypoplasia rather than atrophy and often, but not always, a nonprogressive course. Cerebellar hypoplasia may be differentiated from atrophy by a small cerebellum that does not show the open pattern of folia seen with atrophy and is nonprogressive when examined serially. In a series of nonprogressive ataxia in 78 children from Sweden, no imaging abnormalities occurred in 61%. Among the rest, MRI showed varying patterns of abnormalities including focal or generalized maldevelopment, or extensive malformations consistent with Dandy–Walker syndrome, Joubert syndrome, and cerebellar hypoplasia, as well as lesions that were more consistent with acquired pathology. Some form of genetic etiology was established in close to 20%, including chromosomal abnormality, Angelman syndrome, and Joubert syndrome. Some cases had an autosomal dominant inheritance pattern (see also SCA 29). Others had what appeared to be acquired lesions, including hypoxic-ischemic pathology by imaging. Clinical picture included ataxia with delayed milestones, mental retardation in 60%, refractory and other types of visual problems in 58%, and hearing loss.

Joubert syndrome (JS) is recognized by an autosomal recessive (AR) inheritance, hypotonia, developmental delay, neonatal tachypnea or apnea, and altered eye movements. Infants have mental retardation, episodic hyperpnea or apnea, oculomotor apraxia, and later ataxia. Imaging shows a deep posterior interpeduncular fossa, prominent superior cerebellar peduncles and hypoplasia, and clefting of the superior vermis producing a molar tooth sign (*Fig. 367.2*). Chance et al. in their review describe a number of related clinical phenotypes including the following: Arima syndrome (vermal hypoplasia, retinopathy, polycystic kidneys, AR inheritance); Senior–Loken syndrome (vermal hypoplasia,

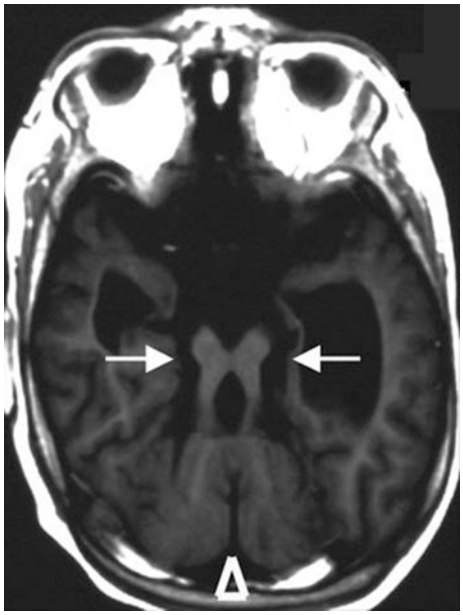

Figure 367.2
Typical molar tooth sign in patient with Joubert syndrome (From Louie CM, Gleeson JG (2005) Genetic basis of Joubert syndrome and related disorders of cerebellar development. Hum Mol Genet 14:R235–R242. With permission)

retinopathy, juvenile onset nephronophthisis, AR inheritance); vermal hypoplasia and retinopathy alone; COACH syndrome (vermal hypoplasia, coloboma, nephronophthsis, hepatic fibrosis); and vermal hypoplasia and nepheonophthisis alone. In Joubert's syndrome, there are no renal, hepatic, or other systemic features, including retinopathy.

The essential feature of many of these conditions include a characteristic set of imaging abnormalities that include a deep posterior interpeduncular fossa, prominent superior cerebellar peduncle and hypoplasia of the superior vermis that lead to a "molar tooth sign" appearance of the upper brainstem on axial images. The clinical picture in Joubert syndrome includes onset in infancy, developmental delay and hypotonia, episodic apnea and hyperpnoea, oculomotor apraxia and hypotonia. Recently, some advances have occurred in identifying genes responsible for such diseases. One variety of JS, associated with cerebral cortical abnormalities has been related to mutations in the AHI 1 gene (Abelson helper integration 1) which encodes the protein Jouberin. Another syndrome associated with nephronophthisis is related to mutations in the NPHP 1 gene, which appears to have a functional role in ciliary function.

Inherited Ataxias

Ataxias can be inherited in autosomal recessive, autosomal dominant, X-linked, and mitochondrial fashion (*Table 367.2*). Childhood ataxias are predominantly autosomal recessive; this group can be further divided in to those diseases which are traditionally classified as ataxias and a second group in which ataxia forms a variable part of a more complex phenotype ("genetic-metabolic" diseases).

Autosomal Recessive Ataxias

Friedreich's Ataxia (FA)

Epidemiology: This is the most common recessive ataxia and perhaps the most common inherited ataxia among Indo-European populations.

Genetics and pathogenesis: FA results from an unstable expansion of a repeated trinucleotide (GAA) sequence within the first intron of the *FRDA* gene on chromosome 9q13-21.1. Most of the normal alleles have fewer than 10 repeats. Long normal alleles (12–40 repeats) appear to be confined to Caucasian populations and serve as the reservoir for expansion into pathogenic mutations. Expanded alleles have 66 to over 1,000 repeats. Over 95% of the affected FA patients have the GAA expansion in both alleles (homozygous expansion). Rarely, patients with clinical findings compatible with FA have only one expanded allele; such patients harbor point mutations in the unexpanded allele. Sequencing of the unexpanded allele to document a point mutation will have to be done in this situation. Point mutations located in the carboxy terminal half of the mature frataxin appear to be associated with a typical FA phenotype. However, missense mutations in the amino terminal half of the protein such as the G130V mutation appear to result in a milder phenotype with less ataxia and greater spasticity and no dysarthria. All the patients with point mutation to date have been compound heterozygotes with one expanded allele. Homozygous point mutations will cause complete lack of frataxin, and this may be incompatible with life. This has been further supported by the fact that complete knockout of the gene in animal models is embryonically lethal.

There is an inverse correlation between the size of the GAA repeat and the age at onset. This correlation is better with the smaller of the two expanded alleles. Cardiomyopathy and diabetes also tend to occur in patients with larger expansions (>700 GAA repeats). All of the variation in age at onset and severity of disease cannot be

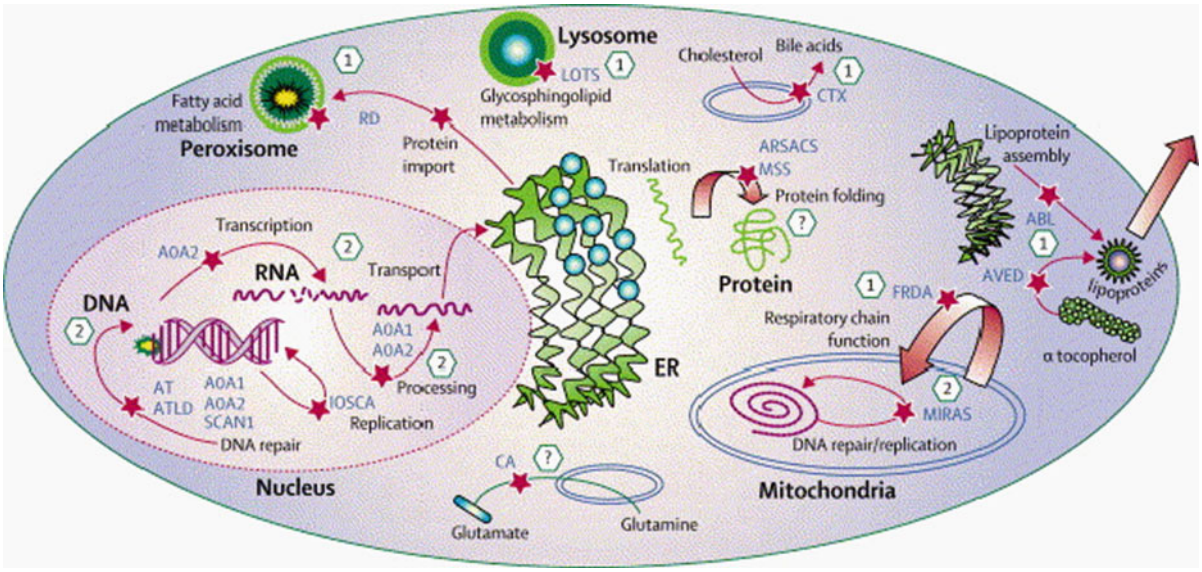

Figure 367.3

Cellular mechanisms in autosomal recessive ataxias. The pathways or sites affected by the various underlying mutations causing the different autosomal recessive ataxias are indicated by a red star. Oxidative stress and DNA repair abnormalities appear major targets in AR ataxias (Numbered 1 and 2). In FA and MIRAS, there are intrinsic mitochondrial abnormalities. In AT and AOAs, DNA repair mechanisms may be affected. ARSACS and MSS may be related to protein folding defects. Other defects depicted include peroxisomal and lysosomal defects and abnormal handling of vitamin E. *ER* endoplasmic reticulum, *FRDA* Friedreich's ataxia, *AVED* ataxia with vitamin E deficiency, *ABL* abetalipoproteinaemia, *RD* Refsum's disease, *LOTS* late-onset Tay–Sachs disease, *CTX* cerebrotendinous xanthomatosis, *MIRAS* mitochondrial recessive ataxia syndrome, *SCAN*1 spinocerebellar ataxia with axonal neuropathy, *AT* ataxia telangiectasia, *AOA*1 ataxia with oculomotor apraxia, type 1 *AOA*2 ataxia with oculomotor apraxia, type 2 *ARSACS* autosomal recessive ataxia of Charlevoix-Saguenay, *IOSCA* infantile-onset spinocerebellar ataxia, *CA* Cayman ataxia, *MSS* Marinesco–Sjögren syndrome (From Fogel BL, Perlman S (2007) Clinical features and molecular genetics of autosomal recessive cerebellar ataxias. Lancet Neurol 6:245–257. With permission)

correlated with the GAA size alone. Other genetic and possibly environmental factors may contribute to this variation. In addition, variation in clinical picture can result from somatic mosaicism of the repeat size with different tissues having significant differences in the size of the expansions.

The mutation in the FA gene leads to a partial deficiency of the protein frataxin. The reduced transcriptional efficiency of the mutated gene has been attributed to an unusual "sticky DNA" configuration of the expanded repeat. In addition, there is evidence for chromatin condensation and remodeling which can further suppress frataxin transcription. The exact role of frataxin in normal biology is still not clear, but many studies suggest that it is a mitochondrial protein (*Fig. 367.3*).

Knockout of the frataxin homologue in yeast leads to accumulation of iron in the mitochondria, a finding of interest in view of the presence of iron in the cardiac muscle in human disease; more recent data suggest that such overt iron accumulation may be a late event. Activity of enzymes, such as aconitase and complex I, II, and III of the respiratory chain, that contain iron-sulfur clusters is reduced in cardiac muscle biopsies of patients with FA. The ISC synthesis defect results from the role of frataxin in the process and probably is the cause of iron accumulation. It has been hypothesized that the presence of excess iron as well as excess oxidative stress related to impaired respiratory chain function can induce oxidative stress via the Fenton reaction and cause progressive nuclear and mitochondrial damage. Frataxin may function both as an iron storage protein and as an iron chaperone with a role in ISC and heme synthesis.

Pathology: There is loss of dorsal root ganglion cells, resultant degeneration of the dorsal columns, degeneration of spinocerebellar and corticospinal tracts, and loss of cells in the cerebellar dentate nucleus.

Clinical features: Typical FA has onset before age 25 years with gait difficulties and clumsiness, usually

around puberty. Examination reveals ataxia which appears related to loss of proprioceptive sense in the limbs. There is loss of tendon reflexes usually in a generalized fashion or just in the lower limbs. These findings are related to the early pathology in the dorsal root ganglion cells. Additional signs indicating involvement of the cerebellum, such as dysarthria, and eye movement abnormalities, such as square wave jerks, appear soon after. Further progression causes disabling ataxia, appearance of upper motor neuron signs such as extensor plantar reflexes and weakness in lower limbs and dysphagia. Rarely, patients may present with cardiac disease or a spinal deformity and then develop neurological disease. Patients tend to lose ambulation within 15 years of onset. At this stage, patients have increasing ataxia of upper and lower limbs, profound proprioceptive loss, areflexia, weakness of lower limb muscles, flexor spasms, dysarthria, and dysphagia. Optic atrophy and hearing loss may occur in a minority of patients. Since the FA mutation was identified, it has been noted that about 15% of patients with the mutation have onset after 25 years of age (late-onset FA or LOFA), occasionally even after 50 years of age. Others continue to retain tendon reflexes (about 10%), a finding not seen in classic cases (FA with retained reflexes or FARR). Some of these patients can be spastic in their lower limbs and have pathologically brisk reflexes.

Heart disease is common with abnormal EKG's in most patients. ECHO-cardiography shows hypertrophic cardiomyopathy in many. Cardiac symptoms, such as atrial fibrillation and occasionally a dilated cardiomyopathy with heart failure, may arise. Cardiac disease is the cause of death in a significant proportion. Skeletal abnormalities such as spinal deformities and foot deformities are common and add to ambulatory and respiratory problems. The mean age of death among patients with FA has been reported to be late in the fourth decade; this however does not take into account the more recent information on late-onset cases. Diabetes occurs in about 10% and appears to be related to both beta cell dysfunction and peripheral insulin resistance.

Diagnosis: Nerve conduction studies show absence or reduction of sensory nerve potentials in a diffuse fashion. Central motor conduction studies show abnormalities that evolve over the course of the disease and may reflect the progression of the disease. MRI scans of the brain reveal no abnormalities in the cerebellum; rather the upper cervical cord shows atrophy. Signal density changes may be seen in the posterior columns by MRI, and the cerebellar dentate has been reported to show increased iron content and volume loss. Diagnosis is confirmed by targeted mutation analysis to detect the homozygous GAA expansion found in the vast majority of patients. Patients with clinical features of FA but only one expanded allele need sequencing of their unexpanded allele to establish the presence of a point mutation. All other types of recessive ataxias figure in the differential diagnosis, but FA is the most common and does not usually have cerebellar atrophy on imaging studies.

Treatment of FA: Based on evidence for excess oxidative stress and poor defense mechanisms of FA tissue to such stress, antioxidant therapy has been tried over the last 10 years. At least 11 studies using idebenone in patients with FA have been reported until 2008. It has been reasonably well tolerated in doses of 900 mg or more per day by FA patients, the main adverse effect being gastrointestinal. At doses of 5 mg/kg/day, it appeared to have beneficial effect on the cardiomyopathy of FA. In a 6 month study, idebenone given in high doses appeared to improve neurological function, as measured by the ICARS scale in ambulatory FA patients. Newer approaches, now in experimental phase, include gene replacement and the use of molecules that may enhance frataxin production even in the presence of the GAA expansion. Recent open label experience suggests some beneficial effect from erythropoietin.

In addition, there have been many attempts at symptomatic therapy of FA patients with possible neurotransmitter replacements such as cholinergic, serotoninergic, and dopaminergic drugs which have shown variable and usually less than optimal results.

The supportive care of FA patients includes adequate rehabilitation efforts aimed at mobility, using appropriate devices. Monitoring and caring for the systemic complications are also important. Such systemic problems include skeletal deformities, cardiomyopathy, and diabetes.

Ataxia with Oculomotor Apraxia Types 1 and 2 (AOA 1, AOA 2)

Oculomotor apraxia refers to a peculiar inability to initiate saccades; eye movement recordings suggest that while saccades can be produced, they have increased latency. Children typically use head thrusts to move eyes from one target to another.

Epidemiology: Ataxia with oculomotor apraxia type 1 is likely the most common AR ataxia in Japan and second only to FA in Portugal. AOA 2 is the most frequent AR ataxia next to FA in European series.

Genetics and pathogenesis: AOA 1 results from mutations in the aprataxin (*APTX)* gene. Nonsense, missense,

and splice site mutations as well as deletions have been described. Aprataxin is a nuclear protein that has an N terminal fork-head associated (FHA) domain resembling PNKP, a histidine triad (HIT) domain and a C terminal zinc finger domain. Most of the mutations affect the HIT domain. The protein may function in base excision repair, a form of single strand DNA repair mechanism. The C terminal is also known to interact with XRCC1 which plays a role in single strand break repair. It is unclear how this functional role is related to neurodegeneration in the cerebellum.

AOA 2 has been linked to mutations in the senataxin gene (*SETX)* which codes for senataxin. Many different mutations have been identified including nonsense, missense and frameshift mutations as well as deletions and duplications. The normal function of senataxin is unclear. Its C-terminal region has homology to the superfamily of helicases, so the DNA/RNA helicase function may contribute to the pathogenesis of neurological dysfunction.

Clinical features and diagnosis: AOA 1 has onset about 10 years of age, with a range from early childhood to the 20s in some cases. It causes progressive ataxia associated with MRI evidence for cerebellar atrophy. Chorea and dystonia occur in about 80% of cases. Oculomotor apraxia appears a mean of 9 years after onset and is seen in over 80% of cases. Children use head movement to fixate on eccentric targets with a head eye lag; this may result from very hypometric saccades and the need for multiple small amplitude saccades to make the movement. Mental retardation can occur in about 40% of cases. Later, patients develop a sensory motor polyneuropathy. Low albumin and high cholesterol levels occur in the majority of patients after some years. Muscle CoQ 10 levels may be decreased in some patients with AOA 1, and symptomatic improvement may occur with high-dose CoQ 10 therapy. There are no other systemic features such as telangiectasia and elevated alpha fetoprotein.

Ataxia with oculomotor apraxia type 2 is a progressive AR ataxia associated with cerebellar atrophy and an axonal polyneuropathy, which are the most prevalent features together with elevation of serum alpha fetopotein. The age at onset is around 15 years, and the disease progresses to a stage requiring significant ambulation devices in about 15 years. Oculomotor apraxia does not occur universally, being seen in about 50% cases. Ocular recordings show increased horizontal saccade latencies and hypometria. Other clinical signs noted are upper motor neuron signs in about 20%, dystonia, chorea, head tremor, and strabismus. Anheim et al. note that with a non-FA patient, the elevation of serum alpha fetoprotein to over 7 μg/l may be predictive of AOA 2. Other features that have been noted infrequently include elevation of serum CK and hypogonadotrophic hypogonadism. No other systemic features such as high risk for malignancy, telangiectasia, or radiation sensitivity are seen.

Treatment: Treatment remains purely supportive.

Ataxia with Vitamin E Deficiency (AVED)

Epidemiology: It is most common in North Africa where its prevalence approaches that of FA.

Genetics and pathogenesis: AVED results from mutations in the α tocopherol transfer protein (αTTP) gene; αTTP is involved in the hepatic handling of vitamin E facilitating the incorporation of vitamin E into very low-density lipoproteins. The mutations in the αTTP gene are variable and include missense, nonsense, frameshift, and splice site mutations; some mutations allow for residual function and thus a milder phenotype.

Clinical features and diagnosis: AVED is a childhood onset ataxia with clinical features similar to FA. The onset is usually in childhood but can be later. There is progressive ataxia and evidence for a polyneuropathy with loss of proprioception and tendon reflexes. Retinitis pigmentosa and visual loss can accompany this syndrome. Patients often have head titubation. Cardiomyopathy can occur but is less common than in FA. Vitamin E levels are very low (less than half the lower limit of normal) but are not the result of impaired absorption.

Treatment: Vitamin E supplementation allows the stabilization of the neurological features, especially when started early in the disease, but some features may show worsening despite therapy.

Abetalipoproteinemia

This disorder results from mutations in the gene *MTTP* which codes for a subunit of the microsomal triglyceride transfer protein; this results in impaired lipid absorption in the intestine including lipid soluble vitamins like vitamin E. The ataxia resembles that in AVED but is associated with evidence for malabsorption. Vitamin E and cholesterol levels are low, and apolipoprotein B is absent on lipoprotein electrophoresis. Acanthocytes are found in peripheral blood smear. Transaminases may be high and INR elevated due to vitamin K deficiency.

Cayman Ataxia

This is an autosomal recessive ataxia described from the Cayman Islands, characterized by early onset of minimally progressive ataxia and mental retardation. The gene involved is on chromosome 19p and codes for a neuron-restricted protein (Caytaxin) that contains a CRAL-TRIO motif common to proteins, including α tocopherol transfer protein, which bind small lipophilic molecules. This suggests a pathogenic similarity to AVED.

Polymerase Gamma Mutations and Ataxia

Recessive mutations in the gene encoding the alpha subunit of polymerase gamma (POLG 1), an enzyme involved in the replication of mtDNA, result in ataxia. Mitochondrial inherited recessive ataxia syndrome (MIRAS) is common in Finland and has onset from childhood to early adult life. Progressive ataxia can be associated with tremor and myoclonus. Schulte et al. recently analyzed the phenotype associated with POLG 1 mutations. Patients who had sensory ataxic neuropathy associated with dysarthria and ophthalmoplegia (SANDO) had a high (80%) prevalence of POLG 1 mutations, whereas only a quarter of patients with ataxia and neuropathy with no eye movement defects had POLG mutations. The syndrome of myoclonic epilepsy, myopathy, sensory ataxia (MEMSA) can also be associated with POLG mutations.

Infantile-Onset Spinocerebellar Ataxia (IOSCA)

This syndrome, also common in Finland, causes an infantile onset of ataxia, mental retardation, seizures, ophthalmoplegia, and neuropathy. Recessive mutations of the gene *C10orf2* which codes for Twinkle, a protein that interacts with POLG 1 in the synthesis of mtDNA have been reported in IOSCA.

Ataxia Telangiectasia

Epidemiology: The occurrence of AT has been estimated to be 1 in 20,000–100,000 live births.

Genetics and pathogenesis: The disease is caused by mutations in the ATM gene on chromosome 11. ATM codes for the ATM protein which appears to be a transducer protein involved in DNA double-strand break repair; this can explain the radiosensitivity seen in AT. ATM is a serine-threonine kinase which autophosphorylates in response to DNA double-strand break and in turn activates many substrates. AT is one of several diseases in which genes involved in DNA repair mechanisms have been implicated in cerebellar ataxia.

Clinical features and diagnosis: This disorder has its onset early in the first decade with truncal instability and impaired gait. This is followed by progressive ataxia associated with evidence for a polyneuropathy such as hypotonia and loss of reflexes. Choreiform movements are frequent. Characteristic eye movement abnormalities are seen with the need for a rapid head thrust for fixating on targets to one side with the eyes following later (eye-head lag). This is referred to as oculomotor apraxia. Telangiectasia tend to appear about 5 years of age and are most frequent on the conjunctivae (Fig. 367.4), but can also occur over the ear lobes and popiteal fossa and other locations.

There is evidence for an immune deficiency with frequent bronchopulmonary infections. The children are at risk for malignancies, especially hematologic tumors like lymphomas and leukemias; other types of cancers occur if the patient reaches adult ages. Because of better care for infections and malignancies, the life span of AT children has increased to over 25 years. Clinical diagnosis is usually apparent, but laboratory features can further support the diagnosis. The serum α fetoprotein is usually elevated (above 10 ng/ml) and immunoglobulin levels are low. Karyotyping often shows chromosomal abnormalities, especially a 7:14 translocation. Increased sensitivity of

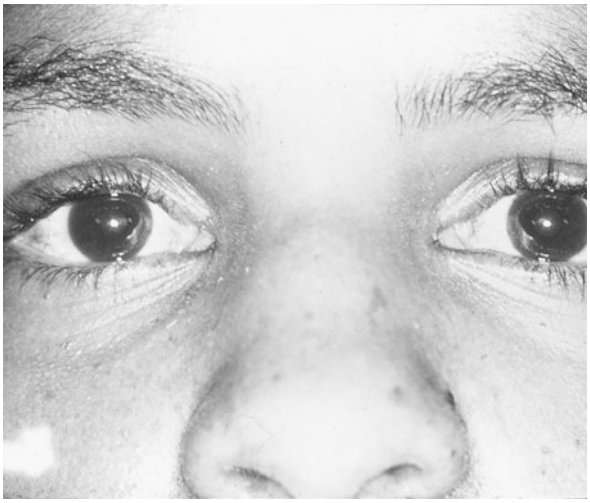

Figure 367.4
Telangiectasia of conjunctiva in ataxia telangiectasia

cultured fibroblasts to radiation can be documented by the "colony survival assay." The definitive way of establishing diagnosis is immunoblotting for the ATM protein; 90% of patients have no protein, 10% have trace amounts, and rare patients have normal ATM levels but no kinase activity ("kinase-dead") (www.geneclinics.org). Further molecular confirmation can be achieved by detecting the mutation; however, this can be difficult because of the size of the ATM gene and the lack of mutation "hot-spots." Sequence analysis of the coding regions of the ATM gene will detect 90% of the mutations but miss intronic alterations and heterozygous deletions. Also benign polymorphisms and pathogenic alterations may be difficult to distinguish. Other types of DNA-based tests include protein truncation tests (examining for premature stop codons) which can detect about 70% of the mutations and mutation scanning using DHPLC which has a sensitivity of 85%.

Treatment: Treatment remains supportive and includes appropriate rehabilitation measures. Children need to be monitored for infections and malignancies. Chronic intermittent immunoglobulin therapy is used to prevent infections, usually in those noted to have very frequent infections. Radiation therapy and investigations with high-dose X-ray exposure have to be managed with great caution and expertise as also chemotherapy because of the radiation sensitivity. Endocrinopathies such as diabetes and gonadal failure need to be looked for and treated appropriately.

Ataxia Telangiectasia–Like Disorder (ATLD)

ATLD is related to mutations in the gene coding for MRE 11, another protein involved in double-stranded DNA break repair. It has a clinical picture resembling AT, but has a milder course, no telangiectasia, and no elevation of serum α fetoprotein.

Spinocerebellar Ataxia with Neuropathy 1 (SCAN 1)

SCAN 1 is a rare disorder, reported in patients from Saudi Arabia, with onset in the second decade; ataxia is associated with sensory motor polyneuropathy, but there are no systemic features. Mutations affecting the tyrosyl-DNA-phosphodiesterase (TDP 1) gene have been identified. TDP 1 gene is involved in single strand DNA break repair.

Other DNA Repair Defects

Both xeroderma pigmentosum and Cockayne syndrome are characterized by photosensitivity. A proportion of these individuals develop neurological problems including ataxia, spasticity, cognitive decline, and seizures.

Autosomal Recessive Ataxia of Charlevoix-Saguenay (ARSACS)

ARSACS was initially identified in children with spastic ataxia among French Canadians in the Charlevoix-Saguenay province of Quebec, Canada, an inbred population with a high carrier frequency for the gene. ARSACS has since then been documented in other geographic areas such as Turkey, Japan, Spain, and Italy. Clinically, it is characterized by very early onset, prominent spasticity followed by ataxia and amyotrophy of distal muscles. Myelinated optic nerve fibers are seen in the French Canadian patients but not in others, and patients from non-Canadian regions have had a more variable phenotype. Mutations in the SACS gene, encoding a protein-labeled SACSIN, are related to ARSACS. The C terminal region of this protein has a DnaJ motif that can interact with Hsp70, and the N terminus has homology to HSp90. Thus, SACSIN may have a chaperone function involved in protein folding.

Marinesco–Sjogren Syndrome

This rare early-onset syndrome is characterized by ataxia, mental retardation, cataracts, and evidence for a myopathy. Peripheral neuropathy, epilepsy, and hypogonadism may be all seen in this disease. Mutations in the gene *SIL 1* have been described; the *SIL 1* product appears to have interactions with one of the Hsp70 chaperone proteins.

Autosomal Recessive Cerebellar Ataxia Type 1 (ARCA 1)

This term has been used to describe an autosomal recessive ataxia in a population isolate of French Canadians from Quebec. The disorder begins in young adult life (17–46 years) and causes progressive ataxia, dysarthria, and mild eye movement problems. Reflexes were normal or slightly brisk, and there was cerebellar atrophy on imaging studies. Molecular studies have revealed that

this is related to mutations in the *SYNE 1* gene. It is thought that *SYNE 1* is a member of the spectrin family of cytoskeletal proteins that may be involved in anchoring actin to the plasma membrane and appears enriched in Purkinje cells.

Autosomal Recessive Cerebellar Ataxia Type 2 (ARCA 2)

This term has been used to denote cerebellar ataxia associated with CoQ 10 deficiency. CoQ 10 is a lipid soluble component of cell membranes and is involved in transport of electrons between complex I and II of the electron transport chain to complex III. Ataxia associated with deficiency of muscle CoQ 10 is heterogeneous. This combination can be seen in some patients with AOA 1 as well as in some with defined abnormalities in CoQ 10 metabolism. Ataxia is associated with pyramidal signs and mild cognitive decline. Some patients may have hypogonadism. CoQ 10 deficiency can be associated with other phenotypes such as an infantile multisystem disease, encephalomyopathy with ragged red fibers, and Leigh's syndrome. Some gene mutations have been identified in the infantile cases. The syndrome may respond to CoQ 10 replacement therapy.

Other Poorly Defined Recessive Ataxias

Among 102 patients with recessive ataxias reported by Anheim et al., extensive molecular studies led to a genetic diagnosis in only 57. The cases that could not be molecularly classified had a slightly later onset (>20 years), and milder course. Cerebellar atrophy is seen in 68% of these individuals and polyneuropathy in about 50%. A small proportion of these individuals had oculomotor apraxia and elevated alpha fetoprotein and serum CK. A number of clinically defined syndromes may be seen in this group, including ataxia with hypogonadism, deafness, and myoclonus.

Autosomal Recessive or X-Linked "Genetic-Metabolic" Diseases with Ataxia as a Feature

A number of disorders of childhood or young adult onset are not classified as an ataxia, yet often have ataxia as a feature. In many, other CNS and systemic features occur, cognitive decline or mental retardation is common, and imaging studies may be distinctive. These tend to separate them from the classical ataxias (◉ *Table 367.3*).

Cerebrotendinous Xanthomatosis

This disease is caused by mutations in the CYP 27 gene encoding 27-hydroxylase that cleaves a side chain off cholesterol and this leads to reduced bile acid synthesis and increased formation of intermediates such as cholestanol and 27-C bile alcohols. There is increased serum and tissue levels of cholestanol and tissue deposits of sterols. The clinical picture includes chronic diarrhea beginning in the first decade and a neurological syndrome that combines spastic ataxia and cognitive decline. Xanthomas can be seen by 15 years of age, usually over Achilles tendon, tibial tuberosities, or fingers (◉ *Fig. 367.5*). Juvenile cataracts are also a feature. Later in the course, osteoporosis, easy fractures, and coronary disease occur. Diagnosis can be established by clinical features and elevated serum cholestanol levels as well as by mutation analysis of CYP 27. Therapy with chenodeoxycholic acid and statins may arrest disease progression.

Urea Cycle Defects

The late-onset varieties of these can present in childhood with episodes of encephalopathy, nausea, and vomiting

Figure 367.5
Achilles tendon xanthoma in cerebrotendinous xanthomatosis

associated with ataxia. One variety (arginase deficiency) can present with spatic paraplegia. Brain MRI may be normal or show edema during episodes. Serum ammonia is elevated to over 80 μmol.

Hartnup Disease

This disease is caused by mutations in the neutral amino acid transporter gene (SLCGA 19) and results in neutral aminoaciduria. Clinical picture includes growth delay, skin rash, diarrhea, ataxia, and psychosis. Tryptophan metabolism abnormality leading to a deficiency of serotonin has been proposed as a mechanism for the clinical picture. Diagnosis is established using plasma and urine amino acid levels.

Pyruvate Dehydrogenase Complex Deficiency

This can be X-linked or autosomal recessive depending on the component of the PDHC complex that is abnormal. The disease presents with episodic dysfunction including ataxia and encephalopathy; later, there are persistent deficits associated with cognitive decline and neuropathy. Optic atrophy is common and MRI may show putaminal necrosis in the brain. Serum and CSF lactate and pyruvate are increased with decreased lactate to pyruvate ration. Diagnosis is established by estimating PDHC activity in cultured skin fibroblasts. Therapy with high-dose vitamin B1 and ketogenic diet may help.

Late-Onset Tay–Sachs Disease (GM1 Gangliosidosis)

Though Tay–Sachs disease is typically infantile in onset, a late-onset form (age at onset 8–36 years) has been described. The clinical picture is characterized by ataxia, neurogenic weakness with atrophy and fasciculations due to anterior horn cell loss, psychosis and cognitive decline. Mutations in the hexosaminidase gene can be established and leuokocyte hexosamonidase A and total hexosaminidase levels are reduced.

Aceruloplasminemia

This disease results from mutations in the ceruloplasmin gene. Ceruloplasmin transports copper and also has ferroxidase activity that allows it to mobilize tissue iron. Both homozygous and heterozygous mutations can cause disease. The former causes ataxia, cognitive decline, chorea, Parkinosinian features, and retinal degeneration. MRI of the brain shows T2 hypointensity in the cerebral and cerebellar cortex, basal ganglia, and the dentate nucleus. Heterozygous mutations cause ataxia, tremor, and chorea with no T2 hypointensity on MRI. Serum and urine copper is low, ferrtitin high, and ceruloplasmin absent. Therapy with chelation may improve the clinical picture.

Vanishing White Matter Disease

This disorder has been linked to mutations in five eukaryotic initiating factor 2B genes (EIF 2B 1–5). Patients present with ataxia and upper motor neuron signs between 2 and 5 years of age. Episodes of rapid progression after stress have been reported. MRI is characterized by cavitating bilateral leukoencephalopathy. An adult variant of this disease has also been seen with a mean age at onset of 31 years and spasticity, ataxia, cognitive decline, and seizures. Imaging studies show cerebral atrophy, cystic breakdown of white matter, and increased T2 signal in cerebellum and corpus callosum.

Refsum Disease

A deficiency of phytanyl CoA hydroxylase results in increased phytanic acid in tissue peroxisomes. The clinical picture is characterized by a polyneuropathy associated with ataxia, hearing loss, and ichthyotic skin changes. Plasma phytanic acid is high, and a low phytanic acid diet may slow disease progression.

Giant Axonal Neuropathy

This autosomal recessive disease is characterized by onset between 2 and 7 years of age. Neurologically, there is severe ataxia, mental retardation, and sensory motor polyneuropathy with weakness and atrophy of muscles. Hair appears kinky and red. Variant phenotypes include a spastic syndrome with mild ataxia and no kinky red hair. MRI shows diffuse white matter changes in the hemispheres and cerebellum. Nerve biopsy shows distended axons with microfilament accumulation by electron microscopy. Mutations in the gene gigaxonin that is involved in microtubular stability are responsible for this condition.

Congenital Disorders of Glycosylation Syndromes (CDG Syndromes)

These are disorders characterized by defective synthesis of N-linked oligosaccharides. There are 21 enzymes in this pathway that are known to be defective in the CDG syndromes. The disorders have a wide phenotypic spectrum with developmental delay, cerebellar hypoplasia, liver disease, and abnormal fat tissue as possible manifestations. During early childhood, patients have hypotonia, ataxia, and delayed language. Peculiar slow rolling eye movements have been described. Other features that can occur include seizures, stroke-like episodes, elevated liver enzymes, coagulopathy, and joint contractures. Systemic features include hepatomegaly, proteinuria, orange peel appearance of skin, hypogonadism, and large ears. Diagnosis can be suspected by an abnormal serum transferring glycoforms detected by isoelectric focusing.

Neuronal Ceroid Lipofuscinoses

These are autosomal recessive lysosomal storage diseases of infancy and childhood which have been classified into many types. Some varieties of this such as the late infantile type, the adult onset type, and the Gypsy-Indian type are associated with ataxia, but other features such as cognitive decline, seizures, and visual loss usually dominate the clinical picture. Measuring palmitoyl priten thiesterase 1 (PPT 1) and tripeptidyl peptidae 1 (TPP1) may be useful indicators of NCL. Electron microscopy of conjunctival or skin biopsies and of the buffy coat may reveal characteristic lysosomal storage material in the form of curvilinear, fingerprint, or granular osmiophilic bodies. Genetic mutations in the genes CLN 1 through CLN 8 have been identified but diagnosis can be difficult.

Niemann–Pick Disease Type C

This is a rare autosomal recessive disease with a wide range of age at onset (perinatal period to over 15 years) and phenotypic variability related to mutations in the genes NPC 1 and 2. A wide variety of motor phenomena are seen with ataxia, dystonia, and dysarthia being very common. Cognitive decline, hearing loss, myoclonus, and seizures are seen commonly at different age groups, and vertical supranuclear gaze palsy appears to be a frequent phenomenon. Cataplexy and hearing loss also have been described. Hepatosplenomegaly is common but may need ultrasound to detect in older patients. Elevation of plasma chitotriosidase may be a diagnostic clue but not specific. Examination of tissue (bone marrow, skin, liver biopsy, lymph nodes) can reveal characteristic foam cells or sea blue histiocytes. Cultured fibroblasts can be subjected to the filipin test to detect typical perinuclear cholesterol filled vesicles. Mutation analysis of the two responsible genes (NPC 1 and 2 associated with 96 and 4% cases respectively) may establish the diagnosis, but novel polymorphisms can be difficult to distinguish from pathogenic mutations.

PLP-1 Related Disease

Classic Pelizaeus–Merzbacher disease is characterized by onset <5 years, nystagmus, hypotonia, spastic ataxia, dystonia, and decreased cognition. A milder variant causes spastic ataxia, mild cognitive decline, and neuropathy. MRI shows diffuse leukoencephalopathy. Diagnosis is established by PLP1 mutation analysis, FISH for duplication or chromosomal microarray.

Adrenomyeloneuropathy

Though this X-linked disorder typically presents as adrenoleukodystrophy in young boys with progressive cerebral and motor problems, milder phenotypes have been described in both males and females. Occasional patients may present with a spinocerebellar ataxia presentation, and imaging abnormalities in the brain may be scant. Screening for this disease by measuring very long chain fatty acids should be done in patients with ataxia in whom other causes have been excluded.

Miscellaneous Disorders

The following disorders can all be associated with ataxia in addition to other more diffuse CNS symptomatology: late-onset maple syrup urine disease, methylmalonic academia, propionic academia, isovaleric academia, arginase deficiency, and Lafora disease.

Mitochondrial Diseases with Ataxia

The term mitochondrial disease refers to a clinical disorder that is thought to have its origin in a primary defect of a respiratory chain component, whether the component is coded by a nuclear or mitochondrial gene. The phenotype

of mitochondrial diseases may include both neurological and systemic features and be quite variable. Many classic phenotypic syndromes related to mtDNA mutations such as Kearns–Sayre syndrome (KSS), myoclonic epilepsy with ragged red fibers (MERRF), mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes (MELAS), neurogenic weakness with ataxia and retinitis pigmentosa (NARP) can all have ataxia as one of the features. While many of the more-recently-recognized nuclear mutations causing respiratory chain defects lead to complex neurological diseases, ataxia may be a feature of nuclear mutations resulting in multiple mtDNA deletions.

Autosomal Dominant Ataxias

Autosomal dominant (AD) ataxias with a progressive course are labeled spinocerebellar ataxia (SCA) followed by a number indicating the particular chromosomal locus or gene mutation that is responsible. At this time, SCA 1 through SCA 31 have been recognized, with the following caveats: SCA 9 was reserved for a family which appears not to have been followed up, and at the moment its status is unclear; SCA 15 and 16 have been recently found to be related to the same gene mutation; SCA 19 and 22 may be allelic diseases, but this has not been settled; SCA 24 was identified in a family which likely has a recessive mode of inheritance, and this is now called Spinocerebellar ataxia with saccadic intrusions (SCASI). The preferred name for SCA 3 is Machado–Joseph disease (MJD). Dentato-rubral pallido-luysian atrophy (DRPLA) is grouped with the ataxias, but has no SCA designation.

In addition, there are autosomal dominant ataxias in which symptoms are episodic; these are labeled as episodic ataxia syndromes (EA) with the numbers (EA 1 through 6) denoting distinct chromosomal loci. There is more experience worldwide with SCA 1, 2, 3 (MJD), 6, 7 and EA 2 than the other AD ataxias, and thus their clinical picture is better defined for the most part. With the other SCAs, clinical experience is restricted to single families or small number of families, and the phenotypic spectrum may change as more experience is accumulated.

Genetics and pathogenesis: Many of the initial gene mutations identified in the SCAs were unstable expansion of CAG triplets within coding sequences of different genes (◉ *Table 367.4*).

The CAG repeat codes for a string of glutamines and, therefore, these ataxias are also called polyglutamine ataxias. Other repeat expansions discovered to cause ataxia occurred in noncoding regions and include a CAG expansion in the promoter sequence for SCA 12, a CTG expansion in the 3'UTR for SCA 8, and an intronic ATTCT repeat expansion for SCA 10 and finally a TGGAA pentanucleotide insertion for SCA 31. More recently, identified gene mutations in the SCAs have been other types of gene alterations, including

Table 367.4
Autosomal dominant ataxias related to expanded nucleotide repeat motifs

Disease	Gene, repeat, and locus	Normal repeat numbers	Mutable normal alleles	Reduced penetrance alleles	Pathogenic alleles
SCA 1	ATXN 1, CAG, 6p23	6–44	36–38		39–91[a]
SCA 2	ATXN2,CAG,12q	<31	None		32–>200
SCA 3 (MJD)	ATXN 3, CAG, 14q	<44		45–51	52–86
SCA 6	CACNA1A, CAG,19p	<18		19[b]	20–33
SCA 7	ATXN 7, CAG, 3p	<19	28–33	34–36	37–400
SCA 8	ATXN8OS, CTG-CAG, 13q	15–50 combined $(CTA{\cdot}TAG)_n(CTG{\cdot}CAG)_n$			71–1,300[c]
SCA 10	ATXN 10, ATTCT, 22q	10–29		280–850	800–4,500
SCA 12	PP2R2B, CAG, 5q	4–32		40–62	51–78
SCA 17	TBP, CAG, 6q	25–42		43–48	49–66
DRPLA	ATN, CAG, 12p	6–35	May exist		48–93

[a]Note the overlap between upper end of normal and lower end of pathogenic range. Normal and pathogenic alleles of the same size can be distinguished by the presence of CAT interruptions in the former. The interruptions can be detected using Sfa NI restriction site testing
[b]19 repeat allele has been seen in asymptomatic elderly persons, in a person with atypical symptoms, in a homozygous individual with typical symptoms and has been shown to expand into a pathogenic range in the offspring of an individual with no symptoms
[c]Alleles of the same size can be seen in asymptomatic individuals

missense and nonsense mutations, insertions, deletions, and chromosomal duplications (Table 367.5).

Lastly, in many SCAs chromosomal loci are known, but the mutations are yet to be identified. The EA mutations identified so far have involved missense and nonsense mutations in ion channel or transporter proteins (Table 367.6).

The pathogenesis of the polyglutamine ataxias has been related mainly to a toxic gain of function by the product of the mutant allele. The protein product of the mutant allele has a longer glutamine tract and undergoes misfolding and aggregate formation, and this is believed to trigger many pathogenic cascades (Fig. 367.6). Examples of such altered cellular pathways include transcriptional dysregulationn of other genes because of the presence of misfolded protein in the nucleus, colocalization of chaperone proteins with the aggregates, disruption of preoteasome pathways and mitochondrial dysfunction and apoptosis. The role of posttranslational modification of the mutant protein such as phosphorylation and the need for nuclear transport and cleavage of the protein for pathogenicity are also being investigated as possible therapeutic targets. Shutting off the mutated gene using siRNA has succeeded in reducing pathology in many model systems. Other types of therapeutic options may include targeting some of the secondary cascades triggered by the mutations.

In the case of the more-recently-discovered non-polyglutamine ataxias, a diverse series of pathogenic mechanisms may play a role. In SCA 8 and SCA 10, repeat expansions in noncoding regions of the gene may be pathogenic due to an RNA-based mechanism with the long transcript being toxic to a number of cellular mechanisms. In other diseases such as SCA 5, SCA 13, SCA 14, and SCA 27, such processes as cytoskeletal integrity, channel function, and signaling pathways may be altered.

In the episodic ataxia syndromes, mutations involve proteins that function as channels or transporters, and they appear to be examples of neuronal channelopathies. Mutant channels may express a variety of aberrant properties and produce haploinsufficiency or a dominant negative effect, leading to abnormal channel physiology.

Clinical features: In general, the SCAs have onset in young to middle adult life and are not high on the diagnostic list in pediatric age groups, though reported range of age at onset is very wide for many of the SCAs. In many of the better known SCAs which result from unstable nucleotide repeat expansions, anticipation in age at onset is prominent and onset in childhood and even neonatal period has been described. Typically, in these diseases, age at onset is inversely correlated with expansion size so that, with larger expansions, onset can be in teen or early childhood years. There are also more-recently-described SCAs unrelated to nucleotide repeat expansions with onset in early years, but with a very slow progression.

The clinical picture of the SCAs is usually dominated by cerebellar ataxia. In some, ataxia is the loan clinical finding. In others, ataxia is associated with evidence for pathology in many other neural systems including the upper motor neurons, basal ganglia, brain stem neurons, anterior horn cells, cortical neurons,and peripheral nerves. Thus, patients with these SCAs have an array of clinical signs in addition to ataxia such as brisk tendon reflexes, spasticity, Babinski signs, akinesia, rigidity, tremor of different types, oculomotor deficits of many

Table 367.5
Autosomal dominant ataxias with defined mutations unrelated to nucleotide expansions

Disease	Gene	Locus	Mutation
SCA 5	SPTBN 2	11p	Deletions, point mutation
SCA 11	TTBK 2	15q	Insertion/deletion
SCA 13	KCNC 3	19q	Point mutations
SCA 14	PRKCG	19q	Deletions, point mutations
SCA 15/16	ITPR 1	3p	Deletions, point mutations
SCA 20	Unknown	11q	Duplication
SCA 27	FGF 14	13q	Point mutations
SCA 28	AFG3L2	18p	Point mutations

AFG3L2 ATPase family gene 3-like 2 gene, *FGF* 14 fibroblast growth factor 14 gene, *ITPR 1* inosine triphosphate receptor 1 gene, *PRKCG* protein kinase C gamma gene, *KCNC 3* voltage gated potassium channel/member 3 gene, *STBPN 2* beta-III spectrin gene, *TTBK 2* tubulin tau kinase 2 gene. In SCA 20, the region duplicated has multiple genes

Table 367.6

Episodic ataxia syndromes (Modified from Manto M, Marmolino D (2009) Cerebellar ataxias. Curr Opin Neurol 22:419–429)

Disease	Phenotype	Onset	Mutation
EA 1	Very brief episodes of ataxia; interictal skeletal myokymia	Early childhood	*KCNA1*
EA 2	Ataxic episodes lasting hours; interictal nystagmus	Childhood to young adult	*CACNA1A*
EA 3	Episodic vertigo and tinnitus		Linked to 1q
EA 4	Episodic vertigo; interictal nystagmus	Late onset	
EA 6	Associated with hemiplegic migraine		
EA 7	Attacks of vertigo, weakness, slurred speech	<20 years	Linked to 19q

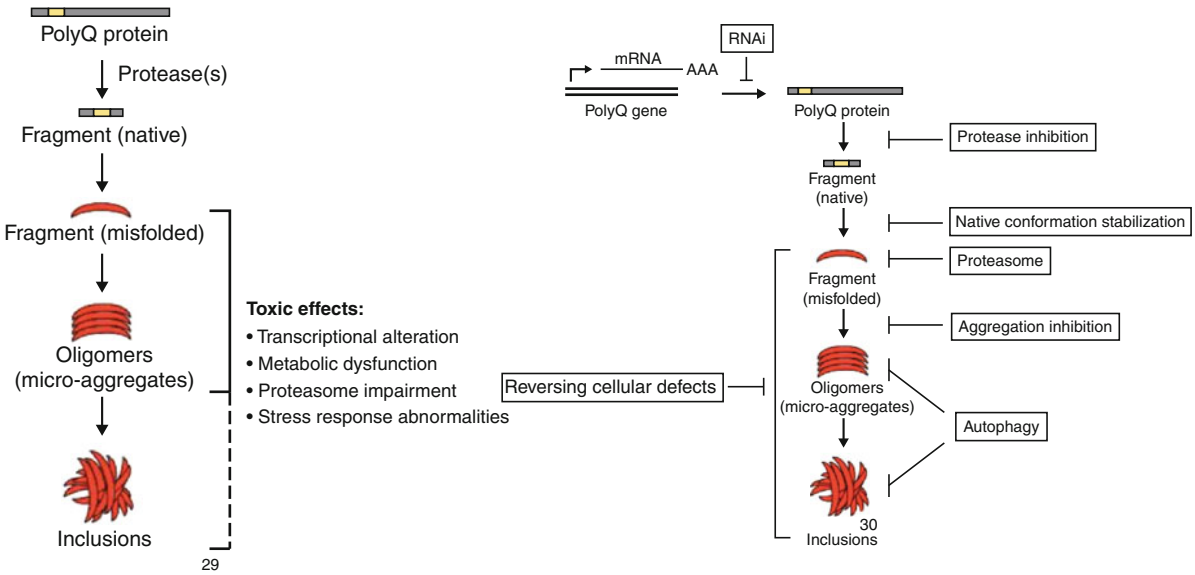

Figure 367.6

Pathogenesis of spinocerebellar ataxias related to CAG repeat expansions. The polyglutamine protein product of the mutated allele tends to misfold and form oligomers and aggregates, sometime after cleavage by proteases. Such misfolded protein can be pathogenic due to a variety of reasons, including interference with transcriptional machinery in general, and with the proteasome, chaperone, and autophagy systems. Numerous secondary events may cascade from these effects including changes in mitochondrial function, apoptosis, and abnormal calcium homeostasis. On the right, some of the potential interventions that may be useful are illustrated, including the use of siRNA to inhibit the mutant gene and therapies that may influence aggregation, autophagy, and proteasome (From Shao and Diamond 2007. With permission)

types, dysarthria, dysphagia, tongue and facial atrophy with fasciculations, muscle atrophy, cramps, muscle fasciculations, sensory loss and areflexia in varying combinations. Seizures, cognitive decline, and retinopathy with visual loss occur in some SCAs.

While the genotypic diagnosis of a particular type of SCA from clinical signs alone is very difficult, certain clinical features may be seen more typically in some SCAs. The course of the SCAs is progressive, with loss of ambulation 15–20 years after onset and death resulting from severe motor disability and resultant complications. Both the array of clinical findings and the course of the disease can be influenced by the repeat expansion size. The diagnosis of an SCA can be made by the documentation of a progressive degenerative ataxic disease with an autosomal dominant inheritance pattern. Further confirmation can be achieved by obtaining mutation analysis for the various SCA genes. In the subsequent section, the SCAs are described in brief with emphasis on those that may have a pediatric presentation.

Spinocerebellar Ataxia 1

The mean age at onset is in the fourth decade, but there is a wide range of age at onset, and childhood onset is possible. In typical cases, clinical picture is characterized by progressive ataxia, dysarthria, upper motor neuron signs, and a mild sensory polyneuropathy. Cognitive decline may occur, especially with younger age at onset. The disease is related to a CAG repeat expansion in the ataxin 1 gene on chromosome 6p.

Spinocerebellar Ataxia 2

Typically, SCA 2 has onset in the fourth decade and is characterized by progressive cerebellar signs associated with slow saccades and polyneuropathy often leading to areflexia. SCA 2 results from a CAG expansion in the ataxin 2 gene on chromosome 12q. Yis et al., Abdel-Aleem and Zaki, Moretti et al., Babovic-Vukasnovic et al. have described a number of pediatric onset cases. In addition to the typical features of ataxia, slow saccades, and loss of reflexes, the childhood cases exhibit cognitive decline and extrapyramidal features. Cases with neonatal onset have hypotonia, developmental delay, ocular problems, and dysphagia. Diagnosis of a dominant condition may be missed because the affected parent (usually the father) may be asymptomatic at the time the children get symptoms. Careful family history and drawing at least a three-generation family pedigree is important. Neonatal cases may have "hyperexpansions" of the CAG tract in the ataxin 2 gene, and these may not be detected by the usual PCR method of mutation detection. When suspicion exists, a "normal" result from such a PCR test should be followed by a Southern blot to detect hyperexpansions.

Spinocerebellar Ataxia 3 or Machado–Joseph Disease

Age at onset can vary from 5 to 75 years, but onset in childhood is rare. There is an inverse correlation between the number of repeats and age at onset, so that pediatric onset typically occurs with repeat sizes over 75 in the mutant allele. This type of early-onset disease is characterized more by extrapyramidal features, including bradykinesia, rigidity, and dystonia, together with spasticity. Ataxia may not be prominent. This has been called the type I MJD phenotype as opposed to type II, which has onset in young adult life and is characterized by ataxia and upper motor neuron findings. Type III disease is characterized by ataxia and neuropathy leading to loss of tendon reflexes. Rare patients with homozygous expansion in the ataxin 3 gene can have a severe phenotype and onset below 10 years of age, but heterozygous expansion also has led to a very early onset. Carvalho et al. reported one homozygous patient who had motor regression and dysphagia starting at age 4, followed by dystonia and spasticity with only minor ataxia.

Spinocerebellar Ataxia 4

SCA 4 has been localized to chromosome 16q and causes a combination of sensory motor neuropathy and ataxia. A "pure" cerebellar ataxia with dominant inheritance, reported from Japan, has an overlapping chromosomal locus and segregates with a single nucleotide substitution in the puratrophin gene within this region; but it is not certain whether this is allelic to SCA 4.

Spinocerebellar Ataxia 5

This dominant adult onset ataxia causes slowly progressive ataxia and has been linked to a mutation in the β spectrin gene (*SPTBN 2)*.

Spinocerebellar Ataxia 6

SCA 6 is characterized by a progressive, pure cerebellar syndrome with onset in the fifth decade and a slow course. It is related to a CAG expansion in the α subunit of the neuronal calcium channel gene (*CACNA1)*.

Spinocerebellar Ataxia 7

SCA 7 is caused by a CAG expansion in the ataxin 7 gene on chromosome 3p. It has wide range of age of onset and the considerable instability of the CAG expansion, especially on paternal transmission, often causes major anticipation in age of onset, with childhood and infantile onset. Adult onset cases are characterized by ataxia and other cerebellar signs, spasticity, and other upper motor neuron signs and a variable occurrence of visual loss related to a cone-rod dystrophy in the retina. Childhood onset has been described both in molecularly confirmed families and in the pre-molecular era. Onset below age was seen with repeat expansion sizes of over 67, and early-onset cases often have visual loss preceding the ataxia,

a situation different from adult onset cases. Early-onset patients also have an accelerated course often leading to death within 5 years of onset and a clinical picture with many features other than ataxia, such as cognitive decline, muscle weakness and atrophy, myoclonus and epilepsy. Infantile onset can be associated with developmental delay, dysphagia, hypotonia, poor visual tracking, and evidence for cardiomyopathy. Similar to that in SCA 2, the "hyperexpansions" associated with such infantile onset can be missed by routine PCR testing and need Southern blotting.

Spinocerebellar Ataxia 8

The CTG expansion in ataxin 8 gene associated with SCA 8 has been seen in both sporadic cases and in some families with dominant ataxia. SCA 8 patients have ataxia, some upper motor neuron signs, and mild sensory loss. The direct role of the expansion in the causation of ataxia is still debated since the same expansion occurs with some frequency in non-ataxic individuals; both an RNA-based mechanism and a "polyglutamine" mechanism based in bidirectional transcription of the gene have been proposed.

Spinocerebellar Ataxia 10

This disease which causes a combination of ataxia and epilepsy is related to a pentanucleotide (ATTCT) expansion in the 5'untranslated region of the ataxin 10 gene and appears confined to people of central and South American ancestry.

Spinocerebellar Ataxia 11

SCA 11 has been described in a limited number of families and causes ataxia, upper motor neuron signs and abnormal eye movements. Mutations have been described in the tubulin tau kinase gene (TTBK2).

Spinocerebellar Ataxia 12

SCA 12 causes a variable combination of ataxia, tremor, basal ganglia signs, and dementia. The causative mutation is a CAG expansion in the promoter sequence of the gene PPP2R2B gene.

Spinocerebellar Ataxia 13

The limited experience with SCA 13 indicated both childhood and adult onset of very slowly progressive ataxia, sometime associated with mild mental retardation. Mutations in a potassium channel gene (KCNC3) are responsible.

Spinocerebellar Ataxia 14

This disorder results from mutations in the protein kinase C γ gene and causes a variable phenotype including childhood onset, though most patients have onset in adult life. The clinical picture has varied from one of pure cerebellar ataxia to one that has additional features including axial myoclonus, choreic movements, diplopia and gaze palsy, and facial myokymia. Rigidity, dystonia, proprioceptive loss, and slow saccades also have been noted from time to time.

Spinocerebellar Ataxia 15 and 16

SCA 15 and 16 were originally reported from Australia and Japan, respectively, but more recent findings suggest that the same gene mutation underlies these entities. The disease causes pure cerebellar ataxia, but the Japanese cases had postural tremor as well. Deletions involving two contiguous genes (SUMF1 and ITPR1) were found in the Australian kindred, but in the Japanese patients, only the ITPR1 gene was deleted, suggesting that this is the critical gene.

Spinocerebellar Ataxia 17

SCA 17 is caused by a CAG expansion in the TATA-binding protein (TBP) gene. It is a polyglutamine disorder. It has a wide range of age at onset, including childhood, and has a very variable phenotype including ataxia, extrapyramidal signs, psychiatric features, epilepsy, and dementia.

Spinocerebellar Ataxia 18

Brkanac et al. described a chromosome 7q22–q32-linked autosomal dominant condition characterized by both ataxia and a sensory motor neuropathy in a five generation American family of Irish ancestry.

Spinocerebellar Ataxia 19

Schelhaas et al. reported a family of Dutch origin with a mild ataxia, myoclonus, irregular postural tremor, and cognitive impairment. Among 11 family members with clinical data, many also had decreased proprioception and tendon reflexes. The disorder in this family was mapped to chromosome 1p21–q21 by Verbeek et al.

Spinocerebellar Ataxia 20

SCA 20 was described in an Australian family with a wide range of age at onset, prominent dysarthria and dysphonia, and the presence of calcification in the cerebellar dentate. The disease is localized to chromosome 11 and appears related to the duplication of a 260 Kb segment on chromosome 11q. Its pathogenesis remains unclear.

Spinocerebellar Ataxia 21

In a family with autosomal dominant ataxia with onset in childhood and young adult life, a new gene locus was established at chromosome 7p. In addition to ataxia, the patients had tremor, rigidity, and cognitive impairment.

Spinocerebellar Ataxia 22

Chung et al. (2003) reported a Chinese family with dominant ataxia, hyporeflexia, onset between 10 and 46 years of age and MRI showing isolated cerebellar atrophy and established a locus at chromosome 1p, overlapping that reported in SCA 19.

Spinocerebellar Ataxia 23

In a single family with adult onset dominant ataxia, the locus was mapped to chromosome 20p.

Spinocerebellar Ataxia 25

In a single family from France, Stevanin et al. noted childhood onset of a dominant ataxia with variable progression and an associated peripheral neuropathy. Linkage studies localized the disorder to chromosome 2p.

Spinocerebellar Ataxia 26

Yu et al. have a described a single family of Norwegian descent with relatively pure cerebellar ataxia with little in the way of extracerebllar signs. Age at onset was from 33 to 60 years. MRI showed cerebellar atrophy, but brainstem was spared. Genetic mapping has localized this disease to chromosome 19p13.3 adjacent to the SCA 6 locus.

Spinocerebellar Ataxia 27

This disease, related to mutations in the fibroblast growth factor 14 gene, has onset in childhood with tremulousness and then progressive ataxia which is slowly progressive. Orofacial dyskinesias, cognitive decline, and aggressive outbursts were noted in some patients.

Spinocerebellar Ataxia 28

There is limited experience with this disease in two families of Italian origin. The phenotype is characterized by juvenile onset (range 12–36), slow progression of ataxia, nystagmus, and later in the disease course, ophthalmoparesis with ptosis and slow saccades. Point mutations have been discovered in the SCA 28 gene in these two families, located on chromosome 18p.

Spinocerebellar Ataxia 29

In an Australian family with congenital, nonprogressive ataxia and "cerebellar hypoplasia" on imaging studies, Dudding et al. identified a locus on chromosome 3p.

Spinocerebellar Ataxia 30

An Australian family with dominantly inherited ataxia of late onset was mapped to chromosome 4q.

Dentato-Rubral-Pallido-Luysian Atrophy (DRPLA)

This disease with a very complex phenotype is usually classified among the ataxias. It is most prevalent in Japan, but molecularly proven DRPLA has been reported from Europe and the USA. The original African-American

family in which the typical neuropathology was described many years ago is now known to carry the same mutation as the Japanese cases. DRPLA has a variable age of onset from infancy to old age and anticipation is common. With onset below 20 years of age, the clinical picture is one of seizures, myoclonus, ataxia, and intellectual decline. With older onset, the disease is characterized by ataxia, chorea, dementia, and psychiatric features. Thus, the differential diagnosis varies with age and includes the progressive myoclonic epilepsy syndromes in children and adolescents, and Huntington's disease in older persons. Diagnosis can be established by documenting an expanded CAG repeat in the atrophin 1 gene.

Episodic Ataxias

The episodic ataxias are characterized by brief, reversible attacks of ataxia of variable duration often associated with other neurological features. However, in some of them, a more persistent neurological deficit may develop or may be present from the very onset, blurring the distinction from the SCAs. Conversely, some of the SCAs (such as SCA 6) may have features reminiscent of episodic attacks. Many of the EA syndromes have pediatric onset.

Onset of EA 1 is in early childhood with very brief episodes of ataxia lasting seconds to minutes associated with a coarse tremor and dysarthria. Between attacks of ataxia, patients have skeletal muscle myokymia that may be detected clinically or only by electrophysiological studies. Children with EA 1 may have other features such as partial epilepsy, transient postural abnormalities, and tight heel cords. Some patients may have only peripheral myokymia with no ataxia, and some may have persistent cerebellar findings and cerebellar atrophy on scans. Mutations in the potassium channel gene, *KCNA 1,* have been identified in EA 1.

EA 2 also has a childhood onset in the majority of patients. Episodes of ataxia last many hours and are associated with other symptoms such as headache, nausea, vomiting, diplopia, and dysarthria. Interictally, many EA 2 patients have mild cerebellar deficits including nystagmus (often downbeating) and difficulty with tandem gait. EA 2 patients may have a progressive ataxia later in life. Unusual features have been described, including children with features of benign paroxysmal vertigo and cognitive decline associated with attention deficit disorder. In addition, the EA 2 mutations may be associated with seizures, coma, and cerebral edema after mild head trauma. EA 2 is allelic to two other diseases, familial hemiplegic migraine (FHM) and SCA 6. All of them are related to mutations in the α subunit of the neuronal calcium channel gene, *CACNA1A*; EA 2 and FHM are related to point mutations in the gene and SCA 6 to a CAG expansion.

Other EAs have been defined by the presence of familial episodic ataxia or vertigo and exclusion of the EA 1 and EA 2 mutations. EA 3 is characterized by brief episodes of ataxia and vertigo, associated with tinnitus. It has been localized to chromosome 1q42. EA 4 has been reported to produce late-onset episodic vertigo and ataxia (vestibulocerebellar ataxia) lasting many hours; linkage to EA 1 and EA 2 loci has been excluded, but no other genetic information is available. EA 5 has clinical features similar to EA 2; mutation in the β4 subunit of the calcium channel gene, *CACNB4,* has been reported in one family. Finally, EA 6 was reported in a single child with episodes of ataxia, hemiplegia, and seizures with a mutation in an astrocytic glutamate transporter gene (*SLC1A3)*. The mutation was shown to have lead to loss of function of the protein with a dominant negative effect on the wild type product by functional studies.

Treatment: EA syndromes respond to many drugs with reduction in the number of episodes. Whether these drugs prevent long-term, progressive deficits is not clear. EA 1 responds to carbamazepine, valproate, and sometimes to acetazolamide. Acetazolamide often leads to dramatic improvement in EA 2; other drugs that may ameliorate attacks include flunarazine and 4-aminopyridine.

For the SCAs, there is no proven therapy at this time. Supportive and rehabilitative care need to be organized as for many other disabling neurological illnesses. As in all genetic diseases, appropriate referral for genetic counseling is indicated.

368 Approach to Diagnosis and Treatment of a Child with Motor Unit Diseases

Mustafa A. M. Salih

Definition/Classification

The anatomical route of the lower motor neuron, which composes the motor unit, has four subunits. These subunits consist of a motor neuron in the brainstem or ventral horn of the spinal cord and its axon, which together with other axons form the peripheral nerve; the neuromuscular junction; and the group of muscle fibers innervated by a single motor neuron. Disorders affecting these motor subunits can be further subdivided into hereditary syndromes and acquired diseases, and into acute and chronic disorders.

Epidemiology

Diseases of the motor unit affect all races and are common in children. A world survey of the commoner neuromuscular diseases estimated an overall prevalence of 286 per million populations. Nevertheless, the prevalence of some disorders in particular countries, such as congenital muscular dystrophy in Finland and Japan, spinal muscular atrophy and severe childhood autosomal recessive muscular dystrophy (SCARMD, limb-girdle muscular dystrophy [LGMD]) in Middle East and North African populations, reflects inbreeding in these communities, which increases the relative incidence of recessive disorders.

Diagnostic Approach

The recent advances in molecular biology has dramatically changed the diagnostic approach to neuromuscular disorders (NMDs), paved the way for accurate genetic counseling and for potential treatment by gene or cell therapy. Yet, a careful history and physical examination remain the cornerstones that guide the molecular and other investigative tools available to the clinician.

Symptoms

In childhood, common presenting symptoms of NMDs include floppiness or hypotonia, delayed motor milestones, abnormal gait, tendency to fall, as well as muscle weakness, cramps, or stiffness. It is also important to ascertain in the history whether certain activities that the child had difficulty with remained static or deteriorated. These activities include running, climbing stairs, and getting up from the floor. Questions pertaining to increase in muscle weakness as the day progresses, fatigue on effort and improvement on rest (suggesting myasthenia), and increased disability with inactivity and improvement with activity (suggesting myotonia) are also important. History of recurrent episodes of muscle weakness points toward periodic paralysis (in channel disorders), myasthenia gravis, dermatomyositis or polymyositis, and rhabdomyolysis or relapsing polyneuropathy. The occurrence of muscle cramps with exertion and their relief by rest may be the manifestation of some of the slowly progressive forms of muscular dystrophy (MD) such as Becker MD. They also occur in metabolic disorders of muscle (glycogenosis types V and VII and lipid metabolic disorders due to carnitine palmitoyl transferase deficiency, as well as other syndromes associated with myoglobinuria). Any observed muscle enlargement (hypertrophy) or wasting should also be ascertained. Difficulty with chewing or swallowing and associated respiratory deficit or disturbed sleep (indicating sleep apnea) are also vital components of enquiry.

Detailed family history of a similar condition is essential in each case and a pedigree chart will point toward an X-linked disease when the male relatives on the maternal

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_368,

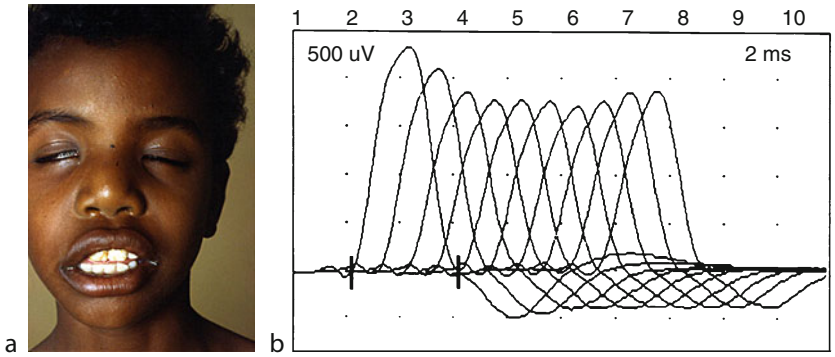

Figure 368.1
(a) Bilateral lower motor neuron facial weakness in a 12-year-old boy with fascioscapulohumeral muscular dystrophy. The patient cannot bury the eyelashes when asked to close his eyes tightly. The mouth is open with trickling saliva. (b) Repetitive electrical stimulation of a motor nerve showing myasthenic decremental response. There is a fall-off in the size of muscle action potential of greater than 10% between the first and fifth response

side are affected. Consanguineous parents having earlier normal generations and affected siblings of both sex may be carriers of autosomal recessive conditions.

Signs

A considerable proportion of the physical examination can be done while the child is still clothed sitting in one of parent's lap. Using an examination couch and undressing a child for formal assessment invites uncooperativeness and irritability. Uncomfortable procedures, like inspecting the tongue (for fibrillations) and palatal movement of a young child should be deferred to the end. An infant can be given an object of interest to handle, like small cubes or one of the parent's keys. This activity will assess the baby's ocular motility and the pincer grasp. It will also assess coordination and ability to raise the arms against gravity. Facial expression should be noted, especially the presence of an open, drooping, or triangular mouth. Ability to raise the eyebrows on looking up speaks against lower motor neuron facial weakness. The older child can be asked to shut the eyes tightly. In the presence of facial weakness, he or she will not be able to bury the eyelashes completely (see *Fig. 368.1a*). The lower face can be assessed by asking the child to pout, blow (or whistle), smile, show the teeth, and puff out the cheeks.

Examination of the upper and lower limbs should take note of muscle bulk, tone and power, whether weakness is proximal or distal, symmetric (involving both sides of the body) or asymmetric. The Medical Research Council (MRC) scale for evaluation of muscle (*Table 368.1*) is a useful and practical guide for comparing muscle groups (proximal vs. distal) initially and during follow-up examinations.

Table 368.1
Medical research council grading scale for evaluation of muscle power

Grade	Muscle response
0	No contraction
1	Flicker of contraction
2	Active movement, with gravity eliminated
3	Active movement against gravity
4	Active movement against gravity and resistance
5	Normal power

Deep tendon reflexes are generally lost in neuropathies and in motor neuron diseases (including spinal muscular atrophy) and are diminished, but preserved, in myopathies and dystrophies. In Duchenne MD, the ankle jerks are often retained and may even be brisk until late in the disease.

Joint abnormalities should also be assessed. These can manifest as laxity of ligaments or limitation of joint movement as a result of permanent shortening (contractures). They usually take the form of flexion contractures of the hips, knees, and other joints in the non-ambulant child. In inherited peripheral neuropathies, pes cavus is the usual

joint abnormality to be seen when the child is still walking. With loss of ambulation, scoliosis usually develops in various neuromuscular disorders, but can be prevented by adequate seating and other supportive measures.

Assessment of gait can start from the time an ambulant child comes into the consulting room. Toe-walking can be a transitory phenomenon in normal children but is a common feature in various neuromuscular disorders, spastic diplegic type of cerebral palsy, and hereditary spastic paraplegias. Walking on heels and heel-to-toe walking along a straight line are also useful in assessment. Ability to sit up from the supine position, get up from the floor, or from a chair are important details to elicit for examining the degree of hip girdle muscle weakness.

Following assessment of a child, it should be easy to determine whether the history and physical signs are indicative of a specific neuromuscular disorder or one outside the neuromuscular system.

Investigations

Three modalities of investigations are still used for diagnosing neuromuscular disorders. These are serum enzymes, electrophysiological procedures, and muscle and sural nerve biopsies. With the advent of molecular genetic markers, DNA analysis has become a routine definitive diagnostic test in several neuromuscular disorders, surpassing electromyography (EMG) and muscle biopsy.

Serum Enzymes

Creatine kinase (CK), which is released by damaged or degenerating muscle fibers is separated into three isoenzymes: MM for skeletal muscle, MB for cardiac muscle, and BB for brain. Serum CK determination is a very useful screening test for a suspected neuromuscular disease. (See Chap. 374, "Hereditary and Acquired Myopathies")

Electrophysiological Investigations

Nerve Conduction Studies

Motor and sensory nerve conduction can be measured by a relatively simple technique using surface electrodes. The conduction velocity is dependent on the diameter and the degree of myelination of the axon. At birth, conduction is about half of the adult value and reaches the mature value by 3–5 years of age. In peripheral neuropathies, the pathology may be primarily in the axon (axonal neuropathy) or, if in the supporting Schwan cell, it leads to segmental demyelination (demyelinating neuropathy). The nerve conduction velocity (NCV) is markedly decreased in demyelinating neuropathies. In axonal neuropathy, the NCV may be normal or slightly decreased, whereas the compound muscle action potential (CMAP) will be significantly low. Determining whether the neuropathy is demyelinating or axonal is of great help in guiding the DNA tests for the various forms of Charcot–Marie–Tooth disease (CMT, hereditary motor and sensory neuropathy [HMSN]).

In dominantly inherited demyelinating CMT, it is also important to assess the NCV in both parents and siblings, to detect subclinical cases. Post-infectious polyneuritis (Guillaine–Barre syndrome and diphtheritic polyneuropathy) may manifest as a demyelinating neuropathy. Measurement of the sensory conduction velocity and sensory action potential are useful diagnostic tools in mixed and complex neuropathies, such as CMT and Friedreich's ataxia, and in hereditary sensory and autonomic neuropathies.

Repetitive electrical stimulation of a motor nerve supplying a muscle aids diagnosis of congenital myasthenic syndromes and myasthenia gravis. Fatiguability of the muscle can be demonstrated by the falloff in the size of the muscle action potential (myasthenic decremental response) (*Fig. 368.1b*).

Electromyography (EMG)

This technique is capable of showing whether a particular muscle is normal or abnormal and whether the abnormality is myopathic or neuropathic. However, it is less useful in children than in adults because it requires insertion of a needle into the belly of a muscle, and because the amount of received information is directly proportional to the degree of cooperation. It has been largely replaced by more specific diagnostic tools, namely DNA analysis (such as in Duchenne MD and spinal muscular atrophy [SMA]) and muscle biopsy. Nevertheless, EMG is the diagnostic modality of choice in muscle diseases manifesting with myotonia, including myotonia congenita, myotonic dystrophy, and Schwartz–Jampell syndrome. It shows the pathognomonic spontaneous myotonic bursts of activity with gradual decrement. A typical sound of the "dive bomber" or "departing motor cycle" sound will be heard on acoustic amplification. It is usually present in dominantly inherited congenital myotonic dystrophy, but appears later

after the age of 2–3 years. The minimally affected mother of a suspected baby will usually show these pathognomonic bursts.

Muscle Biopsy

If a specific diagnosis of hereditary disease is not provided by molecular genetic testing in blood, which is currently available in many centers, a muscle biopsy is essential for establishing a definitive diagnosis in any patient with a suspected neuromuscular disorder. When interpreted by an experienced pathologist, it distinguishes between neurogenic, myopathic, and dystrophic processes. It can also indicate the type of myopathy and specify the deficient protein or enzyme.

An open biopsy, done under local anesthesia is preferable to needle biopsy, since it allows obtaining adequate tissue for additional biochemical studies, such as respiratory chain enzymes for investigating mitochondrial diseases. The vastus lateralis (quadriceps femoris) is the muscle usually sampled. Conventional paraffin sections of the biopsied specimen are not adequate, since that technique does not allow the diagnosis of many congenital and metabolic myopthies. Histochemical studies of frozen sections are, hence, obligatory. Immunohistochemistry is now essential, because it demonstrates the expression of dystrophin protein in Duchenne MD and Becker MD, as well as a number of other dystrophin-associated proteins. Deficiency of the latter causes a variety of autosomal recessive dystrophies. A portion of the biopsy specimen should be fixed in gluteraldehyde for potential electron microscopy, for diagnosis of several congenital myopathies and mitochondrial myopathy.

Sural Nerve Biopsy

The sural nerve is the most commonly biopsied nerve in neuropathies. Electron microscopy of a sural nerve sample can accurately differentiate between axonal and demyelinating neuropathies, as well as assess the types of fibers in hereditary sensory and autonomic neuropathies. Teased fiber preparations are useful in showing segmental demyelination, but are not done routinely since they are labor intensive.

Imaging of the Motor Unit

Differential involvement of muscle occurs in several neuromuscular disorders and this can be assessed by either ultrasound, computed tomography (CT), or magnetic resonance imaging (MRI). Ultrasound, performed by an experienced operator, is a rapid and practical method to apply before sampling a muscle for biopsy. However, in advanced dystrophies a muscle biopsy might need MRI guidance. The latter technique is also useful in inflammatory myopathies of infectious (bacterial and parasitic), as well as immune (dermatomyositis) origin. Imaging of the spinal cord, nerve root, and plexus is best achieved using MRI.

Respiratory and Cardiac Investigations

Respiratory function tests should be done for children with diseases of the motor unit initially and on regular follow-up. In certain conditions with fluctuating weakness, like congenital myasthenic syndromes and myasthenia gravis, sleep studies need also to be arranged to explore the possibility of the occurrence of sleep apnea and hypoventilation. Electrocardiography (ECG) is also important in the clinical evaluation of muscular dystrophies and in inflammatory and metabolic myopathies to explore an associated subclinical conduction defect or cardiomyopathy. Regular follow-up with a pediatric cardiologist (on yearly or biennial basis) and serial assessment by electrocardiography are required in muscular dystrophies and certain congenital and metabolic myopathies.

Floppy Infant Syndrome

The complex of floppiness/hypotonia is a common neurologic symptom in infancy; and the floppy infant syndrome refers to an infant with generalized hypotonia presenting at birth or in early life. The diagnostic work up is often challenging, if a systematic evaluation of infants with hypotonia is not followed. Hypotonia usually manifests as unusual postures, such as lying in frog-leg position when supine (*Fig. 368.2a*). Hypotonia becomes more apparent by positioning the infant in certain ways. On ventral suspension, a floppy infant will lose the ability to maintain the head in line with body. The limbs will be dangling (*Fig. 368.2b*). On pulling to the sitting position by traction on hands, prominent head lag occurs (*Fig. 368.2c*). After the neonatal period, floppy infants usually present with delay in motor milestones.

A Practical Approach to Diagnosis

It has been a standard practice to decide first, whether the hypotonia is a manifestation of a motor unit disease or if it

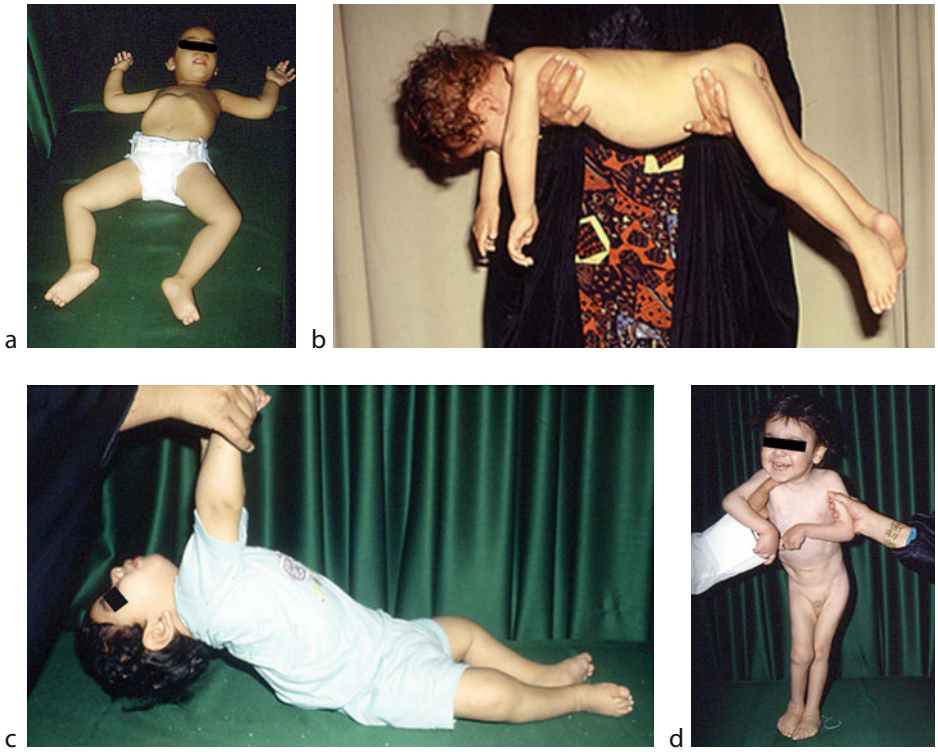

Figure 368.2
(a) A floppy infant with frog-like position when supine. (b) On ventral suspension, the limbs are dangling. (c) Prominent head lag on pulling to the sitting position. (d) Central nervous system (CNS) disorder causing floppy infant syndrome. When assessing the ability to support weight, there is scissoring of legs, flexion of elbows and clenching of the hands

is due to a disorder of the central nervous system (CNS), or another system in the body. Significant degree of weakness is usually associated with motor unit diseases. On the other hand, hypotonia without weakness includes disorders of CNS, and metabolic, nutritional, and endocrine disorders. Assessing weakness can be achieved even in very young infants by observing the spontaneous movements of the face and limbs, response to stroking the soles, and the ability to sustain passively elevated arms or legs. Other features that point to hypotonia being caused by disorders of CNS include the easily elicited (or brisk) deep tendon jerks, whereas in a disease of the lower motor unit, reflexes are typically diminished or absent. With increasing age, hypotonia is gradually replaced by hypertonia in disorders of CNS and there is persistence of neonatal reflexes such as the grasp, Moro, and tonic-neck reflex. When assessing the ability to support weight of such older infants, the legs will be kept crossed (scissoring) and there is plantar flexion of the feet. The elbows are usually flexed, hands are clenched, and the thumb is kept across the palm (fisting position) (*Fig. 368.2d*).

Disorders of the CNS (Cortical, Subcortical, and Cerebellar)

Congenital or acquired disorders of the CNS account for the majority of the causes of floppy infant syndrome (*Table 368.2*).

Clinical Manifestations

History: Pregnancy, Birth, and Perinatal

Important features to ascertain when considering hypotonia due to disorders of CNS include age of the mother at time of birth. Advanced age increases the chance of chromosomal disorders. Other features include history of fever, infections or teratogens especially during early pregnancy, polyhydramnios or oligohydramnios, recurrent abortions or stillbirth, and if any abnormalities were detected on screening ultrasound.

Table 368.2
Disorders of the central nervous system (CNS) manifesting as floppy infant syndrome

Static encephalopathy
Cerebral dysgenesis/dysplasia: Lissencephaly, holoprosencephaly, Joubert syndrome, pontocerebellar hypoplasia
Perinatal hypoxic/ischemic insult, kernicterus and intracranial hemorrhage
Congenital infections: TORCH
Genetic syndromes and chromosomal abnormalities: Down syndrome (Trisomy 18, Prader-Willi syndrome, Cri-du-chat [5p-] syndrome).
Metabolic disorders:
Disorders of carbohydrate metabolism: galactosemia, hereditary fructose intolerance
Disorders of amino acid metabolism: Phenylketonuria, tyrosinosis type 1, sulphite oxidase deficiency, nonketotic hyperglycinemia, argininosuccinic aciduria
Organic acidemias: Maple syrup urine disease (MSUD), methylmalonic academia, glutaric aciduria, propionic academia, malonic aciduria, multiple carboxylase deficiencies (defects in utilization of biotin).
Mitochondrial disorders: Respiratory chain and Kreb cycle disorders, Leigh's syndrome, pyruavete carboxylase deficiency, pyruvate dehydrogenase complex deficiency.
Lysosomal storage disease: Mucopolysaccharidosis, lipidosis (Gauher type 2, Nieman-pick type A, Tay-Sachs disease), mucolipidosis (sialidosis type II, I-cell disease).
Perioxosomal disorders: Zellweger syndrome, rhizomelic chondrodysplasia punctata.

The duration of pregnancy and the birthweight are also vital. Preterm delivery increases the risk of perinatal hypoxic-ischemic insult and intraventricular hemorrhage. The mode of delivery, whether assisted by ventose or through a cesarean section following difficult birth and the Apgar score 5 min after birth is important. If this is not available, asking whether the baby breathed spontaneously and cried immediately after birth gives a reasonable idea, provided the mother has not been under the effect of anesthesia for cesarean section. Difficulties in sucking and swallowing during the first 24 h after birth may reflect the severity of the hypoxic-ischemic insult. Whether the baby needed to be shifted to the neonatal intensive care unit (NICU), required mechanical ventilation or had seizures, and the duration of stay in the NICU are also salient points.

History of delayed motor, speech, or cognitive development following the neonatal period points toward genetic disorders or cerebral dysgenesis. Loss of previously acquired milestones usually heralds neurodegenerative and metabolic disorders. Seizure disorders may be associated with cerebral dysgenesis or chromosomal disorders.

Signs

Obtunded appearance of the baby may reflect consequences of neonatal insult or brain dysgenesis, and the presence of encephalopathy out of the context of birth history points toward an underlying metabolic disorder. Dysmorphic features give important clues to identifying genetic disorders. Skin examination may reveal neurocutaneous signs. Anthropometry (weight, height, and head circumference) should be routine. Obesity and short stature are features of Prader–Willi syndrome, whereas microcephaly is common in chromosome abnormalities, brain dysgenesis (e.g., microcephaly and lissencephaly syndromes), and TORCH (Toxoplasmosis, Other infections, Rubella, Cytomegalovirus, Herpes simplex virus) infections (except for congenital toxoplasmosis, which can present with hydrocephalus).

Ophthalmologic examination may reveal important diagnostic signs. Oculomotor apraxia is a feature of Joubert syndrome, ataxia telangiectasia, and ataxia-oculomotor apraxia syndromes. A cherry red spot indicates an underlying lipidosis. Retinitis pigmentosa may indicate other storage diseases, such as neuronal ceroid lipofuscinosis. Ptosis and ophthalmoplegia (or ophthalmoparesis) are found in congenital myasthenia, congenital myasthenic syndromes, and some mitochondrial disorders.

Examination of the chest, cardiovascular system, and abdomen may reveal an underlying multisystem involvement. In particular, the presence of hepatosplenomegaly may be associated with TORCH infections, glycogen storage disease, and lipidosis (e.g., Nieman–Pick disease types A and C) (*Fig. 368.3a*).

Spinal Cord Lesions

These lesions can follow damage to the spinal cord during delivery, the presence of a congenital tumor, or dysraphic states (tethered cord and myelomeningocele). Traumatic lesions involve either the lower cervical and upper thoracic cord with breach delivery, or the upper cervical region with cephalic presentation. Mid-forceps

Figure 368.3

(a) Floppy infant syndrome due to Niemann-Pick disease. The enlarged liver and spleen are marked. (b) Bone marrow showed the characteristic foam cell (arrow). (c) Bladder distension associated with hypotonia due to spinal cord injury. (d) An infant with Pompe disease (glycogenosis type II). (e) Echocardiography showed hypertrophic cardiomyopathy and small left ventricle (LV). (f) Cranial computed tomography (CT) scan showing periventricular calcification and brain malformation in congenital cytomegalovirus infection (Figs. 3d and e are courtesy of Dr. Elsayed Ali)

extractions with excessive longitudinal traction or rotation are known risk factors.

The clinical picture is characterized by hypotonia, which may persist or evolve into spasticity, associated with paraplegia or tetraplegia, respiratory insufficiency or paradoxical breathing in some cases, bladder distension, impaired bowel control, pyramidal tract signs, and sensory level (*Fig. 368.3c*). The lower roots of the brachial plexus may be affected and manifest with paralysis of the intrinsic hand muscles. Congenital spinal cord tumors present with similar localizing signs.

Diseases of the Motor Unit

Disorders of the motor unit account for 18–47% of the causes of the floppy infant syndrome. In these conditions, the infant has a significant degree of weakness in

Table 368.3
Diseases of the motor unit associated with the floppy infant syndrome

Anterior horn cell
Acquired: Poliomyelitis, other viral syndromes (e.g., Coxsackie A)
Hereditary: Spinal muscular atrophy (SMA) type 1 (Werdnig–Hoffman disease and SMA type 2).
Peripheral nerve
Acquired: Guillaine-Barre syndrome
Hereditary: Congenital hypomyelination neuropathy
Neuromuscular junction
Transient neonatal myasthenia, congenital myasthenic syndrome
Botulism
Muscle
Congenital myopathies: Myotubular myopathy, nemaline myopathy, congenital fiber type disproportion, central core disease, multiminicore disease, Salih myopathy
Metabolic myopathies: Glycogenosis types II (Pompe disease) and III.
Mitochondrial myopathies, lipid storage myopathies, periodic paralysis
Congenital myotonic dystrophy, neonatal Schwartz-Jampel syndrome
Congenital muscular dystrophies

association with hypotonia. The anatomic localization of these disorders is detailed in *Table 368.3*.

Clinical Manifestations

History: Pregnancy, Birth, and Perinatal

It is always pertinent to ask whether the mother has been diagnosed to have a neuromuscular disease such as myotonic dystrophy or myasthenia gravis. History of polyhydramnios is a common feature in congenital myotonic dystrophy. Diminished fetal movements may be noticed by the mother in congenital myotonic dystrophy and spinal muscular atrophy (SMA) type 1 (Werdnig–Hoffman disease). On ultrasound screening, brain abnormalities are detectable in Walker–Warburg phenotype of congenital muscular dystrophy (CMD). Arthrogryposis multiplex can also be noted. Breech presentation is common in neuromuscular births. Poor respiratory effort and difficulties in sucking and swallowing may also be a feature, as in congenital myotonic dystrophy, myotubular myopathy, nemaline myopathy, neonatal myasthenia, congenital myasthenic syndrome, and the Walker–Warburg type of CMD.

Signs

Assessment for associated features should also be done, such as the presence of hepatomegaly, respiratory, and/or cardiac signs in glycogenoses types II (Pompe disease) and III, lipid storage myopathies, and mitochondrial myopathies.

The distribution and degree of weakness may help to distinguish between the various causes of hypotonia of neuromuscular origin. Loss of antigravity movement of the limbs points toward proximal muscle weakness, whereas distal weakness is indicative of a peripheral nerve disorder. In SMA type 1, the intercostal muscles are severely affected and breathing is diaphragmatic. Tongue fasciculation is a helpful sign. Ocular muscle involvement, in the form of ophthalmoplegia and/or ptosis is a feature of disorders of neuromuscular junction (transient neonatal myasthenia, congenital myasthenic syndrome, and botulism), mitochondrial myopathy, some congenital myopathies (e.g., myotubular myopathy), and myotonic dystrophy. Asymmetric ptosis is found in some cases of Salih myopathy. Facial muscle involvement is common in CMD, myotonic dystrophy, and congenital myopathies, but it is not present in SMA. Pursed-mouth appearance during crying is a feature of neonatal Schwartz–Jampel syndrome. Asymmetric association of the sixth and/or seventh cranial nerves is seen in acquired causes of floppy infant syndrome, namely poliomyelitis and diphtheritic polyneuropathy. Facial nerve involvement is symmetric in Guillaine–Barre syndrome. Deep tendon jerks are usually diminished in neuromuscular disorders but absent in SMA.

Contractures and arthrogryposis are common in congenital myotonic dystrophy and CMD. Nevertheless, Ullrich type of CMD is characterized by a peculiar combination of proximal contractures and distal laxity with congenital hip dislocation. Neonatal Schwartz–Jampel syndrome features pectus excavatum, camptodactyly, bowed lower limbs, and talipes.

Systemic Disorders

Apart from disorders of CNS and diseases of the motor unit, certain systemic disorders can present as floppy infant syndrome, as detailed in *Table 368.4*.

Table 368.4
Systemic disorders that may manifest floppy infant syndrome

Endocrine disorders
Hypothyroidism, hyperparathyroidism
Nutritional disorders
Primary: Severe childhood undernutrition (protein-energy malnutrition), rickets
Secondary: Malabsorption syndromes (celiac disease and cystic fibrosis), AIDS, cardiac disease, renal disease, pulmonary disease (tuberculosis)
Electrolyte disorders: Renal tubular acidosis, marble bone-marble brain disease (type III osteopetrosis)
Connective tissue disorders: Congenital laxity of ligaments, osteogenesis imperfecta, Ehlers–Danlos syndrome, Marfan syndrome, arachnodactyly.

Investigations

These investigations should be guided by the clinical presentation, symptoms, and the elicited physical signs. During the neonatal period, especially when there are features of encephalopathy or recurrent vomiting, investigations for inborn errors of metabolism should receive priority. Most inborn errors of metabolism, when presenting in the neonatal period, are lethal if specific treatment is not initiated immediately.

Measurement of serum concentrations of ammonia, bicarbonate, and pH should be done first. Many inborn errors of metabolism cause a metabolic acidosis due to excessive production of ketoacids, lactic acid, and/or other organic anions. Elevation of blood ammonia is usually caused by urea cycle defects. Such infants have normal serum pH and bicarbonate values. Determination of anion gap ($[Na^+] - [Cl] - [HCO_3]$) is the next pertinent step. High anion gap associated with serum ammonia is found in organic acidemias, whereas normal anion gap and normal serum ammonia are found in aminoacidopathies and galactosemia. Lactic acidosis unrelated to an enzymatic defect occurs in hypoxemia. When lactic acidosis results from an enzymatic defect in gluconeogenesis or pyruvate dehydrogenase complex, both lactate and pyruvate are increased and the ratio is normal. In hypoxemia and in mitochondrial diseases due to defects in the respiratory chain, the serum pyruvate concentration may remain normal with an increased lactate:pyruvate ratio. Elevation of lactic dehydrogenase (LDH), serum glutamate-oxaloacetate transaminase (SGOT), and serum glutamate-pyruvate transaminase (SGPT) indicates hepatic involvement in galactosemia, urea cycle defects, aminoacidurias, and organic acidurias. Other blood tests that should be done routinely include complete blood count (for neutropenia and thrombocytopenia seen in organic acidurias), glucose, urea, electrolytes (Na, K, and Cl), creatinine, blood gases, and thyroid function tests.

Biochemical neonatal screening is now available in many countries using tandem mass spectrometry (MS/MS); the diseases being screened emphasize differences in their incidence and prevalence among different populations. In addition to the tandem mass spectrometry, blood spots obtained from a newborn on Guthrie card can also be used to screen for hypothyroidism, biotinidase deficiency, congenital adrenal hyperplasia, and galactosemia, using high throughput fluorometric assays. In suspected cases of nonketotic hyperglycinemia, the diagnosis is highly significative by the demonstration of elevated plasma and cerebrospinal (CSF) glycine levels, with a high glycine CSF/plasma ratio, and confirmed by glycine cleavage enzyme assay on liver biopsy. In organic acidurias, findings in tandem mass spectrometry can be further confirmed by gas chromatography/mass spectrometry analysis of the urine organic acid profile.

In countries where a comprehensive neonatal screening program is not available, simple urine screening tests can be used. These tests include the ferric chloride test (phenylketonuria [PKU], tyrosinosis), the dinitrophenylhydrazine test (PKU, Maple syrup urine disease), the sodium cyanide-nitroprusside test (homocystinuria), Benedict's reagent or Clinitest tablets test (galactosemia), ketones (organic acidurias), and cetyltrimethylammonium bromide (mucopolysaccharidoses). These tests can be used as a basis for initiation of therapy when the clinical manifestations suggest the diagnosis. Nevertheless, they should never be considered definitive.

Special investigations when suspecting a disease of the motor unit include creatine kinase.

In Duchenne and Becker MDs, the level is grossly elevated (up to 50 times the normal limit) in the early stages, whereas in SCARMD and congenital muscular dystrophy, it is 5–10 times normal. Other forms of dystrophy such as Emery–Dreifuss MD may have a more modest elevation. In congenital myopathies with structural muscle abnormalities, it is likely to be normal or only slightly elevated. The levels are usually normal in neurogenic diseases, like the spinal muscular atrophies. Mild degrees of elevation are also seen in some carriers of Duchenne MD and in subclinical malignant hyperthermia.

CK is moderately elevated in congenital muscular dystrophy (CMD) but can range from normal to marked

elevation, depending on the underlying degree of muscle degeneration. It is also likely to be normal or only slightly elevated in several congenital myopathies with structural abnormality, such as central core disease or nemaline myopathy. In Salih myopathy, serum CK is mildly elevated in the first 4 years of life (four times the upper normal limit) and increases slightly more by 10 years (5.5 times the upper normal limit). In SMA types 1 and 2 and other neurogenic syndromes serum CK is usually normal. The transminases (alanine aminotransferase, ALT and aspartate aminotransferase, AST) are also elevated in muscular dystrophy. Finding an associated elevation of CK will spare an unnecessary liver biopsy.

Chest X-ray is helpful in congenital myotonic dystrophy and may show diaphragmatic elevation due to hypoplasia of the diaphragm. It may also show thin ribs, which points to the antenatal origin of the condition. Cardiomegaly in Pompe's disease (type II glycogenosis) can also show on chest X-ray, as well as the radiologic features of rickets and osteopetrosis in the ribs and spine, respectively. Vertebral anomalies can also be seen in mucopolysaccharidosis, although bone survey is more suited for that.

Electrocardiography (ECG) is very useful in SMA since it shows the characteristic tremor (minipolymyoclonus) of the baseline, particularly in the limb leads, probably reflecting the fasciculation of skeletal muscle. In type II glycogenosis (Pompe's disease), ECG reveals features of hypertrophic cardiomyopathy, which is better assessed by echocardiography (*Fig. 368.3d, e*).

Bone marrow aspiration and biopsy helps to show the characteristic cells in type 2 Gaucher disease and the Nieman–Pick disease (NPD) types A and C (*Fig. 368.3b*).

Neuroimaging

Cystic encephalomalacia, intraventricular hemorrhage, porencephaly, and hydranencepahly can be detected by cranial ultrasound. Cranial computed tomography (CT) is helpful in detecting any neonatal intracranial hemorrhage or brain edema secondary to hypoxic-ischemic encephalopathy (HIE), some of the inborn errors of metabolism (e.g., glutaric aciduria type 1), and the presence of lissencephaly. It is also more sensitive than MRI in identifying intracranial calcification, which is seen with congenital TORCH infections, isolated sulphite oxidase deficiency, and marble brain disease with renal tubular acidosis (*Fig. 368.3f*).

Later in infancy, it will show the periventricular leukomalacia and bilateral thalamic calcification of HIE and also of isolated sulphite oxidase deficiency. It may also show the basal ganglia cavitations that characterize biotin-responsive basal ganglia disease.

On the other hand, magnetic resonance imaging (MRI) is superior to CT in showing the features of HIE but it is difficult to use in the perinatal period. Nevertheless, MRI is the most sensitive modality to characterize the brain malformations associated with some forms of congenital muscular dystrophy (CMD). It also delineates the characteristic white matter alterations found in merosin-negative CMD, and basal ganglia and brainstem lesions in Leigh's disease.

Neurophysiology

Nerve conduction velocity (NCV) is a relatively simple technique requiring only surface electrodes, which can identify cases of peripheral neuropathy and characterize whether they are primarily axonal or demyelinating. On the other hand, electromyography (EMG), which requires needle insertion, is more invasive and frightening for babies. It does not detect myotonia in congenital myotonic dystrophy. However, myotonia can be confirmed in the asymptomatic mother on EMG. In a young child with a febrile illness and weakness, EMG is contraindicated in countries where oral poliovirus (OPV) vaccine is used. Intramuscular injection is a known risk factor for the development of vaccine-associated paralytic poliomyelitis. This also applies to places where vaccination coverage is still inadequate. It has long been noted that intramuscular injections administered during the incubation period of wild-type poliovirus causes what is known as "provocation" poliomyelitis. The author has seen a young child with extensive paralysis following an EMG, done at the start of weakness, within a few days after receiving OPV.

Decremental response following repetitive nerve stimulation (RNS) is diagnostic of congenital myasthenic syndrome (CMS) and can be positive when edrophonium test is negative. This test can be life saving in COLQ-mutant CMS where most patients are severely disabled from an early age with respiratory difficulties and no effect, or even worsening, after administration of acetyl choline esterase (AChE) inhibitors.

Muscle Biopsy

The muscle biopsy provides the definitive diagnosis in congenital myopathies and dystrophies, with the exception of congenital myotonic dystrophy when it may lead to

misdiagnosis of other pathologies. In congenital myopathies, the specific structural defect can be revealed by histochemistry of muscle. Accumulation of glycogen is seen in type II glycogenosis (Pompe's disease) and accumulation of lipid in lipid storage myopathy. The characteristic ragged-red fibers may be seen in mitochondrial myopathy associated with absence of COX staining (complex IV of the mitochondrial respiratory chain). Electron microscopy, although time consuming and not widely available, has high diagnostic yield in the congenital myopathies. Dystrophic features are seen in muscular dystrophies, and immunohistochemistry can delineate the missing glycoprotein such as in merosin-deficient CMD.

369 Cranial Nerve Disorders

Mustafa A. M. Salih

Congenital Cranial Dysinnervation Disorders

Congenital cranial dysinnervation disorders (CCDDs) are a group of neuromuscular diseases characterized by motor unit abnormalities involving ocular motility, eyelid, and/or facial muscles. These disorders result from developmental errors of cranial nerve (CN) innervations. The group includes Duane syndrome, congenital fibrosis of the extraocular muscles (CFEOM), congenital ptosis, horizontal gaze palsy with progressive scoliosis (HGPPS), Bosley–Salih–Alorainy syndrome (BSAS), congenital facial palsy (CFP), and Moebius syndrome.

Duane Syndrome

Duane syndrome is characterized by congenital limitation of horizontal eye globe movement and some globe retraction on attempted adduction of the eye. It constitutes the most common of the CCDs with prevalence of 1:10000 (1–4% of strabismus cases), and 10% of cases are familial. The condition results from reduction or absence of the abducent nerve (CN VI) motor neurons associated with aberrant innervations of the lateral rectus by the oculomotor nerve (CN III). In type 1 Duane syndrome (which constitutes about 80% of cases), abduction is affected with normal or minimally defective adduction, associated with narrowing of the palpebral fissure of the adducting eye. Both abduction and adduction are limited in type 3 Duane syndrome, whereas in type 2 Duane syndrome, adduction is limited.

Congenital Fibrosis of the Extraocular Muscles (CFEOM)

Various forms of CFEOM result from primary dysinnervation of oculomotor (CN III) and/or trochlear (CN IV) innervated extraocular muscles. Individuals with CFEOM1 have congenital nonprogressive bilateral external ophthalmoplegia, and congenital bilateral ptosis; inability to raise either eye above the horizontal midline and an infraducted primary position of each eye. The condition is inherited as autosomal dominant and, in most families, results from heterozygous mutations in *KIF21A* gene. Rare probands of CFEOM1 harbor mutations in the *FEOM3* gene.

Individuals with CFEOM2 are born with bilateral ptosis, with their eyes primarily fixed in an exotropic position and severely limited horizontal and vertical eye movements. The condition results from primary developmental defect of both oculomotor (CN III) and trochlear (CN IV) nuclei, and the only normally functioning extraocular muscle is the abducens (CN VI) innervated lateral rectus that pulls each eye outward. The condition is inherited as autosomal recessive and results from *PHOX2A* gene mutations. In CFEOM3, at least one affected family member does not meet CFEOM1 criteria. The condition results from a variable defect of the oculomotor (CN III) nucleus development. Inheritance is autosomal dominant with incomplete penetrance. Mutations of the *KIF21A* gene were detected in a minority of families with CFEOM3. Recently, and in 17 unrelated families and 12 unrelated individuals, CFEOM3 was found to be caused by heterozygous mutations in the *TUBB3* gene. These lead to a common defect in axonal guidance during development, which can result in additional neurologic involvements other than those manifesting in the ocular muscles.

Horizontal Gaze Palsy with Progressive Scoliosis (HGPPS)

Individuals affected with HGPPS are born with absent horizontal gaze movements and develop severe progressive scoliosis, starting in infancy or childhood (*Fig. 369.1a*). Horizontal gaze palsy, which is nonprogressive, results from hypoplasia of the abucens (CN VI) nucleus with interneuron dysinnervation (medial longitudinal fasciculus and pontine paramedian reticular formation). Unlike other CCDDs, the abducens (CN VI) nerve is present bilaterally and the extraocular muscles are normal. Inheritance is autosomal recessive and the

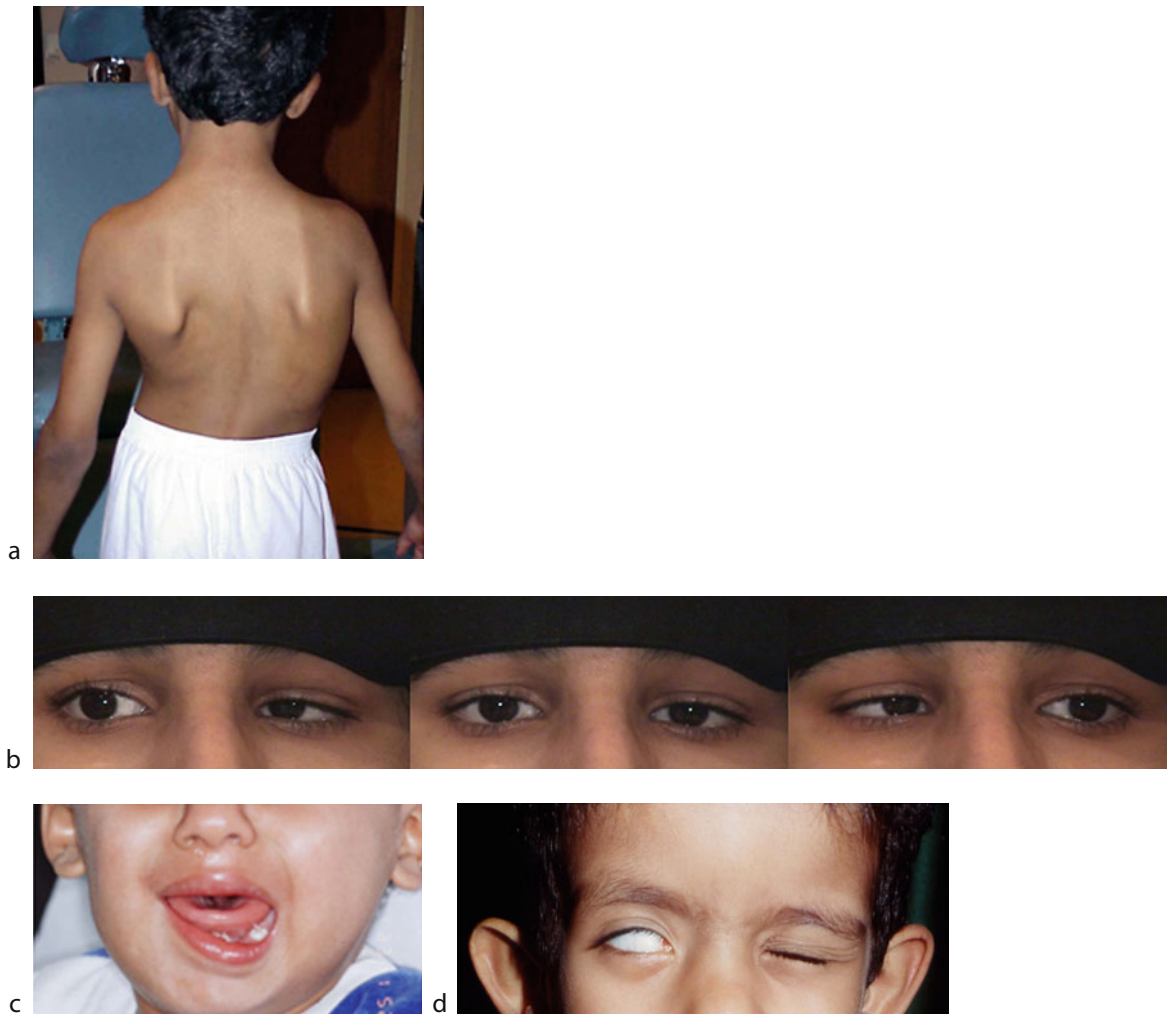

Figure 369.1

(a) Early scoliosis in a patient with horizontal gaze palsy with progressive scoliosis (HGPPS). (b) Bilateral Duane syndrome in an adolescent with Bosley-Salih-Alorainy syndrome (BSAS). There is limitation of horizontal eye globe movement with reduced abduction of both eyes associated with narrowing of the palpebral fissure of the adducting eye (Courtesy of Prof. Thomas M. Bosley). (c) Isolated weakness of the depressor angulae muscle. The right corner of the mouth fails to be lowered on crying. (d) Attempted closure of the eyes showing upward rolling of the right eye (Bell phenomenon) in a patient with right facial (VII cranial nerve) palsy

condition has been reported in consanguineous pedigrees of several different ethnicities. It results from homozygous or compound hererozygous mutations in *ROBO3*. The *ROBO3* gene encodes a transmembrane receptor required for hindbrain axon midline crossing. Electrophysiologic studies and tractography, using magnetic resonance imaging (MRI) diffusion tensor imaging, showed that affected individuals have ipsilateral corticospinal and dorsal column-medial lemniscus tract innervations.

Bosley–Salih–Alorainy (BSAS) and Athabascan Brainstem Dysgenesis Syndromes

Children with BSAS have bilateral Duane syndrome (*Fig. 369.1b*), associated in a subset of them with congenital sensorineural deafness secondary to bilateral absence of the cochlea, semicircular canals and vestibule, malformations of the internal carotid arteries and cardiac

outflow tract, mental retardation and autism in some patients. The phenotype of BSAS overlaps with that of Athabascan brain dysgenesis syndrome (ABDS), which includes, in addition, central hypoventilation, facial weakness, and vocal cord paralysis. Both syndromes result from mutations in *HOXA1*, a homeobox gene essential to the development of head and neck structures, including hindbrain, ear, and occipital and hyoid bones. Homozygous mutations of *HOXA1* have been identified in BSAS consanguineous pedigrees in the Middle East (Saudi Arabia and Turkey) and as a sporadic trait in Native American (Athabascan) children from the American Southwest. In *Hoxa1*-knockout mice, the abducens nerve (CN VI) is absent, and it is likely that abducens (CN VI) development and consequent innervations of the lateral rectus muscle is aberrant in BSAS and ABDS patients.

Congenital Facial Palsy

Congenital nontraumatic facial weakness can occur in isolation or in association with abnormal ocular motility. Isolated congenital facial nerve (CN VII) weakness is thought to result from facial nuclei and/or nerve maldevelopment. The condition is unilateral or bilateral, often asymmetrical, and is inherited as autosomal dominant with variable penetrance. It can rarely be associated with congenital deafness.

Moebius Syndrome

Moebius syndrome is defined as facial weakness combined with an ocular abduction deficit. It is a rare sporadic disorder with an estimated prevalence of one case per 50,000 newborns in the USA and four cases per 189,000 newborns in the Netherlands. Necropsy studies in Moebuis patients have shown defects ranging from hypoplasia to agenesis of the respective cranial nuclei. Nevertheless, it has not been established yet whether nerve, brain stem, or muscle aplasia is the primary event leading to this phenotype. CNs IX (glossopharyngeal) and X (vagus) may be affected. The hypoglossal nerves (CN XII) are involved in a minority of cases, whereas the oculomotor (CN III) and trochlear (CN IV) can be involved on rare occasions.

Clinical Manifestations

The condition presents at birth with facial diplegia, incomplete eye closure during sleep, difficulty in sucking and drooling. Examination reveals masklike immobile facial appearance associated with various gaze palsies in about 80% of patients. Involvement of the hypoglossal (XII) nerve (in approximately 25% of cases) leads to atrophy and inability to protrude the tongue. Musculoskeletal abnormalities may be present in about a third of patients. These include talipes equinovarus, congenital amputations, arthrogryposis, syndactly, brachydactyly, and, occasionally (15% of patients), hypoplasia or absence of the pectoralis muscle and breast associated with ipsilateral hand malformation (also called Poland anomaly). Features of autism are known to be associated with some cases of Moebius syndrome.

Diagnosis and Differential Diagnosis

Most cases are recognized during infancy, but the diagnosis soon after birth may be difficult because of the rarity of the condition. Moebius syndrome can be confused with facial palsy secondary to birth trauma (especially with the use of forceps in breach deliveries), congenital myotonic dystrophy, congenital myopathies, or congenital muscular dystrophy.

On electromyography (EMG), no features of active denervation will be seen in the facial muscles, which are hypoplastic or aplastic. Conversely, in birth trauma, denervation potentials will be recorded 2–3 weeks (or more) after the facial nuclei or nerves are injured.

Cranial computed tomography (CT) may demonstrate bilateral calcifications in the region of the abducens (CN VI) nuclei. Bilateral calcifications of the basal ganglia have also been reported. MRI may show hypoplasia of the brain stem and exclude other associated cerebral malformations.

Treatment

This is generally supportive and symptomatic, depending on the severity of the patient's deficits. Attention should be given to check the development of corneal abrasion/ulceration, aspiration pneumonia, dysphagia, and poor nutrition. Physical and occupational therapies are useful for managing associated musculoskeletal problems. Speech therapy is also helpful, as well as psychiatric management when there is an associated autism. Symptomatic and cosmetic surgical care may be required such as tracheostomy, for supporting airway; gastrostomy, for feeding; and correction of foot deformities. Surgery for strabismus is usually delayed because the condition frequently improves

with age, and plastic surgery may be required to counteract facial nerve paralysis.

Prognosis

Death may occur shortly after birth in 28% of patients, mainly due to bulbar or respiratory problems. Otherwise, Moebuis syndrome is a static neurologic defect with no mortality in its mild form.

Perinatal Factors and Other Causes of Congenital Facial Palsy (CFP)

Due to the relatively superficial course of the extracranial facial nerve (CN VII), it can be damaged during birth. This can follow instrumentation in assisted delivery, and intrapartum compression where the fetal head is compressed against the maternal bony prominences such as the ischeal spines, the pubic rami, and sacral prominence. Apart from Moebius syndrome and Poland sequence, other syndromes have CFP as part of their symptoms. These include Goldenhar syndrome, which is characterized by unilateral facial hypoplasia (occasionally associated with facial palsy), epibulbar dermoid, preauricular skin tags, and cervical vertebral defects. Cardiofacial syndrome can be confused with CFP. However, in this condition, there is isolated weakness of the depressor anguli oris and quadratus labii inferioris muscles, and the lower corner of the mouth on the involved side fails to move downward on crying (*Fig. 369.1c*). On the same side, the lower lip may be slightly everted. In a minority of patients, the condition was found to be associated with congenital heart disease.

Acquired Facial Paralysis

Bell's Palsy

Definition/Classification

Bell's palsy is one of the most common neurologic disorders affecting the CNs and is characterized by abrupt unilateral peripheral facial paresis or paralysis with no detectable cause.

Epidemiology

The annual incidence of Bell's palsy is about 25 cases per 100,000 persons in the USA, similar to the rest of the world except for Japan, which has the highest incidence. The incidence of Bell's palsy is 2.7 per 100,000 in the first decade of life and 10.1 per 100,000 in the second decade. The palsy can occur bilaterally at a rate of less than 1%, and about 1.4% of patients have a family history of the disorder.

Etiology and Pathophysiology

Bell's palsy is thought to be caused by inflammation and swelling of the facial (VII) nerve resulting in its compression as it passes through the bony canal (a portion of the temporal bone commonly referred to as the facial canal). Nevertheless, the precise pathophysiology is still unclear, although it is assumed that herpes simplex virus (HSV) is the etiologic agent, being reactivated after remaining latent in the geniculate ganglion and causing, thereafter, local damage to the myelin of the facial nerve. The efferent component of the facial nerve stimulates the muscles of facial expression, with a small branch to the stapedius muscle in the middle ear. The afferent and smaller portion contains taste fibers to the anterior two-thirds of the tongue, some pain fibers and secretomotor fibers to the lacrimal and salivary glands.

Clinical Manifestations: Symptoms and Signs

Symptoms

The condition may manifest with posterior auricular pain, which precedes the paresis by 2–3 days in a quarter of patients. In the majority, it presents with acute onset of unilateral upper and lower facial paralysis over a period of 48 h. This might be associated with decreased tearing, taste disturbances, and hyperacusis due to paralysis of the stapedius muscle.

Signs

On the affected side, weakness and/or paralysis due to involvement of the facial (VII) nerve affects the entire upper and lower part of the face. When the child is asked to raise the eyebrows or look upward, without moving the head, the forehead with the palsy will remain flat. When asked to smile, the face lateralizes to the side opposite to the palsy. On attempted eye closure, Bell phenomenon is observed: the eye on the affected side rolls upward and outward (*Fig. 369.1d*). This phenomenon is a normal

response to eye closure. Although the disease can affect both sides, bilateral facial palsy should prompt workup for other causes besides Bell's palsy.

Diagnosis

Immediate imaging is not necessary if the history and physical examination lead to a diagnosis of Bell's palsy. Enhancement of the facial nerve, at or near the geniculate ganglion, may be detected on MRI. When the paralysis progresses over weeks, it is no longer Bell's palsy, and MRI brain is mandatory to exclude tumors compressing or involving CN VII, such as schwannoma, meningioma, hemangioma, pontine glioma, and rhabdomyosarcomas.

Differential Diagnosis

Otitis media and mastoiditis should always be considered as antibiotics and/or surgery may be requested. X-rays or CT of the temporal bone are indicated if the history and examination are suggestive. Hypertension is rarely associated with Bell's palsy and should systematically be looked for. Herpes zoster of the geniculate ganglion (Ramsay Hunt syndrome) is an uncommon cause of facial palsy in children. Other viruses that may cause facial weakness include mumps, chicken pox, and Epstein-Barr viruses.

Bacterial causes of facial palsy include Lyme disease (neuroborreliosis), in which it may be an early sign, brucellosis and diphtheria. Facial palsy may be associated with *Mycoplasma pneumoniae* infections, sometimes in the absence of respiratory symptoms. Traumatic paralysis of the facial nerve is revealed by history, and CT scan of the temporal bone may be required. Other causes include Guillain–Barré syndrome (bilateral facial palsy), sarcoidosis, and tumors of the brain stem or meninges.

Investigations

Laboratory studies should include serological tests for Lyme disease (IgG and IgM titres) and brucellosis (ELISA) in endemic areas. Serum titres for *Mycoplasma pneumoniae* (IgM) and for HSV may be obtained. Nerve conduction studies and EMG are useful in severe Bell's palsy. They are most informative when performed 3–10 days after the onset of paralysis. Comparison to the contralateral (unaffected) side has prognostic implications and helps to determine the extent of nerve injury.

Treatment

Impaired eye closure and abnormal tear flow require tear substitutes, lubricants, and eye protection with eye glasses or patches. Significant improvement in outcome was shown in two recent randomized controlled trials, when prednisolone was started within 72 h of symptom onset. The recommended pediatric dose is 1 mg/kg/day up to 60 mg/day for 7–10 days. Despite evidence to support HSV as a major cause of Bell's palsy, a recent trial showed no added benefit with the addition of acyclovir to prednisolone.

Prognosis

The majority of patients (85%) with Bell's palsy will achieve complete recovery, 10% have some persistent facial muscle asymmetry, and 5% have severe cosmotic sequelae. Patients showing complete paralysis during the acute phase are at a higher risk for severe sequelae. Bell's palsy recurs in 10–15% of patients, and recurrences are usually associated with a family history of recurrent Bell's palsy.

370 Anterior Horn Cell Diseases

Mustafa A. M. Salih

Definition/Classification

Disorders of the anterior horn cell (AHC) can either be acquired or inherited. Acquired diseases are mainly of viral origin and most of these run an acute course. They include poliomyelitis and similar diseases due to enteroviruses other than poliovirus. Following the global control of poliomyelitis by widespread immunization, inherited degenerative diseases currently account for most cases of AHC disease.

Paralytic Poliomyelitis

The polioviruses belong to the Piccornaviridae family, in the genus *Entrovirus,* and include three antigenically distinct serotypes (types 1, 2, and 3). They spread by the fecal–oral route and humans are the only known reservoir. Polioviruses are known to be resistant and can retain infectivity for several days at room temperature.

Epidemiology

Paralytic poliomyelitis occurs in about 1/1,000 infections among infants to about 1/100 infections among adolescents. Prior to universal vaccination, epidemics of paralytic poliomyelitis occurred in developed countries primarily in adolescents, whereas in developing countries with poor sanitation, infections occurred early in life resulting in infantile paralysis. When the Expanded Program on Immunization (EPI) was established by the World Health Organization (WHO) in 1974, oral poliovirus (OPV) vaccine was introduced for developing countries to use exclusively. In the pre-EPI era, 600,000–800,000 cases of polio occurred annually, the vast majority in developing countries. Following the WHO program for global eradication of poliomyelitis (from 1988), paralytic poliomyelitis started to disappear. Nevertheless, due to occasional revertants (by nucleotide substitution) of these vaccine strains, a neuro-virulent phenotype leads to vaccine-associated paralytic poliomyelitis (VAPP). The annual incidence of VAPP was determined by the WHO to be 0.4–3.0/million vaccinated children with intercountry variations. The incidence of VAPP in India was estimated to be seven/million birth cohorts, one of the highest in the world. Cases of poliovirus following a circulating vaccine-derived poliovirus were documented in Egypt, the Dominican Republic and Haiti, Madagascar, the Philippines, and Romania.

Pathogenesis and Pathology

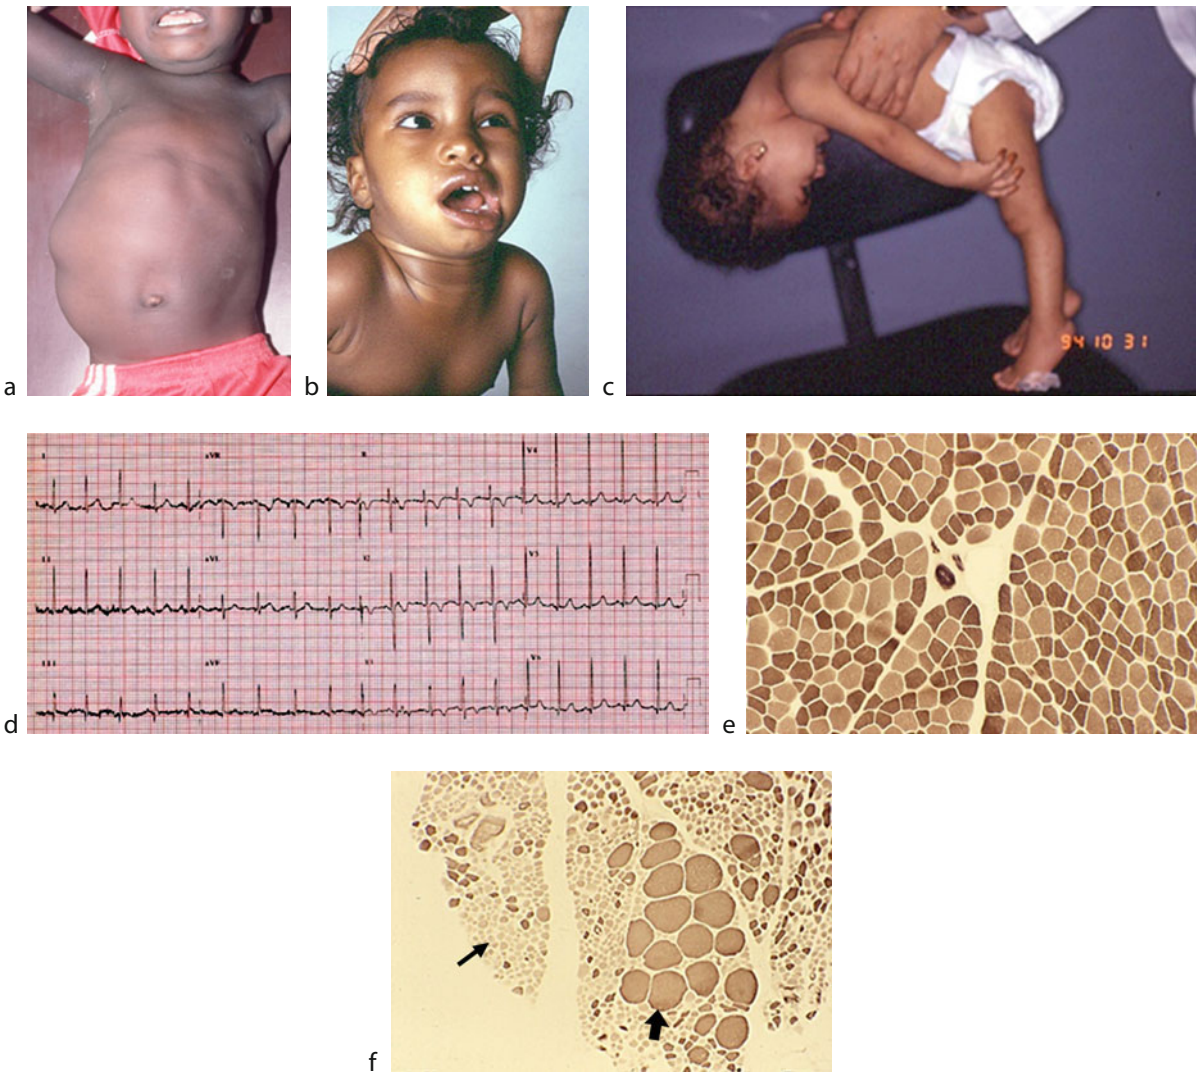
Polioviruses infect cells by adsorbing to poliovirus receptor and gain host entry via the gastrointestinal tract. Wild type poliovirus and neurovirulent revertant vaccine strains probably access the central nervous system (CNS) through the peripheral nerves. Infection by polioviruses is inapparent in 90–95% of cases or is associated with a mild nonspecific febrile illness in about 5% of patients (abortive) poliomyelitis. About 1% of patients infected with wild-type poliovirus develop lymphocytic meningitis (nonparalytic poliomyelitis), whereas paralytic poliomyelitis develops in about 0.1%. The pathological lesions primarily involve the motor neuron cells in the spinal cord (AHC) and the medulla oblongata (the cranial nerve nuclei). Involvement of the reticular formation compromises the vital centers controlling respiration and circulation. Hyperasthesia and myalgia, which are typical of acute poliomyelitis, are caused by the involvement of the intermediate and dorsal horn and dorsal root ganglia in the spinal cord. Other affected areas are the cerebellar vermis and, to a lesser extent, the thalamus and layers III and V of the motor cortex.

Clinical Manifestations

The clinical manifestations usually appear after an incubation period of 8–12 days (range 3–35 days). The initial symptoms comprise fever, malaise, and headache. There may also be sore throat, abdominal or muscle pain, and irregular vomiting. After an apparent recovery for 2–5 days, the previous symptoms recur associated with

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_370,

fever, muscle pain, and sensory and motor phenomena (hyperesthesia, paraesthesia, spasms, and fasciculations). Paralysis appears within 2 days and is characterized by asymmetrical flaccid paralysis involving the legs, arms, and/or trunk with absent tendon reflexes. The proximal areas of the limbs tend to be involved to a greater extent than the distal areas. Sensation is intact and the presence of sensory disturbances suggests an alternative diagnosis. Urinary retention is present at onset in 20–30% of cases. In developing countries, history of intramuscular injections precedes paralytic poliomyelitis in 50–60% of patients (also termed provocation paralysis). Asymmetric involvement of the abdominal muscles results in bulging of the affected side (phantom hernia) (◉ *Fig. 370.1a*). Progression of the paralytic manifestation stops once the temperature returns to normal.



◘ Figure 370.1
(a) Asymmetric involvement of the abdominal muscles resulting in bulging of the right side (phantom hernia) following poliomyelitis. (b) Right lower motor facial nerve palsy in bulbar poliomyelitis. (c) Floppy infant syndrome due to spinal muscular atrophy (SMA) type 1. (d) Electrocardiography (ECG) showing baseline tremors in SMA type III. These are most prominent in leads II and III. (e) The checkerboard pattern in a normal muscle biopsy as compared to (f) which shows group atrophy (thin arrow) and compensatory hypertrophy (thick arrow) of muscle fibres

The bulbar form (bulbar poliomyelitis) is rarely isolated and the cervical cord is involved in at least 90% of cases. All cranially innervated muscles may be affected (*Fig. 370.1b*). Involvement of vital centers in the medulla manifests as irregularities in rate, depth, and rhythm of respiration. It may also manifest as cardiovascular system alterations, including blood pressure changes, cardiac arrhythmias, and rapid changes in body temperature. A rare form of poliomyelitis is polioencephalitis in which higher centers of the brain are severely involved. Spastic paralysis with increased reflexes may be involved. Peripheral or bulbar paralysis may coexist with the condition or ensue during its course.

Diagnosis

Poliomyelitis should be suspected in any unimmunized or partially immunized child with paralytic disease. Paralytic disease occurring 7–14 days after receiving OPV is a major clue to the development of VAPP. In countries where wild-type poliovirus has been eradicated, VAPP can occur later if the OPV has been given to the child or contact.

Cerebrospinal fluid (CSF) examination shows a pleocytosis of 20–300 cells/mm^3. Initially, these cells are predominantly polymorphonuclear cells, followed after 5–7 days by a lymphatic pleocytosis. The cell count falls to near-normal values by the second week. Initially the CSF protein is normal or only slightly elevated but usually rises to 50–100 g/L by the second week. In polio encephalitis, the CSF may show minor changes or remain normal.

Poliovirus may be isolated from the stools of 80–90% of acutely ill patients and from <20% within 3–4 weeks after onset of paralysis. According to the WHO recommendations, two stool specimens should be collected 24–48 h apart, as soon as the diagnosis of poliomyelitis is suspected. Poliovirus isolates should be sent to either the Centre for Disease Control and Prevention in the USA or to one of the WHO-certified poliomyelitis laboratories, located in several regions of the world, where DNA sequence analysis can be performed. This investigation is performed to differentiate between wild poliovirus and neurovirulent revertant OPV strains.

Differential Diagnosis

Even in countries where the disease has been eradicated, the possibility of poliomyelitis should be considered in any case of acute flaccid paralysis. The diagnoses most often confused with polio are Guillaine–Barre syndrome, transverse myelitis, West Nile virus, and other enteroviruses. Guillaine–Barre syndrome differs in the mode of onset, the symmetrical distribution of weakness, and CSF characteristics (few cells but elevated protein level). Transverse myelitis is characterized by acute symmetric paralysis of the lower limbs associated with sensory level and bladder dysfunction. The CSF is usually normal. A syndrome closely resembling poliomyelitis (Hopkins syndrome) has been reported following acute attacks of asthma or status asthmaticus.

Injury of the spinal column, sometimes associated with periostitis or osteomyelitis, may present with a polio-like paralytic syndrome. Other rare causes include snakebite, spider bite, scorpion sting, tick bite, and schistomiasis involving the spinal cord. Chemical poisons that cause paralytic syndromes include arsenic, triorthocresyl phosphate, and organophosphorus insecticides.

Treatment

The management of paralytic poliomyelitis is supportive and there is no specific antiviral therapy. The objectives are to limit progression of the disease, prevent ensuing skeletal deformities, and provide psychological support for the child and family. Intramuscular injections, including insertion of an electromyography (EMG) needle, and surgical procedures are contraindicated since they precipitate provocation paralysis. This can happen particularly in the first week of illness.

The management of bulbar poliomyelitis consists of maintaining the airway, avoiding the risk of aspiration, observing for respiratory insufficiency, and circulatory disturbances. Tracheostomy and mechanical ventilation might be needed when there is vocal cord paralysis or constriction of the hypopharynx.

Prognosis

The mortality in spinal poliomyelitis, with or without less severe bulbar involvement, is about 5–10%. In severe bulbar poliomyelitis, the mortality rate may reach up to 60%. Following the paralytic phase of the illness, which takes 2–3 days, there is a period of stabilization followed by gradual return of muscle function. Recovery of affected muscles takes up to 6 months. Muscles still paralyzed thereafter, remain so indefinitely. Following an interval of 20–40 years, a progressive

motor neuron disease (postpolio syndrome) may affect 30–40% of those who survived paralytic poliomyelitis in childhood.

Prevention

Vaccination is the only effective method that can prevent poliomyelitis. The live-attenuated OPV vaccine is more economic, easy to administer, and limits the replication of the wild poliovirus and its transmission by fecal spread. Nevertheless, it may undergo reversion to neurovirulence and cause VAPP. The more expensive to operate injectable inactivated poliovaccine (IPV) is equally immunizing and does not cause VAPP. In countries where the risk of VAPP is higher than the risk for transmission of poliomyelitis, IPV is being used routinely. Adoption of a policy of initial vaccination by the parenteral route (using IPV) followed by OPV has been shown to greatly reduce the risk of VAPP.

Spinal Muscular Atrophy

Definition/Classification

Spinal muscular atrophy (SMA) is an autosomal recessive inherited motor unit disease characterized by progressive muscle weakness resulting from degeneration and loss of the anterior horn cells in the spinal cord and the brain stem nuclei. The single gene responsible for SMA was mapped to chromosome 5q11.2–13.3 and identified as the survival motor neuron (SMN) gene. Classification of SMA, based on clinical criteria, was found to be useful for prognosis and management, although the phenotype of the disease-causing mutations of the SMN gene spans a continuum with no sharp distinction between the subtypes. These criteria include age of onset and maximum function attained. Spinal muscular atrophy type 1 (SMA I, Werdnig–Hoffman disease) is characterized by onset before 6 months of age, failure to achieve sitting without support and death by 2 years of age. Onset of SMA II (previously named chronic SMA) is between 6 months and 12 months, the patient ultimately attains independent sitting when placed and may live into adolescence or even longer. The onset of SMA III (juvenile SMA or Kugelberg–Welander disease) is after 12 months (usually after 18 months) and all patients walk independently at some stage of their life that extends into the sixth decade. Spinal muscular atrophy type IV is a disease of adults.

Epidemiology

In a world survey, the prevalence of SMA was estimated to be 12/million populations. The estimated prevalence among Norwegian children was $1.7/10^6$. Considerably higher prevalences of 133 and $172/10^6$ populations were found in Saudi Arabia and Tunisia, respectively, reflecting the high rate of consanguinity in these communities. Significantly higher carrier frequency of 5% was reported from Saudi Arabia, i.e., one carrier in each 20 persons compared to one in 50–80 in the USA and Europe.

Pathogenesis

The two genes associated with SMA are *SMN1* and *SMN2*. The *SMN1* gene is believed to be the primary disease-causing gene. Homozygous absence of exons 7 and 8 of *SMN1* is found in 95–98% of individuals with SMA. About 2–5% of patients are compound heterozygotes for absence of exons 7 and 8 of the *SMN1* and a point mutation in *SMN1*. On the other hand, there is a dose relationship between *SMN2* copies; most patients with the milder form (SMA II) have three *SMN2* copies, whereas most patients with the mildest form (SMA III) have three or four *SMN2* copies.

Pathology

Postmortem findings in SMA included decreased number of motor neurons and gliosis in the anterior horns of the spinal cord and motor cranial nerve nuclei V and VII–XII. This is reflected in the changes observed in muscle biopsy with features of acute and chronic denervation.

Clinical Manifestations

Onset of SMA I is from birth to 6 months. Sucking or swallowing problems may be noticed in the first few months of life, along with paradoxical or abdominal breathing. With inhalation, the chest caves in as the diaphragm contracts. There is poor muscle tone associated with muscle

weakness manifesting as the "floppy infant syndrome" (Fig. 370.1c). There is lack of motor development and the child never achieves ability to sit unsupported. Nevertheless, there is normal cerebral function and the baby has an alert appearance. Facial weakness is minimal or absent and fasciculations of the tongue are seen in most, but not all, affected children. Postural tremor of the fingers (minipolymyoclonus), due to fasciculations of intrinsic hand muscles, is seen occasionally. The distribution of muscle weakness is proximal and symmetrical, involving the upper and lower limbs. Contractures are mild, often at the knees and rarely at the elbows. Tendon reflexes are absent and there is no sensory loss. Survival is for about 2 years, although it can be extended with improved respiratory and nutrition care.

The usual onset of SMA II is after 6 months of age, but can be earlier. These patients achieve the ability to sit independently when placed in a sitting position, but will not be able to walk. They have decreased muscle tone, associated with symmetrical proximal muscle weakness and wasting, and may also present as "floppy infant syndrome." A postural tremor of the fingers is seen almost invariably and is a helpful diagnostic feature. Tendon reflexes are absent in 70% of affected children. Patients are cognitively normal with average intellectual skills during the formative years and above average by adolescence.

Onset of SMA III is after the age of 12 months (usually 18 months) and the patient will achieve the ability to walk. Weakness usually manifests between 2 years and 5 years with frequent falls or difficulty in walking up and down stairs. Symmetric proximal limb weakness and wasting ensues slowly with legs more severely affected than the arms. Examination shows a positive Gowers maneuver and absent knee jerks, with preservation of the ankle jerks and upper limb reflexes. Gait is waddling and calf hypertrophy may be present in some patients leading to an erroneous diagnosis of muscular dystrophy. Coarse tremor of the hands is shown by many patients. The disease progresses very slowly but the development of pes cavus is frequent.

Clinical Variants of SMA

A prenatal form of SMA with arthrogryposis associated with a deletion of *SMN* gene has been described. This form presents with weakness at birth with the face being minimally affected. Segmental SMA, with asymmetrical weakness and atrophy involving the distribution of several contiguous spinal roots, is a rare variant. Facial weakness and severe peripheral neuropathies have also been associated with a deletion of the SMA gene.

Diagnosis

Currently, the diagnosis of SMA is based on molecular genetic testing. Neurophysiological tests and muscle biopsy are done when the molecular genetic testing of the *SMN1* gene is normal.

The motor and sensory nerve conduction velocities are normal. Electromyography (EMG) reveals features of denervation and diminished motor action potential amplitude. Spontaneous motor unit activity is a unique feature of SMA and is most commonly seen in SMA I, occasionally in SMA II, but not in SMA III. Positive sharp waves and fibrillations are present in all individuals with SMA. This is reflected in the electrocardiogram (ECG), which shows tremor of ECG baseline even in SMA III (Fig. 370.1d). Muscle biopsy shows signs of denervation in the form of group atrophy in type l and type ll muscle fibers as opposed to the normal checkerboard pattern (Fig. 370.1e and f). Lipid deposits and glycogen are not seen, excluding lipid and glycogen storage disorders.

Differential Diagnosis

Arthrogryposis multiplex congenita (AMC) may be due to causes other than *SMN* mutations. For types I and II SMA, the differential diagnosis includes other causes of the floppy infant syndrome. A diagnosis of muscular dystrophy may be entertained in cases of SMA III with raised CK concentration. Congenital and metabolic myopathies may also present similarly.

Treatment

A recent consensus document has addressed the diagnosis and treatment of patients with SMA. This document included issues of respiratory and nutritional care in patients with SMA I, II, and III. Children with SMA I (Werdnig–Hoffman disease) can survive beyond 2 years of age on tracheostomy and noninvasive respiratory support. However, such an intervention raises ethical questions. Intermittent positive-pressure breathing was found to be effective in children with SMA, as well as other

neuromuscular disorders, and leads to lung volume expansions and clearance of airway secretions. Nighttime use of continuous positive airway pressure prevents daytime fatigue caused by sleep apnea in SMA III patients.

About 50% of SMA patients develop scoliosis before age 10 years. Although orthosis allows the patient to be upright rather than bedridden, it does not prevent the development of scoliosis. Spinal surgery is required especially in those non-ambulatory patients who develop curvatures greater than 50°. Hip dislocation is common in SMA, but does not require surgical correction if it was asymptomatic. Clinic surveillance should be at least every 6 months and weaker children need more frequent visits. Clinical evaluations should include respiratory function, nutritional state, and orthopedic status.

While assessing respiratory function, note should be taken whether there is normal or abdominal breathing patterns. Children over the age of 4 years can accurately use the hand-held spirometer to measure the forced vital capacity (FVC). When FVC is above 40%, decompensation during respiratory infection is less likely. If abdominal breathing is noted and/or the FVC is less than 30%, options for management should be discussed with the family including "do not resuscitate" status.

During periods of intercurrent illness or fasting, children with SMA develop a poorly understood complication consisting of severe metabolic acidosis associated with dicarboxylic aciduria. Judicial administration of intravenous fluids prevents this condition.

Through the use of special education and electric wheelchairs, children with SMA type II can be integrated into normal schools. Parents and families with various types of SMA require active social and psychological support.

Specific medical treatment of SMA still does not exist. Nevertheless, several medications/chemicals that increase the activity of *SMN2* gene are under investigation. These include histone deacetylase (HDAC) inhibitors (aclarubicin), valproic acid, phenylbutyrate (a drug used in the treatment of urea cycle disorders), indoprofen (a nonsteroidal anti-inflammatory drug) and gabapentin. Clinical trials of Rilutek (Riluzole) in infants with SMA and hydroxyurea (a medication that enhances expression of human fetal hemoglobin gene and SMN protein levels) are underway.

Prognosis

Life expectancy reflects the type of SMA, although this has changed over the past few years with better respiratory and nutritional care. Recurrent pneumonia, scoliosis, and hip dislocation punctuate the progress of the disease.

Prevention

The optimal option for prevention is through family planning. In regions with high carrier rate, as in the Middle East, premarital screening is being introduced into the system. When faced with a married couple who are carriers of the disease, discussion of availability of prenatal testing should be made before pregnancy.

Prenatal testing is available for high-risk pregnancies. This can be achieved by analysis of fetal DNA obtained either through chorionic villous sampling (at 10–12 weeks of gestation) or through amniocentesis, usually at about 15–18 weeks of gestation. Samples will be analyzed for the known *SMN1* gene mutation or for the previously identified linked markers. Preimplantation genetic diagnosis (PIGD), available in centers with in vitro fertilization capability, can be done for parents in future pregnancies, when disease-causing mutations have been identified in an affected child.

371 Plexopathies and Radiculopathies

Mustafa A. M. Salih

Several disorders of the brachial plexus and the lumbosacral plexus occur during childhood. These can either be traumatic or inflammatory disorders.

Brachial Plexus Palsy

Definition/Classification

The brachial plexus is composed of a group of nerves arising from the nerve roots of cervical segments 5 through thoracic segment (C5–T1). Injury to the upper plexus (C5 and C6 roots) leads to the Erb–Duchenne type of plexus paralysis. Involvement of the lower brachial plexus cervical 7, 8, and thoracic root 1 result in Klumpke paralysis.

Etiology

Brachial plexus injuries usually occur following shoulder dystocia in large-for-gestational-age newborns (macrosomic infants). This can result from forceful lateral deviation of the head from the shoulder during delivery due to impaction of fetal shoulders within maternal pelvis. Injury of the lower plexus results from traction on the trunk with breech delivery, or from traction on the adducted forearm during vertex delivery. Brachial plexus unassociated with shoulder dystocia or difficult delivery has been reported suggesting an intrauterine origin such as deformation from uterine constraint in cases of bicornuate uterus.

Pathogenesis and Pathology

Brachial plexus palsy has rarely been detected in babies delivered by cesarean section indicating that long-standing in utero stretching of the brachial plexus could lead to the development of palsy. In utero stretching could be due to constriction bands, uterine constraints from oligohydramnios or bicornuate uterus, intrauterine maladaptation or congenital aplasia of the roots of the brachial plexus. The most common and mildest form of brachial plexus injury is neuropraxia, which is due to edema following pressure on the nerve roots. Axonotmesis is more severe and is due to disruption of the axon of the nerve with an intact myelin sheath. Total disruption of the postganglionic nerve constitutes neurotmesis, whereas avulsion designates complete disruption of the ganglia from the spinal cord at both the anterior and posterior roots.

Clinical Manifestations

Paralysis is recognized from the first days of life in the majority of babies. In upper (Erb–Duchenne) palsy, the affected arm hangs limply adducted and internally rotated, with extended elbow, pronated forearm, and variably flexed wrist (*Fig. 371.1a*). The Moro reflex is absent on the affected side (asymmetric Moro reflex), as well as the biceps and brachioradialis reflexes. Associated significant C7 involvement manifests as weakness of the triceps and extensors of forearm and digits. In lower brachial plexus (Klumpke) palsy (*Fig. 371.1b*), intrinsic hand muscles are paralyzed, the grasp is absent and a Horner syndrome is frequently present. Horner syndrome manifests as meiosis, ptosis, and facial anhydrosis, and is caused by injury of the sympathetic fibers of the first thoracic root. The phrenic nerve, arising from C3, C4, and C5, can be involved in brachial plexus palsy resulting in ipsilateral diaphragmatic paralysis and produces symptoms of respiratory distress.

Diagnosis and Differential Diagnosis

Due to the unique physical findings of brachial plexus palsy, the diagnosis is readily apparent. Nevertheless, other possibilities that need to be considered are cerebral injury, cervical spine injury, fracture, dislocation or epiphyseal separation of the humerus, and fracture of the clavicle. Another brachial plexopathy that needs to be considered is brachial neuritis (neuralgic amyotrophy, Parsonage–Turner syndrome). Although pediatric cases are much rarer than in adults, this disease may occur from infancy.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_371,

Fig. 371.1
(a) Erb-Duchenne palsy. The left arm is internally rotated, and the forearm is extended and pronated. (b) Lower brachial plexus (Klumpke) palsy of the right upper limb. The elbow is flexed and the hand is paralyzed and atrophic

Diagnostic work-up for brachial plexus palsy is best achieved by magnetic resonance imaging (MRI) of the spinal cord and roots. It has the advantage of avoiding the ionizing radiation of the computed tomography (CT). It also helps to detect the integrity of the brachial plexus, including root avulsion, and the presence of a pseudomeningocele. Electromyography (EMG) can be used to support the diagnosis of root lesions and is capable of detecting signs of denervation and reinnervation in recovery. Associated phrenic nerve injury leading to diaphragmatic involvement is assessed by plain radiography and real-time ultrasonography at the bedside.

Treatment

During the first 1 or 2 weeks, management consists of partial immobilization and appropriate positioning of the affected limb to prevent the development of contractures. Physiotherapy can be initiated after the first 10–14 days to allow delivery pain to subside. Immobilization should be intermittent, between feedings and while the infant is asleep, by abducting the arm to 90°, with external rotation at the shoulder, full supination of the forearm, slight extension at the wrist, and maintaining the palm turned toward the face. Splinting the wrist in the neutral position and placing a pad in the fist, is to be used in lower arm or hand paralysis. Range of motion exercises constitutes the required physical therapy to prevent ligament tightening and the discomfort following contractures. Monthly evaluations for range of motion, return of function, and development of contractures are required. Recovery of brachial plexus palsy occurs in about 70–80% of affected babies, with the remaining patients having residual deficits. Flaccid paralysis of the extremity, Horner syndrome, and diaphragmatic paralysis herald a poor outcome. Patients who do not show signs of recovery for 3–6 months require surgical intervention. Nevertheless, surgical intervention, which includes neurolysis, nerve grafting, and neurotization, requires the availability of microsurgical technique and intraoperative neurophysiologic recordings, and surgeons familiar with the techniques. For older children who did not improve, muscle release around the shoulder joint and tendon transfers may be required.

Prevention

Prompt recognition of shoulder dystocia and avoidance of excessive downward traction on the fetal head by the attending caregiver is the most important preventive step. Since this task requires skills and teamwork, conducting team training in shoulder dystocia as part of risk reduction strategy for improving perinatal outcome has been recommended.

Other Traumatic Plexopathies

After the neonatal period, brachial plexus injury affects principally adolescents, mainly due to motor vehicle (especially motorcycle) and sports accidents, and has guarded prognosis. Conversely, lumbosacral plexus injuries are rare, have been reported in neonates and children, and have favorable outcomes.

Inflammatory Plexopathies

Neuralgic Amyotrophy (Parsonage–Turner Syndrome, Brachial Plexus Neuritis)

Definition/Classification

Neuralgic amyotrophy is a syndrome characterized by episodes of neuropathic pain and rapid multifocal weakness and atrophy (amyotrophy) in the upper limbs. The syndrome has both an idiopathic and hereditary form with similar clinical symptoms but generally more episodes and an earlier age of onset in the hereditary form.

Etiology

An immune-mediated process is thought to underline the attacks, which may be triggered by viral or bacterial illnesses (influenza, Coxsackie-virus, parovirus B-19, Epstein-Barr virus, Q fever, human immunodeficiency virus (HIV) disease, mycoplasma pneumonia, bacterial pneumonia, typhoid, syphilis, and brucellosis). It can also follow immunizations such as tetanus toxoid, diphtheria, recombinant hepatitis B vaccination, swine flu, and immune sera. It may also be triggered by periods of physical or emotional stress. Hereditary neuralgic amyotrophy (HNA) is inherited as autosomal dominant. The proportion of HNA attributed to the mutations in the only known causative gene (*SEPT9*) is about 85%. Idiopathic neuralgic amyotrophy (INA) has a reported incidence of 2–3/100,000/year. The prevalence of hereditary neuralgic amyotrophy (HNA) is unknown and about 200 families are reported worldwide. Both disorders are likely to have higher prevalence because of underdiagnosis.

Pathogenesis and Pathology

Triggering factors are thought to render the brachial plexus more susceptible to an autoimmune damage. The limited nerve biopsies performed in this condition revealed focal decreases in myelinated fibers within individual nerves in the majority, and multiple perineural mononuclear infiltrates in three of four upper extremity nerve biopsies.

Clinical Manifestations

The disorder usually starts with intense pain localized to the shoulder or involving the whole upper limb. Weakness either develops simultaneously with the pain or follows it by days to few weeks. The mean age of onset of INA is about 40 years (range 10–80 years) with 3% of patients suffering the first attack in childhood (<16 years). The mean age of onset of HNA is significantly earlier at 28 years (range 3–56 years) with 23% having their first attack during childhood. Paralysis affects the upper part of the brachial plexus in the majority of patients (about 70%), the whole plexus in 14%, and involves predominantly the lower plexus in 3–8%. The mean time to onset of amyotrophy ranges between 8 days and 14 days after the initial pain. Sensory symptoms and signs are common during the attack affecting more than two third of patients in the form of large proximal hypoesthetic areas. Diaphragmatic paralysis (unilateral or bilateral) is present in about 7% of patients and may predominate in the clinical picture. Hereditary neuralgic amyotrophy affects a younger age group and is characterized by recurrent, often bilateral attacks. Dysmorphic features in the form of hypertelorism, long nasal bridge, and facial asymmetry can be present.

Diagnosis and Differential Diagnosis

Neuralgic amyotrophy needs to be differentiated from diseases that lead to pain or atrophic paralysis around the shoulder girdle and arm. Poliomyelitis can be distinguished by the absence of constitutional symptoms, cutaneous sensory symptoms and a normal CSF. Cervical disk disease and cervical root compression can be demonstrated by EMG and MRI or CT scan.

Routine laboratory studies are usually within the reference range. Complete blood count (CBC) and erythrocyte sedimentation rate (ESR) are helpful nonspecific indicators of systemic diseases presenting as neuralgic amyotrophy, such as systemic lupus erythematosis and lymphoma. Raised ESR may also point toward neurobrucellosis, sarcoidosis, and other granulomatous infiltrations of the brachial plexus. Human immunodeficiency virus (HIV) serology should be done in regions with high prevalence of childhood AIDS.

Imaging of the brachial plexus, using MRI, may reveal enlarged nerves with increased signal intensity on T2-weighted images. It may also help to rule out carcinomatous or granulomatous infiltration.

Electrodiagnostic tests (nerve conduction studies and EMG) are important for diagnostic and prognostic information. It is also important to rule out other conditions such as radiculopathy, neuropathy, and amyotrophic lateral sclerosis. Approximately 50% of unilateral clinical involvement demonstrates bilateral EMG abnormalities.

Features of denervation in affected muscles can be revealed by EMG 2–3 weeks after onset of disease.

Treatment

In the acute stage of the disease, pain management is the primary goal of therapy. Analgesics, using a nonsteroidal anti-inflammatory drug and opiates (if necessary) are required in the initial period. Immunosuppressive therapy, using steroids, do not alter the outcome of the disease. Intravenous immunoglobulin was reported to result in significant improvement in pain and to accelerate recovery of function. This should be followed by physical therapy in the form of passive and active range of motion exercises to avoid a frozen shoulder. Occupational therapy in the form of assistive devices and orthotics may be required when residual disabilities are established. A randomized placebo-controlled trial of oral prednisone is being conducted in the Netherlands.

Prognosis

Brachial neuritis has an overall good prognosis regarding functional recovery. About 80% of patients recover functionally within 2 years and 90% within 3 years. Patients with upper brachial plexus lesions improve earlier and bilateral disease has a less favorable outcome compared to unilateral disease. The recurrence rate of the idiopathic form is between 5% and 26%, and in the inherited form is approximately 75%.

Prevention

In hereditary neuralgic amyotrophy (HNA), at risk individuals younger than age 18 years are typically not offered genetic testing during childhood. This is because no preventive or ameliorating treatment is available for the disease. Since HNA does not affect intellectual or life span, prenatal testing for the condition is not required. However, preimplantation genetic diagnosis (PIGD) may be available for families in which the disease-causing mutation has been identified, although this technique is usually reserved for life-threatening hereditary diseases.

Lumbosacral Plexopathy

This is similar to neuralgic amyotrophy and constitutes its counterpart in the lower limb. The condition is rare but occasional cases are on record in adolescents and even in toddlers. It presents with pain located in a femoral or sciatic distribution, refusal to walk, or limping. The condition usually follows an intercurrent infection but has also been reported in association with schistosomiasis. Recovery is generally faster than neuralgic amyotrophy although mild residual weakness may persist.

372 Peripheral Nerve Disorders

Mustafa A. M. Salih

Traumatic Mononeuropathy

The sciatic nerve can be injured as a result of injections into the nerve or its vicinity. This can follow intramuscular injections into the buttocks, or following injection of drugs into the umbilical artery leading to thrombosis of the inferior gluteal artery. Other causes include stretch injury following closed reduction of hip dislocation and rarely as a result of breech delivery. The resultant paralysis commonly affects the peroneal nerve but may affect the whole territory of the sciatic nerve. The condition frequently presents with foot drop and amyotrophy of the corresponding leg.

Radial nerve injury or paralysis may result from subcutaneous fat necrosis of the upper arm in the neonatal period or following constraint of the forearm for intravenous infusion. Injury of the median nerve may follow arterial stick at the wrist and attempted catheterization of the radial or humeral artery. Femoral nerve injury may follow attempted puncture of the femoral vein or, rarely, trauma to the nerve along the psoas muscle during herniorrhaphy or appendectomy. Peroneal nerve injury may follow casting and orthopedic appliance to the region.

Entrapment Neuropathy

Carpal tunnel syndrome is rare in childhood and usually presents with motor symptoms and wasting of the thenar muscles, rather than pain and paresthesia, which is more marked in adults. During childhood, it may be associated with mucopolysaccharidosis and hyporthyroidism.

Familial Pressure Neuropathy (Hereditary Neuropathy with Liability to Pressure Palsies)

This is a rare dominantly inherited condition due to a deletion at chromosome 17p11.2 locus that encodes peripheral myelin protein P22 (PMP22). Symptoms usually start after the first decade, but may be earlier. A single nerve trunk is usually involved, the most common being the popliteal nerve as a result of prolonged squatting or sitting cross-legged. The cubital nerve may also be involved secondary to pressure on the elbow and patients may develop a carpal tunnel syndrome of early onset. The diagnosis is made when the amount of trauma is out of proportion to the degree of paralysis and when there is a similar family history. Nerve conduction studies confirm the diagnosis by revealing delay in conduction velocities outside the affected territory. Recovery, which takes days to weeks, is usually complete.

Neuropathy of Infectious Diseases

Diphtheritic Neuropathy

Diphtheritic neuropathy is the most common severe complication of *Corynebacterium diphtheriae* infection. Following the introduction of childhood immunization, the disease became a rarity in the US and Western Europe. Nevertheless, the disease is endemic in countries of the Caribbean and Latin America. In the late 1970s, 1980s, and 1990s, outbreaks were reported in both industrialized (Germany, Sweden) and developing countries (Ecuador, China, Nepal, Sudan, Thailand). A large epidemic occurred from 1990 to 1995 throughout the States of the former Soviet Union. Outbreaks also occurred in Ecuador, Algeria, and Central Asia. Historically, diphtheria infected children less than 12 years and declined following childhood immunization with diphtheritic toxoid. Recently, due to incomplete immunization, or lack of it, the disease shifted to the adult population.

Pathogenesis and Pathology

C. diphtheria produces a 62-kd polypeptide exotoxin, which leads to demyelinating neuropathy because it

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_372,

inhibits the synthesis of myelin proteolipid and other basic proteins. The exotoxin also causes local tissue necrosis and cardiomyopathy.

Clinical Manifestations

Diphtheria neuropathy follows respiratory or cutaneous diphtheritic infection. Respiratory diphtheria usually involves the tonsils, pharynx, and larynx with a characteristic membranous exudate. The latency in development of diphtheritic polyneuropathy ranges between 5 and 70 (mean = 37) days. Bulbar disturbance appears first with nasal speech, nasal regurgitation, diplopia, and dysphoria. Palatal palsy is the commonest, affecting 72% of patients and is the first to appear at a mean of 22 (range 5–41) days after onset of diphtheria. Generalized peripheral neuropathy usually appears between the 5th and 6th week and may be associated with, or shortly followed by, pharyngeal paralysis, abducens (CN VI) palsy, and weakness of neck muscles (*Fig. 372.1a*). Bilateral facial nerve (CN VII) palsy manifest between the 6th and 10th week (mean = 54 days). Patients have sensory disturbances of all modalities in the distal extremities, tendon reflexes are absent or depressed, and plantar responses are flexor. Autonomic instability is common in diphtheritic polyneuropathy and may be difficult to differentiate from myocarditis. Paralysis of the diaphragm and respiratory muscles may occur and require mechanical ventilation. Clinical recovery of the neurological complications of diphtheria follow the same pattern except for pharyngeal paralysis and peripheral weakness, which take longer to resolve (6–7 weeks), and facial weakness, which resolves more rapidly (about 4 weeks).

Figure 372.1
(a) Weakness of neck extensors in a patient with diphtheritic polyneuropathy. (b) Left hand clawing following ulnar nerve mononeuritis in an adolescent with leprosy. Note the atrophy of the small muscles of the left hand and the hypothenar muscles. (c) Guillain-Barre syndrome (GBS). Nasogastric tube feeding was needed due to swallowing difficulties, and there is bilateral foot drop. (d) Bilateral ptosis of eyelids in Miller Fischer variant of GBS. The patient also had ophthalmoplegia

Diagnosis

Nose and throat swabs should be obtained from suspected cases and their close contacts, and cultured to isolate *C. diphtheriae*, determine the biotype (gravis, mitis, or intermedius), and whether the isolate produces toxin (toxigenicity test). Cultures are usually negative if the patient had received antibiotics before reporting to hospital. Nonviable *C. diphtheriae* organism can be detected by polymerase chain reaction (PCR) test from specimens taken after antibiotic therapy has been initiated. It can also confirm infection with toxigenic strains. Toxigenicity tests are not available in many laboratories and isolates need to be sent to a reference laboratory.

Neurophysiology studies show prolongation of distal motor latency, slowing of conduction velocity, and delayed F-wave latency. Because pathological changes appear later in the peripheral nerve segment than in the ganglia and root, the nerve conduction abnormalities might be mild even when the limb weakness is severe. Brainstem auditory evoked potentials (BAEP) may reveal auditory (VIII) nerve impairment, and autonomic tests may show impaired R-R variation on valsava testing.

Treatment

Diphtheritic polyneuropathy has no specific treatment. Attention should be paid to the airway and impending respiratory failure, which needs mechanical ventilation. Autonomic disturbances and circulatory collapse require prompt management.

Prognosis

The overall mortality of diphtheria is about 20% and is mainly due to mechanical airway obstruction or cardiac involvement. Mortality increases with severity of local disease and delay of administration of antitoxin. Gravis strain of *C. diphtheriae* accounts for the most severe and virulent disease. Other prognostic factors include the age and immunization status of the patient.

Prevention

The disease is preventable through routine childhood immunization programs and booster doses of diphtheria vaccine.

Leprosy

Leprosy is a systemic chronic granulomatous disease caused by infection with *Mycobacterium leprae*, and has a marked predilection for nerves and skin. The worldwide incidence of the disease is 2 cases per 10,000 populations and the disease is endemic in Africa and Asia, particularly in the Indian subcontinent. In northern Brazil, 10% of cases develop in children younger than 15 years.

Intimate person to person contact and vertical transmission have been considered the most likely routes of transmission. Hosts with high resistance to the organism develop paucibacillary (tuberculoid) leprosy, and those with low resistance develop multibacillary (lepromatous) leprosy. Borderline leprosy is characterized by the presence of single or multiple skin lesions with a raised central area.

The incubation period is long, averaging 5 years. The disease presents with hypopigmented lesions mostly observed in the cool areas of the body (earlobes, nose, dorsal surface of the hands, and feet). In multibacillary (lepromatous) leprosy, pure sensory polyneuritis develops in a glove and stocking distribution, with loss of touch, pain, and temperature sensation. Deep sensitivity is preserved. Pure mononeuritis is rare and enlargement of the peripheral nerves (such as the posterior auricular and ulnar nerves) may be present (*Fig. 372.1b*). Nerve biopsy is useful for diagnosis and detection of persistent infection. To prevent antimicrobial resistance, treatment uses multidrug therapy including rifampin, dapsone, clofazimine, ofloxacin, minocycline, and clarithromycin. A single dose of bacilli Calmette-Guerin (BCG) vaccine was reported to be 50% protective in preventing leprosy.

Lyme Neuroborreliosis

Lyme disease is a multisystem infectious disease caused by a spirochete, *Borrelia burgdorferi* and affects, most commonly, the skin, nervous system, joints, and heart. It is transmitted from animals (deer) to man by the *Ixodes* tick. The disease is endemic in the US, with incidence averaging 9.1 cases per 100,000 persons. It is also prevalent throughout temperate Europe and Asia, and the estimated incidence was as high as 206 cases per 100,000 populations in Slovenia. Although few studies demonstrated multifocal perivascular inflammation in nerves, the pathophysiology of peripheral nerve and brain involvement remain to be clarified.

Clinical Manifestations

The first stage of the disease is characterized by an erythematous, macular, usually painless rash (erythema migrans), located in the area of the tick bite (the target sign). This is seen in 90% of infected patients and is associated with minor constitutional symptoms. The second stage of disseminated infection can involve the nervous system in approximately 15% of patients. This consists of part or all of the triad of lymphocytic meningitis, cranial neuropathy, and painful radiculitis. The facial nerve (CN VII) is the most commonly involved and may manifest as bilateral facial palsy. Other cranial nerves can be involved. The painful radiculitis may present as brachial plexopathy or lumbosacral plexopathy. A plexopathy resembling Guillain-Barre syndrome may also be seen. The third stage of persistent infection may be observed in untreated infection from one to several years. Its clinical features include chronic arthritis, chronic encephalomyelitis or a mild peripheral neuropathy, and focal mononeuropathy multiplex or polyradiculopathy.

Diagnosis and Differential Diagnosis

The diagnosis of Lyme disease rests on history of exposure in an endemic area, a clinical picture compatible with early Lyme disease (erythema migrans, constitutional flu-like symptoms) and laboratory demonstration of *Borrelia* infection. In suspected cases of neuroborreliosis, lumbar puncture is essential to evaluate the presence of specific antibodies to *B. burgdorferi*. Analysis of cerebrospinal fluid (CSF) will show significant pleocytosis, helping to differentiate the disease from Guillain-Barre syndrome, particularly when there is associated facial diplegia. In patients presenting with peripheral neuropathy, neurophysiologic studies are often consistent with axonal degeneration. Approximately 15–20% of patients with neurologic manifestations of Lyme disease show MRI abnormalities, usually in the form of punctuate lesions of the periventricular white matter.

Treatment

Treatment of neurologic Lyme disease is effectively accomplished with a 2-week course of parenteral penicillin, ceftriaxone or cefotaxime, or oral doxycycline. Approximately 90–95% of patients will be cured when receiving appropriate antimicrobial therapy early. A minority of patients, who had early treatment, develop late sequelae, but this rarely occurs in children.

Prevention

This is achieved by avoiding *Ixodes* tick bites through avoidance of infested areas, wearing appropriate clothing and using tick repellent with lower concentrations to avoid potential neurotoxicity in children.

Neurobrucellosis

On rare occasions, the nervous system is involved in systemic brucellosis. The clinical presentation of neurobrucellosis is diverse and reported neurological presentations in childhood range from acute to chronic forms. The former includes meningitis and meningoencephalitis, whereas the latter includes behavioral disturbance, brain abscess, stroke, myelitis, cerebellar ataxia (with or without cranial nerve involvement), radiculopathy, and peripheral neuropathy. Neurobrucellosis can present as Guillain-Barre syndrome, and bacteriological and serological tests should be part of the work-up for Guillain-Barre syndrome in endemic areas for brucellosis.

Toxic Neuropathies

Many toxins can induce polyneuropathy in children (*Table 372.1*). Antimicrobial drugs that may cause neuropathy include nitrofurantoin, mainly in children with renal insufficiency. Isoniazid interferes with the metabolism of pyridoxine, which should be supplemented in patients treated with tuberculosis. Phenytoin neuropathy

Table 372.1
Exogenous toxins that cause polyneuropathy

Agent group	Name
Antimicrobial	Nitrofurantoin, isoniazid, ethambutol, ethionamide, metronidazole, amphotericin
Chemotherapy	Vincristine, cisplatin, chlorambucil, adenine arabinoside, cytosine arabinoside
Miscellaneous drugs	Phenytoin, lithium, thalidomide, amitriptyline, amiodarone, pyridoxine abuse
Metals	Lead, mercury, thallium, arsenic
Organic chemicals	Organophosphates, N-hexane, triorthocresyl phosphate, carbon monoxide, cyanate, hydroxyquinolines
Biological toxins	Tick bites, serum sickness, immunizations, cassava plant ingestion

is usually subclinical and most drug induced neuropathies are reversible following discontinuation of the causative drug. Lead poisoning rarely presents with peripheral neuropathy in children. Toxicity with other metals and organophosphates is associated with accidental ingestion of insecticides, usually in rural communities. Neuropathy from N-hexane results from glue sniffing, an addictive habit among adolescents. Cassava consumption causes tropical neuropathy because of its high cyanide content, whereas tick paralysis is seen in the US and Australia.

Guillain-Barre Syndrome

Definition/Classification

Guillain-Barre syndrome (GBS), or acute inflammatory demyelinating polyradiculoneuropathy (AIDP), is an inflammatory disease of the peripheral nervous system characterized by progressive motor weakness and areflexia. It can be divided into several forms based on the involved nerve fibers (motor, sensory and motor, cranial), and the predominant mode of fiber injury (demyelinating versus axonal). Autonomic and brainstem involvements are also common.

Epidemiology

Following virtual global eradication of poliomyelitis, GBS is the most common cause of acute paralysis in children. The overall incidence ranges from 0.6 to 2.4 cases per 100,000 population per year, whereas the incidence in individuals younger than 18 years ranges from 0.5 to 1.5 per 100,000. The disease has no racial predilection and males seem to be more susceptible to develop GBS, with a male to female ratio of 1.26:1. Seasonal predilections were observed in some countries with *Campylobacter*-related GBS (China, northern India, Bangladesh, northwestern Iran, Egypt, Mexico) occurring in the summer, and upper respiratory tract illness-related GBS occurring in winter. In children, the average age of onset ranges from 4 to 8 years, but can involve younger children.

Pathology and Pathophysiology

The mechanism of the disease is thought to involve an abnormal T-cell response triggered by a preceding infection. About two-thirds of cases of GBS follow an infection, usually viral (including cytomegalovirus, Epstein-Barr virus, HIV, hepatitis B or C, and smallpox-vaccinia), but sometimes mycoplasmal or bacterial (*Campylobacter jejuni*). An immune-mediated injury to the peripheral nerve occurs including cytotoxic T cell-mediated lyses and membrane damage from cytokines and free radicals. This is thought to be due to the molecular mimicry of the triggering pathogens, which resemble antigens on peripheral nerves including myelin P-2, ganglioside GQ1b, GM1, and GT1a. High titers of IgG anti-GM1, GM1b, or GD1a antibodies are more common in the acute motor axonal neuropathy (AMAN) than in the demyelinating forms of GBS. Acute motor axonal neuropathy is associated with infection by *C. jejuni*, the polysaccharide of which has a GM1 ganglioside-like structure. Other antecedent events associated with GBS include vaccination and surgery.

Clinical Manifestations

Symptoms

Onset of symptoms occurs within 2–4 weeks of illness or immunization. The preceding illness involves upper respiratory tract infection, fever, and muscle pains. History of vomiting is found in the demyelinating form of GBS and diarrhea is more likely to precede AMAN. The chief complaints include weakness and/or ataxia, associated with pain (in about half of affected children), dysesthesia, and urinary retention (in 10–15% of cases).

Signs

Weakness typically starts in the legs and ascends to the upper extremities, involving both sides of the body and evolving over a period of several days (Fig. 372.1c). Evolution is complete after 2 weeks in half of the cases, after 3 weeks in over 80%, and after 4 weeks in over 90%. Weakness can be mild or severe leading to total paralysis and death from respiratory failure. Signs of autonomic dysfunction are common and include sinus tachycardia (in >50% of severe cases), bradycardia, orthostatic hypotension, and fluctuating hypertension and hypotension. Later in the disease course, objective sensory loss can be demonstrated in 75% of cases. Deep tendon jerks are usually absent or markedly diminished.

Other Variants of Guillain-Barre Syndrome

A small group of patients develop primary axonal degeneration associated with severe fulminant paralysis, sensory

loss, and incomplete recovery. This variant is now termed *acute motor and sensory axonal neuropathy* (AMSAN). Conversely, the other variant of GBS (*acute motor axonal neuropathy* [AMAN]), usually follows antecedent *C. jejuni* infection and has a more rapid progression than the demyelinating form of GBS. Some patients with AMAN recover rapidly. The *Miller Fischer* variant of GBS is characterized by ophthalmoplegia, ataxia, areflexia, and relatively little weakness (Fig. 372.1d). Some patients present with *polyneuritis cranialis* variant characterized by facial and ocular motor nerves involvement but infrequent limb weakness. The *pharyngeal-cervical-brachial* form of GBS is characterized by acute oropharyngeal, neck, and shoulder weakness, with sparring of the limb muscles. Another form is termed *acute sensory neuropathy of childhood* that presents as acute sensory loss but no weakness, although nerve conduction studies show features of demyelination. *Acute dysautonomia* variant, with no concomitant motor or sensory deficit, is rare. In this form of GBS, dysautonomia involves both the sympathetic and parasympathetic systems and may manifest with orthostatic hypotension, hypertension, sinus tachycardia, sweating abnormalities, and pupillary dysfunction.

Diagnosis

Support for the clinical diagnosis of GBS is provided by cerebrospinal (CSF) examination, neurophysiologic studies, and occasionally MRI findings. The CSF is acellular in all but 10% of patients; most of these have fewer than 10 cells/mm^3 and mild pleocytosis (10–50 cells/mm^3) may occasionally be seen. The finding of more than 50 cells/mm^3 on CSF examination suggests an alternative diagnosis. The CSF protein level rises about 1 week after the onset of symptoms, is usually elevated by 10 days, and reaches a peak in 3–4 weeks.

Nerve conduction studies (NCS) are frequently normal early. The most sensitive parameter of NCS is the F-wave. Within the first week of symptom onset, absent, impersistent, dispersed, or prolonged F response is seen in 88% of cases. This is compared to the finding, during this period, of increased distal latencies in 75%, conduction block in 58%, and reduced motor and sensory nerves conduction velocity in 50%. Electrodiagnostic criteria of the axonal forms of GBS are severe reduction in compound muscle action potential (CMAP) amplitudes, and minimal features of demyelination, with or without abnormalities in sensory nerves. F-wave latencies and blink response latencies are usually abnormal in Miller Fisher syndrome, but slowing of conduction velocities in the limbs may be absent. Electromyography (EMG) is contraindicated in GBS since the child may be harboring poliomyelitis, and EMG will lead to provocation paralysis.

Lumbosacral MRI may show, about 2 weeks after presentation of symptoms, enhancement of the cauda equina nerve roots with gadolinium in 95% of typical cases. The sensitivity of this study is 83% in acute GBS.

Serological Tests

High titers of IgG anti-GM1, GM1b, GD1a, and GalNac-GD1a was reported in 64% of children who develop the acute motor axonal neuropathy form of GBS, and was associated with more prolonged recovery and residual symptoms. Conversely, anti-GQ1b was found to be associated with Miller Fisher syndrome and anti-GT1a with pharyngeal-cervical-brachial variant of GBS.

Differential Diagnosis

Acute anterior horn infections by poliovirus, Coxsackie virus, and West Nile virus can produce an acute motor syndrome, but in contradistinction to GBS, CSF usually shows pleocytosis. Acute motor paralysis, associated with hyporeflexia or areflexia, can also be seen at the onset of transverse myelitis and acute spinal cord compression. The finding of a sensory level, associated with early involvements of the bowel or bladder, is supportive of these two diagnoses. In particular, acute spinal cord compression should not be missed to prevent the occurrence of a permanent cord infarct. Myasthenic crises and botulism may be considered when ophthalmoplegia is present in GBS. A history of fatiguabilily and fluctuating ocular symptoms favors the diagnosis of myasthenia, in which repetitive nerve stimulation on NCS shows decrement response. The presence of dilated unreactive pupil and severe constipation are indicative of botulism. Other causes of acute neuropathies include organophosphate poisoning, lead and heavy metals poisoning, and chemotherapy with vincristine. In endemic areas, tick paralysis can cause an ascending paralysis that dramatically improves after removal of ticks.

Treatment

Supportive therapy should be instituted immediately. Blood pressure, heart rate, temperature, respiratory capacity, blood gasses (when necessary), and urine output should

be maintained. Children with oropharyngeal weakness with inability to protect their airway, vital capacity below 15 mL/kg body weight, or arterial pressure of oxygen below 70 mmHg should be considered for elective endotracheal intubation. These children and others with autonomic instability should be monitored in the intensive care unit. Orthostatic hypotension and urinary retention need judicious management. Measures to prevent infection (e.g., pneumonia and urinary tract infection), deep venous thrombosis, decubitus ulcers, and contractures should be instituted. After the acute phase, activity with physical and/or occupational therapy should be encouraged.

In children, immunomodulation using intravenous immunoglobulins (IVIG) is the treatment of choice. It reduces the severity of the disease and the duration of symptoms, although the long-term outcome may not be affected. It has several advantages over plasmapheresis, which is equally effective. Plasmapheresis is limited to children weighing more than 10–15 kg, requires a central line vascular access (which indicates intensive care unit management), and has several potential serious complications. These include bleeding due to depletion of clotting factors, autonomic instability, and hypercalcemia. Also, plasmapheresis would only remove free-circulating antibodies whereas IVIG can displace antibodies bound to motor nerves and possibly prevent complement activation. This may particularly be effective in cases of acute motor axonal neuropathy associated with positive autoantibodies.

The recommended dose of IVIG, which is administered by peripheral intravenous route, is 0.4 g/kg given daily for 5 days. This can lead to improvements within 2–3 days after start of therapy. When there are signs of rapid deterioration, IVIG can either be given as a single dose of 2 g/kg, or over 2 days using a single dose of 1 g/kg each day. Adverse reactions and effects to IVIG can occur in about 10% of patients and they are usually minor. These include fever, chills, wheezing and urticaria, headache, and 10% increased risk of aseptic meningitis.

Prognosis

Children with GBS have more favorable outcome compared to adults. The mortality rate is estimated to be less than 5% and usually follows respiratory failure, cardiac arrhythmias, and dysautonomia. The mortality rate is higher in areas with insufficient medical facilities. Approximately 90–95% of patients have full recovery within 3–12 months, 5–10% significant permanent disability and 5% have recurrence of GBS. Affected children with cranial nerve involvement, quadriplegia, and need for ventillatory support usually have significant delay in motor recovery. Patients with acute motor axonal neuropathy have longer recovery time compared to those who have the demyelinating variant of GBS. About 12% of patients may have recurrence 2–3 weeks after IVIG. When that happens, the differential must include *chronic inflammatory demyelinating polyneuritis (CIDP)*, which has a relapsing-remitting course in childhood, and unlike GBS, responds to steroids.

Hereditary Neuropathies

Charcot-Marie-Tooth Disease

Definition/Classification

Charcot-Marie-Tooth (CMT) disease or hereditary motor and sensory neuropathy was first recognized independently by Charcot and Marie in France and by Tooth in England.

Based on neurophysiologic and neuropathologic studies, two major types of CMT have been distinguished. The demyelinating form (CMT1) shows moderately to severely decreased nerve conduction velocity (NCV) of the median nerve (<38 m/s), whereas the axonal type (CMT2) exhibits normal or mildly reduced MCV (>38 m/s). Both CM1 and CMT2 are clinically indistinguishable and are usually inherited (in Europe and North America) as autosomal dominant disorders. A third form is autosomal dominant intermediate CMT, which is characterized by NCV overlapping those observed in CMT1 and CMT2, ranging between 25 and 50 m/s. The clinical, neurophysiological, and neuropathological phenotype of the X-linked forms of CMT is also intermediate between CMT1 and CMT2. The group of progressive motor and sensory axonal or demyelinating neuropathies with autosomal recessive inheritance is known as CMT4. Complex forms of CMT, in which the peripheral neuropathy is associated with other symptoms (ataxia, mental retardation, optic atrophy, pigmentary retinal degeneration) have also been recognized, and their pattern of inheritance and genes involved are being discovered. The autosomal dominantly inherited hereditary neuropathy with liability to pressure palsies (HNPP) is also included in the CMT group, and is clinically characterized by recurrent episodes of peripheral nerve palsies due to mechanical trauma.

Etiology

The disease is an inherited degenerative disorder of the peripheral nervous system with the primary pathological

process affecting the axons of motor or sensory cells or both, or other myelin sheath and associated Schwann cells.

Epidemiology

Estimates of the frequency of CMT vary widely, yet the disease is one of the most common heritable neurologic disorders. A world survey estimated a prevalence of 10 cases per 100,000. The prevalence was reported to be 36 per 100,000 in Norway and 20 cases per 100,000 population in Finland. The incidence in Japan was estimated to be 10.8 per 100,000 population. The demyelinating autosomal dominant form (CMT1) accounts for about 50% of cases, the axonal autosomal dominant (CMT2) for 20–40%, whereas the X-linked inherited form constitutes 10–20% of cases. In contrast, in communities with a high percentage of consanguineous marriages (such as in North Africa and the Middle East), autosomal recessive CMT is likely to account for 30–50% of all CMT cases. In childhood, CMT constitutes approximately 40% of chronic neuropathies.

Pathogenesis

Charcot-Marie-Tooth (CMT) disease is inherited as autosomal dominant, X-linked or autosomal recessive. The inheritance pattern and molecular genetics constitutes the basis of classification of the various types of CMT. Nevertheless, mutations in a single gene are occasionally associated with both autosomal dominant and autosomal recessive inheritance, and/or both axonal, or demyelinating neuropathy. Tables ◉ *372.2–372.4* detail, respectively, the currently known molecular genetics of dominant, X-linked, and autosomal recessive forms of CMT. Demyelinating CMT is caused by diseases of the Schwann cell and the myelin, and the lesions are either diffuse or segmental (i.e., limited to the internode, which is formed by the part of the nerve depending on one Schwann cell). Diffuse demyelination leads to slowing of NCV, whereas segmental demyelination manifests as conduction block in some fibers and temporal dispersion as recorded on nerve conduction studies (NCS). Axonal CMT is characterized primarily by involvement of the axon and manifests with normal or only slightly slowed NCV.

The term *Dejerine–Sottas syndrome (DSS or CMT3)* was described as a hypertrophic polyneuropathy with onset in infancy or early childhood. It was first assumed to be inherited as autosomal recessive. Nevertheless, during the molecular biology era, patients with DSS were found to be heterozygous for point mutations in genes associated with CMT1 including *PMP22* (CMT1A), *MPZ* (CMT1B), and *EGR* (CMT1D). The entity designated as *congenital hypomyelination neuropathy (CHN)* is usually considered as a form of DSS, and can present as floppy infant syndrome. It is also associated with point mutations in *PMP22*, *MPZ*, and *EGR*. *Hereditary neuropathy with liability to pressure palsies* (HNPP) is a dominantly inherited disease characterized by acute onset of recurrent, painless, focal motor, and sensory neuropathy in a single nerve due to deletion or point mutations of *PMP22* gene.

Pathology

The pathology of CMT has mainly been studied by muscle or nerve biopsy. The rare postmortem examinations in CMT1 showed degeneration of the posterior columns, some loss of the anterior hom cells, and degeneration of the anterior and posterior spinal roots. Sural nerve biopsy shows reduced number of myelinated fibers, mainly those of large caliber with preservation of unmyelinated fibers. On electron microscopy, the classical onion bulbs are seen. These are thought to result from repeated demyelination and remyelination of Schwann cell wrappings around individual axons. In CMT2, the disease process is presumed to occur in the axon or cytoplasm of the anterior hom cell, and anterior hor cell loss has been found in two autopsies. Large-caliber fibers are reduced in number and the internodes are shortened and of irregular length. Three of the autosomal recessive forms of CMT (CMT4B1, CMT4B2, and CMT4H) are characterized by the presence, on sural nerve biopsy, of irregular redundant loops of focally folded myelin sheaths (◉ *Fig. 372.2a*). Onion bulbs are seen in CMT4A, CMT4C, CMT4D, CMT4F, and CMT4H. The onion bulbs in CMT4A are characteristically composed of basal laminae (◉ *Fig. 372.2b*).

Clinical Manifestations

Symptoms and Signs

The age of onset of CMT1 ranges from infancy (resulting in delayed walking) to the fourth or later decades but patients usually become symptomatic between age 5 and 25 years. The cardinal symptoms in children are difficulty in running or walking, or foot deformity. Gait disturbance includes clumsy walking, frequent falls, and high steppage gait. Foot deformity is characterized by pes cavus, often

Table 372.2
Genes and proteins involved in autosomal dominant demyelinating. (CMT1) and axonal (CMT2) forms of CMT

Type of CMT	Chromosomal locus of the gene	Gene symbol	Protein product
CMT1: Dominant; Demyelinating			
CMT1A	17p11	*PMP22*	Peripheral myelin protein 22
CMT1B	1q22	*MPZ*	Myelin P0 protein
CMT1C	16p13	*LITAF*	Lipopolysaccharide-induced tumor necrosis factor-alpha factor
CMT1D	10q21	*EGR2*	Early growth response protein 2
CMT2: Dominant; Axonal			
CMT2A1	1p36	*KIF1B*	Kinesin-like protein KIF1B
CMT2A2	1p36	*MFN2*	Mitofusin-2
CMT2B	3q13	*RAB7A*	Ras-related protein Rab-7a
CMT2B1	1q21	*LMNA*	Lamin A/C
CMT2B2	19q13.3	Unknown	Unknown
CMT2C	12q23–q24	*TRPV4*	Transient receptor potential cation channel subfamily V member 4
CMT2D	7p15	*GARS*	Glycyl-tRNA synthase
CMT2E*	8p21	*NEFL*	Neurofilament light polypeptide
CMT2F	7q11	*HSPB1*	Heat-shock protein beta-1
CMT2G	12q12–q13.3	Unknown	Unknown
CMT2L	12q24	*HSPB8*	Heat-shock protein beta-8

*Some individuals with mutations in NEFL, which typically cause CMT2E, have features of demyelination manifesting as slow nerve conduction velocities. This entity is referred to as CMT1F

Table 372.3
Genes and proteins involved in X-linked forms of CMT

Type of CMT	Chromosomal locus of the gene	Gene symbol	Protein product
CMTX1	Xq13	*GJB1*	Gap junction beta-1 protein (connexin 32)
CMTX2	Xp22.2	Unknown	Unknown
CMTX3	Xq26	Unknown	Unknown
CMTX4 (Cowchock syndrome)	Xq24–q26.1	Unknown	Unknown
CMTX5	Xq21.3–q24	*PRPS1*	Ribose-phosphate pyrophosphokinase 1

associated with hammer toes, but pes planus and valgus deviation of the feet may be present in some children. Symptoms are usually insidious and most patients are seen only after several years.

Difficulty in heel-walking is an early manifestation of the disease. Clinical examination reveals symmetrical peroneal muscle atrophy, later involving the calf muscles and eventually the lower third of the thigh, leading to stork leg appearance (*Fig. 372.2c*). Atrophy of the small muscles of the hands (including the thenar and hypothenar muscles) is usually late. When advanced, this leads to claw hands (*Fig. 372.2d*).

Loss of deep tendon reflexes (especially the ankle jerks) is a frequent early manifestation, and can be used to assess at risk children who have affected relatives. Sensory abnormalities are mild, and usually manifest after the age of 5 years. They are limited to subtle deficits in deep sensation, while pain and touch sensation are not impaired. Nerve enlargement is frequent whereas scoliosis, lordosis, and calf muscle hypertrophy may occur.

Table 372.4
Genes and proteins involved in autosomal recessive forms of CMT

Type of CMT	Chromosomal locus of the gene	Gene symbol	Protein product
CMT4A	8q13	*GDAP1*	Ganglioside-induced differentiation-associated protein 1
CMT4B1	11q22	*MTMR2*	Myotubularin-related protein 2
CMT4B2	11p15	*SBF2*	Myotubularin-related protein 13
CMT4C	5q32	*SH3TC2 (KIAA1985)*	SH3 domain and tetratricopeptide repeats containing protein 2
CMT4D (Lom)	8q24	*NDRG1*	Protein NDRG1
CMT4E	10q21	*EGR2*	Early growth response protein 2
CMT4F	19q13	*PRX*	Periaxin
CMT4H	12p11.2	*FGD4*	FYVE, RhoGEF, and PH domain-containing protein 4
CMT4J	6q21	*FIG4*	Polyphosphoinositide phosphatase

The full clinical picture of CMT1 may not occur until the second decade of life, progression is slow over many years, and arrests are common and often prolonged.

The age of onset of hereditary neuropathy with liability to pressure palsies (HNPP) ranges from the first to the eighth decade of life (typically the third or fourth decade), but can present at birth. The recurrent acute mononeuropathy is often related to minor nerve compression, usually after resting on a limb in an awkward position, such as squatting or sitting cross-legged. Affected nerves at sites of anatomic vulnerability to compression include the peroneal nerve at the fibular neck, the ulnar nerve at the cubital tunnel, the radial nerve at the spiral groove of the humerus, and the median nerve at the carpal tunnel. The brachial plexus may also be involved. Examination between episodes of focal weakness may be normal or mildly abnormal.

The clinical features of CMT2 are similar to those of CMT1 but onset is usually later, during the second or third decade, and the course of the disease is slower. Phenotypic variation is common between and within affected families. Areflexia, pes cavus and hammer toes may be less common than in CMT1, but nerve hypertrophy is absent.

In males, symptoms of CMTX1 usually begin in childhood or adolescence. Females are often asymptomatic but may have late onset of mild symptoms because of predominant inactivation of the X chromosomes that bears the normal allele of the gene. Atrophy, particularly of intrinsic hand muscles, paresthesia, and sensory loss, may be more common in this form of CMT than other subtypes.

The onset of the autosomal recessive type of CMT (CMT4) is significantly earlier than either CMT1 or CMT2. In its severe form, it overlaps with Dejerine–Sottas syndrome and can present at birth with congenital hypotonia.

CMT4A was first identified in families in Tunisia. It starts in early infancy with delayed motor development, and distal muscle weakness and atrophy of feet that progress to involve the proximal muscles by the end of the first decade. Atrophy of the hand muscles may occur later and loss of ambulation is often by the age of 30 years. Scoliosis and skeletal deformities may occur. The disease is associated with *GDAP1* mutations, which cause both demyelinating and axonal phenotypes. The axonal form is linked to vocal cord and diaphragmatic paralysis with onset in midlife.

CMT4B1 was first described in an Italian family. Mutations in the causative gene (the first identified autosomal recessive CMT gene) were found in families of Italian and Saudi Arabian ancestory. Onset is usually before the age of 4 years with progressive distal and proximal weakness of the lower limbs. Pes cavus foot deformity is common, and facial, bulbar, and diaphragmatic weaknesses are known associations. Adults frequently require wheelchairs by age 20 years and death may occur as early as the end of the second decade, or in the fourth to fifth decade.

A summary of the salient clinical features of the subtypes of CMT4 is depicted in (*Table 372.5*).

Investigations

Electrodiagnostic Studies

When carefully done, electrodiagnostic studies (including nerve conduction study [NCS] and electromyography [EMG]) are almost always abnormal in cases of CMT.

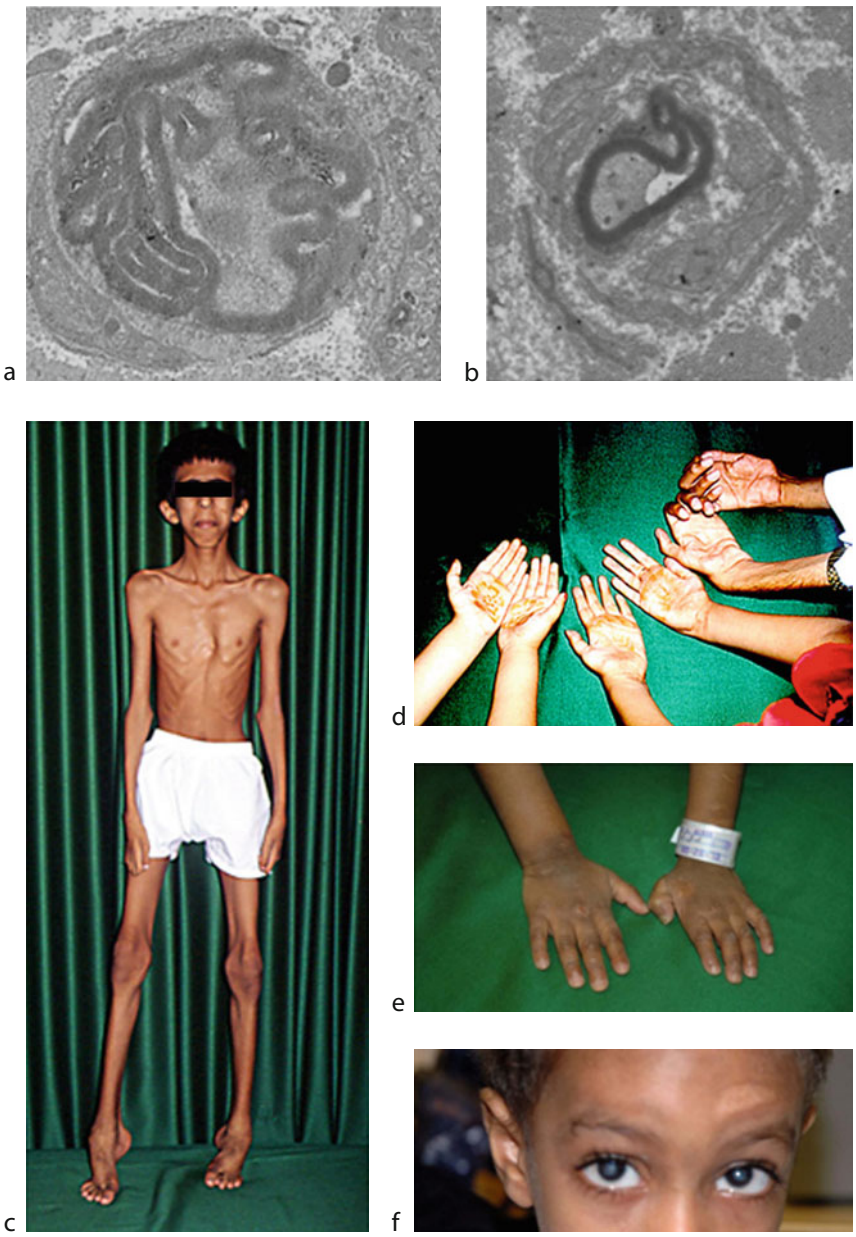

Figure 372.2
(a & b) Electron microscopic examinations of sural nerve biopsies showing (a) redundant loops of focally folded myelin sheaths, and (b) onion bulb formation. (c) Symmetrical distal muscle atrophy in Charcot-Marie-Tooth (CMT) disease. Note the stork leg appearance. (d) Progressive atrophy of the small muscles of the hands in two children and an adult from a family with CMT4B1. Note the development of claw hands in the elder patient to the right. (e) Healed traumatic hand injuries in a child with hereditary sensory and autonomic neuropathy. Note the resorption of the left thumb. (f) The patient had neuropathic keratitis leading to bilateral corneal opacities. Note the traumatic scar over the left eye-brow

Median motor nerve conduction velocity (NCV) is below 38 m/s in CMT1 and above in CMT2. Nerve conduction slowing is diffuse and uniform in CMT1 compared to acquired neuropathies where conduction block and temporal dispersion are common. F-wave responses are usually prolonged and EMG shows evidence of denervation. In CMT2, median NCV is typically above 38 m/s, and is associated with reduced compound muscle action

Table 372.5
Main clinical features of CMT4

Disease	Age at onset	Main clinical features
CMT4A	<3 years	Distal and proximal limb weakness, vocal cord, and diaphragmatic paralysis
CMT4B1	<4 years	Distal and proximal limb weakness. Facial, bulbar, and diaphragmatic weakness
CMT4B2	First decade	Distal and sometimes proximal limb weakness. Early-onset glaucoma
CMT4C	First or second decade	Distal and sometimes proximal limb weakness. Progressive, often severe, and early scoliosis
CMT4D	First decade	Distal and proximal limb weakness, sensorineural hearing loss, and tongue atrophy
CMT4E	Birth	Congenital hypotonia. Dejerine–Sottas syndrome-like presentation
CMT4F	First decade	Distal and sometimes proximal limb weakness
CMT4H	1–2 years	Distal limbs, weakness more in lower than upper limbs. Severe scoliosis
CMT4J	First decade	Severe childhood-onset demyelinating neuropathy

amplitude (CMAP) and reduced sensory nerve action potential (SNAP). Sural nerve sensory responses can be absent and EMG shows signs of chronic denervation. Nevertheless, the distinction between demyelinating and axonal CMT may not always be clear. In children, NCS shows normal results at birth, except for congenital hypomyelination neuropathy and Dejerine–Sottas syndrome. Abnormalities manifest at 2–4 years, as the peripheral nervous system matures, even in asymptomatic patients. The parents should always have NCS to ascertain asymptomatic neuropathy in either of them. In autosomal recessive forms (CMT4), both parents have normal findings on NCS.

Nerve conduction studies in hereditary neuropathy with liability to pressure palsies (HNPP) reveal bilaterally delayed median distal motor latency (DML), slowed median sensory nerve conduction velocities at the wrist, and slowing of peroneal nerve motor conduction velocity or DML.

Sural nerve biopsy is not routinely performed in children, but is occasionally helpful in establishing the diagnosis by showing relatively characteristic lesions in CMT1. It was found to be extremely helpful in autosomal recessive forms of CMT. Identification of myelin outfolding on sural nerve biopsy in two Saudi Arabian families lead to the recognition, and a later discovery in a joint research involving Italian families, of the gene for CMT4B1, which was the first identified gene for the recessive forms of CMT. The axonal form of CMT4A due to GDAP1 mutations is characterized by the presence of onion bulbs composed of basal laminae.

Imaging Studies

Enlarged nerves, both at the level of the spinal roots and also in the limbs, can be shown by magnetic resonance imaging (MRI), as well as subclinical central nervous abnormalities in several subtypes of CMT. Significant involvement of peroneal nerve-innervated muscles was seen in CMT1A patients, in contrast to fatty infiltration involving superficial posterior compartment in CMT2A cases.

Differential Diagnosis

Mental retardation, seizures, dementia, and blindness are not features of CMT and their presence should suggest another diagnosis. Acquired, especially treatable, causes of peripheral neuropathy should also be excluded such as vitamins B_1, B_6, B_{12}, folate, or E deficiencies. Vitamin E deficiency may be due to abetalipoproteinemia and biliary insufficiency that prevents normal emulsion of fat in the bowel lumen resulting in poor absorption associated with steatorrhea. Other diseases leading to fat malabsorption, such as cystic fibrosis and celiac disease, chronic liver disease (especially ductal hypoplasia) can lead to vitamin E deficiency. Other causes of acquired peripheral neuropathy include lead poisoning and heavy metal intoxication, leprosy, neurosyphilis, and immune-mediated neuropathies such as chronic inflammatory demyelinating polyneuropathy (CIDP).

Giant axonal neuropathy is a chronic polyneuropathy of childhood accompanied by characteristically kinky hair, curly eyelashes, and unique posture of legs. Sural nerve biopsy shows typical findings on electron microscopy, with the axons being distended by tightly woven neurofilaments. It is inherited as autosomal recessive and is caused by mutations encoding a protein named gigaxonin.

Hereditary neuropathies may constitute part of more complex neurological diseases involving the central nervous system (CNS). The autosomal recessively inherited

Friedreich's ataxia may present with sensory loss, depressed tendon reflexes, high-arched feet, and hammer toe. Some of the other degenerative disorders are either treatable or deserve accurate diagnosis to anticipate associated complications outside the CNS. These are briefly mentioned in (Table 372.6).

Treatment

Treatment of CMT is symptomatic and therapy should focus on the management and prevention of the development of the physical disability related to CMT. Affected children are better evaluated by a multidisciplinary team

Table 372.6
Complex hereditary neurological diseases associated with neuropathies

Disorder	Brief clinical features	Suggestive diagnostic investigations
Mitochondrial disorders		
NARP	Neuropathy, ataxia, retinitis, pigmentosa	Muscle biopsy for biochemical, morphological, and mitochondrial DNA abnormalities
MNGIE	Mitochondrial neurogastrointestinal encephalomyopathy	Muscle biopsy for biochemical, morphological, and mitochondrial DNA abnormalities
Peroxisomal disorders		
Refsum disease	Ataxia, areflexia, atypical retinitis pigmentosa, deafness, ichthyosis, disorders of cardiac function	Very-long-chain fatty acids and phytanic acid
Juvenile adrenoleukodystrophy	Dementia, personality disorder, sensory ataxia, areflexia	Very-long-chain fatty acids
Leukodystrophies		
Krabbe	Floppiness, loss of milestones, seizures, ocular movement abnormalities	Galactocerebrosidase
Metachromatic	Progressive spastic diplegia, optic atrophy	Arylsulphatase A assay
Sialidosis type 1	Action and intension myoclonus, retinal cherry red spot, no dysmorphism, normal intelligence	Sialidase (α-neuraminidase) assay
Pelizaeus–Merzbacher disease	Rotary nystagmus, hypotonia, dystonia, pyramidal and cerebellar signs, optic atrophy	Intense signal from white matter on T2-weighted MRI sequence and absence of myelin signal on T1-weighted MRI sequence
DNA Processing(damage/repair) disorders		
Xeroderma pigmentosum	Photosensitivity, poikiloderma, skin cancer, hearing loss, cognitive impairment, microcephaly, neurodegeneration	BAEP
Cockayne syndrome	Photosensitivity, growth retardation, hearing loss, cognitive impairment, progeria, microcephaly, neurodegeneraion	Cerebellar atrophy on MRI
Ataxia telangiectasia	Ataxia, oculomotor apraxia, recurrent sinubronchial infections, immune defects, neurodegeneration, choreoathetosis, malignancy	Elevated levels of AFP and CEA, immunoglobulins profile (dysgammaglobulinemia)
Ataxia telangiectasia-like disease	Ataxia, oculomotor aprxia, neurodegeneration. Choreoathelosis	Normal levels of AFP, cerebellar atrophy on MRI
Spinocerebellar ataxia with neuropathy type 1 (SCAN1)	Ataxia, epilepsy (some cases)	Cerebellar atrophy on MRI
Ataxia and oculomotor apraxia type 2 (AOA2)	Ataxia, oculomotor apraxia, neurodegeneration	Normal levels of AFP, cerebellar atrophy on MRI

Abbreviations: AFP: alpha-fetoprotein; CEA: carcinoembryonic antigen; MRI: magnetic resonance imaging

that includes pediatric neurologists, orthopedic surgeons, and physical and occupational therapists. Orthotics and ankle-foot orthosis (AFO) frequently enable patients to continue performing their daily activities while preventing falls that might result in injuries. Special shoes, including those with good ankle support can delay the need for ankle braces. Orthopedic surgery to correct severe pes cavus deformity and scoliosis might be needed at a certain stage. Exercise is encouraged within the child's capacity, daily heel cord stretching exercises are helpful in preventing Achilles tendon stretching, and obesity should be avoided because it makes walking more difficult. Medical conditions, situations, and interventions which can lead to systemic or focal neuropathies should be avoided or early managed. These include diseases such as diabetes mellitus and hypothyroidism, prolonged immobilization of limbs during surgery, vitamin deficiencies, carpal tunnel syndrome, and neurotoxic drugs. Symptoms of sleep apnea, vocal cord, and bulbar paralysis should be detected early and managed promptly.

Maladjustment and depression, especially in teenagers, should also be detected and managed. The importance of investing in education should be emphasized since CMT does not usually affect intellect, life span, or independent living.

Treatment with steroids (prednisone) or intravenous immunoglobulin has been reported to improve a few individuals with CMT1 who develop sudden worsening of their peripheral neuropathy. Other therapies under investigation include the effects of neurotrophin-3 on CMT1A patients. Ascorbic acid reduced PMP22 over expression and ameliorated the phenotype in a transgenic CMT1A mouse model, whereas a progesterone antagonist improved neuropathy in a transgenic rat model of CMT1A. A clinical trial is underway to address the possible role of high doses of ascorbic acid in CMT1A patients.

Prognosis

With the exception of CMT4, Dejerine–Sottas syndrome (DSS) and congenital hypomyelination neuropathy (CHN), life expectancy is normal in most patients with CMT. Nevertheless, the degree of disability varies according to the CMT subtype, and between and within families. Patients with CMT4A and CMT4B1 often require wheelchairs by the end of the second or third decade; and those with CMT4B1 may die by the third to fifth decade. Individuals with DSS are often disabled in early childhood and CHN may lead to early death. Approximately 10% of patients with HNPP have incomplete recovery from the acute nerve palsies, and cases of respiratory failure have been reported.

Prevention

Since CMT does not usually affect intellect, independent living, or life span, most affected parents choose to have children. Prenatal diagnosis for pregnancies at increased risk for some types of CMT4 is possible by chorionic villous sampling (at 10–12 weeks of gestation) and by amniocentesis (by about 15–18 weeks). Preimplantation genetic diagnosis may be available for families in which the disease-causing mutations have been identified.

Hereditary Sensory and Autonomic Neuropathy

Definition/Classification/Etiology

Hereditary sensory and autonomic neuropathy (HSAN) forms part of the inherited peripheral neuropathies where sensory dysfunction prevails and autonomic nervous system is involved to a varying degree. They are clinically and genetically heterogeneous with controversy over terminology. Based on clinical presentations, the distinct populations of affected nerve fibers, associated genes, and inheritance pattern, five types of HSAN have been defined (*Table 372.7*). With the exception of HSAN type I, which is transmitted as autosomal dominant, the other types are transmitted as autosomal recessive traits.

Epidemiology

Type I variant of HSAN is the most frequent and has been described in Portuguese, Belgian, Australian, and English families. HSAN III (Riley–Day syndrome) is most prevalent among individuals of Eastern European Jewish extraction, with incidence of 1 per 3,600 live births. HSAN IV, also known as congenital insensitivity to pain and anhidrosis (CIPA), has been described in most ethnic groups but seems to have high prevalence in Bedouin Arabs living in Israel. Types II and V are rare autosomal recessively inherited forms of HSAN.

Table 372.7
Genes and loci associated with various types of hereditary sensory and autonomic neuropathy (HSAN)

HMSN type	Inheritance	Locus	Gene
HSAN I	Autosomal dominant	9q22.2	*SPTLC1*
HSAN II	Autosomal recessive	12p13.3	*HSN2*
HSAN III (Riley–Day syndrome, familial dysautonomia)	Autosomal recessive	9q31	*IKBKAP*
HSAN IV (Congenital insensitivity to pain and antidrosis [CIPA])	Autosomal recessive	1q21–22	*NTRK1*
HSAN V	Autosomal recessive	1p13.1	*NGFB*

Pathogenesis/Pathology

Mutations in the genes associated with HSAN are thought to lead to malfunction in vesicular transport along the axons. In humans, sensory axons can extend for one or more meters and most proteins must be transported along the axon to reach their destination at the cell bodies of nociceptive neurons. A founder mutation (C133N mutation) estimated to have originated 900–1,600 years ago, was found in British families with the dominantly inherited HSAN1. Pathological examination of this type showed degeneration of the dorsal root ganglia and the spinal dorsal roots supplying the lower limbs. Histopathological findings in HSAN III include loss of neurons in the posterior root, dorsolateral tract (Lissauer tract), and intermediolateral gray columns. The Lissauer tract and dorsal spinal roots are also affected in HSAN IV.

Clinical Manifestations: Symptoms, Signs

Symptoms of HSAN1 appear in late childhood or adolescence with a progressive loss of sensation in the lower extremities leading to acromutilations following episodes of cellulitis and trophic ulcerations of the feet. Spontaneous stabbing (lancinating) pain may occur. Initially, there is predominant loss of pain and temperature sensation with preservation of tactile sensation. Later, all sensory modalities are lost and the distal upper limbs may become involved. Variable distal motor weakness and wasting is also a feature of the disease.

The onset of HSAN II is either congenital or during first to second decades. There is universal absence of pain sensation resulting in burns and mutilations of the lips, tongue, and fingertips. There are also painless fractures, especially of the metatarsals, a delayed development and lack of fungiform papillae on the tongue. Bladder sensation may be impaired leading to its distension, and hearing loss affects 30% of patients.

The clinical manifestations of HSAN III are mainly due to autonomic disturbances. Sucking difficulties, a poor cry, vomiting, and hypotonia are present from birth. Affected children also have pain and temperature sensory loss, alacrima (loss of overflow tears), excessive sweating, and unstable temperature and blood pressure. On examination, they have absence of fungiform papillae on the tongue, and diminished or absent deep tendon reflexes. Death, which occurs in infancy or childhood, is usually caused by bouts of apnea and pneumonia. Intelligence remains normal but the occurrence of kyphoscoliosis, esophageal dilation, and impaired gastric motility are frequent.

The onset of HSAN IV is congenital with markedly decreased or absent sweating leading to episodic unexplained fever and hyperpyrexia, often related to environmental temperature. Insensitivity to pain is universal and promotes repeated traumatic and thermal injuries, and severe mutilations of the hands and feet (*Fig. 372.2e*). Tongue-biting and osteomyelitis, especially of the lower extremities are frequent. Despite normal lacrimation, affected children are prone to neuropathic keratitis, associated with absent corneal sensation and very poor corneal healing, and resulting in corneal ulceration and opacities (*Fig. 372.2f*). Affected children usually have mild mental retardation, frequently associated with hyperactivity and emotional liability. Examination reveals sequelae of anhidrosis in the form of calloused appearance of the skin, lichenification of the palms, areas of hypotrichinosis on the scalp, and dystrophic nail changes. Muscle power and deep tendon reflexes are usually preserved.

The phenotype of HSAN V is similar to that of HSAN IV with the exception of the presence of less severe anhidrosis and lack of mental retardation in patients with HSAN V. Affected patients have severe loss of deep pain perception, which prevents them from recognizing pain from bone fractures and joint injuries resulting in destroyed joints in childhood.

Diagnosis

The congenital or early-onset forms of HSAN can be suspected when an infant shows insensitivity or indifference to

pain inflicted by the first intramuscular routine immunization injection. Attention should also be drawn to the condition when there are bouts of recurrent unexplained fever.

Investigations

Neurophysiologic Tests

Neurophysiologic tests that can be used to assess the various types of HSAN include nerve conduction studies (NCS) and electromyography (EMG). Sympathetic skin responses (SSR), utilizing the routine EMG equipment, can also be used to identify indirect evidence of sweat production via measurement of changes in skin conductance on the palm/sole in response to an electrical stimulus. Another helpful test is quantitative sensory testing (QST), which permits comparison of sensory thresholds by using vibration and temperature perception to assess both large- and small-fiber modalities. However, QST needs cooperation of the patient, which is usually lacking in young children.

Because the involved fibers in HSAN are small myelinated and unmyelinated fibers, motor nerve conduction velocity (NCV) and EMG are usually normal. Nevertheless, sensory NCV is low or absent in all forms except in HSAN V, and EMG may show features of chronic axonal neuropathy in HSAN I. Sympathetic skin responses (SSR) were reported to be absent in HSAN IV and temperature threshold is increased in HSAN V.

The histamine test is also a valuable diagnostic tool. This is done by injecting 0.1 ml of histamine (in a concentration of 0.275 mg histamine phosphale/ml) intradermally using a fine needle tuberculin syringe. In normal individuals, there is a bright red histamine flare (due to capillary vasodilation) within 5 min. Dyautonomic reaction demonstrates only a narrow areola surrounding the wheel. This lack of axon flare is universal and consistent in patients with HSAN II, III, and IV.

Histologic Findings

Sural nerve biopsy can indicate the diagnosis in HSAN by revealing the selective loss of particular fiber types. In HSAN I, there is reduction in the number of small myelinated and unmyelinated fibers, associated with loss of large myelinated fibers. HSAN II is characterized by severe reduction in the number of myelinated axons but unmyelinated fibers are usually normal or slightly diminished. Loss of unmyelinated and myelinated fibers in peripheral nerves, associated with decreased number of large myelinated fibers, characterizes HSAN III. Histopathological findings are striking in HSAN IV by the visual absence of unmyelinated nerve fibers in the peripheral nerves. In HSAN V, there is selective decrease in small myelinated fibers and mild reduction in unmyelinated fibers. Skin biopsy is useful in HSAN IV (congenital insensitivity to pain with anhidrosis) and shows lack of nerve fibers in the epidermis and only a few hypotrophic and uninnervated sweat glands in the dermis.

Treatment

Management of HSAN is symptomatic and preventative. Ulcero-mutilating complications are the most serious and should follow the guidelines given for diabetic foot care. Removal of pressure to ulcers, eradication of infection, and specific protective footwear are of paramount importance to avoid further complications like amputations. Careful daily inspection for unrecognized injury is important. Significant feeding problems, especially when associated with gastroesophageal reflux are managed with gastrostomy and fundoplication. The risk of aspiration pneumonia should be minimized in HSAN III by attention to posture and by meticulous precautions during feeding. Blood pressure liability (postural hypotension and hypertension) should be managed promptly. Alacrema and corneal analgesia, which predispose to corneal ulcerations, require frequent administration of topical lubricants. Control of hyperthermia in HSAN IV is important using acetaminophen and/or ibuprofen or direct cooling in a bath. Smoothing of the teeth or extraction, to prevent self-mutation of the tongue and lips, might be needed in some children. Chlorpromazine has been found to be effective in controlling bouts of rages, hyperactivity, and irritability, as well as behavior modification. Families of affected children need considerable psychological support.

Prognosis

HSAN I is a slowly progressive disease and does not influence life expectancy. Prognosis for the other congenital types is improving with time and increasing numbers of patients are reaching adulthood. This followed improved diagnosis and appropriate interventions and treatments. Understanding the pathomechanism underlying HSAN by knowing specific gene actions will have an impact on definitive therapeutic interventions.

Prevention

Prenatal diagnosis can be done in families where the diseases causing mutation is known. Nevertheless, termination of pregnancy is challenged with ethical justification, especially in HSAN I. Preimplantation genetic diagnosis is also another reproductive option following identification of the disease-causing mutation in the specific family.

373 Neuromuscular Transmission Disorders

Mustafa A. M. Salih

Congenital Myasthenic Syndromes

Definition/Classification/Etiology

Congenital myasthenic syndromes (CMSs) are a heterogeneous group of inherited disorders caused by genetic defects that affect transmission of information to muscles at the neuromuscular junction (NMJ). Based on the site and molecular mechanism of the underlying defect of neuromuscular transmission, they are classified into presynaptic, synaptic (basal lamina-associated), and postsynaptic CMS.

Epidemiology

Postsynaptic CMS are the most frequent accounting for approximately 80% of all genetically diagnosed cases. Synaptic CMS account for about 15% whereas presynaptic CMS are rare (approximately 5%). Patients with CMS are observed less frequently than those with autoimmune myasthenia gravis, but they are often misdiagnosed or remain undiagnosed for several years. Since the majority of CMS are inherited as autosomal recessive, some forms were noted to be endemic in communities of the Middle East where consanguineous marriages are relatively frequent. As of the year 2009, sodium channel entity of CMS has been reported in a single patient, whereas another form caused by a defect in muscle-specific receptor tyrosine kinase (MuSK) has been described in only two families (from France and Sudan).

Pathogenics/Pathology

In humans, the NMJ consists of a presynaptic and a postsynaptic domain separated by the synaptic cleft. A single nerve impulse triggers the release of acetylcholine (ACh) quanta within the presynaptic side into the synaptic space leading to activation of the acetylcholine receptors (AChRs) located on the postsynaptic side resulting in an endplate potential (EPP). This local depolarization of EPP is converted by voltage-gated sodium channels into a propagated action potential that activates muscle contraction. In each form of CMS, the safety margin of neuromuscular transmission is compromised by one or more mechanisms. This safely margin is a function of the difference between the postsynaptic depolarization caused by the EPP and the depolarization required to activate the voltage-gated sodium channels.

Rapsyn (receptor-associated protein at synapse) is a protein synthesized by muscle which, under the influence of agrin and MuSK, concentrates AChRs on the terminal expansion of the postsynaptic junction folds. Dok-7 (downstream of kinase 7 protein) activates MuSK and is therefore critical in endplate development and AChRs aggregation.

The AChR is a transmembrane glycoprotein ligand-gated receptor that has five subunits and is anchored to the muscle membrane and cystoskeleton by rapsyn. The adult isoform of AChR is composed of two alpha (α) subunits, and one beta (β), one delta (δ), and one epsilon (ε) subunit. In humans, the gamma (γ) subunit appears at about the ninth developmental week but is subsequently replaced by the adult epsilon (ε) subunit and is no longer present at fetal end plates after 31 weeks of gestation. Pathogenic mutations residing in different subunits of the AChR may cause *slow-channel syndrome* due to prolongation of the opening events of the AChR. This in turn prolongs the duration of the synaptic potentials and elicits a second compound muscle action potential (CMAP). The prolonged synaptic response also causes cationic overloading of the postsynaptic region resulting in degeneration and loss of the AChR from the folds. The majority of slow-channel syndrome mutations are autosomal dominant, although recessive mutations have also been described. Due to the variable penetrance and expression of the autosomal dominant mutations, they may give the appearance of a sporadic or recessive disorder. On the other hand, pathogenic mutations residing in different subunits of the ACR may cause *fast-channel syndrome* by decreasing the rate at which the channel opens or increasing the rate at which it closes. A third group of mutations

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_373,

lead to primary endplate AChR deficiency characterized by patchy and attenuated AChRs at the junctional folds.

Presynaptic defects causing CMS affect the number of molecules per synaptic vesicle, the size of a single vesicle, or the reorganization of the ACh. Choline acetyl transferase (encoded by *CHAT* gene) is the rate-limiting enzyme in the resynthesis of ACh from acetyl-coenzyme A and choline within the nerve terminal. In the synaptic space, acetylcholinesterase (AChE) hydrolyzes ACh back into choline and acetyl-coenzyme A. AChE is composed of globular catalytic subunits, which are attached to the basal lamina of the postsynaptic membrane by ColQ protein. The absence of the AChE prolongs the lifetime of ACh in the synaptic space, which increases the duration of the endplate current so that it outlasts the refractory period of the muscle fiber and excites a second CMAP. The prolonged endplate currents lead to overloading of the synaptic space with cations, resulting in endplate myopathy and loss of AChRs.

Currently, mutations in ten genes have been identified to cause CMS (Table 373.1). They are classified according to their target at the NMJ as presynaptic, synaptic (basal lamina-associated) and postsynaptic.

Clinical Manifestations: Symptoms, Signs

CMS may present in utero with history of reduced fetal movements. Some patients harboring mutations in the AChR delta subunit, or rapsyn, are born with arthrogryposis multiplex. Escobar syndrome is a prenatal myasthenic syndrome caused by recessive mutations in the fetal gamma subunit of AChR. Affected babies have characteristic facies with mild ptosis and small mouth with downturned corners. They have several musculoskeletal abnormalities including arthrogryposis multiplex, small muscle bulk, and multiple pterygia (webbing of the neck, axilla, elbows, fingers, and/or popliteal fossa), camptodactyly, and rocker bottom feet with prominent heels. Since the fetal gamma AChR subunit is replaced by the adult epsilon subunit and is no longer present at fetal endplates after 31 weeks of gestation, myasthenic symptoms are absent after birth in babies with Escobar syndrome.

During the neonatal period, babies affected with CMS may present with respiratory insufficiency, episodes of apnea, stridor due to palsy of the vocal cords, or choking spells. They are hypotonic with a feeble cry and feeding difficulties due to poor sucking. They have symmetric ptosis and their symptoms are worsened by crying. Motor milestones are usually delayed. In childhood, they may manifest with fatigable ptosis, ophthalmoparesis, dysphagia, chewing and feeding difficulties, and flaccid dysarthria. Symptoms increase by the end of the day and worsen during hot days in countries with high ambient temperature. In such a country, symptoms of these children were noticed to improve following a cold shower or afternoon nap.

Clinical examination reveals fatigable ptosis and extraocular muscle weakness (ophthalmoparesis). There is also bilateral facial weakness with tenting of lips. Dysmorphic features may be present in the form of high-arched palate and prognathism. The muscle bulk is

Table 373.1
Genes known to cause, if mutated, congenital myasthenic syndrome (CMS)

Defect causing CMS	Gene symbol	Name/function
Presynaptic defect Choline acetyltransferase deficiency	*CHAT*	Choline acetyltransferase gene
Synaptic defect (basal lamina) Endplate acetylcholinesterase (AChE) deficiency	*COLQ*	Encodes the triple-stranded collagenic tail (ColQ) of the synaptic cholinesterase
Post synaptic defect Acetylcholine receptor (AChR) mutations	*CHRNA1, CHRNB1 CHRND, CHRNE*	Genes encoding the different subunits of the AChR
Rapsyn mutations	*RAPSN*	Encodes rapsyn protein
Muscle-specific kinase (MuSK) mutations	*MuSK*	Encodes MuSK
Dok-7 mutations	*DOK7*	Encodes MuSK-interacting cytoplasmic protein Dok-7
Sodium channel mutations	*SNA4A*	Encodes sodium channel SCN4A

reduced (muscle hypotrophy) and they may have scoliosis or lordosis (which increases on standing) manifesting later in life. Characteristically, the weakness in slow-channel CMS involves muscles of the neck and distal regions of the upper limbs (especially intrinsic hand muscles and digit extensors) more prominently than other regions. Patients with endplate AChE deficiency may have, as well, slowed pupillary responses to light and prominent respiratory crises.

Family history may reveal affected siblings in autosomal recessive disorders or generational transmission in the autosomal dominantly inherited slow-channel CMS. There may also be history of spontaneous abortions or sudden infant death syndrome.

Diagnosis

The diagnosis of CMS can be confirmed by three main types of investigations:

1. The edrophonium chloride (Tensilon) test is the principal test used to confirm the diagnosis of myasthenia. Edrophonium is an AChE inhibitor with very short action. Because serious respiratory or cardiac complications may rarely occur, resuscitation equipment and a nurse should be present before starting the test. Also an intravenous (IV) line should be established prior to the test. Subcutaneous atropine before edrophonium chloride injection neutralizes the muscarinic cholinergic effects of the drug, which include increased oral and bronchial secretions, bradycardia, abdominal cramps, and red, watery, painful eyes. The dose varies with age, ranging between 1 mg in infants and 8 mg in older children. A test dose of 1 or 2 mg is given first. This is because some patients may have severe muscarinic side effects to even a small dose of edrophonium. The rest of the dose can be given IV over 30–60 s periods if there is no response. Taking serial photographs of the child before and 1 min after injection, or video, allows objective documentation of any change. Intramuscular neostigmine (0.04 mg/kg, up to 1.5 mg total in an older child) may also be used. The effect is slower, starting after 10–15 min and reaching a maximum at 30 min (*Fig. 373.1a, b*). In CMS patients, the edrophonium or neostigmine test is usually positive except in endplate AChE deficiency (*COLQ*-mutant CMS), and in some cases of *slow-channel syndrome*, *DOK7*- and *MuSK*-mutant CMS.

In CMS, serological tests for circulating antibodies directed against AChR, MuSK are negative and help to rule out the autoimmune myasthenia gravis. Tests to exclude botulism may also be required in some infants.

Neurophysiologic Tests

While performing nerve conduction studies (NCSs), repetitive stimulation of nerves at 2–3 Hz will induce a decrement of greater than 10% of the fifth compared to the first-evoked CMAP in multiple muscles, especially those with significant weakness (see Fig. 368.1b of Chap. 368, "Approach to Diagnosis and Treatment of a Child with Motor Unit Diseases"). Single nerve stimulation of rested muscles typically shows repetitive (or double) CMAP in cases of slow-channel syndrome and in endplate AChE deficiency. Needle electromyography (EMG) helps to differentiate congenital myasthenia from myopathies and other neurologic disorders. If repetitive nerve stimulation (RNS) studies fail to show decremental response, then single fiber EMG study is needed. This demonstrates increased "jitter" in contraction of pairs of fibers. As a diagnostic tool, single fiber EMG is more sensitive than NCS, but is difficult to perform in children and is not available in many hospitals.

Differential Diagnosis

CMS appearing during the neonatal period or infancy should be differentiated from other causes of the floppy infant syndrome, as has been detailed in the subchapter on Floppy Infant Syndrome. Extraocular muscle involvement in CMS may also simulate the manifestations of brainstem anomalies, Moebius syndrome, and congenital fibrosis of the extraocular muscles (cranial dysinnervation syndromes). Transient neonatal myasthenia gravis, in infants born to myasthenic mothers, and infantile botulism should always be entertained since they are treatable.

When manifesting in later childhood, AChR or MuSK-seropositive and seronegative autoimmune myasthenia gravis should be considered first. Other important diseases to consider include mitochondrial myopathy and fascioscapulohumeral muscular dystrophy. Slow-channel CMS may simulate radial nerve palsy or peripheral neuropathy.

Treatment

In CMS, there is either decreased or increased synaptic response to ACh. Anti-AChE drugs, which increase the number of AChRs activated by each quantum of ACh, are used in the forms of CMS where there is reduced synaptic

response. Another useful drug is 3,4-diaminopyridine (3,4-DAP), which increases the number of quanta released by nerve impulse. When there is increased synaptic response, as in slow-channel CMS, blockers of the AChR channels: quinidine and fluoxetine are used instead. Acetycholinesterase (AChE) inhibitors (pyridostigmine and neostigmine) are contraindicated in endplate AChE deficiency since they can result in serious complications leading even to fatal outcome. Their long-term use is also harmful in Dok-7 myasthenia and in slow-channel syndrome.

The two commonly used anti-AChE medications are pyridostigmine bromide (Mestinon) and neostigmine bromide (Pyridostigmine). Pyridostigmine acts within 45 min and its effects last from 3 to 6 h. It is less likely to cause muscarinic side effects (diaphoresis, nausea, vomiting, abdominal cramps, bradycardia, and myosis), and may be more effective in controlling bulbar weakness than neostigmine bromide (Pyridostigmine).

Pyridostigmine bromide (Mestinon) is available in 60 mg tablets and as syrup containing 12 mg/ml. The pediatric oral dose ranges between 1.0 and 7.0 mg/kg/day given in divided doses every 4–6 h.

When given orally, neostigmine bromide (Pyridostigmine) acts within 30 min and its effects last for 3–4 h. It is available in 15 mg tablets, and one tablet is equivalent to 60 mg tablet of pyridostigmine bromide (Mestinon). The recommended dose in infants and children is 2 mg/kg/day in divided doses (taken every 3–4 h). Muscarinic side effects can be alleviated by concurrent administration of atropine or glycopyrrolate. Neostigmine methylsulfate is available for intramuscular or intravenous injections. The recommended parenteral dose is 0.01–0.04 mg/kg every 3–4 h.

The adrenergic agents ephedrine and albuterol show positive effects in different forms of CMS such as AChE deficiency and Dok-7 deficiency. In patients seen and followed by the author, ephedrine positively transformed the life of two patients with *COLQ*-mutant CMS, but had severe side effects in a patient with MuSK mutation, who developed respiratory failure during an episode of pneumonia.

In children, the dose of ephedrine is 3 mg/kg/day in three divided doses. It is usually started as 1 mg/kg/day and is increased with caution. Side effects include nervousness, insomnia, palpitation, and hypertension. The dose of albuterol is 2 mg given three to four times daily in children aged 6–12 years and 0.1 mg/kg three times daily in children aged 2–6 years.

Both quinidine sulfate and fluoxetine are long-lived, open-channel blockers of the AChR. They are used only in the slow-channel CMS and are contraindicated in all other types of CMS. The dose of quinidine sulfate is 15–60 mg/kg/day in children, given in four to six divided doses. Side effects include gastrointestinal symptoms (diarrhea), hypersensitivity symptoms, cardiac conduction defects, including aggravation of a prolonged QT interval, and inhibition of cytochrome P450IIDA, which impairs several metabolic pathways. In contrast to quinidine sulfate, fluoxetine is eliminated more slowly, but the dose in children has not been established yet.

Prevention

Drugs known to cause NMJ block should be avoided by CMS patients. These are detailed in *Table 373.2*. Prenatal diagnosis for pregnancies at increased risk for CMS is possible by chorionic villus sampling (at 10–12 weeks of gestation) and by amniocentesis (by about 15–18 weeks). Preimplantation genetic diagnosis may be available for families in which the disease-causing mutations have been identified.

Table 373.2
Medications that may adversely affect neuromuscular transmission

Groups/drug effect	Drugs (other uses)
Antibiotics	
Aminoglycosides	Gentamicin, kanamycin, streptomycin, neomycin, tobramycin
Macrolides	Erythromycin, azithromycin, telithromycin
Fluoroquinolones	Ciprofloxacin, levofloxacin, norfloxacin
Antiarrhythmics	Quinine (also used for treating malaria), quinidine, procainamide, lidocaine, trimetaphan, beta-adrenergic blockers
Miscellaneous	
Drugs with ion channel effects	Chloroquine (used for treating malaria), phenytoin (anticonvulsant), magnesium salts

Myasthenia Gravis

Definition/Classification

Myasthenia gravis is an acquired autoimmune disorder characterized clinically by weakness and increased fatigability on muscular exercise. On the basis of the distribution and severity of weakness, a grading system was recently adopted by the Myasthenia Gravis Foundation of America to help in patient management and for use in therapeutic research trials. Class I is when the disease is ocular, Classes II, III, and IV when it is mild generalized, moderate generalized, or severe generalized, respectively. These three classes are designated IIa, IIIa, or IVa,respectively, when the weakness predominantly involves the limb and/or axial muscles. Subclasses IIb, IIIb, and IVb refer to weakness predominantly affecting oropharyngeal and/or respiratory muscles and when there is a need to use a feeding tube. Class V is defined by the need for intubation, with or without mechanical ventilation, except when used during routine postoperative management.

Etiology

Myasthenia gravis is idiopathic in most patients and is considered to be the prototype of autoimmune antireceptor antibody disorders. The disease is caused by autoantibodies directed against epitopes on or around the AChR in the muscle membrane.

Epidemiology

Because of improved survival and the availability of more effective therapies, estimates for prevalence rates have progressively increased over the years. The most recent prevalence estimate is 1 per 10,000, and approximately 10% of all cases of myasthenia gravis occur during childhood. The disease has a bimodal distribution, between 15 and 30 years old or between 60 and 75 years old.

Pathogenesis and Pathology

Myasthenia gravis results from disruption of the normal neuromuscular transmission by the binding of autoantibodies to proteins involved in signaling at the NMJ. These antibodies are directed against the AChR in 80–85% of cases. The loss of functional AChRs is caused by one of three mechanisms. Rarely, these antibodies attach to ACh binding sites leading to blockade of the AChR. More frequently, there is complement-mediated lysis of the muscle end plate, triggered by the autoantibody response, leading to distortion and simplification of the postsynaptic muscle membrane. A third mechanism is through accelerated internalization and degeneration of the AChRs as a result of cross-linkage of AChR by immunoglobulin G (IgG)

Between 40% and 70% of patients who are seronegative for anti-AChR antibodies have detectable antibodies directed against the MuSK. MuSK plays a critical role in postsynaptic differentiation and clustering of AChRs, resulting in reduced numbers of functional AChRs at the NMJ.

The role of the thymus gland in myasthenia gravis is incompletely understood. Nevertheless, most patients with myasthenia gravis have thymic abnormalities. Thymic tumor is found in 10–15%, and 70% of those without tumor demonstrate lymphoid follicular hyperplasia, especially younger patients and HLA-DR3 positive females. Patients with anti-MuSK myasthenia gravis are less likely to have thymic hyperplasia and rarely have thymoma. Muscle histology may show denervation atrophy in cases of longstanding disease, as well as focal collections of small lymphocytes (lymphorrhages) around necrotic fibers.

Clinical Manifestations

The onset of symptoms is always after 1 year of age and young adolescent females predominate. Initially, the symptoms involve the ocular muscles in up to 85% of patients with myasthenia gravis. This manifests as unilateral asymmetric ptosis, intermittent diplopia, or both. Drooping of the eyelid varies during the course of the day, often worsening after exercise, reading, or exposure to direct sunlight. In 20–40% of patients, weakness remains limited to the extraocular muscles. The majority of others develop the *generalized form* with extension of the weakness to proximal limbs and bulbar muscles. Involvement of the lower limbs is less common and may cause diagnostic difficulties. Early in the course of myasthenia gravis, 20% of patients may have prominent oropharyngeal symptoms, including dysarthria, dysphagia, and difficulty chewing. This percentage is higher in anti-MuSK-positive myasthenia gravis where it may be present with minimal associated ocular symptoms. Dysarthria becomes worse with prolonged talking, and weakness of palatal muscles may result in nasal quality of the voice. Dysphagia may be limited to difficulty with solid foods in mild cases, and nasal regurgitation of liquids and aspiration indicate severe disease. The majority of patients with

respiratory muscle weakness have associated ocular and bulbar involvement. Orthopnea is an early symptom of diaphragmatic weakness, and shallow rapid breathing is indicative of respiratory muscle weakness. In rare cases, weakness may not be focal, that is, affecting distal limb muscles or neck extensors. Affected children feel normal on awakening and by the evening, they may have difficulty chewing and choke on food.

Signs

Characteristic signs of myasthenia gravis include ptosis, ophthalmoparesis, bulbar weakness, and fatigable limb muscle weakness. The eyelid elevators are involved to different degrees, and the pattern of extraocular muscle weakness is typically asymmetric, with the medial rectal muscle being most severely affected followed by the superior and lateral rectus muscles. Pupillary responses are normal. Sustained upward gaze for 30–60 s enhances ptosis and elicits medial rectus weakness. Ptosis may improve following local cooling of the lid. Involvement of the facial muscles is characterized by loss of facial expression and elevation of the eyebrows by contracting the frontalis muscle in an attempt to compensate for ptosis. When asking the patient to smile, weakness of the orbicularis oris produces the characteristic myasthenic snarl. Patients also have difficulty in pursing the lips and weakness of the buccinators leads to difficulty in puffing their cheeks.

Patients with bulbar symptoms may develop nasal speech, and labial and lingual dysarthria when asked to count up to 50. Those with dysphagia should be examined for palatal weakness. Difficulty in chewing is associated with weakness of jaw closure due to masseter and temporalis muscle weakness. This is tested by attempting to separate the clamped jaws by applying downward pressure on the chin for a period of 30 s. Even with relatively severe weakness of the masseter muscles, weakness of jaw opening due to pterygoid muscle weakness is rarely seen in myasthenic gravis.

A patient with weak respiratory muscles may look anxious and have tachypnea associated with shallow breathing. Inspiratory muscle strength can be assessed by asking the patient to inspire forcefully and loudly through the nose (inspiratory sniff). Expiratory muscle function can be assessed by asking the patient to cough or clear his throat. If the diaphragm is weak, the abdominal contents will be pushed upward and there will be no outward protrusion of the abdomen against the examiner's hand. Patients with weak respiratory muscles often have an associated weakness of neck flexion or extension.

Weakness may be limited to the neck flexors when the disease is mild, typically with weaker neck flexion than extension. Isolated neck extensor weakness may be the presenting sign in MuSK-antibody positive myasthenia gravis. In the upper limbs, finger and wrist extensors are most likely to be affected, whereas the foot dorsiflexors and hip flexors are most frequently involved in the lower limbs. Fatigable muscle weakness may be demonstrated by asking the patient to sustain abduction of the arms for 2 min. This results in either the patient becoming unable to hold the arms up, or weakness becomes apparent with subsequent manual testing. The lower limbs can be similarly tested by sustained elevation of leg for 90 s while lying supine. Repeated arising from a low chair (up to 20 times), without using the arms, is capable of testing hip extensor muscle fatigue.

Diagnosis

Autoimmune myasthenia gravis is confirmed by pharmacologic, electrophysiologic, and immunologic tests.

Bedside testing using edrophonium chloride (Tensilon) has a sensitivity of 60–95% in patients with significant ptosis or ophthalmoparesis (*Fig. 373.1c, d*). Nevertheless, the results are subjective and require a carefully performed and judiciously interpreted examination. The protocol for the test is similar to that described previously for congenital myasthenic syndrome. Application of an ice pack locally to a ptotic eyelid may improve ptosis. This adjunctive diagnostic test has a sensitivity of 89% and is particularly helpful if the edrophonium test is contraindicated or not available.

Neurophysiologic tests consist of RNS of a selected peripheral nerve (typically at a frequency of 2–5 Hz) while recording the compound motor action potential (CMAP) produced by the resulting recurrent contractions of selected muscle innervated by that nerve. Characteristically in myasthenia gravis, a decremental response of at least 10% occurs, similar to that observed in CMS (see Fig. 368.1b of Chap. 368, "Approach to Diagnosis and Treatment of a Child with Motor Unit Diseases"). RNS is more likely to be abnormal in clinically weak muscles. The diagnostic sensitivity of RNS ranges between 53% and 100% in generalized form, and 10–17% in ocular myasthenia gravis.

Single fiber EMG is performed when RNS is normal, despite high suspicion of NMJ disorder, as has been previously detailed in the investigations for congenital myasthenic syndromes. It has a sensitivity of 95% or greater in generalized and 90% or greater in ocular myasthenia gravis, when appropriate muscles are tested.

Figure 373.1
Neostigmine test in a child with congenital myasthenic syndrome. (a) There is bilateral ptosis and partial ophthalmoparesis on attempted looking to the right, upwards and to the left. (b) Dissapearance of ptosis and remarkable improvement in ocular motility following neostigmine administration. (c) Bilateral ptosis and ophthalmoparesis in myasthenia gravis. The patient was asked to look at the pen to his right side. Note also the remarkable facial weakness and open mouth. (d) Positive edrophonium chloride (Tensilon) test. Part of the rescuscitation equipment appears behind the patient

Nevertheless, the specificity of this technique is limited since abnormal results can be obtained in a variety of neuromuscular diseases.

Immunologic tests include assay of antibodies that react with AChR proteins. The AChR-binding antibody assay is the most widely used diagnostic test for myasthenia gravis. Anti-AChR-antibodies are detected in 80–85% of patients with generalized myasthenia gravis but only in 55% with purely ocular symptoms. Serum concentration of AChR-binding antibodies cannot reliably predict the severity of disease in individual patients, but tends to decline in successfully treated patients.

Approximately 40% of patients with anti-AChR-antibody negative (seronegative) generalized myasthenia gravis have anti-MuSK antibodies. They may represent a distinct group of autoimmune myasthenia gravis with some characteristics, as a group, that differentiates them from AChR-positive patients.

Since myasthenia gravis often coexists with autoimmune disorders, particularly thyroid disease, testing of thyroid function and antibodies should be arranged. Other autoimmune serologic tests should be considered if clinically indicated.

Differential Diagnosis

The differential diagnosis of myasthenia gravis includes other neuromuscular disorders in which fatigability can sometimes be marked. Seronegative myasthenia gravis may be difficult to differentiate from CMS. Nevertheless, the onset of CMS is in infancy or early childhood and on NCSs, repetitive CMAP can be detected in certain forms (see above). Botulism is characterized by ptosis and ophthalmoplegia, but there is a rapid descending pattern of disease progression associated with pupillary and

autonomic involvement. NCSs reveal low-amplitude CMAP. Mitochondrial disorders are characterized by more gradual onset with no fluctuation of symptoms. There is often no diplopia despite severe ophthalmoplegia. RNS does not show decremental response, as in myasthenia gravis, but single fiber EMG may be mildly abnormal. Structural lesions of the midbrain such as tumors may present with fatigable ptosis and ophthalmoplegia, but careful neurological examination reveals additional defects. MRI brain demonstrates the brainstem lesion.

Treatment

The aims of treatment are to improve neuromuscular transmission, through the use of AChE inhibitors, and to prevent continuing immunological interference with synthesis, maintenance, and catabolism of AChRs by immunomodulating therapy, plasma exchange (plasmapheresis), or thymectomy.

The AChE inhibitor pyridostigmine may be initiated at a dose of 0.5–1.0 mg/kg every 4–6 h with a maximum dose of 7 mg/kg/day. The short-acting AChE inhibitor neostigmine (Pyridostigmine) should be used only if pyridostigmine is unavailable. Details of the use of these medications and their side effects have been mentioned earlier.

Corticosteroids were the first immune-directed therapy for myasthenia gravis and they are the most commonly used therapy today. Their dramatic efficacy since their use in the early 1970s resulted in widespread adoption before placebo-controlled studies could be initiated. Nevertheless, most experts consider corticosteroids a mainstay of therapy for myasthenia gravis. They are indicated when generalized or ocular symptoms of myasthenia gravis are not adequately controlled by AChE inhibitors alone. Long-term treatment with corticosteroids may induce complete remission or cause marked to moderate improvement in most patients.

No single regimen is internationally accepted for corticosteroid treatment of myasthenia gravis. Some use high doses initially to achieve quicker response; others start with low dose and increase gradually. In the high-dose regimen (used in many centers including the author's), prednisone is given in a dose of 1–2 mg/kg/day over several (usually 2–3) months until a positive response is obtained. The patients are then switched to an alternate-day regimen until a good response is sustained, followed by progressive tapering. Transient exacerbation of myasthenic symptoms is not rare at the beginning of high-dose steroid therapy. It has been reported to occur in approximately one-third to one-half of patients, with the severity of weakness requiring intubation in about 9%. Hence, it is advisable that the patients be hospitalized for 5–7 days during initiation of the high-dose daily prednisone, especially when there is significant oropharyngeal or respiratory symptoms. Following admission, the patients also receive intravenous immunoglobulin (IVIG) as a short-term immune-directed therapy, known to prevent steroid-induced exacerbation. In ocular or mild generalized myasthenia gravis, a lower initial dose of prednisone (30–40 mg/day) may be as effective in producing marked improvement or remission. Other centers prefer to use gradually intermittent doses of prednisone on an alternate-day therapy regime until an effect is obtained, then maintaining the effective dose for 3 months before tapering. High-dose pulses of methylprednisolone have been used successfully in children with refractory disease.

The second most commonly used immunosuppresive medication in myasthenia is azathioprine (Imuran), either in conjunction with steroids or in isolation. Patients receiving azathioprine had fewer relapses and a higher incidence of remission. They could also be maintained on a lower prednisolone dose, but these beneficial effects were not seen for 18 months. Hepatotoxicity and leukopenia are important adverse effects but are reversible if the dose of azathioprine is adjusted or discontinued. Cyclosporine has been used mainly as a steroid-sparing agent in patients in whom azathioprine is either ineffective or not tolerated. The most significant side effects are hypertension and nephrotoxicity. The risk of certain malignancies (melanoma, lymphoma) may be increased with long-term use.

Plasma exchange (plasmapheresis) is another modality of short-term immune-directed therapy that is used during myasthenic crises or in patients who have experienced sudden worsening of myasthenia gravis. It is also used in combination with high-dose daily prednisone to prevent steroid-induced exacerbation. A third indication is prior to surgery, especially thymectomy, to achieve rapid postoperative recovery and to shorten the period of assisted ventilation. Plasma exchange reduces the levels of circulating antibodies, and produces improvement within days but this usually begins to wear off after 3–4 weeks. Its availability is restricted to major medical centers and the frequent need for large-bore venous catheter makes it difficult to perform in young children. It can also reduce coagulation factors, particularly with repeated daily treatments, leading to bleeding tendencies.

IVIG was found in randomized controlled trials to have comparable efficacy in treatment response compared to plasma exchange. Its indications are similar to those of

plasma exchange, namely, to induce rapid improvement in patients with severe disease or crises, prior to surgery (thymectomy) for the reduction of perioperative morbidity, and as chronic therapy in selected refractory cases. It is also used during initiation of a high-dose daily prednisone regimen of therapy to prevent steroid-induced exacerbation. Weakness usually improves within 7–10 days and lasts for 4–8 weeks. The dose of IVIG is 2 g/kg in the initial course, divided over 2–5 days depending on patient age, ability to tolerate the volume load and renal function. Maintenance doses for selected refractory patients range from 0.5 to 1 g/kg usually on a monthly basis. The side effects of IVIG have been detailed in the subchapter ◉ Guillain–Barre Syndrome.

Thymectomy has been proposed as first-time therapy in most patients with generalized myasthenia gravis, and is definitely indicated in the presence of thymoma, which is observed in approximately 10–20% of adult patients (mean age of 50 years). The mechanism through which thymectomy works in nonthymomatous myasthenia gravis remains controversial. Nevertheless, it frequently results in significant and lasting improvement in children, although long-term immunosuppressive therapy remains necessary in many cases. In juvenile onset myasthenia gravis (onset 12–18 years), the remission rate increased significantly: up to 60% of those who had thymectomy compared to 29% in a group of nonoperated patients. In a collaborative study involving patients followed by the author, 30 children with myasthenia gravis (aged 4–16 years) had thymectomy. These had mild, moderate, or severe generalized weakness. Complete remission was noted in 43% and improvement in about 47%. Remission rate was 33% at 3 years and about 47% at 5 years of follow-up. Although controversy exists regarding the preferred surgical approach, transcervical–transternal "maximal" thymectomy is adopted in many centers to assure complete resection of all thymic and ectopic thymic tissues. In the above-mentioned study, the presence of ectopic thymic tissue was a significantly poor prognostic factor for outcome of surgery. Thymectomy may be the treatment of choice for children because of the possible side effects of prolonged treatment with AChE inhibitors or immunosuppressants. Even in the absence of complete remission, most patients benefit from thymectomy by way of improvement of their symptoms or reduction of their medications, especially steroids. Thymectomy has been performed with reported favorable results even in patients less than 5 years, including some followed by the author. Currently, there is an ongoing international, prospective, single-blinded, randomized trial of thymectomy (controlling for medical therapy) in nonthymomatous myasthenia gravis.

In ocular myasthenia gravis, AChE inhibitors may control symptoms adequately in some patients, but the benefit is often partial and not maintained and prednisone is often quite effective. Thymectomy is not considered in purely ocular myasthenia gravis.

Myasthenia gravis with anti-MuSK antibodies often manifest with prominent axial, bulbar, and respiratory muscle weakness, and up to 70% of patients were reported to have poor response to AChE inhibitors. In small series, a dramatic response to azathioprine and IVIG has been reported. Effective therapies (other than plasma exchange) included prednisone, cyclosporine, mycophenolate mofetil, and rituximab. Thymectomy is questionable in patients with anti-MuSK antibodies because their thymic tissue lacks the hyperplastic changes seen in patients with anti-AChR-antibodies.

Prognosis

Recent advances in intensive care and immunotherapy have contributed to significantly favorable outcome for myasthenia gravis in most patients. Untreated myasthenia gravis carries a mortality rate of 25–31% and with recent treatment the mortality rate has declined to about 4%. The natural course of juvenile myasthenia gravis is variable and is generally slowly progressive with marked fluctuations. The disease may remain limited to the extraocular muscles in 20–40%. Myasthenic crises, occurring spontaneously or following febrile illnesses, may require assisted ventilation and are potentially fatal. Spontaneous remissions were reported in 30% of children with myasthenia gravis after a 15 year follow-up. Nevertheless, remission rate was significantly lower in patients with extremity weakness.

Prevention

Numerous medications have been reported to worsen preexisting myasthenia gravis and induce myasthenia in previously asymptomatic patients. Drugs that are absolutely contraindicated include curare and related drugs, D-penicillamine, interferon alpha, and botulinum toxin. Caution should also be taken when using certain drugs that may exacerbate weakness in some patients with myasthenia gravis. These include beta-blockers, calcium channel blockers, iodinated contrast agents, lithium, and statin drugs. Other contraindicated drugs known to affect neuromuscular transmission have been detailed in ◉ *Table 373.2*.

Fetal and Transient Neonatal Myasthenia Gravis

In myasthenic mothers, a variety of AChR and other antibodies are transferred to the fetal circulation through the placenta, beginning at 20 weeks of gestation, and are present in the amniotic fluid. The sequelae of these maternal pathogenic autoantibodies may manifest in utero, producing reduced fetal movements, polyhydramnios, arthrogryposis, and stillbirth. Approximately 10–20% of infants born to myasthenic mothers are affected by transient neonatal myasthenia gravis, which may occur in both anti-AChR-positive and anti-AChR-negative mothers.

The onset of symptoms is usually delayed to a few hours after birth and may be up to 3 days. Affected babies show the classical features of the floppy infant syndrome with hypotonia and weakness. They have poor crying, feeding difficulties due to poor sucking and/or swallowing, and facial diplegia. Ptosis is present in only a minority of cases. Some infants may have respiratory distress requiring mechanical ventilation.

The diagnosis is easy, if the mother is known to have myasthenia gravis, and may be difficult if the mother had latent disease, as has been observed in some cases. Confirmation is by intramuscular or subcutaneous injection of neostigmine. NCSs can also be done to look for decremental response. Nevertheless, it is painful and technically difficult to perform at this age.

Treatment is supportive including nasogastric tube feeding and ventilatory support, if needed. Exchange transfusion may be indicated in severe cases with respiratory distress and/or profound hypotonia. Pyridostigmine (0.5–1.0 mg/kg) administered in divided doses 30 min prior to feeding may be useful. Alternatively, neostigmine in a dose of 0.1 mg prior to feeding (adjusting the dose according to need) is often sufficient to permit adequate nutrition. Affected neonates need to be monitored for respiratory failure for 1–2 weeks after birth. Marked hypotonia and weakness may persist beyond the first 3 or 4 weeks in some atypical cases.

Congenital Myopathies

Definition/Classification

The congenital myopathies (CM) are a heterogeneous group of inherited neuromuscular disorders characterized by distinctive and specific morphologic abnormalities in skeletal muscle on light and/or electron microscopy as the main pathological feature. Their onset is typically at birth or in the first years of life with delayed milestones. Within each subgroup, there is wide variation in clinical severity, including onset in childhood or in adulthood. Based on genetic and morphological features, they are divided into 4 main groups and 11 subgroups (*Table 374.1*).

Epidemiology

The exact incidence of CM is unknown because many cases are either not recognized or muscle biopsy is not performed. The incidence of all CM is estimated to be about 0.06/1,000 or one-tenth of all cases of neuromuscular disorders. Studies from western Sweden and Ireland suggest a prevalence of 3.5–5.0/100,000 in the pediatric population.

Pathogenesis

Mutations in genes that encode for muscle proteins have been identified in the various forms of CM (*Table 374.1*). The specific morphological features of muscle biopsy samples may have resulted from loss or dysfunction of these proteins. Some CM are genetically heterogeneous, others exhibit phenotypic homogeneity. Mutations in at least six genes cause nemaline myopathy. Several others cause core pathology and congenital fiber type disproportion. But, mutations in β-tropomyosin can cause nemaline myopathy and cap disease; and mutations in selenoprotein N1 can manifest as multiminicore disease and congenital fiber type disproportion, as well as dystrophic pathology.

Pathology

In CM, muscle pathology is the mainstay of diagnosis, provides insight into pathogenic mechanisms of each subtype, and also guides molecular testing.

Muscle enzyme histochemistry reveals rods, which are the pathological hallmark of nemaline rod myopathy. These are only visible on modified Gomori trichrome (GT) stain as dark purple/red structures (*Fig. 374.1a*).

They are usually subsarcolemmal but may be intranuclear. Electron microscopy shows that the rods (which are derived from the Z-line) are often in continuity with it. Hyaline bodies, which characterize myosin storage myopathy, are subsarcolemmal areas, which are devoid of sarcomeres. They stain pink on hematoxylin and eosin (H&E) and pale green on modified GT staining. Reducing body myopathy is characterized by the presence of round or polymorphic inclusions that stain pink with H&E and purple with modified GT. Central core disease (CCD) is characterized by the presence of clear central areas devoid of oxidative enzyme activity and remarkable type 1 fiber predominance (*Fig. 374.1b*). Electron microscopy shows that the cores are devoid of normal muscle fibrils and of mitochondria and reveals disorganization of myofilaments. On the other hand, multiminicore disease is characterized by the presence of multiple areas of sarcomeric disorganization associated with diminished oxidative activity (*Fig. 374.1c*). They differ in their morphology from central core by the presence of multiple small lesions within one muscle fiber and by never extending the length of the muscle fiber. Other features may include type 1 fiber predominance and increased internal nuclei.

Salih myopathy is characterized by the presence of minicore-like lesions, abundant centrally located nuclei, and remarkable type 1 fiber predominance in muscle biopsies obtained in early childhood (*Fig. 374.1d*). Dystrophic lesions of variable severity are seen in muscle specimens taken in the second decade.

Most fibers in myotubular myopathies are small and round, resembling fetal myotubes, which normally have central nuclei. These central nuclei are large, and there is also predominance of type 1 fibers. Small type 1 muscle fibers (at least 12% smaller in diameter than type 2 fibers)

Table 374.1
Genetic and morphological classification of congenital myopathies

	Gene	Inheritance	Protein
Myopathies with protein accumulation			
Nemaline myopathy	*ACTA1*	AD or AR	Skeletal ∝-actin
	NEB	AR	Nebulin
	TPM3	AD	∝-tropomyosin
	TPM2	AD	β-tropomyosin
	TNNT1	AR	Troponin T
	CFL2	AD	Cofilin – 2
Myosin storage myopathy (hyaline body myopathy)	*MYHZ*	AD	Slow/β-cardiac myosin heavy chain
Cap disease	*TPM2*	AD	β-tropomyosin
Reducing body myopathy	*FHL1*	XLD/R	Four and a half lim domain-1 protein
Myopathies with cores			
Central core disease	*RYR1*	AD or AR	Ryanodine receptor
Core-rod myopathy	*RYR1*	AD	Ryanodine receptor
Multiminicore disease	*SEPN1*	AR	Selenoprotein N1
	RYR1	AD, AR	Ryanodine receptor
Salih myoapthy (congenital myopathy and fatal cardiomyopathy)	*TTN*	AR	Titin
Myopathies with central nuclei			
Myotubular myopathy	*MTM1*	XLR	Myotubularin
Centronuclear myopathy	*DNM2*	AD	Dynamin 2
	B1N1	AR	Amphiphysin
	RYR1	AD	Ryanodine receptor
Myopathies with fiber-size variation			
Congenital fiber type disproportion	*ACTA1*	AD	Skeletal ∝-actin
	SEPN1	AR	Selenoprotein N1
	TPM3	AD	∝-tropomyosin

AD autosomal dominant, *AR* autosomal recessive, *R* recessive, *XLD* X-linked dominant, *XLR* X-linked recessive

characterize congenital fiber type disproportion. Type 1 fiber predominance and reduced or absent type 2B fibers are common features.

Clinical Manifestations

Nemaline myopathy is classified on the basis of age at onset and severity, and distribution of muscle weakness. The mild or typical congenital form of nemaline myopathy is probably the most common. Onset is within the first year with hypotonia, feeding difficulty, and generalized limb weakness. Patients usually have elongated, myopathic, expressions face, tent-shaped mouth, high-arched palate, and retrognathia due to abnormal muscle stresses on the developing mandible (*Fig. 374.1e*). Progression of the disease is either very slow or static, and patients can lead an independent life if stabilized. The severe congenital form (and probably most uncommon) can start in utero, leading to fetal akinesia sequence and polyhydramnios.

Affected babies may die in utero or are born with severe respiratory failure, no antigravity limb movement, and generalized arthrogryposis. Bulbar weakness causes poor feeding and recurrent aspiration, and early mortality is common. The intermediate congenital form presents in early childhood with weakness and delayed milestones followed by contractures. The childhood-onset form manifests with distal leg weakness in the late first or early second decade, with later involvement of the proximal muscles. The adult-onset form presents between 20 and 50 years of age.

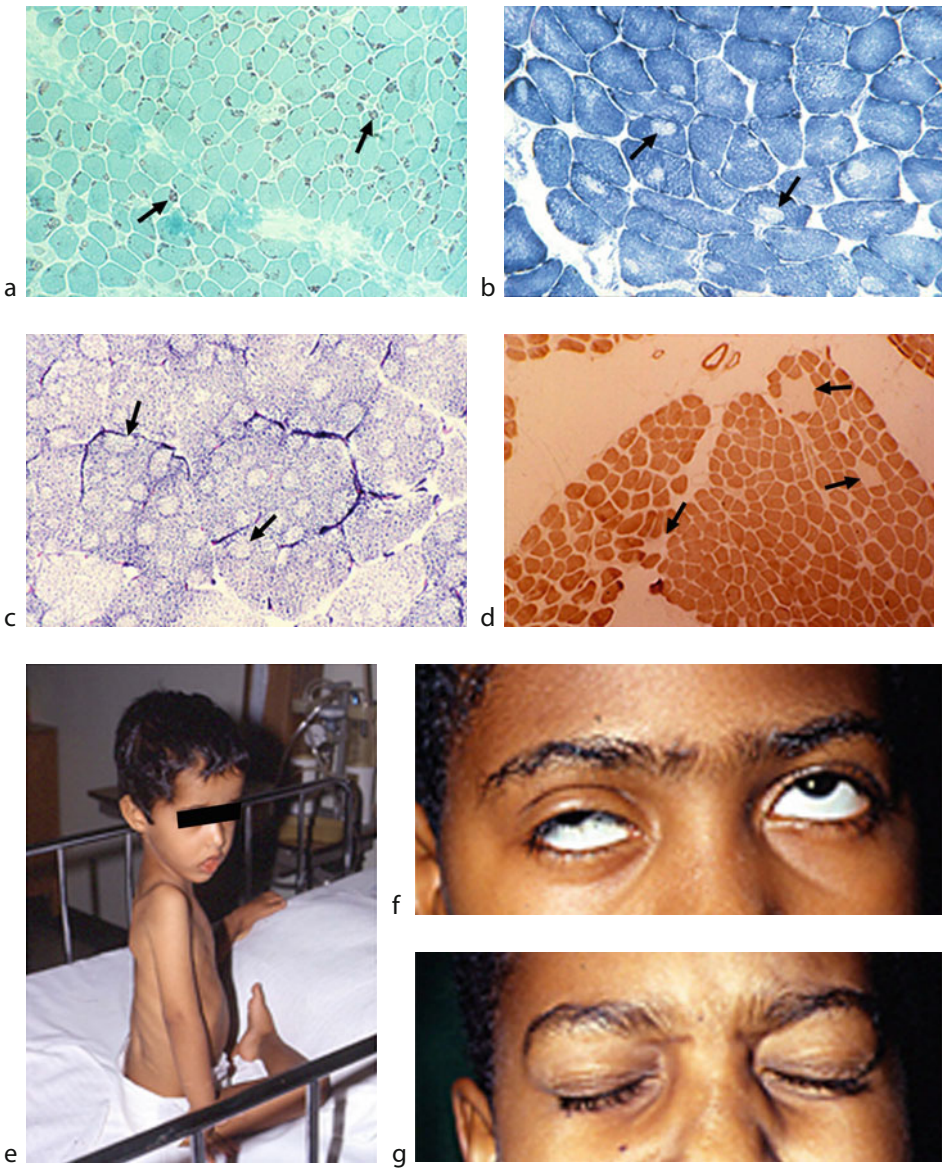

Figure 374.1

Muscle biopsy specimens in congenital myopathies showing (a) nemaline rods (arrows) typical of nemaline myopathy, (b) central cores characteristic of central core disease (arrows), (c) minicores (arrows) in multiminicore disease and (d) type I fibre predominance (dark brown fibres) over type II fibres (pale fibres, arrows) in Salih myopathy. (e) Nemaline myopathy. Note the micrognathia, elongated face, thin slender muscles and hypotonic posture of the lower limbs. (f) Asymmetric ptosis in a patient with Salih myopathy, and (g) bilateral facial weakness of his elder brother revealed by inability to bury the eyelashes on attempted tight closure of the eyes

Older children with nemaline myopathy are usually slender. All skeletal muscles, including the diaphragm, can be affected. Nevertheless, the proximal limb muscles are most severely affected and manifest as a wadding gait in ambulant patients. In congenital nemaline myopathy, respiratory involvement is virtually universal. It is also frequent in patients with onset later in life. Chest deformity may be observed at birth or develop later with age. Cor pulmonale, secondary to the associated respiratory complications, is the most common cardiac complication

of nemaline myopathy. Hypertrophic and dilated cardiomyopathy may also occur. The development of distal and large-joint contractures is common with increasing age, although joint hypermobility may be seen in hypotonic infants and children. Scoliosis is also common with advancing age, and the rigid spine syndrome is occasionally seen. Cognition and central nervous system functions are usually normal in nemaline myopathy. However, the autosomal recessive variant due to mutation in the gene for troponin T, described only in the Old Order Amish, is characterized by jaw and limb tremors starting in the first few months of life and resolving over a few months.

The onset of *myosin storage myopathy* (*hyaline body myopathy*) is in infancy or childhood with variable penetrance. Some patients may even be asymptomatic in the fifth decade of life. The distribution of muscle weakness can be proximal, distal and proximal, or scapuloperoneal, with very slow or minimal progression in the majority of cases. Cardiac arrhythmias may be present in some cases.

The childhood-onset phenotype of the X-linked recessive or dominant *reducing body myopathy* presents in boys with weakness before age 10 years. Ambulation was lost in a boy (who had FHL1 mutation) as a teenager, and another had cardiomyopathy and was ventilator dependent in the second decade. Onset was before the age of 4 years in two girls who presented with severe weakness with rapid progression and death, following respiratory failure, before 10 years of age.

Cap disease, due to mutation in the gene for β-tropomyosin, has congenital or childhood onset with hypotonia associated with facial and slowly progressive proximal muscle weakness. Patients have long narrow face, develop scoliosis, and may die of the disease in teenaged years due to respiratory failure.

Central core disease, due to autosomal recessively inherited mutation in the ryanodine receptor, is typically associated with history of decreased fetal movement or breech presentation. Onset is at birth or in early childhood with hypotonia, nonprogressive limb weakness, and facial weakness. Affected children most commonly present with orthopedic abnormalities including congenital hip dislocation, kyposcoliosis, and foot deformities. Ligamentous laxity may be pronounced in older children. Patients usually have slim habitus due to a general decrease in muscle bulk. Deep tendon reflexes may be normal, decreased, or absent on rare occasions.

Other presentations in autosomal recessive (and autosomal dominant) central core disease include onset in infancy with generalized weakness, external ophthalmoplegia, and bulbar and respiratory weakness. Children with recessive central core disease may present with fetal akinesia, arthrogryposis, and respiratory failure in the neonatal period requiring ventilatory support. The disease may start in adolescence as a slowly progressive limb-girdle syndrome or remain asymptomatic. Such asymptomatic individuals may present with high creatine kinase (CK) level or malignant hyperthermia. Susceptibility to malignant hyperthermia is found in about 25% of patients with central core disease, and extreme care should be taken when surgery is contemplated for such patients and for patients who are relatives of known cases. Slight improvement in functional abilities and muscle strength with age is common. Cardiomyopathy is not a feature of central core disease although conduction defects have been reported in some patients.

More recent studies found that the histopathological spectrum of central core is much wider. An autosomal dominant congenital myopathy with core and rods (*core-rod myopathy*) was found to be caused by mutation in the same gene (RYR1), which is associated with typical central core disease and encodes the skeletal muscle ryanodine receptor.

Multiminicore disease is a clinically heterogenous disorder, and four major phenotypes are now recognized. The classic and most common phenotype is often due to a mutation in the gene for selenoprotein N1. It presents in the neonatal period or first year of life and is characterized by hypotonia, and proximal and axial muscle weakness, which is either nonprogressive or only minimally progressive. A history of reduced fetal movements can be elicited in about a third of cases, and antenatal polyhydramnios may be noted. Congenital abnormalities such as cleft palate, dislocated hips, and arthrogryposis are seen in some patients. There is usually absent head control in infancy because of the characteristic weakness in head flexors associated with delayed motor development. Affected children are often slim due to decreased muscle bulk, and failure-to-thrive is common in children with significant weakness. Intelligence is normal. Facial and bulbar weakness is common, but extraocular muscles are spared.

There is mild-to-moderate weakness of the proximal limb muscles and affected children often show Gowers sign when rising from the floor. Distal muscles are either normal or mildly affected. The limb weakness may be static, slowly progressive, or may appear to improve with age. Nevertheless, weakness of the axial muscles is progressive and often leads to torticollis, chest deformities, rigid spine, and scoliosis. Most patients are ambulatory in adulthood, even in the presence of significant respiratory compromise resulting from axial muscle weakness. Minor, generally nonproblematic, joint contractures may develop in the elbows, knees, and hips. Cardiac involvement is

usually in the form of cor pulmonale secondary to respiratory insufficiency, which may affect about two-thirds of patients in late adolescence or early adulthood.

A second form of multiminicore disease, similar to the classic phenotype and characterized by external ophthalmoplegia, accounts for fewer than 10% of cases and is most often due to a mutation in the gene for the ryanodine receptor.

A third phenotype is characterized by predominant hip girdle weakness with relative sparing of respiratory and bulbar muscles similar to central core disease. It is also due to a mutation in the ryanodine receptor. Other features include joint laxity, hip dislocation, and arthrogryposis.

A fourth and rare phenotype presents in the neonatal period with arthrogryposis multiplex congenita, as a consequence of fetal hypokinesia. Other features include high-arched palate, low-set ears, short neck, clinodactyly, proximal muscle weakness, and respiratory insufficiency. Scoliosis or kyphosis is severe.

Salih myopathy (*Congenital myopathy* and *fatal cardiomyopathy*) is a recently identified congenital myopathy, in patients from Sudan and others of Moroccan ancestry, due to autosomal recessive mutation in the gene encoding for titin (*TTN*). Titin is the largest protein known and spans half of the sarcomere in muscle. The disease manifests as neonatal hypotonia in some patients, and delayed motor development in all of them. Autonomous walking is attained at ages ranging between 20 months and 4 years. Patients later develop symmetric, generalized muscle weakness predominantly affecting proximal limb muscles. Other features include high-arched palate, mild facial muscle weakness, asymmetric ptosis, distal joint laxity, and relative calf muscle hypertrophy (◉ *Fig. 374.1f* and *g*). Progressive dilated cardiomyopathy, with rhythm disturbances, develops between ages 5 and 13 years. Death occurs in all patients before 20 years of age, but the majority survive into their teenage years.

The onset of the X-linked *myotubular myopathy* is prenatal with decreased fetal movements, polyhydramnios, and premature birth. The affected male newborns present with severe weakness and hypotonia, feeding difficulty, and respiratory distress. Many fail to establish spontaneous respiration and lack antigravity movements. Bilateral ptosis, facial weakness, and ophthalmoplegia are common. Tendon reflexes are mostly absent. Other features of the disease include elongated birth length, low birth weight and large head, long face, micrognathia, slender long digits, cryptorchidism, pectus carinatum, and knee and hip contractures. The disease usually follows a fatal course with approximately one-third of patients dying in the first year of life. About 75% of those surviving beyond the first year require ventilatory support, have nonprogressive weakness, and can live into adulthood.

Female carriers are mostly asymptomatic; but may have mild facial and limb weakness evolving into gait difficulty and kyphoscoliosis. Weakness in infancy, feeding difficulties, and skeletal deformities are seen in carriers with skewed X-inactivation.

Most patients with the autosomal dominantly inherited *centronuclear myopathy* due to mutations in dynamin 2 (*DNM2*) have mild phenotype with onset in adolescence or adulthood. Clinical features of the disease include ptosis, facial weakness, axial and distal more than proximal weakness, and contracture deformities. A severe phenotype of centronuclear myopathy due to dynamin 2 mutations has recently been described. Onset is at birth with hypotonia and feeding difficulty. Other features include ptosis, ophthalmoplegia, high-arched palate, joint hyperlaxity, and contractures. Milestones are delayed, although ambulation is usually attained, and weakness is distal more than proximal.

The first causative gene for autosomal recessive *centronuclear myopathy* has recently been identified as amphiphysin 2 (*bridging integrator; BIN1*). The disease may manifest with reduced fetal movements and oligohydramnios, and usually presents at birth. Clinical features include ptosis, ophthalmoplegia, facial weakness, hypotonia, proximal weakness, contractures and dilated cardiomyopathy. Onset of the disease was delayed to 8 years of age in one patient. The course is slowly progressive, and more than half survive childhood.

Centronuclear myopathy caused by dominant mutation in the ryanodine receptor (*RYR1*) gene has been reported in one case in 2007. The clinical features included generalized weakness, extraocular involvement, and moderate bulbar and respiratory impairment similar to the multiminicore disease due to recessive mutations in the *RYR1* gene.

The clinical features of *congenital fiber type disproportion* vary according to the underlying mutated gene. Onset is usually before 1 year of age with mutations in the gene encoding ∝-tropomyosin (*TPM3*), but may be delayed to young adulthood. The disease manifests with hypotonia and delayed motor development, but ambulation is achieved later. Other clinical features include thin body habitus, ptosis, and facial, axial, proximal limb and ankle dorsiflexor muscle weakness, and scapular winging. Respiratory insufficiency develops in most patients, and about half of them need nocturnal noninvasive ventilation between ages 3 and 55 years.

The presentation of the phenotype caused by autosomal recessive mutations in the gene for selenoprotein

N1 is during the first year of life with hypotonia and poor head control. Other features of the disease include neck and axial muscle weakness, scoliosis, which may require spinal fusion surgery, osteoporosis and fractures, wheelchair dependency in adulthood, and respiratory insufficiency requiring nocturnal ventilation in the third decade of life.

The phenotype due to mutations in the gene for skeletal muscle α-actin (*ACTA1*) presents at birth with severe weakness, respiratory insufficiency often requiring invasive ventilation, and feeding difficulties. There is also weakness of the facial, proximal and truncal muscles. Death is usually before 4 years of age following progressive respiratory failure.

Diagnosis

The diagnosis of congenital myopathy depends on the typical histopathological findings on muscle biopsy in combination with suggestive clinical features (see section "Pathology" above).

Pathological examination of muscle should be done in experienced hands, and ultrastructural examination is often necessary since several pathologic features are based on the electron microscopic appearance of muscle. Selective muscle involvement on magnetic resonance imaging (MRI) may complement clinical assessment and guide genetic testing in cases with equivocal features.

In all of the congenital myopathies, serum creatine kinase (CK) is either normal or mildly elevated. Moderately elevated CK is seen in some cases of central core disease (CCD) and in others who are asymptomatic carriers of the ryanodine receptor mutation in CCD.

Nerve conduction studies are normal, and electromyography (EMG) either reveals normal results or shows the typical low amplitude, short-duration motor unit potentials that are seen in myopathies. Fibrillations and positive sharp waves (which characterize anterior horn cell disease like spinal muscular atrophy) are rare.

Electrocardiography (ECG) is important since cardiac disease may be prominent in nemaline myopathy or, sometimes, in other congenital myopathies. Dilated cardiomyopathy is a cardinal feature of Salih myopathy. In cases with abnormal ECG and in Salih myopathy, serial echocardiographic evaluations should be arranged.

Differential Diagnosis

The differential diagnosis varies depending on the age of onset and the symptoms of the patient at the time of diagnosis. In children presenting at birth or within the first 2 years of life, the differential diagnosis includes diseases manifesting as floppy infant syndrome (see section on "Floppy Infant Syndrome"). When infantile hypotonia is associated with ptosis, extraocular muscle and/or facial weakness, infantile myotonic dystrophy, congenital myasthenic syndrome, and mitochondrial cytopathies become important categories to exclude. For patients presenting for diagnosis at a later age, muscular dystrophy, metabolic myopathy, myotonic dystrophy, and type III spinal muscular atrophy take a higher position in the list of differential diagnoses.

Since clinical overlap of symptoms and signs is common in patients with congenital myopathies, the definitive diagnosis is usually reached only by means of muscle biopsy with histochemistry and electron microscopy. Histological changes suggestive of one form of congenital myopathy can be found in a different entity of congenital myopathy or another disease. Rods, which characterize nemaline myopathies, can be seen in many other diseases including inflammatory myopathies, muscular dystrophies, and mitochondrial myopathies. Multiminicores may also be present as a nonspecific feature in mitochondrial diseases, central nervous (CNS) disorders, and denervation. Muscle fibers with central nuclei can be seen in regenerating muscle fibers, in denervation, and in any chronic myopathy. Fiber type disproportion occurs as a secondary phenomenon in a wide range of skeletal and neuromuscular disorders.

Treatment

No specific treatment is currently available for any of the congenital myopathies. In the severe forms, which manifest at birth, survival depends on the degree of respiratory intervention, and the decision regarding the duration of respiratory support that should be made on an individual basis rather than on diagnosis alone. In congenital myopathies, respiratory failure can occur at any age but may be independent of the degree of limb weakness. Close monitoring of the respiratory function is needed with baseline pulmonary function tests (PFTs) that are repeated in at least yearly intervals. Early treatment of respiratory infections, manually assisted cough, and chest physiotherapy should be adopted. Noninvasive ventilation and tracheostomy combined with ventilation may be required during the course of the disease.

Maximal functional ability and ambulation should be maintained by preventing the development of contractures through exercises, bracing, passive stretching, and

surgical release procedures. The management of scoliosis requires either bracing or surgical correction.

Special caution should be taken to avoid the development of malignant hyperthermia following the use of muscle relaxants as succinylcholine and volatile anesthetics in patients with congenital myopathies. Malignant hyperthermia is known to occur in patients with central core disease and has been reported in patients with minicore disease and centronuclear myopathy. Hence, anesthetics should be given with caution and formal testing for a predisposition to malignant hyperthermia should be considered prior to elective anesthesia, especially in children with central core disease. Restricting calories by a diet tailored to caloric needs of the child is needed for children with restricted mobility.

An open-label pilot trail of salbutamol (a beta-2 against) therapy in children with central core and minicore disease reported a small but significant improvement in strength measured by myometry and Medical Research Council Scores, and in the vital capacity relative to baseline.

Prognosis

The prognosis generally depends on the form of CM, the mode of inheritance, and the underlying gene defect. Severe disease often results in death in the neonatal period. A disease with moderate severity can result in lifelong disability, whereas cases who are milder from the outset may achieve reasonable quality of life with minor disability. Mortality from CM is usually related to pulmonary insufficiency, which may be of insidious onset. It is more common or more severe in X-linked and autosomal myotubular/centronuclear myopathy, nemaline myopathy, multiminicore disease, and reducing body myopathy.

Prevention

Definitive prenatal and preimplantation genetic diagnoses are possible if the disease-causing mutation is known. Genetic counseling is particularly important in families with central core disease to help avoiding malignant hyperthermia in asymptomatic relatives.

Muscular Dystrophies

Definition/Classification

Muscular dystrophies (MDs) are a heterogeneous group of genetically determined, progressive primary myopathies. The term *dystrophy* means abnormal growth, and is derived from the Greek *trophe* meaning "nourishment." By adopting this definition, nonhereditary myopathies such as dermatomyositis are excluded. The definition also excludes nonprogressive myopathies such as the congenital myopathies, and diseases where muscle atrophy is secondary to neurogenic disorders such as spinal muscular atrophy.

Before the era of molecular genetics, MDs were classified clinically according to the pattern of inheritance, age at onset, rate of disease progress, and the distribution of selective muscle weakness and wasting (i.e., proximal versus distal). Although this clinical classification is still useful, delineation of the pathogenesis of MDs through molecular biology had its impact in the nomenclature and grouping of the various types. It became evident that some categories of dystrophies, such as limb-girdle muscular dystrophy, constitute syndromes, which include several distinct myopathies.

Epidemiology

In a world survey of inherited neuromuscular diseases by Emery, the overall prevalence of muscular dystrophy (MD) was estimated to be 286 per million population. However, there is a wide regional variation in the estimated prevalence of each of the major types of MD.

Pathogenesis

Cloning of the Duchenne MD gene and identification of its protein product (dystrophin) paved the way for delineating the pathogenesis of MDs. Dystrophin is a component of the membrane skeleton of muscle cells. Its absence in the inner face of the plasma membrane leads to membrane instability and ultimately results in myofiber destruction. Identification of dystrophin has led to the discovery of a large complex of sarcolemmal glycoproteins that are associated with dystrophin. In skeletal muscle, this dystrophin-glycoprotein complex (DGC) spans the sarcolemma to provide a linkage between the subsarcolemmal cytoskeleton and the extracellular matrix. This transmembrane complex has several functions, including structural support and signaling across the membrane.

Apart from Duchenne MD and Becker MD, disruption of this DGC causes most of the congenital MDs, and several of the limb-girdle MDs. This is due to the mismatch between muscle breakdown and repair, which is reflected in the markedly elevated creatine kinase (CK) values during the period of maximal muscle breakdown.

Pathology

The common pathological features shared by all muscular dystrophies include necrosis of fibers with signs of regeneration, and a mixture of atrophic and hypertrophic fibers. These fibers are randomly distributed without grouping of abnormally small fibers (as seen in spinal muscular atrophy), or selective involvement of a specific histochemical fiber type (as seen in congenital fiber type disproportion). Hypercontracted and hyalinized fibers may also been seen together with mononuclear inflammatory cell infiltrates as a reaction to muscle fiber necrosis. There is also marked proliferation of collagen and fat between the remaining muscle fibers, especially in late stages of the disease (*Fig. 374.2*). This proliferation of connective tissue and fat is largely responsible for the pseudohypertrophy, which characterizes the major types of MD.

Duchenne and Becker Muscular Dystrophies (MDs)

Definition/Classification/Etiology

Duchenne and Becker MDs are common inherited disorders of muscle affecting all races and ethnic groups. Both are transmitted as X-linked traits, are caused by mutations of the dystrophin gene, and are therefore named *dystrophinopathies*. Fundamentally, both types of MD are the same, but clinically Becker MD follows a milder and more protracted course.

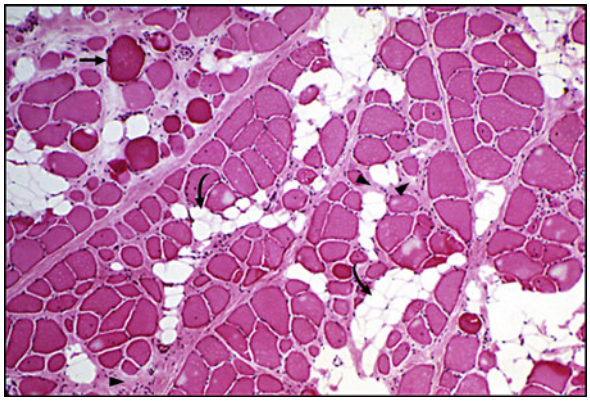

Figure 374.2
Pathological features of muscular dystrophy in haematoxylin-eosin (H&E) stained histological section of muscle. Note necrosis of fibres, irregular caliber of fibres, intramuscular fibrosis (arrowheads) and fat proliferation (curved arrows), and hypercontracted and hyalinized fibres (arrow)

Epidemiology

Duchenne MD is the most common hereditary neuromuscular disease with an incidence of 1 in 3,500 male births, and estimated overall prevalence of 32 to 63 cases per million population. The estimated prevalence of Becker MD is 24 cases per million.

Pathogenesis

The dystrophinopathies are inherited as X-linked recessive. However, one-third of these cases are due to spontaneous mutations. These de novo mutations may have occurred in the maternal ova at the time of the affected child's (proband) conception and is therefore present in every cell of the proband's body. Alternatively, the mutation may have occurred after conception and is thus present in some but not all cells of the proband's body (somatic mosaicism).

The gene causing dystrophinopathies is at the Xp21 locus and is one of the largest genes, occupying almost 2% of the X chromosome and nearly 0.05% of the entire genome. The gene product dystrophin is a 427-kd cytoskeletal protein, which consists of two opposed globular heads with a flexible rod-shaped center (*Fig. 374.3*). One of the globular heads, carboxyl-terminus (or C-terminus) attaches to the sarcolemma via β-dystroglycan, whereas the other head amino-terminus (or N-terminus) attaches to the actin myofilaments. A cysteine-rich domain is also related to the carbonyl-terminus of α-actinin.

β-dystroglycan anchors DGC to the basal lamina via α-dystroglycan and laminin-α2 (merosin). Dystrophin is also expressed in the heart, brain, and smooth muscles.

About 65% of patients with dystrophinopathies have deletions, and only 7% exhibit duplication of the dystrophin gene. Deletions or duplications that do not disturb the reading frame still permit translation of coding sequence further downstream on the gene. These "in frame" changes, particularly when located within the amino-terminal or central regions, produce a semifunctional dystrophin expressed clinically as Becker MD. In contrast, mutations that disrupt the reading frame, including premature stop codons, result in severely truncated, unstable dystrophin manifesting as classic Duchenne MD. The functional loss of dystrophin results in secondary loss of the DGC components, sarcolemma breakdown, oxidative cellular injury,

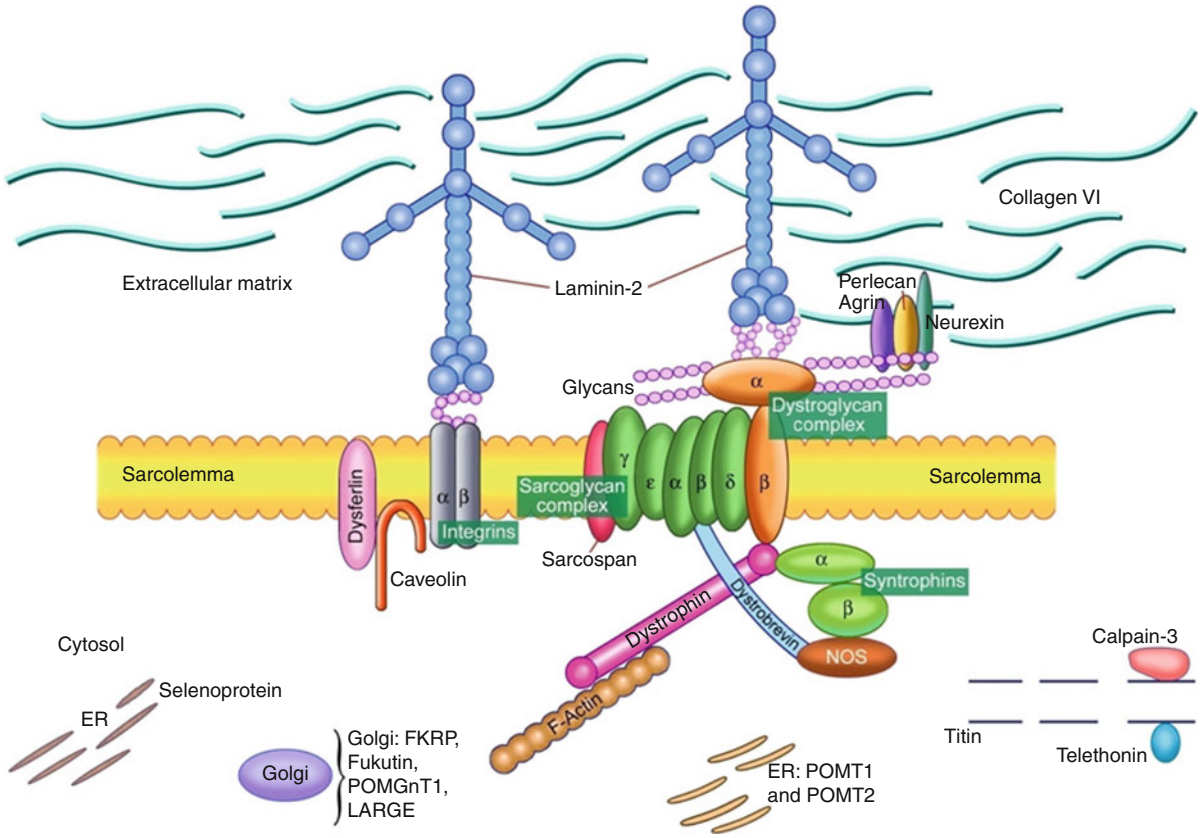

Figure 374.3
Schematic presentation of the main proteins involved in muscular dystrophies, their localization and interactions. Abbreviations: ER, endoplasmic reticulum

and phospholipase activation following calcium ion influx. This leads to muscle fiber necrosis.

Clinical Manifestations

The onset of Duchenne MD is in early childhood, but the first manifestations are often overlooked. Walking may be delayed past 15 months, and waddling gait, manifesting in children aged 2–6 years, is often the first symptom. Difficulties with climbing stairs, arising from floor secondary to hip girdle muscle weakness, are also early symptoms of the disease. A modified Gowers sign is often evident by age 3 years and is fully expressed, with the patient climbing up the legs, in 5–6 years (*Fig. 374.4a*). Muscle weakness and atrophy are symmetrical and contrast with the hypertrophy of the calf muscles, and less frequently the tongue, the vastus lateralis, the deltoids, and the forearm muscles. Patients with classic Duchenne MD become wheelchair dependent before the age of 13 years. Nevertheless, some are confined to a wheelchair by 7 years. Immobilization in bed and surgical operation may be associated with rapid progress of the disease. Weakness later involves the neck flexors, shoulders, and arms, with relative preservation of the function of distal muscles. The deep tendon reflexes progressively decrease, but the ankle jerk is preserved unless ankle contractures are severe. Following loss of ambulation, scoliosis often develops and may be rapidly progressive leading to further respiratory compromise.

Cardiomyopathy, manifesting as persistent tachycardia and cardiac failure, is seen in 50–80% of patients, and its severity does not correlate with the degree of weakness found in skeletal muscle. The incidence of cardiomyopathy increases steadily in the teenage years with one-third of individuals being affected by age 14 years, and all individuals after age 18 years.

Intellectual impairment is a remarkable feature of many cases of Duchenne MD, although only 20–30% fall in the subnormal range with IQ <70. Recently, a specific cognitive profile of boys with Duchenne MD has emerged,

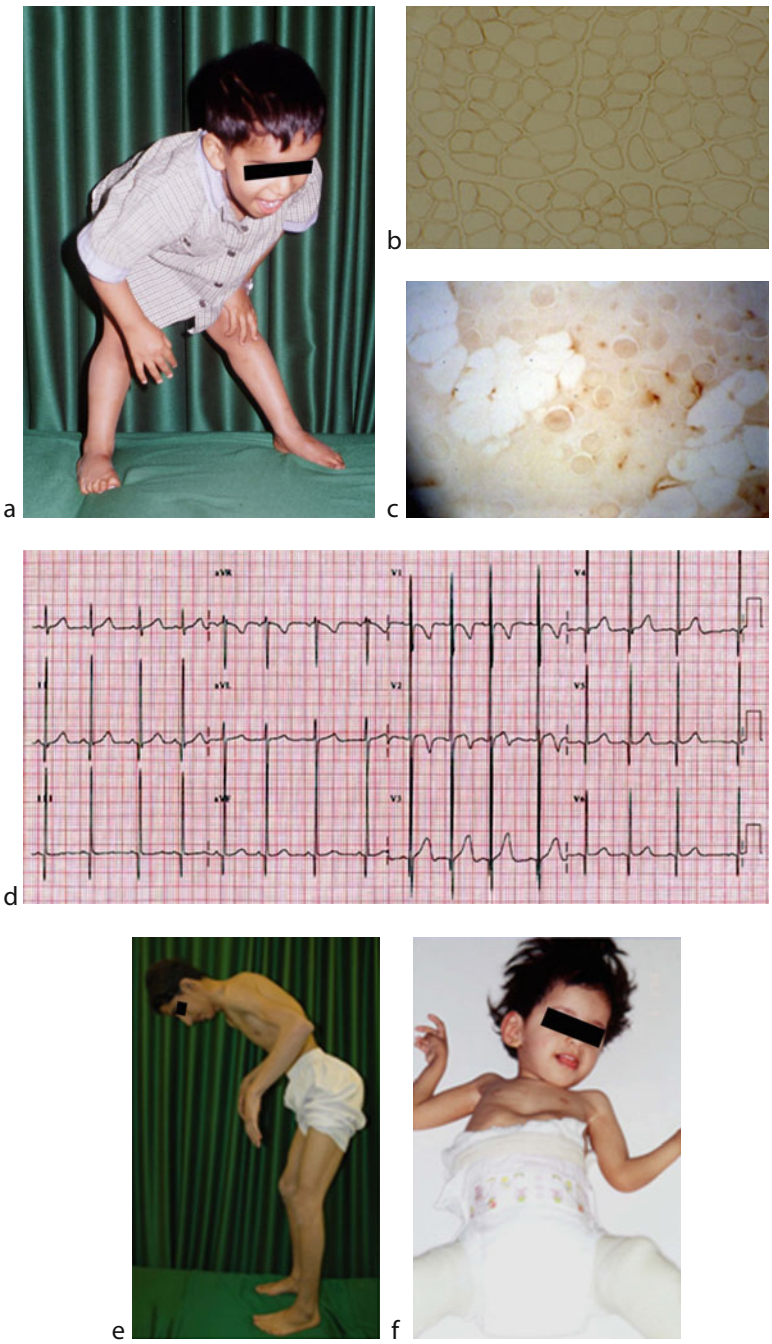

Figure 374.4

(a) A 3 ½ - year - old boy with Duchenne muscular dystrophy (DMD) showing modified Gowers sign. (b) Normal dystrophin staining demonstrated by immunohistochemical reactivity in the muscle biopsy. The sarcolemmal membrane in every fibre is strongly stained. (c) In Duchenne dystrophy the myofibres express no detectable dystrophin. (d) Electrocardiography (ECG) in DMD shows deep Q waves and tall right precordial (leads VI and V2) R waves. (e) An adolescent with Emery-Dreifuss muscular dystrophy due to mutation in *FHL1* gene. Note the limitation of neck flexion, contracture of elbow flexors, and wasting of the biceps, triceps and peroneal muscles. (f) Ullrich congenital muscular dystrophy with bilateral congenital dislocation of the hip joints. Note the hypotonic posture and chest deformity

demonstrating deficits in working memory and executive function. Nevertheless, the majority of children with Duchenne MD can function in a regular classroom, with remedial help.

Death usually occurs at 18–20 years, commonly caused by respiratory complications and cardiomyopathy.

Becker MD is characterized by later-onset skeletal muscle weakness with preservation of ambulation until late adolescence or early adult life. Calf pseudohypertrophy is a feature of the disease, and heart failure from dilated cardiomyopathy is a common cause of morbidity and the most common cause of death. Death often occurs in the mid to late 20s, and the mean age of death is in the mid-40s.

Occasionally, females have clinical features of Duchenne MD as a result of X-chromosome rearrangements involving the Duchenne MD locus. Females with Turner syndrome (i.e., complete or partial absence of an X chromosome) who carry a disease-causing *DMD* gene mutation present with Duchenne MD phenotype. Also, more than 90% of female carriers with skewed X-chromosome inactivation (defined as ≥75% of nuclei harboring the mutant *DMD* gene on the active X chromosome) develop moderate-to-severe muscular dystrophy.

Diagnosis

Serum creatine kinase (CK) is always increased in patients with Duchenne and Becker MDs, even in presymptomatic stages, including at birth. It is often raised to levels that are 50–200 times the reference range (i.e., as high as 35,000 IU/L [normal <160 IU/L]). Other lysosomal enzymes present in muscle such as aldolase and aspartate aminotransferase (AST), as well as the liver specific alanine aminotransferase (ALT) are also elevated. The associated presence of high CK should rule out considering a liver biopsy.

If the clinical features and serum CK are consistent with the diagnosis, blood polymerase chain reaction (PCR) for the dystrophin gene mutation is the primary test to be done. Currently, most laboratories use multiplex PCR to detect deletions, which account for appropriately 65% of mutations in individuals with Duchenne MD and 85% of those with Becker MD. This method has a 98% detection rate for deletions. Duplications, which account for 6–10% of mutations, can be detected by several quantitative techniques.

In patients without detectable mutations of the dystrophin gene, diagnosis requires muscle biopsy for dystrophin protein quantification. The ideal muscle to biopsy is one that is easily accessible and exhibits moderate weakness (i.e., has 80% strength). The most common muscles sampled are the vastus lateralis (quadriceps femoris) and the gastrocnemius. Histochemical examination of frozen muscle biopsy shows florid features (see section "Pathology" above). Immunohistochemical staining of frozen sections using antibodies directed against the rod domain and the carboxyl and amino terminals of dystrophin shows no detectable sarcolemmal staining in boys with Duchenne MD (*Fig. 374.4b* and *c*). Patients with Becker MD show deficient but not totally absent dystrophin expression, with more fragmented and patchy staining of sarcolemmal regions. Immunoblot analysis of muscle biopsy homogenate is also used by some laboratories to quantify the dystrophin molecule. Patients with Duchenne MD have greatly decreased or absent amounts of dystrophin, whereas patients with Becker MD exhibit moderately reduced amounts of dystrophin but with an altered molecular size.

Electrocardiography (ECG) provides a simple mean for aiding in the diagnosis since it may demonstrate deep Q waves and elevated right precordial R waves early in the course of the disease (*Fig. 374.4d*). It may also uncover sinus arrhythmias later on. Echocardiography is also important for revealing subclinical cardiomyopathy.

Electromyography (EMG) is not diagnostic and is difficult to conduct in young frightened children. When performed, it shows myopathic features in the form of short-duration, polyphasic motor unit action potentials with normal to reduced amplitudes.

Radiographs to screen for scoliosis are important, particularly in patients with Duchenne MD after they become wheelchair dependent. Serial chest X-rays are also required when dyspnoea develops in a patient. Baseline pulmonary function testing is recommended in patients with Duchenne MD before confinement to a wheelchair (usually at the age of 9–10 years).

Differential Diagnosis

Severe childhood autosomal recessive muscular dystrophy (SCARMD) is a subgroup of limb-girdle muscular dystrophy (LGMD), which closely resembles Duchenne MD but occurs in both sexes. This phenotype of dystrophy is more prevalent in communities with high consanguinity rate (see "SCARMD" below). From the authors previous experiences, several boys with SCARMD are referred and managed as having Duchenne MD. In children with SCARMD, creatine kinase (CK) is usually lower than in cases of Duchenne MD, and muscle biopsy reveals normal

dystrophin staining. Becker MD may also be mistaken for other forms of LGMD with either autosomal recessive or autosomal dominant inheritance.

Treatment

Since there is currently no medical cure for Duchenne or Becker MD, attention is focused to improve the quality of life of affected children, anticipate, and treat the complications and prolong lifespan.

Supportive care requires coordinated and multidisciplinary team approach. Maximizing functional status and delaying wheelchair dependence may be achieved by daily joint-stretching exercises, night splints, and braces such as ankle-foot orthosis and knee-ankle foot orthosis. Ambulation may be prolonged by as long as 2 years with judicious use of tendon release surgeries. Excessive exercise or training should be avoided, since it can cause further damage to the muscle cells, and gentle sports or activity (such as swimming and tricycle/bicycles) may be encouraged.

As recommended by The American Academy of Pediatrics, complete cardiac evaluation is required for optimal care at least every 2 years. For patients with Duchenne MD, this should begin in early childhood. At approximately 10 years, or at the onset of cardiac signs and symptoms, evaluation should be annual. Complete cardiac evaluation is recommended about age 10 years, or at the onset of signs or symptoms, for Becker MD patients. This should continue at least every 2 years.

Before confinement to a wheelchair (usually at about 9–10 years), baseline pulmonary function testing should be performed for children with Duchenne MD. Twice yearly evaluation by a pediatric pulmonologist is required after the age of 12 years, confinement to a wheelchair or reduction in vital capacity below 80% predicted. As the disease continues to progress, sleep studies followed by noninvasive ventilator support may be required. The two major minimally invasive and easy to use options in this regard are the bilevel positive airway pressure (BiPAP) or continuous positive airway pressure (CPAP). Annual administration of pneumococcal vaccine and influenza vaccine is recommended.

At the stage of wheelchair dependency, adaptive devices to maximize upper extremity mobility and cushioning to prevent pressure sores, and customizing the chair for the patients needs will be required. Monitoring for orthopedic complications, especially scoliosis, is important at this stage. Spinal instrumentation or fusion may become necessary with worsening of spinal curvature.

Dietary modifications can prevent excessive weight gain and exposure to sunshine, and a balanced diet rich in vitamin D and calcium improves bone density and reduces risk of fractures. Social and psychological supports are crucial for improving psychosocial dynamic of families with an affected child.

Corticosteroids are the only medication, which have demonstrated some success in modifying the course of Duchenne MD. They prolong ambulation by 2–3 years, maintain strength and function, delay the development of scoliosis, and demonstrate favorable effects on cardiac function. Their mechanism of action is thought to be through reduction of tissue inflammation, stimulation of myoblasts, improvement of calcium homeostasis and suppression of cytotoxic cells. Nevertheless, corticosteroids have significant side effects, which include excessive weight gain, cushingoid appearance, short stature, decrease in linear growth, hypertension, diabetes, cataracts, and behavioral changes. There is also an increased frequency of vertebral and long bone fractures with prolonged corticosteroid use. Recommendations by the American Academy of Neurology and the Child Neurology Society advise starting prednisone (0.75 mg/kg/day) in boys with Duchenne MD who are older than age 5 years. This dose should be maintained if side effects are not severe, and should be decreased to 0.5 mg/kg/day if excessive weight gain occurs (>20% over estimated normal weight for height over 12 month period). In case excessive weight gain still continues, the dose should be further decreased to 0.3 mg/kg/day after 3–4 months.

To reduce the incidence of steroid-associated side effects, other regimens were adopted by several centers, including alternate day dosing, lower dose daily regimes (e.g., 10 days on/10 days off); high dose on weekends.

Deflazacort is a synthetic derivative of prednisolone used in Europe but not currently available in the USA. It has a more favorable side effect profile compared to prednisone, including less excess weight gain and less slowing of growth, but has a higher risk of asymptomatic cataracts. It can be used to treat Duchenne MD in a dose of 0.9 mg/kg/day. Currently, an international trial is evaluating the efficacy of deflazacort 0.9 mg/kg/day versus prednisone 0.75 mg/kg/day versus prednisone 0.75 mg/kg/day used as 10 days on, followed by 10 days off.

To date, clinical trials have not shown favorable results with the use of myoblast transplantation or stem cell transplantation into patients with Duchenne MD. Nevertheless, recent promising preclinical and clinical trial results of antisense oligonucleotides (AOs) could provide a therapeutic option for the majority of children with Duchenne MD. Oligonucleotides are small synthetic

RNA molecules that can bind to specific sequences within the dystrophin pre-mRNA. They are capable of reestablishing an open reading frame of the dystrophin gene, resulting in a functional dystrophin mRNA, which is translated into functional dystrophin protein. This technique could possibly benefit 70–80% of Duchenne MD patients. Clinical trials are currently underway to evaluate its efficacy, safety, and tolerability.

Prognosis

Apart from Duchenne and Becker MDs, the clinical spectrum of dystrophinopathies ranges from a severe neonatal MD to asymptomatic children with persistent elevation of CK levels (>1,000 IU/L). In general, patients with Becker MD have much greater phenotypic variability compared to those with Duchenne MD. They may become wheelchair bound as early as age 20 years or as late as age 70 years.

Prevention

A crucial step in prevention of Duchenne and Becker MDs is carrier detection to guide the genetic counseling of affected families, which remains the sole intervention for preventing the disease. About two-thirds of asymptomatic female carriers of Duchenne and Becker MDs have elevated serum CK values, usually in the magnitude of hundred or a few thousand. Nevertheless, it should be remembered that some ethnic and racial groups (e.g., African Americans) have normally elevated CK levels without the presence of any pathology. Muscle biopsy of suspected female carriers may detect an additional 10% in whom serum CK is not elevated by showing mosaic pattern for dystrophin immunofluorescence. However, many female carriers of Duchenne or Becker MDs show no abnormality in dystrophin immunostaining. Molecular genetic testing is increasingly being used in suspected female carriers to identify heterozygosity for a deletion, duplication or point mutation. Female carriers should have cardiac surveillance since they may develop cardiomyopathy without muscle weakness. Prenatal testing is possible for pregnancies of women who are carriers if the Duchenne MD mutation has been identified in a family member or if linkage has been established. Testing is done either by chorionic villus sampling (at about 10–12 weeks of gestation) or by amniocentesis, which is usually performed at approximately 15–18 weeks of gestation. Preimplantation genetic diagnosis (PGD) is also available for families in which the disease-causing mutation has been identified.

Emery–Dreifuss Muscular Dystrophy

Definition/Classification

Emery–Dreifuss muscular dystrophy (EDMD) is a rare hereditary disorder characterized by joint contractures that begin in early childhood, slowly progressive muscular dystrophy with humeroperoneal preponderance and cardiac involvement.

Epidemiology

Accurate data on the frequency of EDMD is lacking although the disease has been described in various ethnic groups. The combined prevalence of X-linked (due to emerin mutations) and autosomal EDMD has been estimated to be about 1–2 cases per 100,000 people.

Pathogenesis

Emery–Dreifuss muscular dystrophy (EDMD) is a genetically heterogeneous disorder. The disease can be transmitted in a recessive X-linked manner as a result of mutations in *EDM* gene, encoding the emerin protein, or in an autosomal dominant or recessive mutations in *LMNA*, encoding the lamin A and C proteins. The precise functions of emerin and lamins A and C are still unknown, but both are components of the nuclear envelope and interact with each other. Sequence variants in *SYNE1* and *SYNE2* genes were recently identified in patients with EDMD-like phenotype. These two genes encode, respectively, nesprin 1 and 2 proteins that bind both emerin and lamins A and C, and form a network in muscle linking the nucleoskeleton to the inner and outer nuclear membranes. It is postulated that disruption of the inner nuclear membrane and the nuclear lamina, due to mutations in these genes, causes disorganization of nuclear chromatin and gene expression or leads to structural and signaling defects in mechanically stressed tissues of the heart and skeletal muscles. Most recently, several families, including one followed by the author, had EDMD caused by mutations in *FHL1* gene. Reduced *FHL1* expression may have an impact on myogenin expression, myoblast fusion, maintenance of cellular structural integrity, and on the regulation of cell signaling.

Pathology

Routine histochemical studies of muscle biopsies show unspecific myopathic picture characterized by variation in fiber size, significant increase in internal nuclei, mild increase in endomyseal connective tissue, associated occasionally with necrotic and regenerating fibers. Type 1 fibers are predominant and often relatively atrophic in EDMD caused by emerin mutations and in lamin A/C-associated disease. Immunohistochemical staining shows absence of normal staining of the inner nuclear membrane by antiemerin antibody in the X-linked EDMD caused by mutations in emerin gene. This lost staining can be observed in buccal cells, peripheral leukocytes, and skin fibroblasts. In female carriers of this X-linked phenotype of EDMD, immunostaining of muscle nuclei is lost in ranging proportions.

Clinical Manifestations

Age of onset, severity, and progression of muscle and cardiac involvement demonstrate both inter- and intrafamilial variability. The features of the disease tend to develop independently from one another so that the diagnosis can be difficult in young patients. Generally, joint contractures appear during the first 2 decades, and are followed by muscle weakness and wasting. Early contractures involve the elbow flexors, Achilles tendons (heel cords), and neck extensors resulting in limitation of neck flexion, followed by spinal rigidity (*Fig. 374.4e*).

Weakness and wasting are slowly progressive and follow scapulohumeroperoneal distribution. There is symmetric weakness of the biceps, triceps, and peroneal muscles associated with scapular winging. The wasting of the biceps is often quite striking, affecting the proximal more than the distal portion. Ocular and facial muscles are spared. In the lower limbs, the thigh muscles are usually preserved or occasionally hypertrophied. Cases of EDMD with mutations in FHL1 gene have additional features characterized by facial weakness in some cases and dysphonia due to vocal cord paralysis.

Cardiac involvement usually starts after onset of weakness and manifests in the second or third decade as atrial fibrillation, flutter and standstill, supraventricular and ventricular arrhythmias, and atrioventricular conduction defect. Late findings may include dilated cardiomyopathy. Conversely, some patients with FHL1 mutation have hypertrophic cardiomyopathy. About 10–20% of female carriers have cardiac conduction defects, weakness, or both, and are prone to die suddenly.

Diagnosis

The diagnosis of EDMD is based on the phenotype of the disease and other ancillary investigations.

Serum creatine kinase (CK) is either normal or moderately raised (2–20 times the upper normal limit). Elevated CK is seen at the early rather than the late stage of the disease. Neurophysiological investigations reveal normal nerve conduction studies, and electromyography (EMG) usually shows myopathic features. Neurogenic features have been reported in the X-linked phenotype associated with emerin deficiency and in the autosomal dominant EDMD. Characteristic findings in the calf muscles on MRI have also been reported in the latter form. Muscle histopathology and immunohistochemistry are helpful diagnostic tools (see section "Pathology" above). Molecular diagnosis detects mutations in *EMD* (emerin) and *LMNA genes* in about 35% of EDMD patients.

Differential Diagnosis

The phenotype of EDMD is relatively easy to recognize and differentiate from other forms of childhood-onset muscular dystrophies (MDs) or myopathies. Nevertheless, myopathies and MDs presenting as the rigid spine syndrome may closely mimic EDMD. This syndrome is characterized by marked limitation in flexion of spine, including cervical spine, and is associated with limited extension of the elbows and ankles. It was found to be caused by a mutation in the selenoprotein N gene (*SEPN1*) and can present as a congenital myopathy or rigid spine muscular dystrophy 1 (see section "Congenital Muscular Dystrophy").

Treatment

The general care and nonspecific treatment of children with EDMD are similar to that detailed for Duchenne/Becker MD (see above). Cardiac complications of the disease require specific treatments including antiarrhythmic drugs, cardiac pacemaker, implantable cardioverter defibrillator (ICD), and therapy for heart failure. Heart transplantation may be performed in patients who do not have severe skeletal muscle and respiratory involvement. Heterozygous carriers of the X-linked EDMD phenotype (due to either *EMD* [emerin] or *FHL1* gene mutations) may manifest cardiac disease and require similar management.

Prognosis

Patients with EDMD often die in mid adulthood from progressive pulmonary or cardiac failure. Sudden cardiac death, which is a frequent cause of early mortality, can be prevented with early cardiac pacing.

Prevention

Similar to Duchenne and Becker MDs, prenatal testing is possible for pregnancies at increased risk for EDMD if the disease-causing mutation of an affected family member is known. Preimplantation genetic diagnosis may also be available for families in which the disease-causing mutations have been identified.

Congenital Muscular Dystrophy

Definition/Classification

The category of congenital muscular dystrophy (CMD) embraces a number of genetically and clinically heterogeneous disorders characterized by congenital hypotonia, delayed motor development, progressive muscle weakness of early onset, and dystrophic features on muscle biopsy. Following the rapid increase of separate variants of CMD in the molecular era, a classification of CMD based on the primary biochemical defect has been proposed. As of 2009, identified genetic defects in CMD involve:

1. Proteins of the extracellular matrix or peripheral membrane. These include collagen VI which causes Ullrich CMD, laminin-α2 chain (or merosin), which results in merosin-deficient CMD (MDC1A); and integrin-α7 causing CMD with integrin deficiency (◉ *Fig. 374.3*).
2. Putative or demonstrated glycosyltransferases, which affect the glycosylation of α-dystroglycan. These include protein O-mannosyltransferase 1 and 2 (POMT1 and POMT2, respectively), O-mannose beta-1, 2-N-acetylglucosaminyltransferase (POMGnT1), fukutin, fukutin-related protein (FKRP); and LARGE. These diseases are collectively referred to as α-dystroglycanopathies.
3. Selenoprotein N gene (*SEPN1*), which encodes an endoplasmic reticulum protein of unknown function and causes, when mutated, rigid spine muscular dystrophy1.
4. Lamins A and C, which were recently found to be associated with clinicopathological features overlapping with congenital muscular dystrophy.

Epidemiology

The estimated prevalence of CMD is 4.7 cases per 100,000 children in Italy while in Sweden the incidence is estimated at 6.3 cases per 100,000 births. However, the frequencies of the different subtypes of CMD show regional and ethnic variations. Merosin-deficient CMD (MDC1A) accounts for 30–40% of all forms in the European continent and in Brazil. Ullrich CMD is the second most common subtype in Europe, Australasia (12%), and Japan (9.4%). In Japan, it comes after Fukuyama CMD, which has a rate of approximately 50%. Congenital muscular dystrophies (CMDs) due to defects in O-glycosylation of α-dystroglycan are estimated to account for 25–50% of all cases.

Pathogenesis

Ullrich CMD is an autosomal recessive (or more rarely dominant) disorder caused by mutations in one of three collagen type VI genes (*COL6A1*, *COL6A2*, *COL6A3*). Collagen VI, which is manufactured primarily in interstitial fibroblasts, has cell adhesion properties and binds to numerous extracellular matrix proteins, including perlecan and other collagens (◉ *Fig. 374.3*). Anchoring the basement membrane to the underlying connective tissue is thought to be the major role of collagen VI.

Laminins are glycoproteins that form the backbone of the basement membrane. Laminin-α2 (merosin) is a heterotrimer (α2 – β1 – γ1), which binds to a member of molecules including α-dystroglycan and integrin-α7 (◉ *Fig. 374.3*). Loss of laminin-α2 (merosin) results in mechanical instability of muscle associated with a secondary loss of α-dystroglycan and integrin-α7. The α2 subunit of laminin (merosin) is also expressed in the basal lamina of Schwan cell-axon unit, and a peripheral demyelinating neuropathy is a feature of merosin-deficient CMD.

Integrin-α7 deficiency is inherited as autosomal recessive and is caused by mutations in the gene encoding for this protein. Integrin-α7 comprises transmembrane adhesion molecules composed of one α and one β chain, and plays a role in the formation of myotendinous and neuromuscular junctions. It forms a transmembrane link between laminin-α2 (merosin) and the muscle membrane that is independent of the dystrophin-glycoprotein complex (◉ *Fig. 374.3*).

Rigid spine muscular dystrophy1 is an autosomal recessive disease due to a mutation in the selenoprotein N gene (*SEPN1*). Selenoprotein N is an endoplasmic

reticulum protein of unknown function, which is involved in oxidation/reduction reaction (Fig. 374.3).

Six genes are involved in O-glycosylation of α-dystroglycan. These are *POMT1*, *POMT2*, *POMGnT1*, *FCMD*, encoding fukutin, *FKRP*, and *LARGE*. Mutations in any of these six genes will result in abnormal glycosylation and therefore abnormal function of α-dystroglycan. Through its binding with the transmembrane β-dystroglycan, α-dystroglycan is thought to act as a link between the basal lamina and the cytoskeleton, and is crucial in the formation and maintenance of the basement membrane. The binding of α-dystroglycan to the extracellular matrix proteins laminin-α2 (merosin), agrin, perlecan, and neurexin is glycosylation dependent.

Pathology

Various degrees of dystrophic features (muscle fiber necrosis and regeneration with endomyseal and perimyseal regeneration) occur in merosin-deficient CMD and in α-dystroglycanopathies. In complete merosin (laminin-α2) deficiency, infiltrates of mononuclear cells may be seen in biopsy samples obtained in infancy. Mild myopathic features, with little or no necrosis, are often seen in partial laminin-α2 (merosin) deficiency. Regarding α-dystroglycanopathies, muscle tissue may look normal shortly after birth in babies with muscle-eye-brain disease or fukutin-related proteinopathy due to FKRP gene mutations.

Muscle histology varies from mildly myopathic to dystrophic in Ullrich CMD, and in integrin-α7 deficiency, mild variations in fiber size are noted. Rigid spine muscular dystrophy1 due to deficiency of selenoprotein N manifests with myopathic features associated with type1 fiber predominance or atrophy. Muscle fiber necrosis is rare, and minicores may be present.

Clinical Manifestations

Ullrich congenital muscular dystrophy presents in the neonatal period with hypotonia, torticollis, kyphosis of the spine and hip dislocation (Fig. 374.4f). There are also proximal joint contractures combined with distal joint hyperlaxity and protruding calcaneus. Contractures eventually affect the previously lax ankles, wrists, and fingers excluding the interphalangeal joints, which tend to remain lax. Evolution of motor weakness is variable; most patients never walk but others walk and lose ambulation, mostly due to contractures, after 2–10 years. The skin shows follicular hyperkeratosis, keratosis palmaris, and keloids. Intelligence is normal, but ventilatory insufficiency invariably develops in the first or second decade. Ullrich CMD is allelic to and shares similar features with Bethlem myopathy, an autosomal dominant condition, also due to mutation in the gene for collagen VI.

Merosin-deficient CMD (*MDC1A or Classic CMD*) presents at birth or in the first months of life with hypotonia, weakness, feeding difficulty, and respiratory insufficiency usually not requiring assisted ventilation. Most infants eventually sit unsupported, usually by the age of 3 years, but standing or walking with support is rare. Weakness is minimally progressive or static, but functional abilities regress with increase in flexion deformities at the hips, knees, ankles, and elbows, followed by rigidity and scoliosis of the spine. Intelligence is usually normal although mild mental retardation or perceptual-motor difficulties may be observed in few cases. Even with normal intelligence, periventricular white matter changes are constantly seen on magnetic resonance imaging (MRI). About 30% of patients develop seizures, a subclinical demyelinating motor and sensory neuropathy is present in many, and neuronal migration defects have been found in few patients. In severe cases, death may occur after 10–30 years due to respiratory failure.

Mild allelic variants of partial deficiency of laminin-α2 (merosin) have frequently been described. Despite their hypotonia and weakness early in life, these patients may reach the ability to walk unsupported, in contrast to patients with complete laminin-α2 (merosin) deficiency who never achieve this ability. They also demonstrate cerebral white matter changes on MRI and peripheral demyelinating neuropathy.

Integrin-α7 deficiency causing CMD is a rare disorder and has been described in only two children. They presented with hypotonia and delayed milestones. One patient had mental retardation with brain MRI changes, and another had contractures and respiratory failure.

Congenital Muscular Dystrophies Caused by Defects in the Glycosylation of α-Dystroglycan (α-Dystroglycanopathies)

These are autosomal recessive disorders, which are clinically and genetically heterogeneous, caused by deficiency of one of the glycosyltransferases leading to a hypoglycosylation of α-dystroglycan. Mutations in at least six genes *POMT1*, *POMT2*, *POMGnT1*, *FCMD*, *FKRP*, and *LARGE* are known to result in α-dystroglycanopathy. Clinically, they either manifest with pure

muscular involvement or variable degrees of central nervous system and/or ophthalmic involvement.

Fukuyama Congenital Muscular Dystrophy

This autosomal recessive disorder was first described in 1960 by Fukuyama and associates. It represents one of the most common autosomal recessive disorders in the Japanese population and is caused by a founder mutation of the fukutin gene (*FCMD*). In the general population, this founder mutation is observed with a frequency of 1 in 88 individuals and is rare outside the Japanese population.

Onset of the disease is often in utero with decreased fetal movements, but severe arthrogryposis is rare. Hypotonia, weak sucking, and poor head control are noticed early in life. Most patients can stand or walk a few steps at the age of 2–8 years. Those with severe disease may be able to sit only with support. Progressive weakness ensues and is associated with respiratory failure in the mid-to-late teens. Enlargement of tongue, quadriceps, and calf muscles is common. Profound mental retardation is associated with severe weakness, although most patients manage to speak short sentences. Seizures occur in about 50% of patients, usually before age 3 years. Similar to the other α-dystroglycanopathies, MRI shows the characteristic cobblestone (type II) lissencephaly, with abnormalities ranging from cobblestone polymicrogyria and/or pachygyria to complete agyria due to neuronal migration abnormalities. Cerebellar cysts and dysplasia of the pyramidal tracts are common, and there is usually transient delay of myelination. Ocular involvement is seen in about 50% of cases. This ranges from abnormal eye movements, poor visual pursuit and strabismus to microphthalmia, severe myopia, hyperopia, cataracts, and retinal detachment.

Mutation in the fukutin gene was reported in a limb-girdle phenotype of muscular dystrophy (LGMD2M) with normal intelligence and brain MRI (see section ❯ "Limb-Girdle Muscular Dystrophy").

Muscle-Eye-Brain (MEB) Disease

First reported from Finland in 1997, this autosomal recessive disorder is characterized by CMD, structural eye abnormalities, and cortical malformations. Mutations in *POMT1*, *POMT2*, *POMGnT1*, *fukutin*, and *FKRP* can cause this syndrome. The condition was initially considered to be exclusive to the Finnish population, but following advances in molecular biology, it was found to have a worldwide distribution and broader clinical spectrum.

The congenital eye abnormalities are variable but are more severe than those of Fukuyama CMD. They include severe myopia, glaucoma, cataracts, hyperplastic primary vitreous, optic nerve hypoplasia, retinal hypoplasia, and retinal detachments. Similar to Fukuyama CMD, MEB shows clinical variability with regard to muscular or mental involvement. Severely affected patients manifest profound motor and cognitive delay or even autistic features, while some patients with milder disease are able to walk and develop speech. Patients with severe disease never achieve sitting and may die during the first years of life. Intra-familial variability of the clinical features has been reported. Seizures are common and central nervous system abnormalities are constant findings, including moderate-to-severe mental retardation.

Brain MRI changes are similar to those seen in Fukuyama CMD but are more variable. Severe changes include cobblestone (type II) lissencephaly with pachygyria and/or polymicrogyria/agyria. Mild changes include flattening of the pons, vermal hypoplasia, and cerebellar cysts. Evidence of dysmyelination may be seen on MRI, and severe ventricular dilatation may result in obstructive hydrocephalus requiring shunt placement.

Walker–Warburg Syndrome

Mutations in all six glycosyltransferases (*POMT1*, *POMT2*, *POMGnT1*, *fukutin*, *FKRP*, and *LARGE*) can result in this most severe of the α-dystroglycanopathies. The condition is inherited as autosomal recessive CMD in combination with eye malformation and cobblestone (Type II) lissencephaly, not compatible with survival beyond 2–3 years of age. Affected children do not achieve any motor or mental milestones; and encephaloceles and severe hydrocephalus are often detected prenatally.

The congenital ocular anomalies are both anterior and posterior eye malformations and frequently lead to blindness. They include microphthalmia, buphthalmos, megalocornea corneal opacity, coloboma and other iris malformations, congenital or infantile glaucoma, cataract, hypoplastic optic nerve, and retinal detachments (❯ *Fig. 374.5a*).

Brain malformations include complete type II lissencephaly (cobblestone lissencephaly), with absence of sulcation and an irregular gray-white matter junction, marked ventriculomegaly, and severe dysplasia of posterior fossa structure, including cerebellar and brainstem hypoplasia (❯ *Fig. 374.5b* and *c*). Meningocele or encephalocele, usually of the posterior fossa, is present in

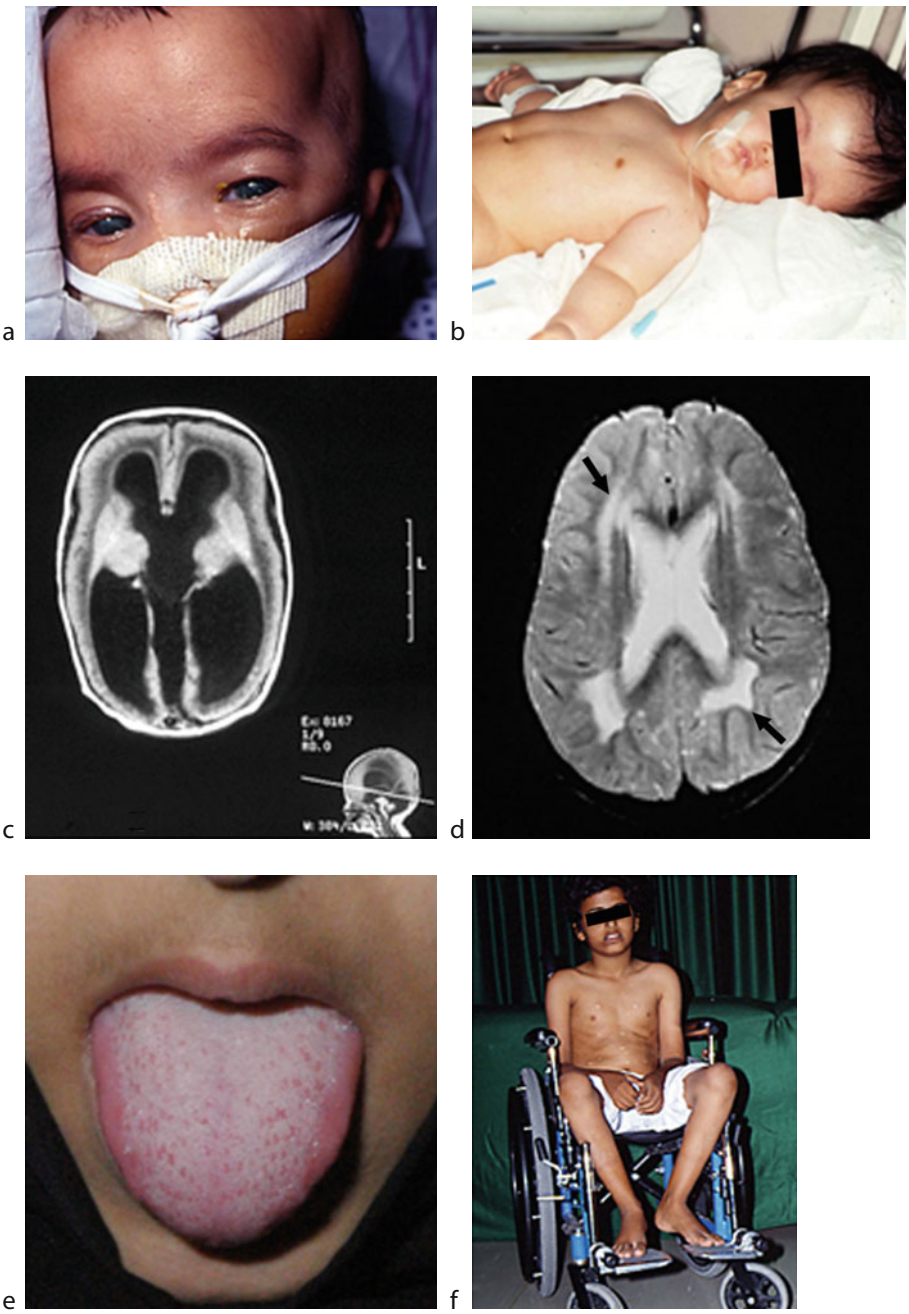

Figure 374.5

(a) Ocular malformations in Walker-Warburg syndrome (WWS). Note the megalocornea and corneal opacities associated with glaucoma. (b) Hydrocephalus in WWS. Note the hypotonic posture of the upper limbs. (c) Magnetic resonance imaging (MRI) in WWS. There is cobblestone lissencephaly with absence of sulcation, an irregular grey-white matter junction, and marked ventriculomegaly. The small saggital image on the right hand corner shows a large posterior fossa and severe dysplasia of posterior fossa structures. (d) Brain MRI in merosin-deficient congenital muscular dystrophy showing periventricular white matter changes (arrows). (e) Enlargement of the tongue in severe childhood autosomal recessive muscular dystrophy (SCARMD). (f) A 13-year-old male who had SCARMD mistaken for Duchenne muscular dystrophy. Muscle biopsy showed normal dystrophin and absent adhalin (α-sarcoglycan)

25% of patients. Obstructive hydrocephalus and microcephaly are common.

Congenital Muscular Dystrophy Type 1C (MDC1C)

This was reported in 2001 as a form of CMD with secondary laminin-α2 (merosin) deficiency and abnormal glycosylation of α-dystroglycan due to fukutin- related protein gene (*FKRP*) mutations. The features of this phenotype included weakness and hypotonia from birth or the first few months of life and a marked delay of motor milestones. Sitting and taking a few steps can be achieved by some patients in the first decade. Nevertheless, progressive weakness leads to respiratory insufficiency and death or ventilatory dependence in the first or second decade. There is pseudohypertrophy of the calf and thigh muscles followed by tongue enlargement. Intelligence is normal, and there are no radiological features of CNS involvement in MRI. However, a wide spectrum of phenotypes were found to be associated with *FKRP* mutations, from in utero or lethal Walker–Warburg syndrome, or muscle-eye-brain disease to a limb-girdle phenotype of muscular dystrophy (LGMD2I, see section "Limb-Girdle Muscular Dystrophy").

LARGE Congenital Muscular Dystrophy

This was described in a 17-year-old female adolescent who had compound heterozygous mutation in the *LARGE* gene. She presented with weakness and hypotonia at age 5 months, and had severe mental retardation. Neuroimaging revealed defects of brain migration and white matter abnormality. An abnormal electroretinogram suggested eye abnormalities.

A phenotype similar to Walker–Warburg syndrome was reported in two siblings who were seen by the author, and had a homozygous intragenic deletion in the *LARGE* gene. They presented at birth with severe hypotonia and respiratory difficulty, both had eye abnormalities and died within 6 months. Creatine kinase was markedly elevated, and cranial computed tomography showed severe hydrocephalus and features of structural brain disease.

Rigid Spine Muscular Dystrophy

This is an autosomal recessive condition, which presents with axial hypotonia and weakness in the first year of life, and motor difficulties secondary to mild-to-moderate proximal muscle weakness. The majority of patients eventually walk, but a few never gain independent walking. Ambulation is usually maintained into adulthood. Facial and palatal weakness (manifesting as nasal speech), and scapular winging are common. The overall muscle bulk may be reduced. The most characteristic pattern is spinal rigidity and scoliosis, which may develop between 3 and 12 years of age. Contractures are usually mild and affect the ankles. Respiratory insufficiency is common and progressive, and ventilatory assistance may be needed as early as the first decade of life to treat nocturnal hypoventilation. There is usually no cardiac involvement, and intelligence and MRI are normal.

Diagnosis

The diagnostic workup for CMD relies mainly on biochemical, imaging, and muscle biopsy studies.

Remarkable elevation of creatine kinase (2–150 times normal) is seen in most patients with CMD due to laminin-α2 (merosin) mutations or abnormal glycosylation of α-dystroglycan. Normal or mildly elevated levels (≤5 times normal) is seen in patients with Ullrich CMD, integrin-α7 deficiency, and rigid spine muscular dystrophy1 (due to deficiency of selenoprotein N).

Brain MRI is normal in patients with Ullrich CMD, integrin-α7 mutations, and in rigid spine muscular dystrophy1. The changes on MRI seen in CMD due to laminin-α2 (merosin), with periventricular white matter changes (increased T2 signal) being the most common abnormality, may be mistaken for a leukodystrophy (*Fig. 374.5d*). These white matter changes appear as hypodensity on cranial computed tomography (CT) scan.

Nerve conduction studies are normal except in patients with laminin-α2 (merosin) deficiency where features of demyelinating motor and sensory neuropathy can be revealed. Electromyography shows myopathic features and is usually not a helpful diagnostic procedure in children with CMD. However, myotonic discharges can be detected in older children who present with myotonic muscular dystrophy simulating CMD.

Brain auditory evoked responses (BAER) may reveal features of sensorineural hearing loss in patients with laminin-α2 (merosin)-deficient CMD and in an unclassified variant of CMD (seen by the Author) associated with cobblestone (type II) lissencephaly without eye malformations (OMIM 601170).

Muscle Biopsy

Muscle biopsy is essential in suspected cases of CMD for diagnostic confirmation and for the exclusion of other causes of weakness. The histopathological features of the various forms have been detailed previously in the "Pathology" section. Immunohistochemical studies also need to be done since they are of help in differentiating the various subtypes of CMD. In Ullrich CMD, collagen type VI staining around surface of muscle fiber is usually reduced or absent. However, staining may occur in connective tissue. Integrin-α7 deficiency CMD is characterized by decreased staining for integrin-α7, but this can also be seen in CMD with laminin-α2 (merosin) deficiency.

All of the α-dystroglycanopathies are characterized by decreased staining for α-dystroglycan, which is localized to the muscle cell surface. There is also decreased molecular weight of α-dystroglycan on western blot studies.

Patients with the classical MDC1A phenotype show complete loss of staining for laminin-α2 (merosin) on immunohistochemical staining. This is observed in both muscle and skin, since normal skin also expresses laminin-α2 in the basement membrane at the junction of the dermis and epidermis. Partial staining is seen on the allelic variants characterized by partial merosin (laminin-α2) deficiency, and in any CMD associated with α-dystroglycanopathy. Laminin-α2 (merosin) antibodies should be used against both the 300- and 80-kd subunits of the protein. Muscle biopsies in cases of CMD with partial laminin-α2 (merosin) deficiency may demonstrate an absence of laminin-α2 with one antibody but not the other.

Differential Diagnosis

This includes diseases, which present as the floppy infant syndrome. However, clinical evaluation of a child with suspected CMD, followed by immunohistochemistry and immunostaining of a muscle biopsy, can usually indicate specific genetic testing. Nevertheless, one rare entity can cause confusion and is important to recognize despite its rarity. It is the autosomal recessively inherited systemic hyalinosis, characterized by hyaline deposits in the papillary dermis and other tissues. The condition typically presents at birth or infancy with severe pain with movement, progressive joint contractures, and often with severe motor disability. Nonsteroidal anti-inflammatory drugs are cardinal in the management of such babies, and physiotherapy for joint contractures should be within the patient's tolerance for pain. Another important disease to differentiate is Marinesco–Sjögren syndrome. This is characterized by cerebellar ataxia with cerebellar atrophy, congenital or early-onset cataract, mild-to-severe mental retardation, hypotonia, and muscle weakness. Muscle biopsy shows myopathic features, leading to the condition being mistaken for one of the forms of CMD with mental retardation.

Treatment

Nonspecific treatment for CMD is similar to that detailed for Duchenne MD. A multidisciplinary approach is vital for children with CMD due to the various associated anomalies. Management of nonmuscle-related issues requires ophthalmic care, assessment for gastric tube feeding, management of seizures, and handling of profound mental retardation. Patients with fukutin-related proteinopathy commonly have cardiac complications, which are also occasionally seen in patients with laminin-α2 (merosin) deficiency. In such cases, treatment of dilated cardiomyopathy with ACE inhibitors and beta-blockers may be necessary.

Prognosis

The prognosis of CMD depends on the particular subtype. Children with Walker–Warburg syndrome rarely survive beyond 3 years of age. Occasionally, patients with laminin-α2 (merosin) deficiency and some patients with mutations in *FKRP* (fukutin-related proteinopathy) have a relatively normal life span.

Prevention

In laminin-α2 (merosin)-deficient CMD (MDC1A), prenatal diagnosis is possible by laminin-α2 (merosin) staining, since laminin-α2 is expressed in 9-week trophoblasts, allowing detection of the protein in chorionic villus. However, protein detection may not be reliable in families with partial laminin-α2 deficiency. Collagen VI immunostaining of the trophoblast can also be used for prenatal diagnosis of Ullrich CMD. A combination of linkage or direct mutation detection is possible for prenatal diagnosis in these two conditions (MDC1A and Ullrich CMD), and other types of CMD, when the disease-causing mutation is known. Preimplantation genetic diagnosis may also be available for families in which the diseases-causing mutation has been identified in an affected family member.

Limb-Girdle Muscular Dystrophy

Definition/Classification

Limb-girdle muscular dystrophy (LGMD) is a descriptive term with a wide range of phenotypic variability. Historically, the LGMD has been reserved for childhood-or-adult-onset muscular dystrophies (MDs) that are distinct from the X-linked forms. It is characterized by weakness involving the shoulder or pelvic-girdle muscles, expression in either male or female sex and autosomal recessive, or less frequently, autosomal dominant inheritance.

With the advent of molecular genetics, LGMD classification was changed during a consortium meeting, under the auspices of the European Neuromuscular Centre, in 1995. The suggested classification was based on identified genetic loci for LGMD. The dominant LGMD loci were designated LGMD1A, B, C, etc. and the recessive forms as LGMD2A, B, etc. in the order of their identification. Nevertheless, the classification of LGMD is still an ongoing process.

Epidemiology

The overall prevalence of all forms of LGMD has been estimated to range from one in 14,500 to one in 123,000. Different populations often have different frequencies of the various forms of LGMD.

Pathogenesis

Identification of dystrophin has led to the discovery of a large oligomeric complex of sarcolemmal glycoproteins that are associated with dystrophin. These dystrophin-associated glycoproteins span the sarcolemma to provide linkage between the sarcolemmal cytoskeleton and the extracellular matrix (*Fig. 374.3*). They were first identified by their molecular weight in kilodaltons (kd). The 156-kd dystrophin-associated glycoprotein (156 DAG, α-dystroglycan) is located extracellularly and provides a binding site for laminin-α2 (merosin:muscle-specific isoform of laminin). α-dystroglycan (156 DAG) is linked to β-dystroglycan (43 DAG), which is a transmembrane protein that binds intracellularly with dystrophin and extracellularly with α-dystroglycan. β-dystroglycan also interacts with the sarcoglycan complex, which is formed of adhalin (α-sarcoglycan, 50 DAG ["adhalin" is derived from the Arabic word "adhal," which means "muscle"]), β-sarcoglycan, γ-sarcoglycan, and δ-sarcoglycan. Adhalin (α-sarcoglycan) can also be replaced by ε-sarcoglycan, forming a minor complex in skeletal muscle, but the major sarcoglycan in smooth muscle, where α-sarcoglycan is not expressed. Deficiency of one or more these dystrophin-associated glycoproteins disrupts the linkage between sarcolemmal cytoskeleton and extracellular matrix, thus rendering muscle cells susceptible to necrosis.

Other molecular components (*Fig. 374.3*) that are known to be associated with LGMD include calpain-3, which is expressed exclusively in muscle and is likely anchored by titin, and telethonin protein (titin-cap protein), which is present in the Z disk that binds to titin and several other Z-disk proteins. Titin is the largest protein found in humans, spans the entire sarcomere from the M line to the Z disk, and plays a mechanical role in muscle contraction. Myotilin is a sarcomeric protein that binds to α-actinin and is associated with the Z-line, whereas lamin A/C is an intermediate filament in inner nuclear membrane and nucleoplasm of almost all cells. Dysferlin protein is a large membrane protein, which is thought to be involved in the docking and fusion of intracellular vesicles to sarcolemma during injury-induced membrane repair, whereas calveolin-3 is a protein involved in membrane trafficking in the myofiber.

Binding of α-dystroglycan to extracellular matrix proteins laminin-α2 (merosin), neurexin, agrin, and perlecan is glycosylation dependent (*Fig. 374.3*). In mammals, a unique carbohydrate structure containing O-linked mannose has been found on α-dystroglycan. Defects in O-glycosylation of α-dystroglycan lead to its disruption, and several genes encode for proteins, which are involved in the glycosylation of α-dystroglycan. Abnormalities of these glycosyltransferases usually result in several phenotypes of congenital muscular dystrophy but were also found recently to manifest as LGMD in some cases. Putative or demonstrated glycosyltransferases, which affect the glycosylation of α-dystroglycan include protein O-mannosyltransferases1 and 2 (POMT1 and POMT2). They also include O-mannose beta 1, 2-N-acetylglucosaminyltransferase (POMGnT1), fukutin, fukutin-related protein (FKRP), and LARGE.

The molecular genetics of the 14 autosomal recessive and 3 autosomal dominant forms of LGMD with currently known genes is detailed in *Table 374.2*.

Pathology

On muscle histology, pathological features of the LGMDs are generally similar to those seen in Duchenne and Becker

Table 374.2
Molecular genetics of the limb-girdle muscular dystrophies (LGMDs) with currently known genes

	Locus	Gene symbol	Protein product
Autosomal recessive LGMDs			
LGMD2A	15q15.1–q212.1	*CAPN3*	Calpain – 3
LGMD2B	2p13.3–p13.1	*DYSF*	Dysferlin
LGMD2C	13q12	*SGCG*	γ-sarcoglycan
LGMD2D	17q12–q21.3	*SGCA*	Adhalin (α-sarcoglycan)
LGMD2E	4q12	*SGCB*	β-sarcoglycan
LGMD2F	5q33	*SGCD*	δ-sarcoglycan
LGMD2G	17q12	*TCAP*	Telethonin
LGMD2H	9q31–q34.1	*TRIM32*	Tripartite motif protein 32
LGMD2I	19q13.3	*FKRP*	Fukutin-related protein
LGMD2J	2q24.3	*TTN*	Titin
LGMD2K	9q34.1	*POMT1*	Protein O-mannosyltransferase 1
LGMD2L	9q31	*FKTN*	Fukutin
LGMD2M	1p34–p33	*POMGnT1*	Protein O-linked-mannose beta-1,2-N-acetylglucosaminyltransferase 1
LGMD2N	14q24.3	*POMT2*	Protein O-mannosyltransferase 2
Autosomal dominant LGMDs			
LGMD1A	5q31	*TTID*	Myotilin
LGMD1B	1q21.2	*LMNA*	Lamin A/C
LGMD1C	3p25	*CAV3*	Caveolin-3

MD. However, the various forms of LGMD are characterized by variable degrees of fiber degeneration and regeneration, central nuclei, fiber-size variation, and endomyseal fibrosis. In addition, significant inflammatory changes are sometimes observed in LGMD2B (dysferlinopathy) and the presence of myopathic changes with rimmed vacuoles characterizes LGMD2G (telethoninopathy). Dystrophic features are often associated with inflammatory infiltrates in LGMD2L, LGMD2M and LGMD2N; and with type 1 fiber predominance in LGMD2I (*Table 374.2*).

Clinical Manifestations

Severe childhood autosomal recessive muscular dystrophy (SCARMD) was recognized as a precise nosological entity in 1983 following studies from Sudan and Tunisia on a Duchenne-like phenotype of muscular dystrophy, which affects both sexes equally (autosomal recessive).

Except for LGMD1B (dysferlinopathy), mutations in all autosomal recessive LGMD genes can present as SCARMD phenotype. The phenotype of SCARMD is seen in mutations of the genes encoding for the sarcoglycans, which account for about 20–25% of the LGMDs. Adhalin (α-sarcoglycan) deficiency accounts for 40% of the sarcoglycanopathies, followed by LGMD2C (γ-sarcoglycan) and LGMD2E (β-sarcoglycan), each accounting for about 23%. LGMD2F (δ-sarcoglycan) is rare outside Brazil where it constitutes 14% of cases. Sarcoglycanopathies (LGMD2C, 2D, 2E, and 2F) usually present as SCARMD, although unusual Becker-like phenotypes have been described.

Typically, SCARMD is characterized by onset before the age of 5 years (mean 8-5 years) in both sexes. Weakness progresses steadily until the child is unable to walk at about 10–15 years of age. Both sexes may become completely dependent by 16 years and die by 20 years or during the third decade. Selective muscle weakness in the upper and lower limbs has the same pattern as that seen in classical Duchenne MD. The facial muscles are mildly involved, as the disease progresses. Hypertrophy of the calf and other muscles is common, and the tongue may become enlarged (*Fig. 374.5e*). Intelligence is normal, a feature which differentiates SCARMD from Duchenne MD.

LGMD2A (*Calpainopathy*) is a common form of LGMD and accounts for about 30% of cases. The average age of onset is between 8 and 15 years, and the course of

the disease resembles that of Becker MD. Calf muscles are atrophic, and there is no facial or cardiac involvement.

LGMD2A (*Dysferlinopathy*) starts in late adolescence (onset between 17 and 23 years). The distribution of muscle weakness is distal and/or pelvic-femoral with no scapular winging. Rarely, there is transient hypertrophy of the calf muscles.

LGMD2G (*telothinoninopathy*) and *LGMD2H* (*TRIM32-related dystrophy*) tend to have a mild phenotype, with limb-girdle weakness. However, there is phenotypic variability between and within families in telethoninopathy, and patients eventually develop distal weakness. Mild cardiac involvement occurs in about 50% of patients.

The phenotype of LGMD2I (*fukutin-related proteinopathy*) can vary from severe congenital muscular dystrophy to mild, late-onset LGMD. Patients can present with typical SCARMD phenotype similar to that seen in sarcoglycanopathies (LGMD2C-2F).

The onset of *LGMD2J* (*titinopathy*) is at 5–25 years with proximal weakness. The disease follows Becker MD course with no facial muscle or cardiac involvement. It is noteworthy that mutations in the *titin* gene cause the autosomal recessive Salih myopathy and the dominant distal (tibial) muscular dystrophy described in Finnish patients (see section on "Congenital Myopathies" above).

Four phenotypes of LGMD are associated with defective glycosylation of α-dystroglycan due to mutation in genes also known to cause congenital muscular dystrophy (*Table 374.2*). *LGMD2K* (*due to POMT1 gene mutation*) is characterized by onset between 1 and 6 years, mental retardation, severe proximal weakness with slow progression, hypertrophy of the calves and thighs, and development of contractures in some patients. *LGMD2L* (*due to fukutin gene mutation*) presents with hypotonia before 1 year, proximal muscle weakness affecting the lower more than the upper limbs, and normal intelligence. Affected children have worsening of their weakness after intercurrent illness, which improves with steroids.

One affected female was reported with *LGMD2M* (*due to mutation in POMGnT1 gene*). Onset was at 12 years with proximal more than distal muscle weakness, calf hypertrophy, severe myopia, and normal intelligence. Ambulation was lost at 19 years. The phenotype of *LGMD2N* (*due to POMT2 mutation*) is characterized by slowness in running and getting up, scapular winging, mild lordosis, calf hypertrophy, and mental retardation. One of the described female patients was asymptomatic at 5 years.

The autosomal dominant *LGMD1A* (*myotilinopathy*) is a disease of adulthood, whereas *LGMD1B* (*laminopathy*) can start from childhood (<10 years) to the mid-30s. LGMD1B is due to mutations in the gene encoding for lamin A/C and can present as Emery–Dreifuss or congenital muscular dystrophy phenotypes, or as axonal Charcot-Marie-Tooth disease. The disease manifests with proximal lower limb weakness and mild contractures of elbows. Cardiac disease develops between 25 and 45 years and is in the form of arrhythmias and dilated cardiomyopathy.

The onset of *LGMD1C* (*calveolinoapthy*) ranges from the first decade to late adulthood. Childhood-onset disease is characterized by mild-to-moderate proximal weakness, exercise-induced cramps, and calf muscle hypertrophy. Cardiac involvement is also common.

Diagnosis

Serum creatine kinase (CK) is always increased in autosomal recessive LGMD. Levels are elevated by 10–150 times normal in sarcoglycanopathies (LGMD2C-2F) and in dysferlinopathy (LGMD2B). Elevations of CK are 3–80 times normal in other autosomal recessive LGMDs. Autosomal dominant LGMDs result in CK levels between normal and 15 times normal, but high results (ranging between 4 and 25 times normal) can be seen in LGMD1C (calveolinopathy).

Magnetic resonance imaging shows hyperintense signal changes on T1-weighted image in more severely affected muscles. Patients with LGMD2D (adhalinopathy, α-sarcoglycanopathy) and those with Becker MD show more severe MRI changes in the anterior thigh compartment than in the posterior thigh. In LGMD2I (fukutin-related proteinopathy), the most severe changes are in the posterior and adductor thigh muscles, with less severe changes in gluteal and calf muscles. Patients with LGMD2A (calpainopathy) have more severe and selective involvement of the medial gastrocnemius and soleus muscles associated with severe involvement of the posterior and adductor thigh muscles.

Nerve conduction studies are normal in LGMDs. Electromyography (EMG) shows myopathic features but is usually not a helpful diagnostic tool in children. Neurogenic features on EMG, in the form of fibrillations and positive sharp waves, should raise the suspicion for an inflammatory myopathy, such as polymyositis.

Electrocardiography (ECG) provides a simple means for aiding in the diagnosis, especially in young boys with LGMD. In sarcoglycanopathies, it may show ST-segment and T-wave changes involving leads II, III, and AVF, suggesting basal myocardial involvement with the dystrophic process, but none of the tall right precordial R waves in the lateral and left leads which are characteristic of

Duchenne MD. It will also detect cardiac involvement, which is common in the other recessive LGMD2G (telethoninopathy) and LGMD2I (fukutin-related proteinopathy). Cardiac involvement is also common (50–65%) in the autosomal dominant LGMD1A (myotilinopathy) and LGMD1B (laminopathy).

Muscle biopsy is an important diagnostic tool in LGMD. Histochemical examination of frozen muscle biopsy shows typical dystrophic features in most cases (see "Pathology" in Duchenne and Becker Muscular Dystrophies (MDs)). Severe dystrophic features are often seen in the sarcoglycanopathies (LGMD2C-2F) and in LGMD2I (fukutin-related proteinopathy). In LGMD2A, (calpainopathy) the muscle biopsy may show perimyseal and perivascular T-cell infiltrates similar to the histological findings in polymyositis.

Immunohistochemical staining is essential to help in guiding the molecular pathological investigations. Dystrophin should be tested first by using antibodies to N-terminus, rod, and C-terminus. Nevertheless, it should be remembered that minor reduction in dystrophin staining can be seen in sarcoglycanopathies, and minor reduction in sarcoglycan staining may occur in dystrophinopathies. Hence, both dystrophin and sarcoglycan immunostaining must be performed in the same sample. Normal dystrophin immunostaining and complete deficiency of the sarcoglycans suggest mutations in one of the sarcogycan genes as being causative. All sarcogycans are usually absent in β- and δ-sarcoglycanopathies. In adhalinopathy (α-sarcoglycanopathy), α-sarcoglycan (adhalin) is most reduced and there is selective preservation of γ-sarcoglycan, while in γ-sarcoglycanopathy, α-sarcoglycan is most reduced with variable preservation of other sarcoglycans. Nevertheless, no immunostaining pattern is specific enough to identify which of the four sarcoglycan genes may be involved. Muscle biopsy shows decreased staining for α-dystroglycan in the five phenotypes of LGMD associated with defective glycosylation of α-dystroglycan (*Table 374.2*: LGMD2I, LGMD2K, LGMD2L, LGMD2M, LGM2N). There is also decreased molecular weight of α-dystroglycan on Western blot studies. Laminin-α2 (merosin) staining may also be deficient.

Protein analysis of LGMD2A (calpainopathy) needs to be interpreted with caution since sensitivity and specificity for both immunostaining and Western blot analysis are reduced. Deficiency of calpain-3 on immunostaining is seen in LGMD2A (calpainopathy) as well as in many types of LGMD as a secondary effect. In LGMD2B (dysferlinopathy), immunohistochemistry of muscles reveals absence of dysferlin, but partial deficiency has been observed in some cases.

Differential Diagnosis

Careful clinical assessment and raised serum CK help to limit the differential diagnosis of LGMDs. However, SCARMD phenotype, especially in males, is usually mistaken for Duchenne MD (*Fig. 374.5f*). Becker MD may also be mistaken for the milder forms of LGMDs. Type III spinal muscular atrophy (Kugelberg–Welander disease) and subacute or chronic polymyositis may on occasions need to be considered as differential diagnoses. Metabolic myopathies, such as glycogenosis, can give a clinical picture that resembles LGMD.

Treatment

No specific treatment is available for any of the LGMDs. As detailed previously for Duchenne and Becker MDs, a team approach is needed to provide supportive care, prevent and correct skeletal abnormalities, manage cardiopulmonary complications, and maximize functional ability. In LGMD1B (laminopathy), cardiac arrythmias can be a major cause of morbidity and mortality due to sudden cardiac death, and placement of a pacemaker may be life-saving.

Clinical trials of steroids in LGMDs have not been reported yet. However, a beneficial effect of steroids on LGMD2D (adhalinopathy, α-sarcoglycanopathy) and LGMD2I (fukutin-related proteinopathy) has been reported.

Experimental gene transfer has been tried in sarcoglycanopathies and in calpainopathy using non-viral and viral vectors (adenovirus and adeno-associated virus). More recently, human clinical trials have begun in human sarcoglycan deficiencies. The possibility of restoring muscle function by cell therapy, using stem cells or early precursor cells capable of regenerating damaged tissue, has been studied in sarcoglycanopathies and in dysferlinopathies.

Prognosis

The development of cardiomyopathy, cardiac arrhythmia, pulmonary insufficiency, joint contractures, and scoliosis are the major operating factors regarding mortality. These are dictated by the specific genetic mutation, as outlined previously (see section "Clinical Manifestations" above).

Prevention

Genetic counseling helps affected families regarding future pregnancies. Prenatal diagnosis for pregnancies at

increased risk is possible for some types of LGMD through chorionic villus sampling (at about 10–12 weeks of gestation) or amniocentesis (at about 15–18 weeks' gestation). Prior knowledge of the disease-causing alleles in an affected family member is required before performing this test. Preimplantation genetic diagnosis is available for families in which the disease-causing mutation has been identified.

Facioscapulohumeral Muscular Dystrophy

Definition

Facioscapulohumeral muscular dystrophy (FSHD) is characterized by progressive weakness and wasting with a facioscapulohumeral distribution due to an autosomal dominantly inherited muscular dystrophy.

Epidemiology

The estimated prevalence of FSHD is between 4 and 10 per 100,000 population, and the disease is the third most common muscular dystrophy. A molecular genetics-based epidemiological study in central Italy found a prevalence of 4.6 per 100,000.

Pathogenesis

Facioscapulohumeral muscular dystrophy (FSHD) is inherited as autosomal dominant. In 70–90% of affected individuals, the disease-causing deletion is inherited from a parent and 10–30% has the disease as a result of de novo deletion. Approximately half of the de novo FSHD cases result from mosaicism, and mosaic males are more susceptible to FSHD than mosaic females.

About 95% of individuals with FSHD have a contraction mutation of the repeat sequence of the D4Z4 locus in the subtelomeric region of chromosome 4q35. However, as of 2009, no causative FSHD-specific transcription has been identified from the D4Z4 locus or the 4q35 region. In unaffected individuals, both D4Z4 alleles have 11–100 repeat units, whereas in affected individuals, one D4Z4 allele is contracted to between 1 and 10 repeat units, and the other D4Z4 allele is normal (11–100 repeat units). Recently, specific sequence variations within the 4q35 region were found to be associated with FSHD. Haplotypes (i.e., different combinations of single nucleotide polymorphisms [SNPs] at one locus that are inherited together) telomeric to the D4Z4 locus, designated 4A and 4B, contribute to the pathogenicity of a contracted D4Z4 mutant allele. Whereas contractions of the D4Z4 allele on the haplotype designated 4A161 cause FSHD, other contractions on the haplotype designated 4A166 and 4B are nonpathogenic.

Clinical Manifestations

The usual presentation of FSHD is between the first and third decades. However, the age of onset is variable and rare infantile cases have been described. More than 90% of affected individuals show clinical features by age 20 years. Disease manifestation is higher in males; asymptomatic cases are more common in females. Severe infantile FSHD present with weakness at birth, whereas some individuals remain asymptomatic throughout their lives.

Shoulder weakness is the most common initial finding and is the presenting symptom in more than 82% of patients. Weak scapular fixation results in scapular winging and its upward movement when attempting to flex or abduct the arms (*Fig. 374.6a*). Some individuals have facial weakness before the onset of shoulder weakness. Facial affection presents with inability to purse the lips, bury the eyelashes when attempting to close the eyelids tightly, or turn up the corners of the mouth when smiling, resulting in a transverse smile. Extraocular and pharyngeal muscles are spared.

The biceps and triceps muscles are selectively involved, while the deltoids remain minimally affected until late in the disease. The contrast between the atrophic upper arm and the spared forearm muscles gives the appearance of "Popeye arms." Abdominal muscle weakness results in exaggerated lumbar lordosis and protuberance of the abdomen. Lower abdominal muscles are weaker than upper abdominal muscles, resulting in upward displacement of the umbilicus upon flexion of the neck in supine position (Beevor sign).

The legs are variably involved, but tibialis anterior muscle weakness is characteristic and posterior muscles of the leg are spared, resulting in foot drop. Tendon jerks are often diminished, whereas sensation is preserved.

Slow and continuous progression of the disease is usual, although a fluctuating course with periods of disease inactivity followed by periods of rapid deterioration is described by many patients. About 20% of affected individuals become wheelchair-bound.

Reported extraocular manifestations in patients with FSHD include high-tone sensorineural hearing loss in about 60%, atrial arrhythmias in 50%, and restrictive

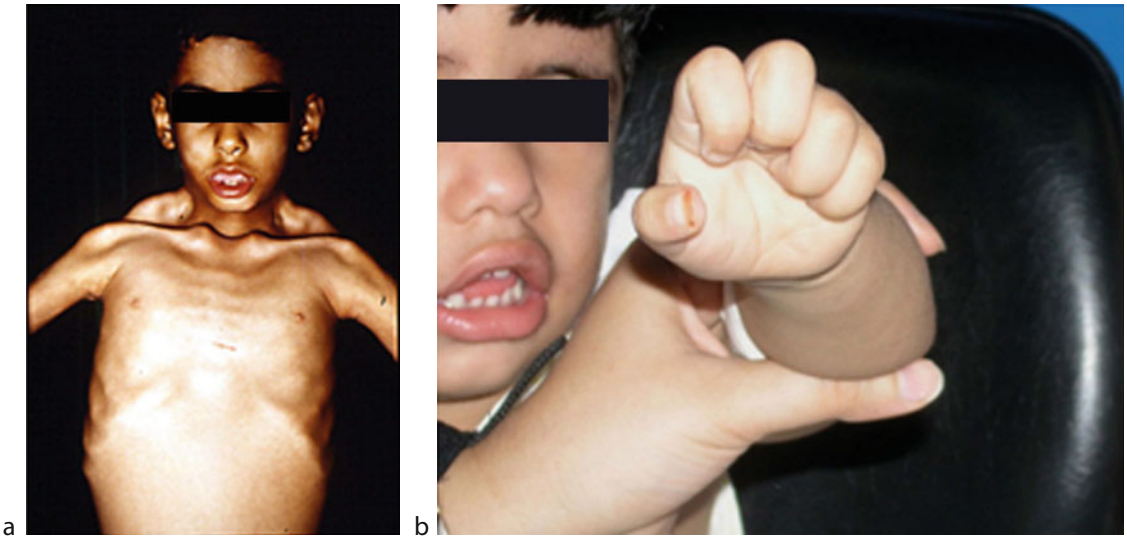

Figure 374.6
(a) Upward lifting of scapula in fascioscapulohumeral muscular dystrophy when abducting the arms. Note the facial weakness, open mouth and atrophic upper arm muscles. (Courtesy of the late Dr. Awad H. Mahdi). (b) Grip test in myotonic dystrophy (dystrophia myotonica). After contraction of the fist, the patient is unable to relax the muscles of the hand. Note the myopathic face and open mouth

respiratory disease in 1%. Ocular manifestations include retinal telangiectasia and micro aneurysms, seen in 40–60%, usually without affecting vision, and Coats syndrome (retinal vasculopathy with telangiectasia, exudation, and retinal detachment). Mental retardation and epilepsy have been reported in early-onset FSHD, often with associated deafness and retinopathy.

Clinical variants of FSHD in individuals with a contraction mutation of the D4Z4 locus in the subtelomeric region of chromosome 4q35 include scapulohumeral dystrophy with facial sparing, and FSHD with chronic progressive external opthalmoplegia (reported in one kindred).

Diagnosis

Serum Creatine Kinase (CK) is normal or mildly raised (three to five times the upper limit of normal), and CK level over 1,500 IU/L suggests an alternative diagnosis. Electromyography usually shows mild myopathic changes.

Muscle biopsy is indicated in suspected cases of FSHD, in whom molecular genetic testing was not confirmed. Nonspecific chronic myopathic changes are the most common pathological features, and mononuclear inflammatory reaction is present in up to 40% of muscle biopsies. The intensity of the inflammatory reactions may, on rare occasions, suggest an inflammatory myopathy. Molecular genetic testing is the preferred method to confirm the diagnosis.

Differential Diagnosis

Certain neuromuscular disorders may simulate FSHD but can be differentiated by their specific clinical features and distinct muscle histopathology. These include congenital myopathies, polymyositis, and mitochondrial myopathies. Scapuloperoneal muscular dystrophy syndromes and myotonic dystrophy (types 1 and 2) with mild facial weakness may be challenging to differentiate from FSHD. Definitive exclusion of these two conditions can be done by molecular genetic testing.

Treatment

Currently, no definitive therapy is available for FSHD. General care should include the use of lubricants to prevent exposure keratitis in individuals who sleep with their eyes partially open. Aerobic training may improve exercise performance. Assessment and surveillance of sensorineural hearing loss, and evaluation for the need for assistive

devices are important components of management. Ankle/foot orthosis can improve mobility. Surgical fixation of the scapula to the chest wall (scapulopexy) often improves range of motion of the arms. Surveillance of retinal telangiectasia is crucial, and retinal photocoagulation may prevent serious consequences of Coats syndrome.

Prognosis

The size of the DNA deletion affects disease severity and prognosis. Individuals with a large contraction of the D4Z4 locus tend to have earlier-onset disease and more rapid progression than those with smaller contractions of the D4Z4 locus. On average, de novo mutations are associated with larger contraction mutations of D4Z4. Nevertheless, life expectancy is normal in most patients with FSHD.

Prevention

Prenatal testing is available for pregnancies at 50% risk of FSHD by analysis of DNA extracted from chorionic villus sampling at approximately 10–12 weeks of gestation or from fetal cells obtained by amniocentesis (at approximately 15–18 weeks' gestation). Since FSHD does not usually affect the life span, prenatal diagnosis for the purpose of pregnancy termination should be discussed with the concerned family within its ethical perspective.

Myotonic Dystrophy

Definition/Classification

Myotonic dystrophy (dystrophia myotonica, DM) comprises a group of dominantly inherited, multisystem diseases that share the common features of myotonia, weakness, and early onset cataracts. Classic DM (first described by Steinert and called Steinert's disease or myotonic dystrophy type 1 [DM1]) was identified to be associated with the presence of an abnormal expansion of CTG trinucleotide repeat on chromosome 19q13.3 (the DM1 locus). A similar but distinct and less common disorder was found to be caused by alterations in a different gene on chromosome 3q21, and was designated as myotonic dystrophy type 2 (DM2).

Epidemiology

Myotonic dystrophy has an estimated prevalence ranging between 5 and 20 per 100,000. Higher prevalence has been reported from certain regions around the world including Sanquenay-Lac St. Jean region of Quebec, Canada (162 per 100,000), Istria region of Croatia, Basque region of Spain and Norbotten in North Sweden. In a population survey in the eastern province of Saudi Arabia, the prevalence of myotonic dystrophy was recorded to be 88 per million population. Myotonic dystrophy type 1 (DM1) has been rarely reported in sub-Saharan Africa, Australia, Southern China, Thailand, and the Pacific Islands. The proportions of myotonic dystrophy caused by DM1 and DM2 are unknown. A higher prevalence of DM2 was observed in Germany and Poland in individuals of German or Polish descent.

Pathogenesis

Myotonic dystrophy type 1 (DM1) is caused by expansion of a CTG trinucleotide repeat in the dystrophia myotonica protein kinase (*DMPK*) gene on chromosome 19q13.3. The disease is inherited as autosomal dominant, and in most cases, the mother is the affected parent because the gene is less stable in the maternal DNA of the ovum than in the paternal contribution in the sperm. Normal individuals have 5–30 CTG trinucleotide repeats in leukocyte DNA, whereas patients with DM1 have a wide range of CTG repeat sizes, with more severely affected individual having repeat sizes in the thousands.

One of the characteristics features of DM1 is the phenomenon of anticipation, which is defined as the earlier onset of more severe clinical manifestations in offspring of affected individuals. This is due to the progressive increase in the size of the CTG repeats in successive generations in the eggs of the female and the sperm of the males who carry the DM1 mutation. The CTG repeat enlargement occurs to a greater degree in the eggs than in the sperm of affected individuals, and explains the almost exclusive restriction of cases of congenital MD1 to offspring of mothers with DM1.

The molecular pathomechanism leading to the manifestations of DM1 is likely to result from a toxic effect of the abnormally expanded RNA that accumulates in the target tissues. These include the insulin receptor and the muscle-specific chloride channels and lead to insulin resistance and myotonia, respectively. Other sequela of expanded RNA is inhibition of myoblast differentiation, leading to muscle maturational arrest, impairment of muscle regeneration, and an aberrant alternative splicing of a number of genes in the cortical neurons leading to mental retardation.

Myotonic dystrophy type 2 (DM2), which is a disease of adult life, results from an unstable four nucleotide

repeat expansion, CCTG, in intron 1 of the zinc finger protein 9 (*CNBP*) gene on chromosome 3q21.

Pathology

The muscle biopsy in congenital myotonic dystrophy (DM1) shows true maturational arrest with myoblasts, myotubes, mature myofibers, and histochemically undifferentiated myofibers within the same fascicles. There is persistent fetal expression of vimentin and desmin intermediate filaments. Occasionally in congenital DM1, muscle fiber – type disproportion is observed, and manifests as uniform smallness and more than 80% predominance of type 1 fibers.

Clinical Manifestations

Onset of the congenital form of myotonic dystrophy (DM1) is prenatal. Polyhydramnios is present in about half of the cases because of inadequate fetal swallowing of amniotic fluid. Breech and premature deliveries are frequent. Congenital contractures manifest at birth and range from simple equinovarus deformities to arthrogryposis multiplex congenita involving the lower limbs more than the upper limbs. Hypotonia, weakness, and facial diplegia are the most striking features. Pharyngeal weakness and dysphagia are common and usually necessitate gavage feeding and eventually gastrostomy. Respiratory insufficiency due to diaphragmatic and intercostal muscles weakness occurs in about half of the patients. A hemidiaphragm may be nonfunctional. Apnea is common, and neonatal or early infancy death is frequent. Other commonly seen features include undescended testis of male infants, poor peristalsis due to smooth muscle involvement leading to abnormal distension, and cholelithiasis or cholestasis due to poor muscle function of the gall bladder. Endocrine abnormalities may include insulin resistance, and involvement of the thyroid and adrenal medulla. The resulting abnormal regulation of blood sugar requires special vigilance for the development of hypoglycemia. Congenital cataracts are frequent and electrocardiographic (ECG) abnormalities are found in a minority, usually in the form of conduction defects rather than cardiomyopathy. Affected babies do not develop seizures unless secondary to intrapartum asphyxia. Almost all of the less severely affected patients who survive the neonatal period develop mental impairment.

The clinical presentation of myotonic dystrophy type 1 (DM1) is variable, and varieties may occur in the same kindred. Myotonia is demonstrated by percussion of the thenar muscle or tongue, the thumb remaining opposed, the tongue being dimpled for several second, after percussion of its side using a triangular hammer. Ocular myotonia is elicited by having the patient shut the eyes tightly for seconds, and then ask to suddenly open them. The orbicularis oculi remains closed before slowly opening. Grip myotonia is elicited by shaking hands or having the patient squeeze the examiner's fingers, and then asking to suddenly let go. After contraction of the fist, the patient is unable to relax the muscle of the hand (*Fig. 374.6b*).

There is selective distribution of muscle weakness and atrophy, which begins in the face and involves the masseters and temporal muscles, giving the phenotype of long thin face and hollowed temporal fossae. There is also facial diplegia with tent-shaped upper lip, open mouth, and mild ptosis. Involvement of the limbs includes wasting of the brachioradialis and the muscles of the anterior compartment of the leg. When atrophy is visible before 20 years of age, it is likely to be progressive, and severe distal weakness becomes established by middle adult life. Smooth muscle involvement leads to decreased gastric motility and chronic constipation. Cataracts are usually not seen before 8–10 years of age and may occur in isolation in asymptomatic DM1.

Patients with DM1 who present in the second and third decades usually develop progressive dysarthria, gastric regurgitation, difficulty swallowing, insulin resistance, hypogonadism, deficient release of growth hormone, and cognitive and neurophysiological alterations. They also usually develop sleep apnoea, hypersomnia, decreased forced vital capacity, conduction cardiac disturbances, and other subclinical cardiac involvement manifesting as decreased myocardial Doppler velocities. Lifespan may be shortened due to respiratory failure, cardiac conduction disturbances, or pneumonitis.

Diagnosis

The diagnosis of the classical form of DM1 is usually easy. EMG shows the myotonic discharges confirming the diagnosis. However, neonatal DM1 closely simulates congenital myopathies, congenital myasthenia, and congenital muscular dystrophies. Examination of the mothers for myotonia is the best clue, and EMG is likely to show myotonic discharges. EMG of the neonate is not helpful since myotonia is not yet developed. Muscle biopsy is

indicated only when examination of the mother and the genetic marker of the disease are equivocal.

Required imaging studies for neonatal DM1 include chest and abdominal X-rays, which frequently demonstrate thin ribs and help determine the status of diaphragmatic and gastrointestinal functions. To further define diaphragmatic hemiparesis, ultrasound or fluoroscopy may be needed. Electrocardiography is important in all cases of myotonic dystrophy. A slit-lamp examination for congenital cataracts is necessary since direct ophthalmoscopy is not adequate.

Serum creatine kinase (CK) is not diagnostic and is usually normal. Endocrine studies for blood sugar, thyroid function, serum cholesterol and insulin should be arranged.

The gold standard for establishing the diagnosis of DM1 is to determine the presence of abnormal expansions of CTG repeats in 19q13.3 myotonic dystrophy type1 gene.

Treatment

Neonatal myotonic dystrophy requires prompt and multidisciplinary management regarding the respiratory and feeding requirements. Arthrogryposis requires early physiotherapy and might need surgical correction. Attention to gastrointestinal motility and cardiac function is important.

The basic approach of DM1 in later childhood is also symptomatic and required surveillance for cardiac, respiratory, and ophthalmic complications. Myotonia in DM1 is typically mild to moderate and rarely requires treatment. Anecdotal reports describe individuals who have responded to mexiletine, imipramine, or carbamazepine.

Prognosis

Infants with DM1 who have respiratory insufficiency and dysphagia have poor prognosis and most of them die early. Survivors usually have learning disabilities later in life or mental retardation. The life-threatening complications in DM1 are primarily respiratory (respiratory failure) and cardiac (heart block or other serious conduction disturbances).

Prevention

Prenatal diagnosis is available from either chorionic villus samples or amniocentesis. The analysis of DNA from these samples shows accuracy in CTG repeat size that predicts the severity of neonatal disease. Both prenatal diagnosis and preimplantation genetic diagnosis require prior confirmation of the diagnosis of DM1 by molecular genetic testing in an affected family member.

Schwartz-Jampel Syndrome

Schwartz-Jampel syndrome (SJS) is a term applied for two different autosomal recessive disorders namely, SJS type I and SJS type II. Type I SJS is a rare myotonic syndrome, which is relatively more prevalent in communities of the Middle East with high consanguinity rate. It is characterized by mask-like facies, narrow palpebral fissures (blepharophimosis), microstomia, generalized myotonia, muscular hypertrophy, osteochondro-dysplasia, and growth retardation. Type I SJS is divided into two subtypes IA and IB, which are similar. The classical type IA SJS is apparent in childhood and is less severe, whereas type IB is apparent immediately at birth and is more severe clinically.

Both types IA and IB are caused by mutations of the same gene, the *HSPG2* gene that codes for perlecan, a heparin sulfate proteoglycan, which is the major proteoglycan of the basement membranes (*Fig. 374.3*). The exact role of perlecan in the causation of myotonia in SJS is still unknown.

The diagnosis of SJS is made by the clinical features, which resemble those seen in myotonic disorders. Electromyography (EMG) typically shows the continuous and spontaneous electrical activity (dive bomber or "departing motor cycle") activity, similar to that observed in myotonic dystrophy. However, the electrical activity often lacks the waxing and waning quality seen in the latter condition. X-ray can reveal the skeletal deformities, minor elevations of serum creatine kinase and aldolase may be detected, whereas muscle biopsy is consistent with myopathy.

Morbidity in type I SJS is mainly related to the muscle stiffness, the problems with blepharospasm, and skeletal abnormalities. The disease is associated with increased risk for the development of malignant hyperthermia.

Treatment modalities include medication with anticonvulsants (e.g., phenytoin and carbamazepine) and antiarrhythmics (e.g., mexiletine), which are useful in myotonic disorders. In children, carbamazepine is a safer option.

Significant cosmetic and functional improvement of blepharospasm was reported following judicious use of BOTOX (botulinum toxin) injections. If not working,

surgical intervention may maintain a sufficiently wide-open eye. The risk of the development of malignant hyperpyrexia should always be kept in mind.

Inflammatory Myopathies

See chapter Dermatomyositis and Polymyositis "Pediatric Rheumatology section."

Ion Channel Disorders

Chloride Channel Disease: Myotonia Congenita

Myotonia congenital is a genetic disorder caused by mutations in chloride channel gene (*CLCN1*) on chromosome 7q. The disorder is transmitted as either autosomal dominant or recessive trait, and is often sporadic.

The autosomal dominant form (Thomsen disease) is often present from birth or infancy. It is characterized by painless muscle stiffness after rest and difficulty to initiate movement, which disappears following activity. The stiffness increases by exposure to cold, and many patients have generalized muscle hypertrophy as a consequence of continuous muscle contraction.

The recessive form (Becker disease) is more severe and is characterized by stiffness associated with weakness. Onset is between 3 and 12 years of age, and the disease is often progressive to age 30 years. Muscle hypertrophy may coexist with distal atrophy.

The diagnosis of myotonia congenita is established by demonstrating myotonia clinically and neurophysiologically by electromyography (EMG). Absence of type 2B fibers is found on muscle biopsy, which is rarely indicated. The condition may be associated with malignant hyperthermia, and treatment in the more severe cases may be with carbamazepine in the usual anticonvulsant dosage.

Periodic Paralyses

Definition/Classification

These are heterogeneous group of nondystrophic muscle diseases, characterized by episodes of flaccid muscle weakness, which occur at irregular intervals. Periodic paralyses can be divided into primary or secondary disorders. The primary periodic paralyses (PP) are hereditary disorders resulting from defective ion channels, which might be associated with myotonia. Most PP are associated with alteration in serum potassium level.

Epidemiology

The prevalence of hypokalemic periodic paralysis is estimated to be 1 case per 100,000 population. The frequencies of other types of periodic paralyses (PP) are not known.

Pathophysiology

Sodium channel diseases are due to various mutations in the sodium channel gene (*SCN4A*) on chromosome 17q. These include hyperkalemic PP (or HyperPP), hypokalemic PP (HypoPP2), paramyotonia congenita, and potassium-aggravated myotonia.

Calcium channel disease manifests as hypokalemic PP (HypoPP1). On the other hand, *potassium channel diseases* include Andersen–Tawil syndrome, and hyperkalemic PP or hypokalemic PP.

The physiologic basis of flaccid weakness in all of these channel disorders is inexcitability of the muscle membrane (i.e., the sarcolemma). Alteration of potassium metabolism is a result and not a principal defect in primary PP.

Clinical Manifestations

Hyperkalemic Period Paralyses

The age of onset of this group of disorders is before 10 years of age and may even occur in infancy. Attacks are often triggered by moderate exercise and last for few minutes to less than 2 h (mostly <1 h). Weakness starts in the thigh and claves, spreads to arms and neck, and myotonia is often associated with the weakness. Electrical myotonia may be detected in 50–75%, but clinically apparent myotonia is seen in $<20\%$ of patients. In children, a myotonic lid lag (lagging of upper eyelid on downward gaze) may be the earliest symptom. Triggering factors for the attacks include exposure to cold, low carbohydrate intake (fasting), and rest following exercise. Other triggering factors include infections, trauma, and emotional stress. Paresthesias and muscle pains may be reported by some patients.

Hypokalemic Periodic Paralysis

Onset is usually between 5 and 16 years, but mild cases may present as late as the third decade. The intensity and extent of weakness are very variable and range from slight transient weakness of an isolated muscle group to severe generalized weakness. Severe attacks commonly begin in the morning and are often precipitated by meals rich in carbohydrate or by exercise following rest. Exposure to cold may also be a trigger. Other reported precipitating factors include Chinese food, lack of sleep and fatigue, fever and upper respiratory tract infections, and change in the barometric pressure or humidity. Weakness affects proximal limb muscles in some patients, and is generalized in others, facial muscles are rarely affected, whereas extraocular and respiratory muscles are not involved. Because of intracellular accumulation of water in muscles, urinary output is decreased. Hypertrophy of the calves has been observed in some patients. The age of onset is earlier in the calcium channel disease HypoPP1 (10 years) compared with the sodium channel disease HypoPP2 (16 years). The duration of symptoms is longer in HypoPP1 (20 h) compared to that seen in patients with HypoPP2 (1 h). About 70% of patients with HypoPP1 develop fixed proximal weakness, but this does not occur in HypoPP2.

Potassium-Aggravated Myotonia

This rare autosomal dominantly inherited disorder resembles Thomsen disease (the dominant form of myotonia congenita). The myotonia is aggravated by potassium intake and cold exposure, and muscle weakness is not a significant feature. It has been divided into three categories, namely, myotonia fluctuans, myotonia permanens, and acetazolamide-responsive myotonia congenita (MC). Stiffness and muscle pain due to myotonia are episodic in myotonia fluctuans and acetazolamide-responsive MC, but are continuous in myotonia permanens.

Paramyotonia Congenita

This is a dominantly inherited sodium channel disease characterized by myotonia, which is present from infancy and involves especially the eyelids, facial muscles, hand muscles, and sometimes the pharyngeal muscles. Myotonia worsens with activity (paradoxical myotonia), cold temperatures, and potassium loading, but in some patients, lowering of the serum potassium may precipitate the attacks. Many patients also experience episodes of weakness, which usually last for a few minutes, but may last for days. Patients may also develop muscular atrophy. Pathologically, the condition has been associated with absence of type 2B fibers.

Andersen–Tawil Syndrome

This is a potassium channel disorder, which is characterized by the triad of dysmorphic features, periodic paralysis, and cardiac arrhythmias. The periodic paralysis, which is not associated with myotonia, may be spontaneous but usually follows physical activity, and lasts for a few hours to several days. The dysmorphic features include hypertelorism, micrognathia, low-set ears, and clinodactyly of the fifth finger. Patients also have short stature and scoliosis. The most common cardiac manifestations are prolonged QT interval and ventricular arrhythmias.

Secondary Periodic Paralyses

Secondary hypokalemic periodic paralyses are mainly caused by urinary or gastrointestinal losses of potassium. Urinary potassium wasting occurs in hyperaldosteronism, Bartter syndrome, Conn syndrome, Licorice intoxication, renal tubular acidosis, amphotericin B therapy, and thiazide treatment. Gastrointestinal potassium wasting occurs with severe diarrhea and vomiting, and draining intestinal fistulae. Hypokalemic periodic paralysis is often associated with hyperthyroidism in Oriental patients, but this occurs rarely in Western countries.

Secondary hyperkalemic periodic paralysis may result from potassium load, therapy with potassium-sparing diuretics, chronic renal failure, ileostomy with tight stoma, Addison disease, and hyporeninemic hypoaldosteronism.

Diagnosis

The diagnosis of hypokalemic periodic paralysis can be suspected from the characteristics of the paralysis and family history. Although serum potassium may be as low as 1.5 mmol/L, it is often only slightly lowered. A random urine potassium-creatinine ratio of less than 1.5 indicates poor intake, gastrointestinal loss, and potassium shift into the cells. Serum creatine kinase (CK) is raised during the attacks. Electrocardiographic (ECG) changes include bradycardia, prolonged PR and QT intervals, and flattening of T waves.

The diagnosis of hyperkalemic periodic paralysis (PP) may be confirmed by demonstration of ECG changes, such as peaked T waves, and the finding of elevated potassium concentration (to as high as 5–6 mmol/L). Serum sodium level may fall as potassium level rises, and increase in CK level may also occur at the end of an attack.

Electrophysiologic studies reveal declining of the compound muscle action potential (CMAP) amplitude during the paralytic attack more often in hypokalemic PP. In hyperkalemic PP, repetitive nerve stimulation may show progressive decrement in CMAP (accentuated by cooling) without tendency to recover as in myasthenia gravis. The presence of myotonia on electromyography (EMG) excludes the diagnosis of hypokalemic PP. Myotonia is often associated with the weakness in hyperkalemic PP, and no abnormality is detectable between attacks.

Differential Diagnosis

The differential diagnosis of periodic paralyses (PP) includes peripheral neuropathy of acute onset, such as Guillain-Barre syndrome and porphyria. The presence of sensory level and sphincter involvement help to differentiate myelopathy (due to transverse myelitis, cord abscess, trauma or ischemia) from periodic paralyses. The finding of ptosis and extraocular muscle involvement helps exclude myasthenia gravis and Lambert–Eaton syndrome (which is rare in children).

Treatment and Prevention

Treatment of acute attacks of hypokalemic PP, in patients with normal renal function, is by oral potassium chloride administration in a dose of 5–10 g, which may be repeated. Intravenous potassium is reserved for cardiac arrhythmia, accessory respiratory muscle paralysis, or airway compromise due to ictal dysphagia. Both acetazolamide and dichlorphenamide can be used as prophylaxis against the attacks. Potassium-sparing diuretics (triamterene and spironolactone) are used as second-line drugs in those who do not respond to carbonic anhydrase inhibitors.

In hyperkalemic periodic paralyses, the attacks are usually mild and rarely require treatment. Weakness responds well to high-carbohydrate foods and also to beta-adrenergic stimulants, such as salbutamol (contraindicated in patients with cardiac arrhythmias). Treatment of severe attacks includes administration of glucose and insulin, with continuous ECG monitoring. Prevention is by avoidance of cold and by administration of thiazide diuretics and carbonic anhydrase inhibitors.

Treatment of paramyotonia congenita is aimed at reducing myotonia since weakness is uncommon. Mexiletine has been shown to be helpful in this respect. On the other hand, treatment with mexiletine or a thiazide diuretic may reduce the severity of myotonia in potassium-associated myotonia.

Combined therapy of amiodarone and acetazolamide may result in long-lasting improvement in Andersen–Tawil syndrome. Other reported effective treatments included potassium-sparing diuretics, potassium supplementation, and beta-adrenergic blockers. Cardiac defibrillator has rarely been implanted.

Hypokalemic periodic paralysis (PP) with calcium channel mutations may be associated with malignant hyperthermia susceptibility. Patients with PP undergoing surgery require to be monitored for this complication.

Metabolic Myopathies

Definition/Classification

Metabolic myopathies are a heterogeneous group of muscle disorders caused by inherited enzymatic defects, which result in skeletal muscle dysfunction. They are classified into abnormalities of glycogen, lipids, purine, or mitochondrial biochemistry. Metabolic myopathies due to abnormalities of glycogen are referred to as glycogen storage diseases (or glycogenosis). They are named by Roman numerals that correlate to the time of their discovery, according to their defective enzyme function, or by an eponym. For example, Pompe disease, due to acid maltase deficiency, is glycogenosis type II. McArdle disease, due to muscle phosphorylase deficiency, is termed glycogenosis type V.

Etiology

Metabolic myopathies are caused by inability of muscle fibers to maintain adequate energy and adenosine triphosphate (ATP) concentrations.

Epidemiology

Due to difficulties in diagnosis and application of diagnostic techniques to large populations, the exact incidence and prevalence of metabolic myopathies are uncertain. Pompe disease (glycogenosis type II, acid maltase deficiency) is seen in about 1 in 40,000 population, whereas McArdle disease

(glycogenosis type V, muscle phosphorylase deficiency) affects approximately 1 of 100,000 people.

Compiling recent epidemiologic studies, the incidence of mitochondrial diseases is at least 1 in 5,000 live births. However, the gene frequency of the various types varies between different populations.

Pathogenesis

The energy demands of exercising muscle require a sustained supply of adenosine triphosphate (ATP), which is obtained through glycogen and lipid metabolism, and from phosphocreatine stores and mitochondria. Glycogen is the main form of stored carbohydrate in the muscle, and is degraded to glucose to provide the needed energy for muscle during exercise. Disturbances in either the synthesis or the degradation of glycogen result in glycogenosis (or glycogen storage disease). The genetics and enzyme deficiencies of the common glycogenoses, which present as metabolic myopathies are detailed in *Table 374.3*.

Mitochondria, which convert fuel from food into ATP, have two membranes that define four compartments. These consist of the outer membrane, the inner membrane, the intermediate space between the inner and outer membranes, and the mitochondrial matrix consisting of the region defined by the inner membrane.

During sustained exercise or fasting, long-chain fatty acids constitute the major source of energy. Their passage through the mitochondrial membrane for beta-oxidation requires binding with carnitine, which is mainly synthesized in the liver and is actively transported into the muscle. This binding to carnitine by acylcarnitine transferases, such as carnitine palmitoyltransferase I (CPT I), occurs in the outer mitochondrial membrane. Through the action of acylcarnitine translocase, the resulting new compound passes through the inner mitochondrial membrane. Carnitine palmitoyltransferase II (CPT II) splits this transferred compound to free fatty acids and carnitine, within the mitochondrial matrix where the beta-oxidation of the long-chain fatty acids is then carried out. Myopathic carnitine deficiency is attributed to impairment in the active transportation of carnitine from the plasma into muscle cells. On the other hand, impaired hepatic biosynthesis and/or excessive renal excretion of carnitine leads to systemic carnitine deficiency. Two carnitine palmitoyltransferase (CPT) enzymes are essential in the transport of long-chain fatty acids from the cytosol to the mitochondria. These are CPT I and CPT II. The more common deficiency of CP II is inherited as autosomal recessive, and the gene is located on chromosome 1p32.

During anaerobic exercise, ATP is replenished through the reaction of myoadenylate deaminase enzyme, which catalyzes transformation of adenosine monophosphate (AMP) to inosine monophosphate (IMP) and ammonia.

Apart from enzymes for the beta-oxidation of fatty acids, other enzymes within the mitochondrial matrix include enzymes for the Krebs cycle (tricarboxylic acid cycle), the pyruvate dehydrogenase complex, and the peptidases plus chaperonins necessary for mitochondrial protein import and oxidative phosphorylation enzyme assembly. Pyruvate carboxylase is a biotin-dependent mitochondrial enzyme, which catalyzes the conversion of pyruvate, the glycolytic end-product, to oxaloacetate (an important component of the Krebs cycle). It is inherited as autosomal recessive, and the gene has been localized to chromosome 11q13. On the other hand, pyruvate dehydrogenase is a multienzyme complex, which controls the entry of pyruvate into mitochondria for oxidative metabolism.

Mitochondria are involved in various pathways of metabolism, including the generation of cellular energy through the respiratory chain, disposal of potentially toxic ammonia, removal and production of reactive oxygen species, and programmed cell death (apoptosis). The most

Table 374.3
Genetics and enzyme deficiencies of the common muscle glycogenoses

Type (eponym)	Inheritance (gene location)	Deficient enzyme
Glycogenosis type II (Pompe disease)	Autosomal recessive (17q23)	Acid maltase
Glycogenosis type V (McArdle disease)	Autosomal recessive (11q13)	Muscle phosphorylase
Glycogenosis type VII (Tarui disease)	Autosomal recessive (12q13.3)	Phosphofructokinase
Glycogenosis IX	X-linked recessive (Xq13)	Phosphoglycerate kinase
Glycogenosis X	Autosomal recessive (7p12–pl3)	Phosphoglycerate mutase
Glycogenosis XI	Autosomal recessive (11p15.4) (Isoenzyme LDH-M on chromosome 11; LDH-H on chromosome 12)	Lactate dehydrogenase (LDH)

critical mitochondrial function is oxidative phosphorylation (OXPHOS), which results in the synthesis of ATP from adenosine diphosphate (ADP) and inorganic phosphate. This entails transformation of energy derived from metabolism of nutrients to the synthesis of ATP in the presence of oxygen. The respiratory chain, or OXPHOS, is the terminal step for energy production after metabolic substrates have undergone glycolysis and fatty acid oxidation, and then entered the Krebs cycle (tricarboxylic acid cycle), which produces residual metabolites ($NADH_2$, $FADH_2$). The system of OXPHOS includes five large multienzyme complexes, designated complexes I through IV and ATP synthase (Complex V). These enzyme complexes are composed of many different proteins encoded by either nuclear or mitochondrial genes.

The mitochondrion is the only organelle other than the nucleus, which contains DNA. The mitochondrial DNA (mtDNA) codes for 13 polypeptide subunits of the OXPHOS enzymes with the remaining 70 subunits encoded by the nuclear DNA. Apart from the 13 genes coding for the protein subunits of the respiratory chain complex, human mtDNA encodes 22 transfer RNA (tRNA) genes, and 2 ribosomal RNA (rRNA) genes.

The term "mitochondrial diseases" usually refers to primary disorders of mitochondrial metabolism affecting oxidative phosphorylation (OXPHOS). These diseases can be caused by mutations of nuclear or mtDNA. Nuclear DNA mutations are transmitted by autosomal recessive, autosomal dominant, X-linked, or rarely isodisomy mechanisms. Mitochondrial DNA (mtDNA) defects are transmitted by maternal inheritance. At birth, each human cell contains thousands of copies of mtDNA, which are usually all identical (homoplasmy). Individuals with mtDNA mutations may harbor a mixture of mutant and wild-type mtDNA within each cell (heteroplasmy). The proportion of mutant mtDNA must exceed a critical threshold level before a cell expresses a biochemical abnormality of the respiratory chain (the threshold effect).

Nuclear DNA mutations decrease mitochondrial coenzyme Q10 (CoQ10) levels, which leads to OXPHOS impairment. On the other hand, CoQ10 impairs the flow of electrons from complexes I and II to complex III resulting in reduced ATP synthesis.

Pathology

In the infantile form of acid maltase deficiency (Pompe disease, glycogenosis type II), there is massive accumulation of glycogen in liver, heart, and skeletal muscles. In juvenile acid maltase deficiency, glycogen excess in muscle is relatively less marked, and is little or absent in liver and heart. On muscle biopsy, glycogen storage is demonstrated with a classical vacuolar appearance. The vacuoles contain PAS-positive material and stain intensely for acid phosphatase (one of the lysosomal enzymes) (*Fig. 374.7a*). On electron microscopy, glycogen is shown to be mainly contained within single membrane-limited lysosomal sacs.

In lipid metabolic disorders, muscle histochemistry shows an increase in the number of lipid droplets, mainly in type I muscle fibers, with minimal or no increase of mitochondria on electron microscopy.

Histochemistry of muscle biopsy in mitochondrial diseases may show proliferation of subsarcolemmal and intermyofibrillar mitochondria with myofibril degeneration,

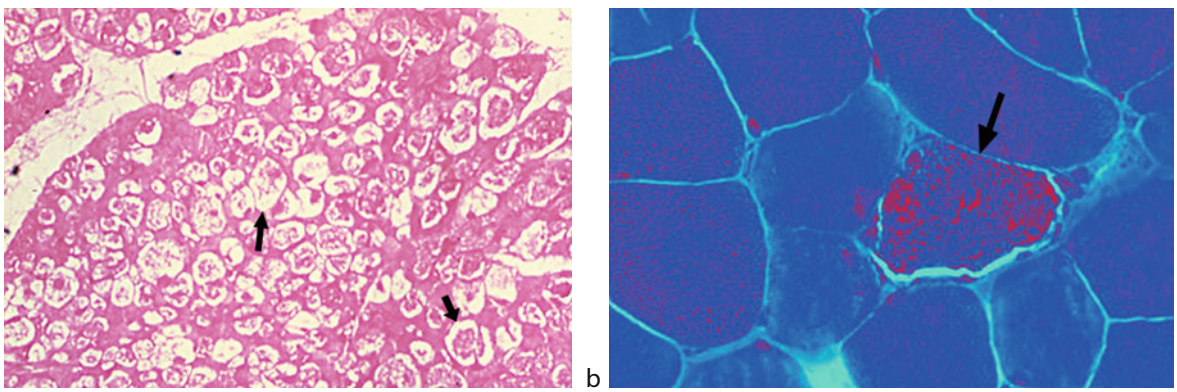

Figure 374.7

(a) Classical vacuolar appearance of muscle (arrows) in a case of glycogenosis type II (Pompe disease). (b) Ragged-red fibre (arrow) in a 13-year-old boy with Kearns-Sayre syndrome. Note the deposits of the red material representing mitochondria mainly in the subsarcolemma of the muscle fibre

giving the characteristic ragged-red fibers detected by Gomori-Trichrome staining (*Fig. 374.7b*). The percentage of ragged-red fibers may range from 2% to 70% of the total fibers, and they also have mild accumulations of glycogen and neutral lipid.

Staining with succinate dehydrogenase (SDH) also shows mitochondrial proliferation (ragged-blue fibers), whereas staining for cytochrome c oxidase (COX) usually shows that ragged-red fibers are Cox-negative. The number of COX-negative fibers is frequently larger than the number of ragged-red fibers. However, in patients with the syndrome of mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes (MELAS), ragged-red fibers are usually COX-positive. Blood vessels characteristically show an increased succinate dehydrogenase reaction. Nevertheless, in many individuals, the muscle histology is normal or shows nonspecific changes but does not usually display dystrophic features in the form of increased connective tissue or significant muscle fiber necrosis.

Clinical Manifestations

Glycogen Storage Diseases (Glycogenoses)

The classic infantile acid maltase deficiency presents before 12 months and is fatal by 2 years of age. The condition presents as "floppy infant syndrome" with hypotonia and weak bulky muscles. There is also macroglossia, cardiomegaly and congestive heart failure, and hepatomegaly. Death is usually caused by cardiorespiratory failure. Another form of the disease is the nonclassic infantile acid maltase deficiency, which is similar, but milder than the classic type.

The onset of juvenile acid maltase deficiency ranges from 2 to 18 years. It presents with delayed motor milestones and weakness, which is usually greater in the proximal than in distal muscles. Rarely, the tongue and liver are enlarged, and enlargement of calf muscles may occur. There is usually no cardiac involvement but respiratory muscles are selectively involved and lead to death from respiratory failure, usually in the second decade of life. Some patients may live longer than 20 years, and the condition has been reported to be associated with basilar aneurysm, which may lead to subarachnoid hemorrhage.

McArdle disease (glycogenosis type V, myophosphorylase deficiency) is a pure myopathy, which usually presents in childhood or early adolescence. The disease is characterized by exercise intolerance and cramps, but the patients are able to continue with their activities after 10 minutes of exercise (i.e., second-wind phenomenon). Rhabdomyolysis and myoglobinuria occur in 50%, and in older patients, mild muscle weakness is common.

Exercise intolerance and myoglobinuria also characterize glycogenoses types VII, IX, X, and XI (*Table 374.3*). Patients with types VII, X, and XI glycogenoses have normal muscle strength whereas those with glycogenoses IX develop slowly progressive weakness. Other clinical features include the presence of mild hemolytic anemia in glycogenosis VII, and seizure and mental retardation in one form of glycogenosis type IX.

Disorders of Lipid Metabolism

Primary muscle carnitine deficiency manifests during childhood or early adult life. It is characterized by proximal limb weakness, exertional myalgia, or rarely, myoglobinuria. Systemic carnitine deficiency can produce muscle symptoms or episodes of hepatic and cerebral dysfunction precipitated by fasting or sustained exercise, often simulating Reye syndrome. Cardiomyopathy and congestive heart failure, which are common, may be the direct cause of death.

Carnitine palmitoyl transferase (*CPT*) deficiencies are mostly associated with intermittent manifestations following fasting conditions or prolonged effort. The onset of disease is usually in late childhood or adolescence with myalgia and fatiguability. Severe cramps are not observed, whereas myoglobinuria is common. The severity of the disease is variable, partial deficiencies may be observed, and respiratory muscles may be involved. Permanent weakness is rarely observed, and fatal rhabdomyolysis may occur. Deficiencies of CPT I or CPT II may cause a rare but severe fatal disease in the neonatal period or early infancy. CPT I deficiency has been identified in a few patients who presented with episodes of severe hypoglycemia without ketonemia triggered by fasting or intercurrent illness. CPT II may manifest in infancy with hypoketotic hypoglycemia, lethargy, seizure, hepatomegaly and hepatic failure, and coma.

Abnormality of purine metabolism secondary to *myoadenylate deaminase* deficiency is a familial trait. Deficiency of myoadenylate deaminase has been found in muscle samples of patients with infantile hypotonia, with progressive myopathies of childhood onset, and in asymptomatic individuals.

Mitochondrial Diseases

Mitochondrial diseases might present at any age, usually involve multiple organ systems and often present with

prominent neurologic and myopathic features. The ubiquitous presence of mitochondria in all cells is likely to be responsible for the various organ dysfunctions. Also, the proportion of abnormal mitochondria can vary widely from one tissue to another, thus accounting for different presentations of the same defect. As a generalization, nuclear DNA abnormalities present in childhood and mtDNA abnormalities (either primary or secondary to a nuclear DNA abnormality) presented in late childhood or adult life.

Although there is often considerable clinical variability, many patients manifest a cluster of clinical features that fall into a discrete clinical syndrome. The primary and additional features of these syndromes are summarized in *Table 374.4*.

Diagnosis

The definitive diagnosis of all types of glycogenosis depends on the demonstration of glycogen storage by muscle biopsy (see section "Pathology" above) and the reduction or absence of the corresponding enzyme in muscle.

Table 374.4
Mitochondrial diseases: clinical syndromes

Syndrome	Clinical features
Chronic progressive external ophthalmoplegia (CPEO)	Onset in adolescence or adult life
	Bilateral ptosis, progressive external ophthalmoplegia (PEO), mild proximal myopathy
Kearn-Sayre syndrome	Infantile, childhood or adolescent onset
	Primary features include PEO, pigmentary retinopathy, and one of either raised cerebrospinal fluid (CSF) protein (>1 g/L), heartblock, or cerebellar ataxia. Other features include myopathy, bilateral deafness, dysphagia, hypoparathyroidism, diabetes mellitus, and dementia
Leigh disease (Subacute necrotizing encephalopathy)	Infantile onset of subacute relapsing encephalopathy, associated with cerebellar and brainstem signs
	Basal ganglia lucencies on cranial computed tomography (CT) scan
	Bilateral hyperintense signals on T2-weighted magnetic resonance images (MRI) in the basal ganglia, thalamus, brainstem, or cerebellum
Infantile myopathy and lactic acidosis (fatal and nonfatal forms)	Present in the first year with hypotonia, and feeding and respiratory difficulties
	Cardiomyopathy and/or the de Toni-Debri-Fanconi syndrome is associated with the fatal form of the disease
Pearson syndrome	Childhood sideroblastic anemia, pancytopenia, and exocrine pancreatic failure. Additional features include renal tubular defects
Mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes (MELAS)	Stroke-like episodes, seizures, cerebellar ataxia, recurrent migraines, hearing loss, diabetes mellitus, pigmentary retinopathy, short stature, cognitive impairment, and cardiomyopathy (initially hypertrophic; later dilated)
	Ragged-red fibers on muscle histochemistry and/or lactic acidosis
Neurogenic weakness with ataxia and retinitis pigmentosa (NARP)	Onset in late-childhood or adulthood of peripheral neuropathy, ataxia, and pigmentary retinopathy
	Findings include features of sensorimotor neuropathy, abnormal electroretinogram, and basal ganglia lucencies
Myoclonic epilepsy with ragged-red fibers (MERRF)	Progressive myoclonic epilepsy, mitochondrial myopathy with ragged-red fibers, ataxia, hearing loss, optic atrophy, peripheral neuropathy, spasticity, multiple lipomata, and slowly progressive dementia
Leber hereditary optic neuropathy (LHON)	Onset is usually in adolescence or early childhood, but may be quite variable even in the same kinship. Males are more affected than females (ratio of about 4:1)
	Characterized by subacute painless bilateral visual failure
	Associated neurological features may include ataxia, dystonia, paraplegia, and cardiac pre-excitation syndromes

Creatine kinase (CK) is elevated in 95% of patients with acid maltase deficiency (Pompe disease, glycogenosis type II), being highest in the infantile form (usually ten times the upper normal limit). The liver enzymes aspartate aminotransferase (AST) and alanine aminotransferase (ALT) are raised in most patients but may be normal in the adult form. Electrocardiography (ECG) and echocardiographic abnormalities are most common in the infantile form, and giant QRS complexes and very short PR interval are suggestive features. Marked thickening of the interventricular septum and posterior left ventricular wall is seen on echocardiography, associated with trabecular hypertrophy and left ventricular outflow obstruction (see Fig. 368.1e of Chap. 368, "Approach to Diagnosis and Treatment of a Child with Motor Unit Diseases"). Selective atrophy and fatty changes of the hamstrings and paraspinal muscles are useful diagnostic findings when using CT or preferably MRI. Biochemical analysis of enzyme activity can be performed on dried blood spots (DBS), muscle tissue, lymphocytes, or skin fibroblasts. If the enzyme was found to be reduced on DBS, confirmatory assay in cultured skin fibroblasts is required.

The diagnosis of McArdle disease is confirmed by the ischemic exercise test and by muscle biopsy. Increase in serum venous lactate, which is normally greater than 2 mmol/L, fails to develop and cramps may occur during the ischemic exercise test. About 90% of patients have increased levels of CK, and elevated potassium level during exercise may be seen in some. Definitive diagnosis requires the biochemical demonstration of decreased myophosphorylase activity in muscle.

Plasma, liver, and muscle carnitine levels are reduced in systemic carnitine deficiency. In myopathic carnitine deficiency, carnitine level is reduced in muscle, but is normal or slightly decreased in plasma and liver. Plasma carnitine level may be increased in CPT I deficiency, but is usually normal in CPT II. Definitive diagnosis of CPT deficiency requires the biochemical demonstration of marked decrease or complete absence of enzyme activity in the muscle, or by identification of the genetic defect.

Mitochondrial disorders should be considered in the differential diagnosis of any progressive multisystem disorder. Clinical tests, which are used to support the diagnosis of mitochondrial disease include measurement of serum lactate and pyruvate. Fasting blood lactate concentration above 3.0 mmol/L, cerebrospinal fluid (CSF) lactate concentration above 1.5 mmol/L, or increased lactate/pyruvate ration (normal less than 20) in blood or CSF supports a diagnosis of mitochondrial disease.

Normal plasma or CSF lactate concentration does not exclude the presence of mitochondrial disease. Elevated fasting glucose may indicate diabetes mellitus.

Cardiac involvement in the form of cardiomyopathy or atrioventricular conduction defects can be investigated by electrocardiography and echocardiography.

Electroencephalography (EEG) may reveal generalized slow wave activity in patients with encephalopathy, and focal or generalized spike and wave discharges in those with seizures. In patients with limb weakness, nerve conduction studies may be normal, or show axonal sensorimotor polyneuropathy. Electromyography (EMG) is usually normal but may show myopathic features. An abnormal electroretinogram is seen in mitochondrial diseases associated with retinal degeneration.

Neuroimaging is helpful in mitochondrial diseases. Both cranial CT and MRI can depict suggestive features, as detailed in *Table 374.4*. Cerebellar atrophy is a prominent feature in pediatric cases of mitochondrial diseases. Brain MRI may also reveal generalized leukoencephalopathy, and brain magnetic resonance spectroscopy (MRS) may reveal elevated lactate peaks.

Specific tests require a muscle biopsy, which is analyzed for histochemical evidence of mitochondrial disease (see section "Pathology" above). Studies on respiratory chain complex are carried out on skeletal muscle or skin fibroblasts, but require a laboratory with special expertise.

An important cause of mitochondrial diseases, which is amenable to treatment is due to coenzyme Q10 deficiency. Phenotypes associated with CoQ10 deficiency include isolated myopathy, Leigh syndrome, severe infantile multisystemic disease with nephrosis and cardiomyopathy; cerebellar ataxia with cerebellar atrophy syndromes (including patients with aprataxin gene mutations); and recurrent myoglobinuria, mental retardation, ataxia, seizures, and ragged-red fiber myopathy. Muscle coenzyme Q10 (CoQ10) quantitation on serum or cultured fibroblasts is essential to diagnose its deficiency.

Quantitative mtDNA analysis is important for diagnosing mtDNA depletion diseases, and direct sequencing of nuclear genes or mtDNA is available in specialized laboratories.

Differential Diagnosis

Infantile acid maltase deficiency presents as "floppy infant syndrome," but has associated cardiac features, which will guide the diagnosis. The juvenile form of acid maltase deficiency, and myopathies due to glycogenoses and lipid storage disorders, may simulate Becker muscular

dystrophy, limb-girdle muscular dystrophy, or polymyositis. Exercise-induced muscle cramps and myoglobinuria are important differentiating clinical features.

Mitochondrial syndromes with ptosis and external ophthalmoplegia may be confused with congenital myasthenic syndromes or myasthenia gravis. However, in mitochondrial disorders, the ocular manifestations are fixed and do not worsen as the day progresses. Mitochondrial diseases associated with white matter abnormalities might also mimic leukodystrophies. Other causes of lactic acidosis should also be kept in mind since elevated blood and CSF lactate can be seen following a seizure or ischemic stroke.

Treatment

A multidisciplinary team including a neurologist, genetic counselor, cardiologist, pulmonologist, metabolic disease specialist, and physical therapist is required for the management of acid maltase deficiency (Pompe disease, glycogenosis type II). A high protein diet (25–30% protein) combined with physical training was found to help in decreasing glycogen deposition. Enzyme replacement therapy with intravenous recombinant acid alpha-glucosidase (rhGAA, Myozyme) is effective in the infantile form of acid maltase deficiency by prolonging survival, and improving motor development and cardiac function. Myozyme is administered as 20 mg/kg infusion biweekly. Side effects include anaphylactic reactions and fever.

A diet high in complex carbohydrates (65%) and low in fat (20%), low-dose creatine (60 g/kg/day), and regular aerobic dynamic exercise at low or moderate intensities were found to be effective and useful in McArdle disease.

Management of carnitine palmitoyltransferase deficiency consists mainly of avoidance of fasting and prolonged exercise. A high-carbohydrate low-fat diet and frequent small meals may reduce the frequency of attacks.

Management of mitochondrial diseases should also be multidisciplinary because many of the phenotypes display multiorgan involvement. In an attempt to increase mitochondrial ATP and decrease free radical production in OXPHOS diseases, several metabolic therapies are used. Those with the best data supporting a therapeutic benefit include coenzyme Q10 (CoQ10), creatine monohydrate, folinic acid, and L-arginine.

Clinical and metabolic improvement with low-dose CoQ10 (30–300 mg/day) administration was reported in a number of OXPHOS diseases. Patients with CoQ10 deficiencies can show significant responses to CoQ10 treatment. High-dose therapies are preferred because of difficulties in achieving appropriate tissue levels of CoQ10. The recommended dose in children is 4.3 mg/kg/day in 2 divided oral doses. Creatine monohydrate, given at dosages of 0.1–0.2 mg/kg/day and divided into two or three dosages, was reported to improve cycle ergometry in children with mitochondrial disease.

Secondary cerebral folate deficiency can be associated with certain groups of mitochondrial diseases, and it manifests as leukoencephalopathy and seizures. Dramatic improvement of these symptoms was reported following treatment with folinic acid or 5-methyltetrahydrofolate.

Patients with MELAS may be prone to stroke due to reduced nitric oxide levels in cerebral vasculature. Supplementation with oral L-arginine in a dose of 0.5 g/kg/day may increase the nitric oxide levels and reduce the risk of stroke. Patients with complex I and/or complex II deficiency may benefit from oral administration of riboflavin.

Additional treatment considerations for patients with mitochondrial diseases include management of diabetes mellitus, cardiac pacing, ptosis correction, intraocular lens replacement for cataracts, cochlear implants for hearing loss, and liver or cardiac transplantation when other organs are likely to be spared.

The role of exercise therapy in mitochondrial myopathies is currently being evaluated since aerobic training not only protected patients against deconditioning but also improved their exercise capacity.

Prevention

In acid maltase deficiency (Pompe disease, glycogenosis type II), prenatal diagnosis is possible on trophoblasts or amniotic cells.

Decompensation in patients with mitochondrial diseases may be prevented by avoiding exposure to agents known to induce mitochondrial dysfunction. These include antiretroviral drugs (e.g., zidovudine); haloperidol, chlorpromazine, and thioridazine (which lead to complex I inhibition); cylclosporin (complex V inhibition); nonsteroidal anti-inflammatory drugs like aspirin and diclofenac (OXPHOS uncoupling); and chloramphenicol and aminoglycosides (impaired mitochondrial protein synthesis). Of paramount importance is to avoid the use of valproate for managing epileptic seizures, which is the first recognized symptom in about 53% of patients with mitochondrial encephalomyopathies. Valproate is known to induce reactive oxygen species generation, impair fatty acid oxidation, worsen disease

activity in patients with MELAS, and induce liver failure in patients with mitochondrial diseases.

Prenatal testing is possible in families with mitochondrial disease due to nuclear DNA mutation. For mtDNA disorders, interpretation of prenatal genetic testing is difficult because of mtDNA heteroplasmy. The percentage of mutant mtDNA in a chorionic villus sample may not reflect that found in other fetal tissues. Preimplantation genetic diagnosis (PIGD) may be available for families in which the disease-causing mutation has been identified in an affected family member.

375 Parainfectious and Autoimmune Disorders

Tanuja Chitnis

General Approach

In this section, we have focused on immune-mediated demyelinating diseases, including ADEM, multiple sclerosis, and neuromyelitis optica. In each section, we have provided a brief overview, epidemiology, pathophysiology, clinical presentation, and definitions, as well as diagnostic evaluation, differential diagnosis, treatment, and outcomes (◉ *Fig. 375.1*).

Acute Disseminated Encephalomyelitis

Acute disseminated encephalomyelitis (ADEM) is defined as a monophasic demyelinating disease associated with vaccination or a systemic viral infection, which may affect both adults and children.

Epidemiology

ADEM can occur at any age, but it is generally more prevalent in children than in adults. The mean age of presentation reported in recently published pediatric cohorts was 5–8 years. Rare cases in older adults have been reported.

A recent study conducted in San Diego County, USA, found the mean incidence of ADEM as 0.4/100,000/year among persons less than 20 years of age living in that region. ADEM was more common in the winter and spring months. Five percent of these patients had received a vaccination within 1 month prior to the ADEM event, and 93% reported signs of infection in the preceding 21 days. A similar study conducted in Germany found the incidence of reported pediatric ADEM patients, defined using the International Pediatric MS Study Group criteria, to be 0.07/100,000 persons under the age of 16 years. There was a threefold increased incidence in patients under the age of 10 years, compared to those 10–15 years old. In contrast, the mean incidence of multiple sclerosis (MS) in persons under the age of 16 years in this study was 0.3/100,000. Some regional cases of ADEM are linked to specific vaccines, including the Semple rabies vaccine, small pox vaccine, and older forms of the measles vaccine. In both the San Diego and German studies, there was no gender predominance in ADEM cases. However, a male predominance has been described in other pediatric ADEM cohorts, with reported F:M ratios of 0.4, 0.6, and 0.8. These results contrast to the 2:1 female preponderance frequently described for postpubertal onset MS.

Pathophysiology

Postinfectious forms of ADEM typically begin within 2–21 days after an infectious event; however, longer intervals have also been described. Viral infections commonly associated with ADEM include influenza virus, enterovirus, measles, mumps, rubella, varicella-zoster, Epstein-Barr virus, cytomegalovirus, herpes simplex virus, hepatitis A, and coxsackievirus. Bacterial triggers include *Mycoplasma pneumoniae*, *Borrelia burgdorferi*, *Leptospira*, and beta-hemolytic *Streptococcus*. Acute hemorrhagic leukoencephalomyelitis (AHLE) typically follows influenza or upper respiratory infection.

The only epidemiologically and pathologically proven association between ADEM and vaccinations is with the Semple form of the antirabies vaccine. Patients with serum antibodies to myelin basic protein had a higher incidence of neurological complications. Other immunizations that have been temporally related to ADEM include hepatitis B, pertussis, diphtheria, measles, mumps, rubella, pneumococcus, varicella, influenza, Japanese encephalitis, and polio. Vaccines produced in neural tissue culture including the Semple form of the rabies and Japanese B encephalitis vaccines carry a higher risk of developing ADEM, which may be related to contamination with host animal myelin antigens. It is important to note that vaccines with historically high rates of complications are no longer in use and have been replaced by modern formulations based on recombinant proteins.

Pathologically, ADEM is characterized by perivenular infiltrates of T cells and macrophages, associated with

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_375,

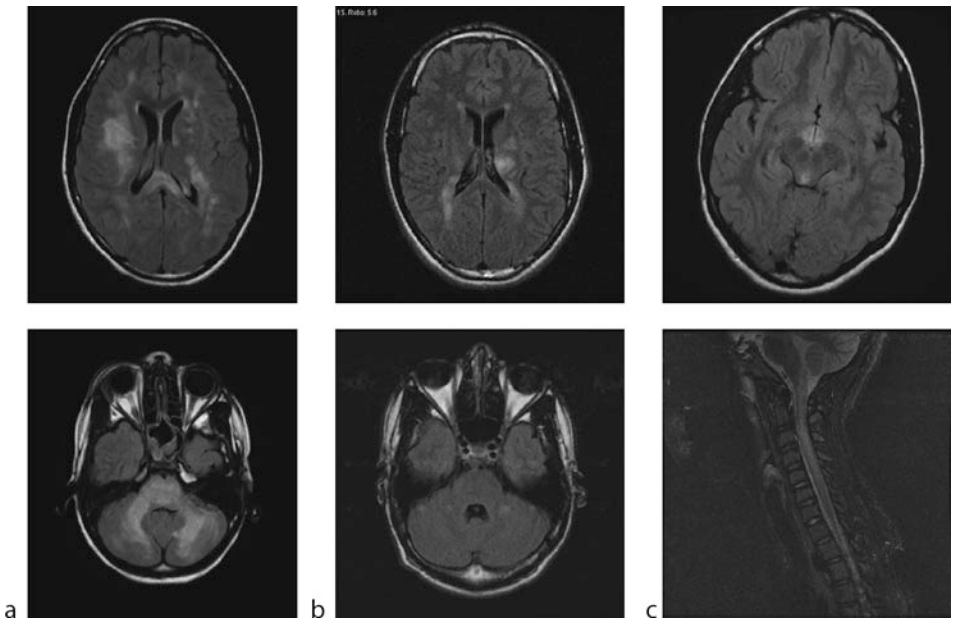

Figure 375.1

(a) Brain FLAIR image of a 13-year-old boy with ADEM. Lesions are located in the subcortical white matter and diffusely in the pons and middle cerebellar peduncles. (b) Brain FLAIR image of a 13-year-old boy with multiple sclerosis. Lesions are located in the periventricular white mater and focal lesions in the middle cerebellar peduncles. (c) Brain FLAIR image of a 14-year-old girl with neuromyelitis optica, and T2-weighted image of the spinal cord from the same patient. Lesions are located in the peri-third and peri-fourth ventricular areas. There is a longitudinally extensive lesion from the brainstem to C7

sleeves of perivenular demyelination. ADEM shares common pathological features with MS; however there are no systematic studies comparing the histopathology of these two diseases. The CNS white matter contains perivascular inflammatory infiltrates, as well as demyelination. Although ADEM is typically described as demyelination with relative preservation of axons, axonal damage confined to the perivenular area has been described. The CSF is characterized by elevated protein and white blood cells. Oligoclonal bands may occur in up to 30% of ADEM patients, and may be transient.

Acute hemorrhagic and acute necrotizing hemorrhagic leukoencephalitis (AHEM, AHL, ANHLE) of Weston Hurst shares some inflammatory histological features with ADEM; however, demyelination is often more widespread throughout the CNS and is frequently associated with a pronounced neutrophilic infiltrate. ANHLE is also characterized by destruction of small blood vessels associated with acute and multiple small hemorrhages and fibrin deposition superimposed on demyelination.

The most likely mechanism by which ADEM occurs is molecular mimicry. Experimental evidence has shown that T cells isolated from patients with ADEM are ten times more likely to react with MBP than controls, likening this disease to EAE in animal models. Because of the monophasic nature of the illness, it appears that the immunological response occurs acutely, but in contrast to MS, further amplification of inflammation within the CNS is suppressed.

Clinical Presentation

The initial symptoms and signs of ADEM usually begin within 2 days to 4 weeks after a viral infection or vaccination, and include a rapid onset of encephalopathy associated with a combination of multifocal neurological deficits, leading to hospitalization within a week. A prodromal phase with fever, malaise, headache, nausea, and vomiting may be observed shortly before the development of meningeal signs and drowsiness. The clinical course is rapidly progressive developing maximum deficits within 2–5 days.

ADEM can also present as a subtle disease, with nonspecific irritability, headache, or somnolence lasting more than 1 day. In some cases, there is rapid progression

of symptoms and signs to coma and decerebrate rigidity. Respiratory failure secondary to brainstem involvement or severe impaired consciousness occurs in 11–16% of cases.

A wide variety of neurological symptoms in children have been described at clinical presentation, according to the distribution of demyelinating lesions. Unilateral or bilateral pyramidal signs (60–95%), acute hemiplegia (76%), ataxia (18–65%), cranial nerve involvement (22–45%), visual loss due to optic neuritis (7–23%), seizures (13–35%), spinal cord involvement (24%), impairment of speech [slow, slurred, or aphasia] (5–21%), and hemiparesthesias (2–3%). Mental status is invariably involved, ranging from lethargy to coma. Seizures are mainly seen in children younger than 5 years of age, usually as prolonged focal motor seizures.

Peripheral nervous system (PNS) involvement in ADEM patients has been reported in children, while PNS involvement is observed in 16/36 (44%) adult patients.

A unique ADEM phenotype has been reported in association with group A-beta hemolytic streptococcal infection. The syndrome affected children under the age of 6, with prominent behavioral disturbances, dystonic movements, and basal ganglia abnormalities on MRI. The condition usually followed an acute pharyngitis infection and was associated with elevated antibasal ganglia antibodies.

Rarely, children may present with recurrent or multiphasic ADEM, which are defined below. These cases may be difficult to distinguish from pediatric multiple sclerosis.

ADEM Definitions

To avoid misdiagnosis and develop a uniform classification, the International Pediatric MS Study Group (Study Group) has proposed that the following three terms be applied to variations of ADEM.

1. *ADEM*: A first clinical event with a polysymptomatic encephalopathy, with acute or subacute onset, showing focal or multifocal hyperintense lesions predominantly affecting the CNS white matter; no evidence of previous destructive white matter changes should be present; and no history of a previous clinical episode with features of a demyelinating event. If a relapse takes place within 4 weeks of tapering steroid treatment or within the first 3 months from the initial event, this early relapse is considered temporally related to the same acute monophasic condition and would replace the terms "steroid-dependent ADEM" or "pseudorelapsing ADEM."
2. *Recurrent ADEM*: New demyelinating event fulfilling diagnostic criteria for ADEM, occurring at least 3 months after the initial ADEM event and at least 4 weeks after completing steroid therapy, showing the same clinical presentation and affecting the same areas on MRI as the initial ADEM episode.
3. *Multiphasic ADEM*: Refers to one or more ADEM relapses, including encephalopathy and multifocal deficits, but involving new areas of the CNS on MRI and neurologic exam. Relapses take place at least 3 months after initial ADEM attack and at least 4 weeks after completing steroid therapy.

Diagnostic Evaluation

Basic diagnostic evaluation for ADEM includes neurological examination, MRI of the brain and spine, serum and CSF testing for infections in suspicious cases, and standard CSF evaluation including cell count, bacterial and fungal cultures, and oligoclonal bands and IgG Index testing. Fundoscopic examination, visual evoke potentials, and orbital MRI should be considered in cases where optic neuritis is a concern. MRI usually demonstrates multifocal white matter lesions involving the cerebrum, brainstem, cerebellum, and spinal cord, which may or may not enhance with gadolinium. Brain lesions generally involve the subcortical and cortical white matter, and may involve cortical and deep gray matter nuclei. Several MRI patterns have been described, and include the presence of: (1) small focal punctate lesions, (2) bithalamic lesions, (3) diffuse large white matter lesions, and (4) hemorrhagic, demyelinating lesions, consistent with AHLE. Lesions generally resolve over time; however, the clinical picture may precede MRI improvement. CSF is characterized by normal pressure, moderately elevated cell count (5–100/μL), moderately elevated protein (40–100 mg/dL), and normal glucose. The presence of red blood cells may indicate a diagnosis of hemorrhagic leukoencephalitis. CSF evaluation should include testing for infections, including viral encephalitides if suspected. Oligoclonal bands may be present and have been described in up to 29% of ADEM patients, and are generally transient.

Differential Diagnosis

The association of an acute encephalopathy and disseminated demyelination of the CNS in a child represents a diagnostic challenge. A large number of inflammatory

and noninflammatory disorders may have a similar clinical and radiological presentation and should be considered in the diagnostic evaluation.

Due to the acute therapeutic implications, the exclusion of acute CNS infections should be the first and most important diagnostic step to be considered in every child with a febrile illness and neurological signs, by lumbar puncture and further microbiological laboratory tests. Serology for suspected organisms, CSF viral, fungal, and bacterial cultures, as well as CSF viral polymerase chain reaction assay for HSV, CMV, EBV, enterovirus, VZV, and West Nile should be performed. Mycoplasma serology may reveal an underlying infection. Neuroimaging may play a particularly helpful role in the differential diagnosis. A standard MRI scan of the brain and spinal cord, with and without gadolinium enhancement will be useful to define the regional distribution of demyelination and MRI lesion appearance.

Treatment

Acute episodes of ADEM should be treated with intravenous corticosteroids. The usual dose is 1 g/day of methylprednisolone for 5 days in adults and 20–30 mg/kg/day for 5 days for children up to 40 kg. Treatment with corticosteroids requires careful monitoring of blood pressure, urine glucose, serum potassium, and administration of gastric protection. Refractory cases have been treated with 5 exchanges or plasmapheresis or IVIG up to 2 g/kg distributed over 2–5 days. Cases that are suspicious for MS should be followed with annual or biannual MRI studies.

Supportive care in the acute stage is critical and early antiviral treatment with acyclovir (30 mg/kg/day) is highly recommended acutely, particularly when viral encephalitis, particularly herpes simplex encephalitis, is a consideration. Antibiotic prophylaxis for suspected bacterial meningitis may also be instituted in cases where this is a consideration.

Use of high-dose intravenous immunoglobulin (IVIG) for acute ADEM treatment has been reported in several case studies. The usual total dose of IVIG is 2 g/kg, administered over 2–5 days. IVIG may be useful in cases refractory to intravenous steroid treatment, and our policy is to start treatment 2–3 days following a 5-day steroid course. IVIG may also be useful in cases of steroid-dependent demyelination, when new or fluctuating signs and symptoms occur as corticosteroids are tapered.

The use of plasmapheresis in ADEM has been reported in a small number of severe cases, who were generally unresponsive to corticosteroid or IVIG treatment. 3–5 exchanges are generally employed, which is felt to be sufficient to reduce antibody and inflammatory factors. Moderate to severe anemia, symptomatic hypotension, hypocalcemia, and heparin-associated thrombocytopenia have been described related to TPE.

Acute hemorrhagic leukoencephalitis is often considered the most acute and severe form of ADEM, with high rate of mortality within hours to days after the onset of neurologic symptoms if untreated. Survival in pediatric patients has been reported in a small number of children receiving combined high-dose IV corticosteroid therapy, IVIG, TPE, and decompressive craniotomies. In cases of progressive deterioration due to increased uncontrolled intracranial pressure, aggressive strategies such as surgical decompression should be considered to prevent secondary injury to the brain and brainstem.

Outcomes

There is limited data regarding the natural history of ADEM. In the available case studies, there is considerable diversity with respect to antecedent infections, clinical presentation, and neuroimaging findings, further complicating outcomes analysis. Case series from Japan, India, and Russia suggest that the natural history of untreated ADEM in most children is one of gradual improvement over several weeks, with 50–70% of patients experiencing full recovery. Studies from other centers in largely treated patients demonstrate similar outcomes with 8–30% experiencing residual focal neurological deficits, and 4–30% having residual behavioral or cognitive problems. Behavioral problems were most prominent in the young-onset ADEM group with poorer visuospatial/visuomotor function, even in those with fully resolved MRIs. In most cases, the MRI appearance improves significantly; however, the continued presence of residual MRI lesions may correlate with chronic deficits.

Recovery may depend in part on antecedent infections based on serology. In a cohort of patients with detailed serology, antecedent infections included rubella (33%), varicella (29%), and unknown (22%). Seventy percent of the ADEM cases without a defined infection had a good outcome, versus 54% and 43% reported for post-varicella and post-rubella ADEM, respectively. Specific recovery times were described as approximately 3 weeks for post-rubella ADEM and up to 12 weeks for multiphasic ADEM, with intermediate but more variable recovery time in the post-varicella and unknown ADEM groups. Taken together, these reports suggest that approximately two-thirds of patients make a complete recovery.

Children who have experienced an episode of ADEM are at higher risk of developing recurrent or chronic demyelination than the general population. Some children may develop recurrent or multiphasic ADEM. While others may go on to develop MS. The distinction between recurrent or multiphasic ADEM in some instances is unclear, and our policy has been to consider chronic immunosuppressive therapy in children with more than two clinical episodes.

At present, there are no clear prognostic factors that determine whether a child who has experienced an acute demyelinating event will develop MS. Clinical studies have been hampered in part by the lack of consistent definitions used across publications, and the small numbers of subjects at any one site. In available studies, the risk of developing MS after ADEM has been reported as 0% in a study from Argentina, 9.5% in a study from San Diego, 18–29% in studies from France. Varying criteria used to define ADEM and pediatric MS, which may have contributed to the wide range of incidence among these publications.

The KIDMUS study group from France examined pediatric patients with an acute demyelinating syndrome, including clinically isolated syndromes and ADEM events, and showed that overall, 57% developed a second attack, 86% of patients with initial optic neuritis developed MS, while 50% of those with an initial brainstem syndrome developed MS. The majority of children converted to MS within a 2-year period. Overall, positive predictive factors for the development of MS were: age at onset 10 years or older or optic nerve lesion. A lower risk of developing MS was found in patients with mental status change at presentation, suggesting that the presence of encephalopathy may be a negative predictive factor. Of patients with an initial diagnosis of ADEM, 29% developed MS. In a subsequent publication by this group, when the diagnosis of ADEM was redefined by the KIDSEP study to include "change in mental status" as a qualifying criterion, 18% of children were found to develop MS, as defined by the development of a second event after a mean follow-up of 5.4 years.

Multiple Sclerosis

Epidemiology

Multiple sclerosis (MS) affects approximately 400,000 persons in the United States, with an onset predominantly in early adulthood. It is increasingly recognized that MS can present in childhood or adolescence. The youngest onset of MS in the medical literature is 2 years of age; however the majority of children are diagnosed in their early teens. Studies have estimated the prevalence of pediatric onset MS, to range from 2.7% to 10.5% of total MS populations. We have recently found that 3.06% of our adult MS population of 4,399 patients with an electronic MS history record experienced a first attack under the age of 18 years, suggesting that these patients may represent a pediatric-onset population. Recent studies have suggested that there are significant differences in ethnic and racial characteristics of children with MS as compared to an adult MS population. In our study of adults MS patients from one Center, we found a higher proportion of non-Caucasian patients in the pediatric-onset group (11.7%) when compared to an adult-onset group (6.18%; $p = 0.014$), supporting this finding. Moreover, of patients from our pediatric MS Center, 33.3% were non-Caucasian, compared to 5.5% in the comparative adult MS cohort.

Pathophysiology

There is limited data regarding the underlying immunopathophysiology of pediatric MS. There are no systematic studies comparing the immunopathophysiology of pediatric MS to adult MS, which would shed light on the similarities and differences between these two age groups. A recent study of a large cohort of children with CNS inflammatory demyelination, type I diabetes (T1D) and CNS injury demonstrated that children with CNS inflammatory demyelination, CNS injury, and T1D exhibited heightened peripheral T-cell responses to a wide array of self-antigens. Children with autoimmune diseases and CNS injury also exhibited abnormal T-cell responses against multiple cow-milk proteins. A smaller study evaluating T-cell responses to myelin basic protein (MBP) and myelin oligodendrocyte glycoprotein (MOG) epitopes in adult and pediatric MS found similar responses predominantly to MBP 83–102, 139–153, 146–162, and MOG- 1–26, 38–60, and 63–87, in both groups to the same set of peptides. Interestingly, responses to fetal-MBP were minimal, and similar in both groups. Using a tetramer approach, up to 20% of children with ADEM, but none with pediatric MS demonstrated elevations of anti-MOG antibodies.

Cerebrospinal fluid (CSF) studies have demonstrated that children younger than 11 years exhibit a distinct cellular profile in comparison to their adolescent counterparts. Younger children with their first MS event were more likely to lack OCB or elevated IgG index, and had a higher percentage of neutrophils in their CSF suggesting an activation of the innate immune response as opposed to an activation of the adaptive response in older patients.

The absence of neutrophils in the CSF was associated with an earlier second event.

Studies examining markers of axonal damage in the CSF found minimal changes in the majority of children with MS; however, a subgroup with prominent clinical symptoms at the time of CSF examination exhibited elevated levels of tau protein.

Clinical Presentation

Children with MS overwhelmingly experience a relapsing-remitting course at onset. Primary progressive MS is extremely rare. We have recently shown that children with MS experience two to three times as many relapses than adults with MS. The International Pediatric MS Study Group recently proposed new clinical criteria for pediatric MS and related demyelinating disorders; however, definitive MRI criteria for these conditions are still lacking.

Common presenting symptoms of MS in children include sensory deficits (26%), optic neuritis (21.6%), cranial nerve or brainstem symptoms (12.9%), and gait disorders (8.6%). Pediatric patients typically have a polysymptomatic presentation, although monosymptomatic presentations are not uncommon. Other features that are more common in children compared to adults with MS are encephalopathy and seizures, likely representing the overlap of acute disseminated encephalomyelitis (ADEM) and MS that is almost exclusive to children (see ADEM discussion below). In addition to physical disability, children with MS are particularly vulnerable to cognitive dysfunction. A recent cross-sectional study found that 59% of pediatric MS patients demonstrated deficits in at least one major area, and 35% were impaired in two areas. Areas that were predominantly affected were complex attention, recall, language, naming, and visual-spatial functions. Forty-nine percent reported fatigue as a major symptom. In a subset of patients who underwent psychiatric evaluation, almost half were diagnosed with depression or an anxiety disorder. These findings underline the need for routine neuropsychological testing and psychiatric evaluation as a part of the management of childhood MS. Interaction with the school system is critical in order to insure that a tailored educational program is implemented for each child.

MRI lesions in children with MS are generally located in the periventricular and subcortical white matter. It is unknown whether cortical lesions are present, and some preadolescent children with MS may present with atypical MRI patterns. Recent studies have shown that at the time of their MS defining attack, children meet adult MS McDonald MRI criteria only 67% of the time, suggesting a low lesion burden than adults at the time of diagnosis; however, a formal comparison to adults has not been performed. Few studies have formally compared the extent and distribution of lesions in children with MS compared to adults with MS. One study of 58 children with CIS and adults with RRMS found that children with CIS had fewer lesions infratentorially overall; however, in a subset of patients with brain lesions, children had higher volumes of infratentorial lesions. Another study of 4 pediatric-onset patients found a higher frequency of large confluent T2 lesions and fewer black holes in comparison to adult-onset MS. We have recently shown that children with MS demonstrate anisotropic abnormalities on diffusion tensor imaging in major white matter tracts including the corpus callosum, longitudinal association fibers, and the corticospinal tracts.

Pediatric MS Definition

The International Pediatric MS Study group proposed that for a diagnosis of pediatric MS the McDonald criteria for MS may be applied to patients under the age of 10 years, including dissemination in time by MRI. Neurological events should be separated by at least 3 months, and occur while off steroids for at least 1 month to prevent confusion with steroid-dependent relapses. The MRI must show three of the following four features: (1) nine or more white matter lesions or one gadolinium enhancing lesion, (2) three or more periventricular lesions, (3) one juxtacortical lesion, and (4) an infratentorial lesion. The combination of an abnormal CSF and two lesions on the MRI, of which one must be in the brain, can also meet dissemination in space criteria; the CSF must show either oligoclonal bands or an elevated IgG index. These definitions stipulated that an event of ADEM cannot contribute to an MS diagnosis; however, several studies have since suggested that ADEM may be the presenting feature of MS in younger children.

Diagnostic Evaluation

Evaluation of a child with suspected multiple sclerosis includes neurological examination, MRI of the brain and spine, fundoscopic examination and visual evoked potentials and potentially MRI of the orbits. CSF examination may be performed, especially in younger children, or in those with progressive or atypical presentations. Serology to rule out other mimics of multiple sclerosis should include ANA, ESR, CRP, ACE level and chest x-ray, folate,

B12 levels, and TSH. Testing for other disorders should be considered on a case-by-case basis.

Differential Diagnosis

The differential diagnosis of pediatric multiple sclerosis includes tumor, infections, vascular disorders, metabolic disorders, mitochondrial disorders, nutritional disorders, and other autoimmune disorders (Table 375.1). Patients presenting with white matter lesions should be subclassified into those with static versus progressive disorders. Patients with longstanding static white matter lesions should be closely evaluated for perinatal hypoxic ischemic injury. Determining whether the presentation is episodic or progressive is critical, since in most cases MS in children is an episodic disorder. Progressive presentations should be fully evaluated for other structural, vascular, or metabolic defects. Evaluation should include a dermatological exam to look for stigmata of neurofibromatosis, tuberous sclerosis, Lyme disease, SLE, Fabry's disease, and Behcet's

Table 375.1
Differential diagnosis of pediatric MS

Demyelinating
–Optic neuritis
–Transverse myelitis
–Devic's disease (neuromyelitis optica)
–ADEM
–AHEM
–Recurrent ADEM
–Multiphasic ADEM (MDEM)
Tumor
–Lymphoma
–Astrocytoma
–Metastasis
Immunologic
–SLE
–Anti-phospholipid syndrome
–Rheumatoid arthritis
–Post-streptococcal syndrome
–Behcet's disease
–Sarcoidosis
–Sjogren syndrome
–Wegener's granulomatosis
–Lymphomatoid granulomatosis
–Langerhan cell histiocytosis
–Hemophagocytic lymphohistiocytosis
–Hashimoto's thyroiditis
Infection
–Lyme disease
–HIV
–HSV
–HTLV-1
–PML
–Neurosyphilis
–Cat scratch disease (*B. henselae*)
–Whipple's disease
Vascular disorders
–Stroke
–AVM
–Sickle cell disease
–Moya moya
–CADASIL
–Complicated migraine
–Isolated angiitis of the CNS
–Susac's syndrome
Nutritional
–B12 deficiency
–Folate deficiency
o(Methylenetetrahydrofolate reductase deficiency)
Metabolic
–Fabry's disease
–Biotinidase deficiency
–3-Methylglutaric acid deficiency
–Neuronal ceroid lipofuscinosis
Leukodystrophy
–Adrenoleukodystrophy or adrenomyeloneuropathy
–Metachromatic leukodystrophy
–Alexander's disease
–Krabbe disease
–Pelizaeus–Merzbacher disease
–Vanishing white matter disease
Mitochondrial Disease
–MELAS
–LHON
–Leigh's disease
Degenerative
–Hereditary spastic paraparesis
–Friedrich's ataxia
–Spinocerebellar atrophy

disease. Disorders that should be considered in cases of optic neuritis include sarcoidosis, Leber's hereditary optic neuropathy (LHON), vitamin B12 deficiency, and adrenoleukodystrophy (ALD). The differential of immune-mediated transverse myelitis includes HTLV-1, ischemia, and vitamin B12 deficiency. Devic's disease (NMO) should be considered, particularly in cases associated with optic neuritis (see section below). Complicated migraine, antiphospholipid syndrome, CADASIL, and arteriovenous malformation (AVM) should be considered in cases where headache is a prominent feature. Basal ganglia lesions may suggest Leigh's disease, Wilson's disease, post-streptococcal syndromes, histiocytosis, and Moyamoya syndrome. Friedrich's ataxia and the inherited spinocerebellar ataxias should be considered in cases with predominant cerebellar deficits. In the presence of white matter lesions with a peripheral neuropathy, adrenomyeloneuropathy (AMN), Krabbe's disease, metachromatic leukodystrophy (MLD), and mitochondrial disorders should be considered.

Treatment

Acute relapse–related care for pediatric MS typically involves intravenous corticosteroids. Typical dosing is methylprednisolone 20–30 mg/kg to a maximum of 1 g daily for 3–7 days. Intravenous immune globulin (IVIG) at a dose of 0.4 g/kg/day for 5 days or plasma exchange (five to seven exchanges) are employed in refractory cases.

Beta-interferons (Avonex, Betaseron and Rebif) and glatiramer acetate (Copaxone) have been used as prophylactic therapy with reasonable success in children. Available studies have shown that both treatments are relatively safe, and the side effect profile is similar to that observed in adults. Typical side effects of the beta-interferons include post-injection flu-like symptoms and myalgias, headaches, depression, increased liver function tests, and, rarely, suppression of white blood cell counts. Side effects of glatiramer acetate include injection-site reactions, lymphadenopathy, and, rarely, immediate post-injection anxiety syndromes. Although placebo-controlled double-blind studies have not been performed in children, the majority of studies have demonstrated a reduction in relapse rate following the initiation of first-line treatments. However, some children continue to experience breakthrough disease. The definition of treatment failure is not uniform across clinicians and centers; however, evidence of ongoing relapses, MRI activity, and disability accrual may suggest switching first-line treatment or escalating to second-line therapy.

There are few studies describing the use of second-line treatments in children with MS. We conducted a retrospective study of 17 children, aged 9–18 years, treated with cyclophosphamide at either pulse or induction therapy. In the majority of cases, the relapse frequency and EDSS improved 1 year following cyclophosphamide therapy. There are several reports of natalizumab (Tysabri) treatment in adolescents with MS. Although natalizumab was effective in controlling relapse rates in these very active cases, the risks of PML and other serious side effects in children requires further assessment.

Outcomes

Several studies have demonstrated that initial disease progression is slower as measured by the EDSS scale, in patients with pediatric-onset MS (POMS) compared with geographic-region-matched patients with adult-onset MS (AOMS). Cognitive dysfunction can present early in the course of pediatric multiple sclerosis. One study of 37 children with MS found that 60% experience cognitive difficulties in one major domain and 35% have difficulties in 2 domains. The areas that were most commonly affected were complex attention, naming, delayed recall, and visual memory. In contrast, verbal fluency and immediate recall were relatively intact. Another study of 61 children found that 31% of patients exhibited significant impairment in three assessed domains of cognitive functioning and 53% failed at least two tests.

Neuromyelitis Optica

Neuromyelitis optica (NMO) or Devic's disease is a subtype of MS characterized by clinical episodes of optic neuritis and transverse myelitis, and the demonstration of contiguous lesions in the spinal cord.

Epidemiology

NMO occurs rarely in children. The current literature is limited to small series or case reports of NMO in children. The largest series from the Mayo clinic described a cohort of 88 children who were found to be seropositive for the NMO IgG antibody. Of those with available clinical information, 42 patients (73%) were non-Caucasian and 20 (34%) had African ethnicity. Median age at symptom onset was 12 years (range 4–18); 88% were girls. In another series of children with demyelinating disease,

seven to nine of those with a relapsing NMO phenotype were seropositive for the NMO antibody. In contrast, no children with relapsing-remitting MS were NMO IgG seropositive. Additional autoantibodies were detected in 57 of 75 patients (76%) and 16 of 38 (42%) had a coexisting autoimmune disorder recorded (systemic lupus erythematosus, Sjogren syndrome, juvenile rheumatoid arthritis, Graves disease).

Pathophysiology

NMO has a distinct lesion distribution compared to multiple sclerosis or ADEM, although there may be some overlap between the syndromes. NMO is characterized by optic neuritis and longitudinally extensive transverse myelitis (LETM). Lesions typical of MS are characteristically absent on brain MRI; however lesions may be present in aquaporin-4-rich areas, including the periaqueductal gray area. Pathologically, NMO is characterized by demyelination with extensive macrophage infiltration associated with large numbers of perivascular granulocytes and eosinophils and rare CD3(+) and CD8(+) T cells, as well as a pronounced perivascular deposition of immunoglobulins (mainly IgM) and complement C9neo antigen in active lesions. A serum antibody to aquaporin-4, a water channel present predominantly on the astroyctic foot processes of the blood–brain barrier (BBB), is observed in approximately 76% of those presenting with an NMO phenotype and appears to be a sensitive and specific marker of the disease. In vitro, it has been shown that NMO-IgG binds to astrocytes and alters aquaporin-4-polarized expression and increases permeability of a human BBB endothelium/astrocyte barrier. In vitro models demonstrated astrocyte killing by NMO-Ab-dependent cellular cytotoxicity and complement-dependent granulocyte attraction through the BBB model.

Clinical Presentation

NMO can present with either optic neuritis or transverse myelitis. The clinical symptoms of optic neuritis include blurred vision, pain on eye movement, and loss of color vision. Typically children may complain of eye pain and frequent eye rubbing occurs. Transverse myelitis may present with lower extremity and upper extremity weakness or numbness. Gait may be affected, and bowel or bladder retention or incontinence is common. Pain in the lower extremities and a band-like sensation around the torso may be present. Lesions in the brainstem or area postrema may result in nausea, vomiting, or hiccups. In children, an encephalopathic syndrome has been described, which may in some cases overlap with the clinical presentation of ADEM. In the Mayo clinic series, 45% of children had episodic cerebral symptoms (encephalopathy, ophthalmoparesis, ataxia, seizures, intractable vomiting, or hiccups).

Diagnostic Definition

The International Pediatric MS study group proposed the following diagnostic definition for pediatric NMO, adapted from the 2006 NMO adult criteria:

1. The presence of optic neuritis and myelitis
2. Spinal cord lesion extending over 3 or more vertebral segments or NMO antibody positive
3. Brain MRI relatively normal; exceptions with lesions in aquaporin-4-rich areas (hypothalamus, peri III, IV ventricles, corpus callosum)

Diagnostic Evaluation

Diagnostic evaluation of suspected NMO includes serum NMO IgG, testing for other autoimmune disorders including SLE (ANA, ESR), Sjogren's syndrome, rheumatoid arthritis, and autoimmune thyroid disease. In some cases, NMO IgG in the CSF may be positive in the absence of serum antibody. Standard CSF testing demonstrates elevations in WBC (5–600) with approximately equal lymphocyte and neutrophil proportions. Protein may be elevated. Oligoclonal band testing is generally negative. MRI of the brain can demonstrate lesions in the subcortical white matter, periaqueductal gray, and the hypothalamus. Spinal cord MRI typically demonstrates longitudinally extensive lesions. Optic neuritis may be diagnosed clinically but is supported with fundoscopic examination, visual evoked potential testing, and orbital MRI.

Differential Diagnosis

The differential diagnosis of NMO largely includes MS and ADEM. LHON and B12 deficiency may be considered in cases of chronic optic neuritis. ALD, HTLV-1, and ischemia should be considered for transverse myelitis presentations.

Treatment

There is no FDA-approved treatment for NMO. Intravenous steroids are typically used for acute relapses, and are administered at a dose of 20–30 mg/kg (up to 1 g/day) for a 3–5 day period. Plasmapheresis may be used as first- or second-line treatment for acute attacks, and five exchanges are administered every other day or as tolerated. NMO titers may be reduced following plasmapheresis, suggesting that the antibody is linked to relapses. IVIG (up to 2 g/kg divided into two to five doses) has been used as third-line therapy by some investigators. Prophylatic therapies used for NMO in adults include Rituximab (anti-CD20 antibody), azathioprine, mycophenolate mofetil, and mitoxantrone. The same treatments have been used in children with NMO, and one group has outlined their approach as initial immunosuppression with azathioprine or mycophenolate mofetil, while refractory cases are treated with Rituximab.

Outcomes

In adults with NMO disability can accrue after relapses; however, disease progression that occurs in MS is typically absent. It is unknown whether this applies to children. In one study of children with NMO, after resolution of the acute attacks, visual impairment persisted in 26 patients (54%) and 21 patients (44%) had residual weakness. Cognitive dysfunction in children with NMO has not been systematically studied.

Conclusion

This past decade has seen significant advances in pediatric immune–mediated demyelinating diseases. However, several outstanding questions remain, including the identification of optimal treatment and greater insight into the causes of these diseases in children. National and multinational studies are underway to address these questions and should lead to promising insights in the next 5 years.

376 Cerebrovascular Disorders in Children

Warren Lo · Geoffrey Heyer · Steve E. Roach

Clinicians have become increasingly aware of cerebrovascular disorders in children, and the widespread application of noninvasive diagnostic studies in recent years has made diagnosis more straightforward. The general term *stroke* is used to include either ischemic brain infarction or hemorrhage into the brain parenchyma. Intracranial hemorrhage includes subarachnoid hemorrhage (SAH), intracerebral hemorrhage (ICH), or hemorrhage into the subdural or epidural space. By convention, an ischemic neurological deficit that resolves within 24 h is referred to as a *transient ischemic attack* (TIA). However, many of these patients have radiologic or pathologic evidence of cerebral infarction despite the rapid resolution of their symptoms.

This chapter will describe the etiology, clinical manifestations, diagnosis, and treatment of non-traumatic cerebral hemorrhage, acute ischemic infarction, and cerebral venous sinus thrombosis.

Etiology of Stroke

The occurrence of multiple strokes generally predicts a poor long-term outcome, and the identification and treatment of stroke risk factors is essential if additional strokes are to be prevented. Often, the risk factors themselves contribute to the patient's long-term outcome. Numerous risk factors for childhood stroke have been identified (*Tables 376.1* and *376.2*). Although there is considerable overlap, the conditions that promote ischemic stroke are relatively distinct from those leading to hemorrhage. If a complete assessment is done, one or more risk factors can be identified in about three quarters of the children with ischemic infarction. A likely cause can be pinpointed in most children with hemorrhagic stroke.

Causes of Hemorrhage

Congenital vascular anomalies such as arteriovenous malformations, cerebral aneurysms, and cavernous malformations are collectively the most common risk factor for nontraumatic brain hemorrhage in children. *Table 376.1* summarizes the risk factors identified from several case series. When case series were pooled, just over half of the hemorrhagic strokes were found to have occurred in children with an intracranial vascular anomaly. Other children have thrombocytopenia or coagulation defects. Hemorrhage into a brain tumor is a surprisingly common cause of hemorrhagic stroke. Typically, these children have a highly malignant tumor and present with acute signs and symptoms that are identical to those of a hemorrhagic stroke in the absence of a tumor. In contrast to adults, systemic hypertension is not a common cause of brain hemorrhage in children.

Causes of Infarction

There are too many risk factors for ischemic stroke in children to discuss them individually, but many of the common and unusual risk factors are listed in *Table 376.2*. One or more risk factors can be identified in about three fourths of the children with ischemic stroke, provided that a thorough diagnostic evaluation is performed. The most common risk factors for acute ischemic stroke in children are various forms of congenital heart disease and sickle cell disease.

Congenital or acquired heart disease accounts for about 20% of the children with ischemic stroke in most series. Complex cardiac anomalies carry the greatest stroke risk, but stroke has been documented with most cardiac lesions. Most children with stroke due to a cardiac lesion were known to have had heart disease prior to the stroke, although occasionally an obvious cardiac lesion is discovered after a stroke occurs. A right-to-left cardiac shunt may allow a venous (paradoxical) embolus to bypass the pulmonary circulation and reach the brain.

About a fourth of the individuals with sickle cell disease develop symptomatic ischemic brain infarctions, and half or more of the patients develop clinically silent ischemic lesions that are readily apparent on magnetic

Table 376.1
Risk Factors for intraparenchymal hemorrhage in children (Modified from Biller (1994))

AVM/AVF
Cavernous malformation
Aneurysm
Brain tumor (primary or metastatic)
Hematologic/Coagulopathy
Afibrinogenemia
Disseminated intravascular coagulation
Leukemia
Sickle cell disease
Thrombocytopenia
Bone marrow transplantation
Hemophilia (Factor VIII or factor IX deficiency)
Factor VII (proconvertin) deficiency
Factor XIII (fibrin stabilizing factor) deficiency
Liver failure
Liver transplantation
Warfarin therapy
Vitamin K deficiency
Anticoagulant/thrombolytic/antiplatelet agents
Hemorrhagic infarction
Venous sinus thrombosis
Intracranial dissection
Moyamoya disease or syndrome
Miscellaneous
HIV infection
Systemic lupus erythematosus
Herpes simplex encephalitis
Angiophilic fungal organisms
Drug related (amphetamines, cocaine, etc)
Vasculitis of the cerebral arteries
Systemic hypertension

AVM = arteriovenous malformation; AVF = arteriovenous fistula
PCP = Phencyclidine.

Table 376.2
Risk factors for ischemic stroke in children (Modified with permission from Roach and Riela (1995))

Congenital Heart Disease	**Hematologic Disorders/ Coagulopathy**
Ventricular septal defect	Hemoglobinopathy
Atrial septal defect	Thrombotic thrombocytopenic purpura
Aortic stenosis	Thrombocytosis
Mitral stenosis	Polycythemia
Coarctation	Disseminated intravascular coagulation (DIC)
Cardiac rhabdomyoma	Leukemia or other neoplasm
Complex congenital heart defects	Oral contraceptives
Acquired Heart Disease	Pregnancy/postpartum period
Rheumatic heart disease	Antithrombin III deficiency
Prosthetic heart valve	Factor V Leiden mutation
Libman-Sacks endocarditis	Hyperhomocysteinemia
Infectious endocarditis	Protein S deficiency
Cardiomyopathy	Protein C deficiency
Myocarditis	Prothrombin mutation
Atrial myxoma	Lupus anticoagulant
Arrhythmia	Anticardiolipin antibodies
Systemic Vascular Disease	**Structural Anomalies**
Systemic hypertension	Arterial fibromuscular dysplasia
Volume depletion or systemic hypotension	Arterial agenesis or hypoplasia
Hypernatremia	Sturge-Weber syndrome
Diabetes	Intracranial arterial aneurysm
Vasculitis	**Trauma**
Meningitis	Fat or air embolism
Systemic infection	Foreign body embolism
Herpes simplex encephalitis	Carotid ligation (e.g., with ECMO)
Systemic lupus erythematosus	Abrupt cervical rotation
Polyarteritis nodosa	Traumatic arterial dissection
Granulomatous angiitis	Blunt cervical arterial trauma
Takayasu's arteritis	Arteriography
Rheumatoid arthritis	Carotid cavernous fistula
Dermatomyositis	Coagulation defect with minor trauma
Inflammatory bowel disease	Amniotic fluid/placental embolism
Drug abuse (cocaine, amphetamines)	**Vasospastic Disorders**
Hemolytic-uremic syndrome	Migraine
Vasculopathies	Ergot poisoning
Ehlers-Danlos type 4	Vasospasm & subarachnoid bleed
Moyamoya syndrome	
Fabry disease	
Malignant atrophic papulosis	
Pseudoxanthoma elasticum	
NADH-CoQ reductase deficiency	
Transient vasculopathy	
Williams syndrome	

resonance imaging (MRI). Vascular lesions sometimes occur in individuals with other hemoglobinopathies or in those who are heterozygous for sickle hemoglobin, although much less often than with homozygous sickle hemoglobin. Children between birth and 5 years of age have the highest risk of ischemic stroke, but stroke can occur at any age. About two thirds of the sickle cell disease

patients who survive an initial stroke go on to have additional strokes.

Arterial dissection is probably under diagnosed in children with stroke. Traumatic dissection occurs more often in adolescents and in males. However, spontaneous arterial dissection and stroke is well recognized, and the injury preceding dissection is not always severe. Fibromuscular dysplasia and other arterial abnormalities increase the risk of arterial dissection. Except for the absence of trauma, the clinical manifestations of spontaneous and traumatic arterial dissection are identical. Neurologic deficit can begin immediately after the dissection or be delayed for several hours or days.

Carotid artery occlusion after peritonsillar injury is well documented. The internal carotid artery courses behind the pharyngeal tissue and can be injured during surgery or when the child falls with an ice cream stick, toothbrush, or pencil in the mouth. The intraoral injury may not seem severe, but intimal injury leads to arterial dissection with ischemic infarction distally.

Causes of Sinovenous Thrombosis

Thrombosis of a cortical vein or dural sinus often occurs in an individual with a hypercoagulable state (*Table 376.3*). The likelihood of a venous thrombosis is greater in individuals with adjacent infections such as chronic otitis, sinusitis or orbital cellulitis. Other risk factors include hemoglobinopathy, congestive heart failure, polycythemia, and dehydration. Many individuals with sinovenous thrombosis have multiple risk factors.

Table 376.3
Risk factors for cerebral venous sinus thrombosis in children

Hematologic Disorders
Autoimmune hemolytic anemia
Paroxysmal nocturnal hemoglobinuria
Polycythemia
Thrombocytosis
Leukemia
Iron deficiency anemia
Sickle cell disease
Thalassemia
Hyperviscosity
Thrombotic thrombocytopenic purpura
Coagulation Disorders
Antithrombin deficiency
Protein C deficiency
Protein S deficiency
Homocystinuria
Activated protein C resistance with or without factor V Leiden mutation
Prothrombin gene mutation G20210A
Fibrinogen disorders
Plasminogen activator inhibitor disorders
Anticardiolipin antibodies and lupus anticoagulant
Hypercoagulable state with malignancy
Pregnancy or postpartum period
Infections
Bacterial meningitis
Mastoiditis
Ear infections
Tonsillitis
Sinusitis
Systemic Conditions
Dehydration
Congestive heart failure
Hypoxia
Post-strangulation
Diabetes mellitus
Inflammatory bowel disease
Nephrotic syndrome
Systemic lupus erythematosus
Thyrotoxicosis
Behçet's disease
Trauma
Closed head injury
Hydrocephalus or shunting
Post-lumbar puncture
Post-catheterization
Jugular and subclavian vein catheterization
Medications
L-asparaginase
Oral contraceptives
Corticosteroids
Erythropoietin

Epidemiology

Schoenberg and colleagues analyzed the number of children with stroke in Olmsted County, Minnesota, from 1965 through 1974. They identified three children with hemorrhagic stroke and one with an ischemic stroke in an at risk population of 15,834 over ten years, for an estimated annual incidence rate of 2.52/100,000 children/year for children through 14 years of age (1.89/100,000/year for hemorrhagic stroke and 0.63/100,000/year for ischemic stroke). Similarly, Broderick and colleagues found an estimated 2.7 pediatric stroke cases/100,000/year. A more recent report found a stroke risk of 13.0/100,000 children/year. Several reports suggest that stroke occurs more often in boys than in girls, even after adjusting for the increased likelihood of trauma in boys.

Data from the US National Hospital Discharge Survey from 1980 through 1998 indicate a stroke rate during the first month of life of 26.4/100,000 (hemorrhagic stroke occurred in 6.7/100,000 and ischemic stroke occurred in 17.8/100,000). Based on these numbers, stroke in neonates occur in approximately 1 per 3,000 to 4,000 live births per year.

Early incidence calculations almost certainly underestimate the risk of ischemic stroke in children, and full ascertainment continues to be problematic. The early reports antedate the widespread use of MRI. These studies typically exclude neonates, who have the highest stroke rate among children, as well as children with preceding trauma, perhaps eliminating patients with stroke due to arterial dissection. Most estimates of childhood stroke incidence analyze medical record discharge diagnoses, but these records are often incomplete and incorrect. One recent analysis, for example, found 2.4 ischemic strokes per 100,000 patient-years, a figure that is three to four times the incidence in other papers. Yet only about a fifth of these children were identified via ischemic stroke diagnosis codes in the medical records; the other cases were identified by analysis of radiographic reports and selected other diagnosis codes.

The incidence of stroke in children is somewhat of a mobile target. Surgical correction of congenital heart lesions tends to be done earlier now, reducing the time spent at highest risk for stroke. Aggressive transfusion therapy for high risk individuals with sickle cell disease has lowered the risk of ischemic stroke in these individuals. Vaccines for varicella and the common meningitis-causing organisms have all but eliminated the risk of stroke due to these infections. In contrast, the occurrence of stroke in children is now more widely known by physicians, and thus the identification of stoke in these patients has probably become more common.

The reported frequency of hemorrhagic and ischemic stroke in children varies. After the first month of life, hemorrhagic stroke accounts for 37–54% of all childhood strokes, a substantially higher proportion of hemorrhagic stroke than occurs in adults. One large population-based study found that hemorrhagic stroke accounted for 54% of non-traumatic strokes occurring after the neonatal period. Another small population-based cohort registered five children with hemorrhagic stroke and three children with ischemic stroke. Analysis of a national US administrative database indicated that hemorrhagic stroke constitutes 39% of all children with a stroke diagnosis. Together these studies suggest that hemorrhagic stroke accounts for almost half of the cases of childhood stroke.

Clinical Manifestations

The signs and symptoms of cerebrovascular disorders in older children generally resemble those of adults, but younger children tend to have more subtle and variable findings. The clinical manifestations are largely determined by the size and location of the lesion and whether the stroke is ischemic or hemorrhagic. The nature of any underlying risk factors also plays a significant role in the clinical presentation of some children.

Intracranial Hemorrhage

Classically, individuals with an ICH complain of sudden, severe headache followed by vomiting and progressive deterioration of consciousness. Seizures occur in up to a third of the children with brain hemorrhage. Children with smaller hemorrhages often have less dramatic manifestations, which are clinically indistinguishable from those of ischemic infarction. Younger children may have surprisingly few signs and symptoms even with a larger lesion, especially when the lesion does not involve the motor pathways or brainstem. The array of the focal neurological deficits due to a brain hemorrhage depends on the location of the bleeding and whether cerebral herniation has occurred.

Severe SAH is heralded by sudden, severe headache, vomiting, meningismus, and alteration of consciousness. Less severe subarachnoid bleeding may produce a less distinctive presentation, limited to unexplained

irritability, vomiting, photophobia or seizures. Location of the headache does not dependably predict the origin of the bleeding, but more severe hemorrhage is more likely to generate more impairment of consciousness. Focal or generalized seizures occur in up to a quarter of the children with SAH. Signs of increased intracranial pressure are typical, and papilledema may be found within a few hours, although it is difficult to document in an uncooperative child with photophobia.

Acute Ischemic Stroke

Acute ischemic stroke in children results from occlusion of one or more of the brain's arteries either by an embolism or by intraluminal thrombosis. Regardless of the stroke's pathophysiology, the clinical manifestations depend primarily on the size and location of the occluded artery. Most cerebral emboli in children result from cardiac lesions, while the artery to artery emboli that are common in adults with stroke due to carotid artery atherosclerosis are rare in children.

The arteries most frequently occluded by an embolus are the supraclinoid internal carotid arteries and the middle cerebral arteries, so the most common resulting clinical signs are hemiparesis, hemisensory loss, and aphasia. However, emboli to other arteries produce an array of signs or symptoms. Classically, an embolus causes sudden-onset symptoms with an almost immediate maximum deficit followed, in some individuals, by an equally dramatic resolution of the deficit as the embolism breaks apart and allows reperfusion of the tissue. However, this pattern occurs infrequently, especially in very young children, who are more likely to present with a deficit of unknown duration.

Arguably the most frequent location of acute ischemic infarction in children is the basal ganglia and thalamus. As with adults, children with small infarctions in this area develop deficits such as pure motor hemiparesis, monoparesis, or hemianesthesia. These lesions in children seldom result from chronic hypertension. Instead, basal ganglia infarctions in children often result from occlusion of the small end arteries of the region secondary to occlusion of the adjacent internal carotid artery or the middle cerebral artery. Ischemic infarction within the vertebrobasilar circulation typically presents with ataxia, depressed consciousness, or cranial nerve dysfunction.

Cerebral infarction in neonates constitutes a special subset of acute ischemic stroke in pediatrics. Affected babies most often present with focal motor seizures on the first or second day of life, although a few are identified later because of developmental delay or epileptic seizures. The majority of cerebral infarctions in neonates occur in the left cerebral hemisphere, suggesting that these lesions arise via embolism that is facilitated by the unique features of the fetal circulation. Radiographic findings suggest that some of these babies develop an infarction prior to delivery.

Transient Ischemic Attacks (TIAs)

Transient ischemic deficits are rare in children, although some of the transient deficits seen with moyamoya syndrome may arise from an artery to artery embolism. In children, TIAs sometimes result from small emboli or local hemodynamic factors, which temporarily prevent adequate perfusion. Small infarctions can sometimes be demonstrated radiographically or pathologically, even in patients whose clinical dysfunction resolved completely within a few hours.

Sinovenous Occlusion

Thrombosis of a cortical vein or dural sinus can be overlooked because the clinical findings are often less obvious than with arterial occlusion and because a sinovenous occlusion is not always apparent with routine computed tomography (CT) and MRI procedures. Focal or generalized seizures commonly occur after a cortical vein thrombosis. Dural sinus thrombosis often results in increased intracranial pressure, and visual loss may occur in individuals with severe or prolonged pressure elevations. As with acute ischemic infarction, focal neurologic dysfunction is common with sinovenous occlusion although such deficits are sometimes confused with a postictal deficit in individuals with focal seizures.

Diagnostic Evaluation

Risk Factor Evaluation

Space limitations do not allow a complete discussion of each of the many risk factors for stroke in children. Often, a likely explanation for the stroke is obvious, as in patients known to have sickle cell disease or congenital heart disease. Even in these individuals, however, there may be secondary

risk factors that contribute to the risk of recurrent stroke. Even after a thorough assessment, no obvious risk factors are identified in about a quarter of the children with ischemic stroke. However, a likely cause is identified much more often in children with intraparenchymal hemorrhage.

The initial evaluation should include simple noninvasive tests with low cost and high yield. A complete blood count may identify polycythemia, hemoglobinopathy, infections, or isoimmune thrombocytopenic purpura. Hemoglobin electrophoresis should be done on patients at risk for hemoglobinopathy if they have not been tested already. A sedimentation rate, prothrombin time (PT), and partial prothrombin time (PTT) are usually done. Tests to identify coagulation disorders are reasonable even when one or more risk factors are already known to exist. Many children have more than one risk factor, and it is often more practical and cheaper to do several studies at the same time, adding or deleting specific studies to fit the clinical situation.

Cardiac lesions are the leading cause of ischemic stroke in children, although most of the time the diagnosis is known even before the stroke occurs. Nevertheless, it is reasonable to obtain a consultation from a pediatric cardiologist, with an electrocardiogram, and a chest x-ray. Ambulatory cardiac rhythm monitoring and echocardiography are sometimes helpful, but their yield is low if the cardiac examination and earlier cardiac studies are normal. The significance of a patent foramen ovale, if any, is still being investigated.

Any child with an unexplained acute focal neurological deficit who does not have significant mass effect should undergo a lumbar puncture. Nonvascular disorders such as herpes simplex encephalitis can mimic vascular lesions, and the diagnosis may be evident only by lumbar puncture. Cerebrospinal fluid analysis is mandatory in a stroke patient with unexplained fever or signs of central nervous system infection. Chronic meningitis or early tuberculous meningitis can present with stroke; bacterial meningitis often causes stroke although not typically as the presenting sign. Syphilis serology should be done in at risk adolescents with an unexplained ischemic stroke; some reports also link human immunodeficiency virus to cerebrovascular dysfunction. Mild SAH, unapparent on CT, can be demonstrated via lumbar puncture, although a lumbar puncture is usually unnecessary when the subarachnoid bleeding is obvious radiographically.

Radiographic Evaluation

A stroke can usually be depicted by radiologic studies such as MRI and CT. These studies also enable the clinician to eliminate nonvascular conditions from consideration. Magnetic resonance angiography (MRA), CT angiography (CTA), and catheter angiography often allow one to identify the specific vessel that is responsible for the stroke and to pinpoint the cause of the vascular dysfunction.

Cranial CT or MRI should be done early in the evaluation. Cranial CT is often done first because it can be performed quickly and is widely available after hours. CT effectively demonstrates ICH and SAH (*Fig. 376.1*). Either scan will often confirm a cerebrovascular lesion and help to eliminate other diagnoses. Smaller ischemic infarctions are more reliably seen with MRI, and recent infarctions are often evident with diffusion weighted MRI before they are apparent with CT (*Fig. 376.2*). However, CT and MRI often provide complementary information.

MRA and magnetic resonance venography (MRV) provide a non-invasive way to image the intracranial vessels (*Fig. 376.3*). These studies are ideal for patients at extra risk for catheter angiography or those whose diagnosis is suspected but not definite. However, MRA is less reliable than catheter angiography especially when evaluating the smaller arteries, and one must also consider the risk to the patient should a diagnosis be missed. In experienced hands, the reliability of CT angiography approaches that of catheter angiography, and it is becoming the modality of choice for imaging the intracranial arteries.

In neonates, cranial ultrasonography can be done without sedation at the bedside without transporting a critically ill baby to an outside imaging suite. The presence of an infarction, hemorrhage, or even a vascular malformation may often be visualized on ultrasound and the age of the lesion estimated. However, ultrasonography is less precise and less reliable than either CT or MRI, and it is easy to miss lesions in the anterior or posterior regions of the hemispheres. Transcranial Doppler is also useful in certain situations.

Catheter angiography remains the most accurate imaging technique for visualizing smaller intracranial arteries and demonstrating subtle changes in larger vessels. In skilled hands, catheter angiography carries a low risk, but it is an invasive test so some complications are inevitable. For this reason, CTA or MRA are often substituted for catheter angiography despite its superior reliability.

Catheter angiography is especially important for individuals with hemorrhagic stroke because of their high frequency of congenital intracranial vascular lesions (*Fig. 376.4*) and the risk of re-bleeding from these treatable lesions.

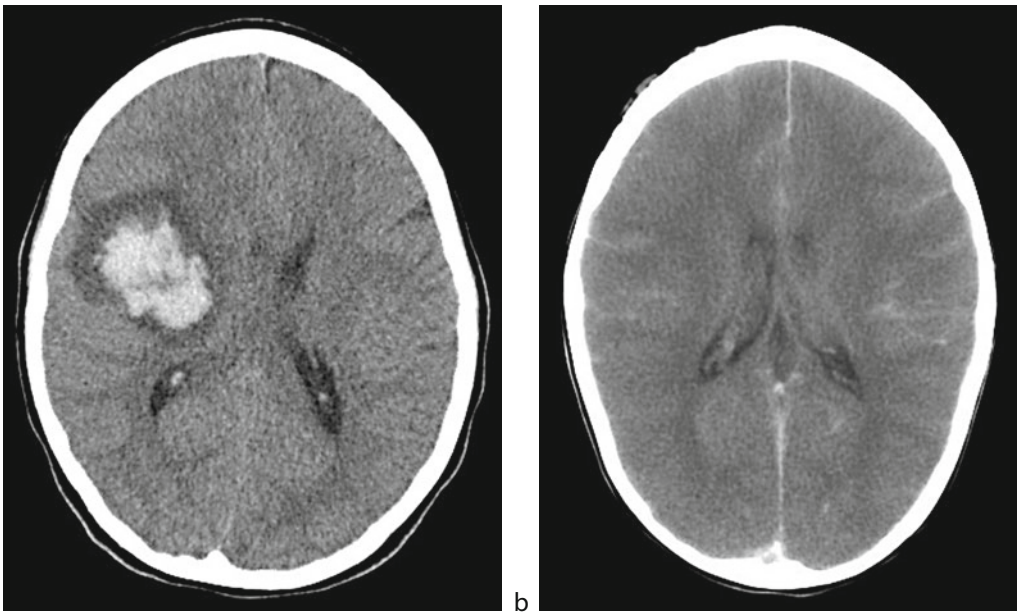

Figure 376.1
(a) Axial CT shows an intracerebral hemorrhage in the right frontal and parietal lobes with compression of the adjacent lateral ventricle. (b) Cranial CT scan shows blood filling the subarachnoid space and cerebral sulci. Diffuse cerebral edema is also evident

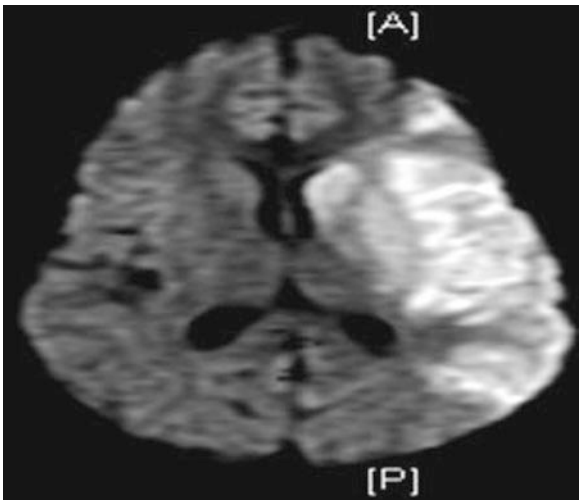

Figure 376.2
Magnetic resonance brain scan. Diffusion-weighted MRI reveals cerebral infarction in the left middle cerebral artery territory

Delayed Diagnosis of Childhood Stroke

Several studies confirm that delays in diagnosis occur at multiple stages in children with stroke. Although there is sometimes a delay in seeking medical attention, the majority of the delays occur after the child reaches medical care. Delayed diagnosis is a particular problem for ischemic stroke occurring after the neonatal period. Stroke is relatively rare in children, and acute focal deficits are relatively common with nonvascular disorders as well as with stroke. Nevertheless, failure of clinicians to appreciate that stroke occurs in children is probably responsible for many of the delays. The key to rapid, accurate diagnosis is a high index of suspicion for a diagnosis of stroke in children with acute neurological deficits. The astute clinician will suspect a stroke if a child's acute neurological deficits can be explained by ischemia or hemorrhage involving a vascular distribution of the central nervous system.

Differential Diagnosis

Any nonvascular lesion that produces acute neurological dysfunction can mimic stroke, and some vascular disorders cause gradual or intermittent loss of function. One retrospective chart review from a tertiary care children's hospital in the USA found that of 79% of 143 consecutive consultations for suspected stroke had a stroke diagnosis, but 30 children (21%) eventually were shown to have another condition that mimicked stroke, such as complicated

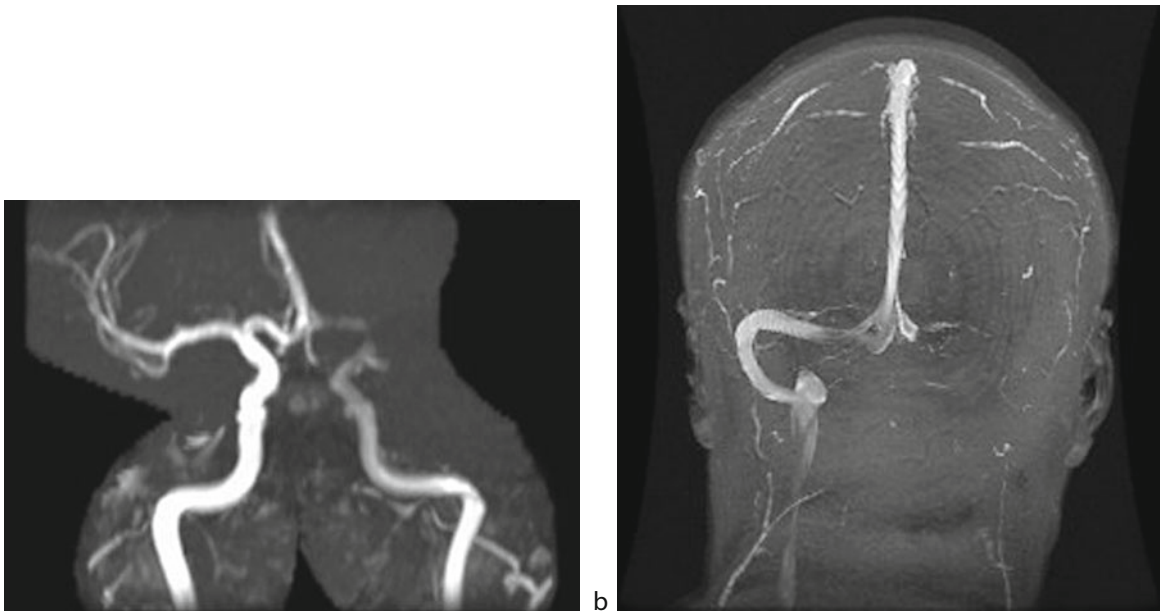

Figure 376.3
(a) Magnetic resonance angiogram shows occlusion of the left internal carotid and left middle cerebral arteries. Photograph courtesy of Dr. Khaled Zamel. (b) Magnetic resonance venogram demonstrates an occluded left transverse sinus

migraine, epilepsy, or psychogenic disorders. Moreover, cerebrovascular lesions can develop concurrently with disorders such as meningitis, abscess, and encephalitis. The diagnostic evaluation should be complete enough to eliminate nonvascular conditions and, once a cerebrovascular lesion has been identified, find its cause.

Focal intracranial infections must be considered because they sometimes cause acute neurological deficits that resemble those of stroke. Particularly important are herpes simplex encephalitis, intracerebral abscess, and tuberculoma. Cerebral infarction is a common complication in children with arteritis due to bacterial meningitis, although not usually as a presenting sign. Stroke can be the means of presentation in chronic or subacute meningitis, as in the early stages of tuberculous meningitis or even viral meningitis. Even an apparently straightforward cerebral abscess can be confusing because a common cause of abscess is a septic cardiac embolus.

A neoplasm can produce acute symptoms that mimic a vascular lesion via several mechanisms. Hemorrhage into a tumor or tumor infarction with acute edema can cause headache, focal deficits, and depressed consciousness, findings very similar to those of an ICH in the absence of a tumor. Localized compression or invasion of intracranial vascular structures can produce thrombosis and infarction,

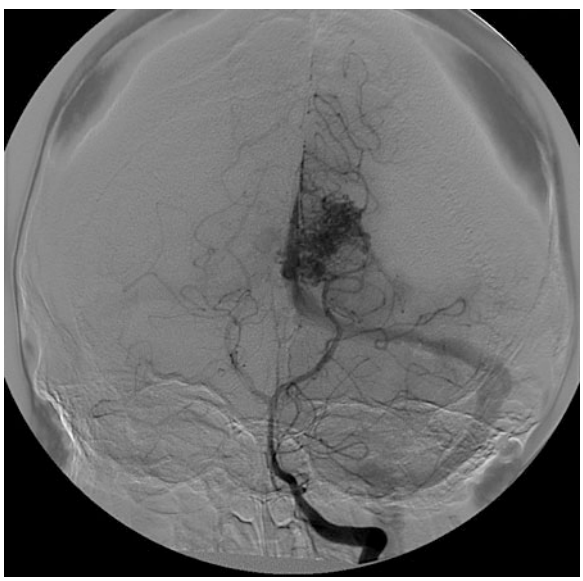

Figure 376.4
Catheter cerebral angiogram via the left vertebral artery confirms an arteriovenous malformation. Note the tangle of abnormal arteries and the early filling of the transverse sinus

so it is possible for the same individual to have both tumor and stroke. Brain herniation is another mechanism for acute deterioration due to tumor. Acute obstruction of the ventricular system by an intraventricular tumor produces sudden headache and deterioration of consciousness similar to the pattern seen with ICH or SAH.

Transient hemiplegia or other focal deficits sometimes follow protracted seizures. If the seizure is witnessed and prolonged, there is seldom any confusion about the nature of a post-ictal deficit. Prolonged focal seizures are more likely to leave a focal post-ictal deficit, but the dysfunction typically begins to improve within an hour or two after the seizure stops and has completely resolved within 24 h. Failure of a post-ictal deficit to resolve within this time frame suggests that a seizure is not the sole cause of the persisting dysfunction. Vascular occlusion or hemorrhage, for example, may cause both focal deficits and seizures, often leading to the mistaken diagnosis of a post-ictal deficit.

Treatment

General Treatment Measures

The supportive measures used in children with cerebrovascular dysfunction are the same for intracranial hemorrhage, acute ischemic stroke, and sinovenous thrombosis. The patient should be carefully monitored by an experienced staff, and clinical deterioration warrants transfer to an intensive care unit for more intensive monitoring and possible intervention. The unit should be able to monitor brain functions including intracranial pressure (ICP), and if available, cerebral blood flow and cerebral blood oxygenation. Children with a stroke are at risk for depressed consciousness, aspiration, and hypoventilation. Supportive care must insure airway protection and adequate oxygenation. While there is no current evidence that hypothermia improves outcome, fever increases cerebral metabolism; so, fever should be treated.

Elevated blood pressure should be managed with care in order not to compromise cerebral perfusion pressure. Severe elevation of blood pressure may promote re-bleeding from an aneurysm, but there is little evidence that lowering of the blood pressure reduces clot expansion with an ICH. An elevated blood pressure may reflect an effort to preserve cerebral perfusion pressure via cerebral autoregulation, and overly aggressive treatment may induce cerebral hypoperfusion. While it is clinically appropriate to treat severe hypertension, there are no data that support the lowering of blood pressure to a specific range.

Both convulsive and non-convulsive seizures increase the cerebral metabolic rate. Convulsive seizures can also increase the risk for re-bleeding from an aneurysm or arteriovenous malformation (AVM), so seizures should usually be treated and seizure prophylaxis may be considered especially in individuals with SAH.

If there is no clinical evidence for increased ICP, the patient can be observed carefully. There are multiple means to treat increased ICP, all of which have limitations. Intubation and hyperventilation to a pCO_2 of 30–35 mm Hg can reduce ICP, but the ICP effect is often temporary and excessive hyperventilation can reduce cerebral blood flow. Treatment with intravenous mannitol and hypertonic saline can reduce ICP, but these measures can complicate fluid and electrolyte management, and there is limited evidence that hyperosmolar treatment improves outcome. Ventriculostomy and cerebrospinal fluid (CSF) drainage should be performed if there is acute hydrocephalus. Intravenous sedation, neuromuscular blockade, and barbiturate coma can reduce the ICP, but can promote a range of problems including systemic hypotension, atelectasis, and pneumonia.

Therapy of Intracranial Hemorrhage

Rational therapy of hemorrhagic stroke is hampered by a paucity of randomized controlled trials from which to develop evidence-based guidelines, and such studies are nonexistent in children. The recent American Heart Association recommendations for the diagnosis and treatment of pediatric stroke reflect the sparse data but provide consensus guidelines for the treatment of hemorrhagic stroke in children. In addition to specific measures to alleviate the effects of the hemorrhage, conditions that led to the hemorrhage should be corrected whenever possible.

The management of ICH related to anticoagulation warrants special mention. Patients treated with warfarin who develop intracranial hemorrhage can be treated with intravenous vitamin K, fresh frozen plasma, prothrombin complex concentrate, or recombinant factor VIIa to increase levels of coagulation factors and to decrease the risk of acute recurring bleeding. Patients treated with unfractionated heparin can be treated with protamine sulfate; however, it only reverses the effect of low-molecular weight heparin by 70%. All of these measures pose some risk of thromboembolic complications.

There is little data to suggest that craniotomy improves the outcome of most patients with a supratentorial ICH. Limited data suggest some benefit for the evacuation of superficial lobar clots in patients with mild neurological deficits (GCS > = 9). Patients should undergo ICP monitoring in an intensive care unit and further clinical deterioration should be monitored with CT scans. Ventriculostomy and external drainage are helpful when hydrocephalus develops or when intraventricular hemorrhage is present. Cerebellar hemorrhage that is large (>3 cm in adults), and causes brainstem compression or hydrocephalus should be evacuated early. If a cerebellar hemorrhage is small and there is no brainstem compression, then the hemorrhage can be managed medically.

Given the frequency of congenital vascular lesions in children with brain hemorrhage and the risk of re-bleeding with these lesions, surgical obliteration or endovascular occlusion of AVMs is indicated. Partial occlusion of an AVM may make the lesion more amenable to later surgical correction. Radiotherapy may be useful for deep-seated cavernous malformations or small arteriovenous malformations. Death or poor outcome due to re-bleeding is a particular concern in patients with an aneurysm, so early intervention to occlude an aneurysm should be pursued when the patient is sufficiently stable. Calcium-channel blocking agents, such as nimodipine, may benefit vasospasm due to SAH. While there are no well-controlled studies that blood pressure control reduces re-bleeding, sustained severe hypertension should be treated without compromising cerebral perfusion to reduce the risk of re-bleeding.

Therapy of Acute Ischemic Stroke

A complete discussion of the therapeutic options for children with acute ischemic stroke is beyond the scope of this chapter, but recently published evidence-based consensus guidelines provide additional detail. Much of the therapeutic effort is aimed at secondary prevention and modification of risk factors. Early correction of congenital cardiac lesions, for example, reduces the risk of ischemic stroke. Similarly, treatment of cerebral arteritis and stroke-related metabolic conditions should diminish the risk of stroke.

Anticoagulation with warfarin or low molecular weight heparin is recommended for children thought to have a high risk of recurrent cardiogenic embolism, patients with a severe hypercoagulable state, and individuals with a cervical arterial dissection. Anticoagulation is continued for 3–6 months in patients with dissections, and until the risk diminishes in patients with cardiac disease. Anticoagulation is not recommended for an intracranial dissection because of the tendency of these individuals to develop an SAH. Detailed instructions for initiating and maintaining anticoagulation in children have been published.

Aspirin is often prescribed in children in an effort to prevent recurrent stroke following TIA or stroke. Long-term aspirin at the recommended doses (1–5 mg/kg/day) seems to be safe in children, but data about its effectiveness and optimal dosing are limited. Randomized controlled trials do not exist, and the results of cohort trials have been mixed, which is hardly surprising given the small numbers of patients studied and the variable nature of the risk factors. Despite this paucity of data, aspirin is recommended for secondary stroke prevention in children who do not require anticoagulation. Other antiplatelet agents are sometimes utilized, but information about their safety and efficacy in children is largely nonexistent.

Several case reports document the successful use of tissue plasminogen activator (tPA) in children, but additional studies are needed to confirm the safety and efficacy of thrombolytic therapy in children. While it may be reasonable to use tPA in selected older children, the appropriate dose, timing, and exclusion criteria for children have not been established.

Periodic blood transfusions limit the production of sickle hemoglobin and dramatically reduce the likelihood of stroke due to sickle cell disease, although toxicity from iron overload requires the concomitant use of a chelating agent. Chronic transfusions have long been started after the initial stroke because of the very high risk of subsequent infarctions. A controlled clinical trial showed that periodic transfusions also strikingly reduce the likelihood of an initial stroke even in high risk individuals. The current recommendation is to begin transfusions after an ischemic stroke due to sickle cell disease and in individuals with a very high stroke risk based on abnormal transcranial Doppler findings. Hydroxyurea is not as well studied but may be of use in some patients.

Therapy of Sinovenous Thrombosis

Supportive treatment of cerebral venous sinus thrombosis (CSVT) includes hydration, control of seizures, control of increased intracranial pressure, and the administration of appropriate antimicrobials to children with an adjacent infection. Very ill children require admission to an intensive care unit, and those at high risk for clinical or subclinical seizures may benefit from continuous

electroencephalographic monitoring. Discontinuation of estrogen-containing medications may reduce the risk of recurrent CVST.

Adults with cerebral venous sinus thrombosis evidently benefit from anticoagulation, even when there is an associated brain hemorrhage. The evidence for a similar improvement in children, however, is less robust. Several case reports and small case series of children suggest that anticoagulation is well tolerated. A prospective study of anticoagulants in 30 children with CVST documented 3 deaths among 8 untreated children, but no deaths among the 22 anticoagulated children. Thus, older children with or without parenchymal hemorrhage should probably be anticoagulated. Although there is little objective data to guide the duration of treatment, the most common approach is to treat patients with warfarin or low molecular weight heparin for 3–6 months. Anticoagulation is not usually recommended for neonates except for those with a severe prothrombotic disorder, progressive clinical deterioration, or radiologic evidence of clot propagation. Thrombolysis has been used successfully in a few children, but is not routinely used.

Prognosis

Arterial Ischemic Stroke

The acute mortality of arterial ischemic stroke in children is comparable to that in adults. Recent estimates of mortality following ischemic stroke in children range from 3% to 5.3%. The likelihood of ischemic stroke recurrence in children depends on the type of risk factors that are present, ranging in published series from 7% to 19%. The risk factor associated with the highest percent of recurrences was a primary abnormality of the cervical or cerebral vessels (vasculopathy). In a prospective cohort of 212 neonates and children in a British tertiary care center, 14% had a recurrent stroke, 2% died of a recurring stroke, and 20 of 103 clinically asymptomatic children had another infarction detected by neuroimaging. Low birth weight and the presence of moyamoya vasculopathy were independent predictors for recurrence in the entire group .

The eventual cognitive function following a perinatal middle cerebral artery ischemic infarction ranges from normal to severe impairment. There is no precise relationship between the size or side of the infarct with cognitive function; individuals with triplegia or quadriplegia tend to have severe cognitive impairment. The presence of seizures also increases the likelihood of cognitive impairment. Similarly, the use of seizure medication and dependence upon others for activities of daily living predicted lower levels of functioning after stroke in older children. Stroke occurring very young in life or in the teenage years is associated with a worse outcome. In one case series of 21 children, mean IQ fell within the normal range, but the patients had deficits in specific areas such as digit span, arithmetic, divided attention, and alertness. Attention deficit-hyperactivity disorder symptoms were more frequent than in the general population.

Hemorrhagic Stroke

Few studies examine the outcome after hemorrhagic stroke in detail. The existing studies are retrospective and differ in their definition of outcome and the type of outcome measures used. Nevertheless, several broad conclusions are supported by the collective reports. About 35% of children had a good outcome with little or no impairment. Approximately 30% of the patients died from the acute hemorrhage, recurrent hemorrhage, or their underlying disorder. The remaining patients were left with impairments ranging from mild to severe.

In two case series, the outcomes were examined in more detail. One study performed neuropsychological examinations of 31 survivors. No cognitive deficits were found in 15, mild or diminished cognitive function were found in 8, and 7 had moderate to severe global cognitive deficits. Another study of 26 patients found that half of the survivors had cognitive deficits and 38% had motor deficits.

Cerebral Venous Sinus Thrombosis

In one report, follow-up data were available in 143 of 160 consecutive children with cerebral venous sinus thrombosis. There were 12 deaths (8%), half of which resulted from the venous thrombosis. Seventy seven of these children (54%) were neurologically normal and 54 (38%) had some type of residual neurological deficit. Over half of these children were treated with anticoagulants; nevertheless, these numbers illustrate the serious nature of venous sinus thrombosis in children.

377 Head Injury in Children

Daniel S. Tsze · Thomas H. Chun

Definition/Classification

A head injury can be broadly defined as an acute traumatic insult to the head by an external force. While any part of the head can be injured in this way, the focus of this chapter is injuries to the scalp, skull, brain parenchyma, and their associated anatomic structures. Acute head injuries thus covers a wide spectrum of severity, ranging from benign contusions to intracranial hemorrhage, which may result in increased intracranial pressure, brainstem herniation, and death. The term traumatic brain injury (TBI) has also been used to encompass the alteration in brain function resulting from a blunt or penetrating force to the head, manifesting as confusion, altered level of consciousness, seizure, coma, or focal sensory or motor neurologic deficit.

Head injuries can be classified in many different ways. Isolated injuries to the scalp, skull, and brain can and do occur. However, injuries to more than one structure are commonly encountered. As such, a system of classifying injuries solely on the basis of anatomic location lacks clinical utility. Similarly, classifying injuries on the basis of mechanism (e.g. "blunt vs. penetrating") fails to define head injuries in a clinically meaningful way, as each type of mechanism does not exclusively result in either an open or closed head injury. Therefore, one should not assume that a given mechanism of injury is consistently synonymous with a particular type of injury incurred. Distinguishing open from closed head injuries is another system that is commonly used. Open head injuries occur when blunt or penetrating trauma transgress the scalp and skull, exposing the brain to the external environment. By definition, all open head injuries require emergent neurosurgical consultation. With closed head injuries, on the other hand, the traumatic sequelae or the condition of the intracranial contents may not be readily apparent. Care of these patients will depend on their clinical condition and may also depend on the results of diagnostic imaging.

In summary, no single classification system captures all the relevant clinical information of head injuries. The most clinically useful method of categorizing head injuries incorporates elements of all these systems, and includes an assessment of clinical neurologic status (e.g. Glasgow Coma Scale).

Etiology & Epidemiology

Traumatic brain injuries are a global phenomenon that affects over ten million people annually. Despite the ubiquitous nature of head injuries, there are differences in incidence and etiology between countries, due to a multitude of factors.

The global rate of TBI has been reported to be as high as 193 per 100,000. Developing areas of the world have higher rates of TBI, led by Sub-Saharan Africa, Latin America and the Caribbean, and India, with rates of 359, 258, and 250 per 100,000, respectively. These numbers, however, may still underestimate the true incidence for a number of reasons. Access to health care in these countries may be challenging, resulting in milder TBI going unreported and more severe events ending in death prior to reaching a hospital. In such instances, TBIs may not be accurately recorded in the country's health statistics. Most data is also derived from urban hospital-based studies, meaning that injuries that present to primary care services or in rural areas are also neglected. Countries with lower rates of TBI include China and countries of the Middle Eastern Crescent, with reported rates of 115 and 123 per 100,000. However, these statistics may also be subject to the same limitations described earlier. Countries with established market economies (e.g. France, USA) have reported rates of 144 per 100,000.

Traumatic brain injuries cause tremendous mortality and morbidity. In high income countries such as the United States, an estimated 1.4 million TBI hospitalizations and ED visits occur each year, with 50,000 deaths amongst these events. An estimated 80,000 to 90,000 people experience permanent disability as a result of their injury. Children are heavily affected as well, as TBI is the most frequent cause of disability and death in the US. The burden of TBI is also significant in low and middle income countries. India, for example, has an estimated two million people who are injured and 200,000 who die from TBI. Specific regions have reported as many as 30% of their TBI cases to be children less than 15 years old, which account for 75% of all pediatric trauma hospitalizations and 80% of pediatric trauma deaths.

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_377,

When examining the causes of TBI worldwide, etiologies vary from country to country. Road traffic injuries (RTI) are the most common cause globally. In developing countries, RTIs account for as much as 60% of TBIs. The World Health Organization (WHO) estimates that by the year 2020, RTI will be the third leading cause of premature death amongst all age categories. The next most common mechanism of TBI is falls, which account for approximately 20–30% of TBIs. Of these fall-related TBIs, 50% of these injuries are reported in India. Ten percent of TBIs result from violence, which is more common than falls in countries like Sub-Saharan Africa, Latin America and the Caribbean. In Sub-Saharan Africa, violence and war account for 33% and 53%, respectively, of TBIs. Finally, an additional 10% of TBIs worldwide occur from a combination of work place and sports-related injuries.

In developed countries, etiology is strongly associated with socioeconomic status. In more affluent communities, TBIs are dominated by RTIs, falls, and recreational activities, with less than 10% related to violence. Areas characterized by dense population, poverty, high rates of unemployment, crime, and substance abuse report rates of TBI due to violence as high as 34%. Adolescents and young adults, males and ethnic minorities are also at increased risk of TBI due to violence and RTI.

TBI is particularly relevant to pediatric populations because the incidence of TBI is tri-modal, with peaks in early childhood, late adolescence/early adulthood, and in the elderly. Falls dominate among children as the most common cause of TBI in high income and low income countries alike, whereas RTI and violence account for the majority in adolescents and young adults. Unfortunately, the majority of these injuries occur in the poorest countries. The WHO estimates that over 98% of childhood injuries occur in these countries, with injury rates as much as five times higher than their industrialized counterparts.

Pathogenesis

When a child experiences head trauma, significant intracranial injuries (ICI) may result. Intracranial injuries are divided into primary and secondary brain injuries. Primary injuries are the mechanical damage directly caused by the traumatic event. These include penetrating foreign bodies, the brain impacting the skull interior, or shearing forces that tear white matter tracts or bridging blood vessels.

Secondary brain injury refers to the metabolic events that follow the initial insult, and damage neurons which were previously unharmed. These events include hypoxia, hypoperfusion, ischemia, and metabolic derangements. The most deleterious secondary event is brain ischemia resulting from inadequate cerebral blood flow. This can occur from vasospasm of cerebral vasculature, especially associated with subarachnoid hemorrhages, excessive extracranial bleeding causing systemic hypovolemia, or thrombosis leading to tissue infarction. Brain ischemia can be further aggravated by hyperthermia, which increases cerebral metabolism. Hyperglycemia can also hasten cerebral injury in the injured brain, as can inflammatory mediators released in response to brain injury.

An important sequelae of primary brain injury is increased intracranial pressure (ICP). The intracranial space is a fixed volume occupied by the brain, cerebrospinal and interstitial fluid, and blood. Hemorrhages, large cerebral contusions, or diffuse brain swelling can cause any of these components to increase in volume. A decrease in either one or both of the other intracranial spaces must occur to avoid increases in ICP. The main compensatory mechanism is displacement of CSF into the spinal canal, but once the limits of compensation have been reached, any subsequent increases in volume in the intracranial spaces will result in rapid increases in ICP. Increased ICP may cause compression of CSF outflow tracts resulting in ventricular dilatation and hydrocephalus, or compression of ventricular spaces due to increases in brain or blood volume. Increased ICP may also impede cerebral blood flow and perfusion, leading to ischemic damage.

The most dramatic consequence of increased ICP are cerebral herniation syndromes (Fig. 377.1), in which part of the brain is forced through an inappropriate passage or space due to increased ICP. Each syndrome is defined by the anatomic location of the herniation. The most well known syndrome is tentorial herniation, in which the uncus of the temporal lobe is forced through the space between the cerebral peduncle and the tentorium. This results in compression of the oculumotor nerve and an ipsilateral dilated nonreactive pupil; hemiparesis or decerebrate posturing from compression of the cerebral peduncle; and bradycardia, hypertension, and irregular respirations (Cushing's Triad) due to brainstem compression. Bilateral signs may occur if there are bilateral lesions or diffuse swelling. If this progression is not treated, respiratory arrest and death may ensue.

Clinical Manifestations: Symptoms, Signs

An important part of clinically assessing a child who has suffered a head injury is to determine their level of

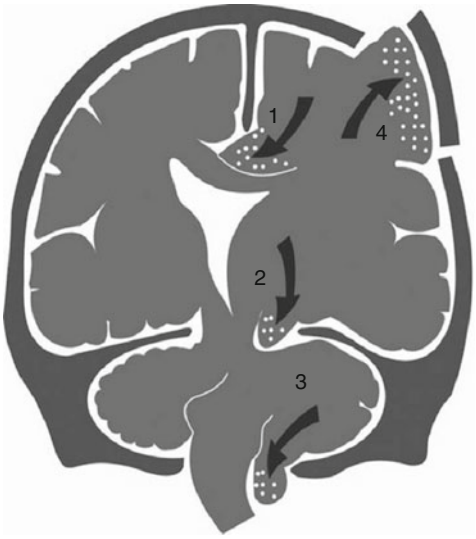

Figure 377.1
Cerebral herniation syndromes (1) Cingulate (subfalcine); (2) Uncal (transtentorial); (3) Tonsillar; (4) Transcalvarial (Dempsey and Hwang, 2010)

consciousness. The Glasgow Coma Scale (GCS) is an internationally recognized neurological scale for rating the severity of a head injury and objectively monitoring neurologic status during the acute management of head injuries. The GCS is modified for use in very young children (e.g. less than 2 years old) who may not be able to communicate and obey commands like adults (*Table 377.1*). The resulting scores, however, are still interpreted in the same manner: the lower the score, the more severe the injury. Scores of 3 to 8 indicate a severe brain injury; 9 to 12 are moderate injuries; and 13 and greater are minor injuries.

Skull fractures can be hidden beneath hair and difficult to appreciate by palpation unless severely depressed. Skull fractures may be associated with overlying soft tissue swelling or hematoma. Basilar skull fractures should be suspected if there is hemotympanum, CSF otorrhea or rhinorrhea, periorbital ecchymosis ("raccoon eyes", as shown in *Fig. 377.2*), or postauricular ecchymosis (Battle's sign, as shown in *Fig. 377.3*).

All ICIs can present with similar signs and symptoms, including headache, vomiting, irritability, focal

Table 377.1
Glasgow Coma Scale and Pediatric Glasgow Coma Scale

Score	Adult	Pediatric
Eye Opening Response		
4	Spontaneous	Spontaneous
3	Open to verbal command, speech, or shout	Open to verbal command, speech or shout
2	Opens to pain	Opens to pain
1	None	None
Verbal Response		
5	Oriented and converses	Coos or babbles (normal activity)
4	Confused, but able to answer questions	Irritable and continually cries
3	Inappropriate responses, words are discernable	Cries to pain
2	Incomprehensible speech or sounds	Moans to pain
1	None	None
Motor Response		
6	Obeys commands for movement	Spontaneous or purposeful movement
5	Purposeful movement to painful stimuli	Withdraws from touch
4	Withdraws from pain	Withdraws from pain
3	Decorticate posture, abnormal flexion	Decorticate response, abnormal flexion to pain
2	Decerebrate posture, extensor response	Decerebrate response, extension to pain
1	None	None

neurologic symptoms, and altered level of consciousness. Seizures may occur, but are less common. Injuries resulting in cerebral herniation may present with unilateral, bilateral, or autonomic changes as described in the pathogenesis section. Posterior fossa involvement may present with cerebellar findings such as ataxia or nystagmus.

Certain features may be useful in differentiating ICI's. The classic presentation of an epidural hematoma is an initial loss of consciousness, followed by a "lucid interval" of up to several hours, and finally a deterioration in neurologic status as the expanding hematoma exerts

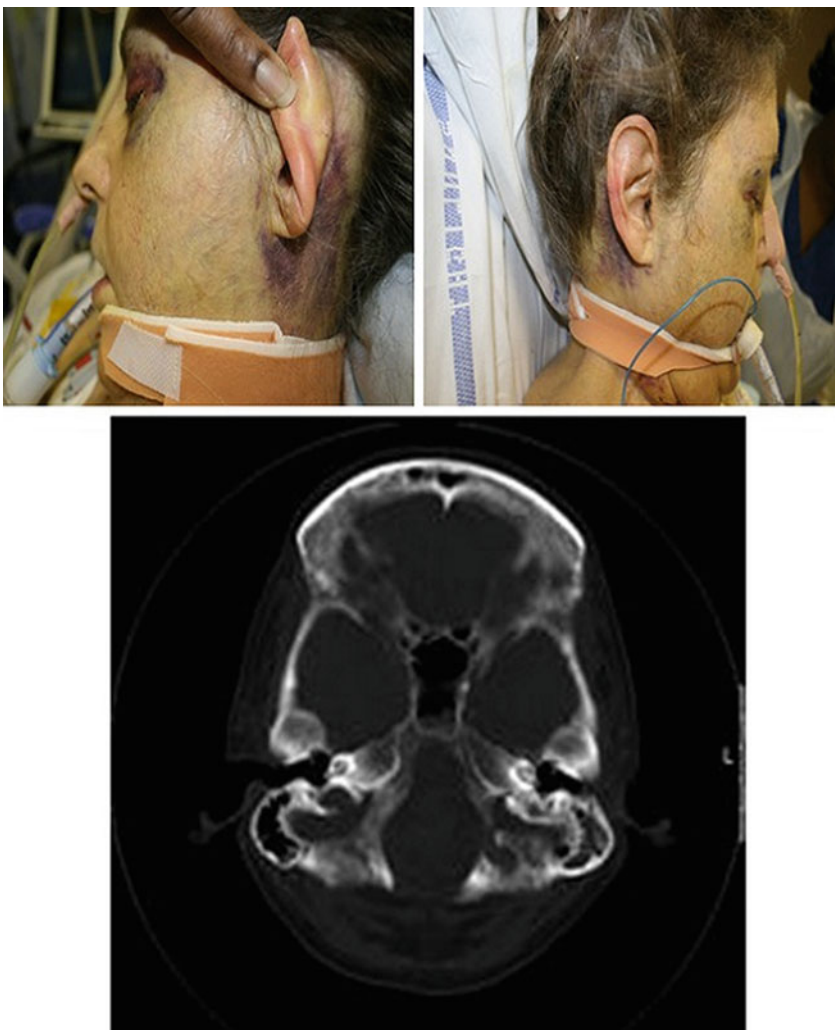

Figure 377.3

a mass effect on the brain. A subarachnoid hemorrhage (SAH) may cause meningeal irritation and may thus mimic the signs and symptoms of meningitis, e.g. nuchal rigidity and photophobia. Patients with diffuse axonal injury (DAI) and cerebral contusions can present with a wide range of symptoms, from headache to loss of consciousness. Most patients with diffuse brain swelling will be comatose and continue to deteriorate with time. Signs of cerebral herniation as described previously should alert the clinician and prompt immediate intervention.

The clinical signs and symptoms of a concussion are quite varied. Loss of consciousness may or not be present. Symptoms may be somatic (e.g. headache), cognitive (e.g. feeling disoriented or clouded, slowed reaction times), or emotional (e.g. lability, irritability). Physical signs include loss of consciousness, amnesia, or sleep disturbances (e.g. drowsiness). Some people describe the experience of having a concussion as being momentarily stunned or dazed.

Seizures after a head injury may occur at three distinct points in time relative to the head injury. "Immediate" (sometimes also called "impact") seizures occur within seconds of the traumatic event. These seizures are probably the result of traumatic depolarization of the cerebral cortex. They are usually brief, self limited, generalized seizures, with a rapid return to near or full baseline neurologic functioning. While most impact seizures occur in the absence of significant ICI, one should maintain a high suspicion for such pathology if other concerning signs or symptoms are present. "Early" seizures occur within a week of the head injury, with most occurring within the first 24 h. There is usually an underlying ICI associated with early post-traumatic seizures. The occurrence of such a seizure should thus prompt an evaluation for an ICI. "Late" seizures occur more than 1 week after the head injury. Late seizures are usually due an ICI, one which is already apparent by the time that the seizure occurs. Many of these patients will have subsequent seizures, either during the course of the current injury or later in life after the acute event has resolved.

Diagnosis, Investigations

The most definitive means of determining whether an ICI is present is to perform a computed tomography (CT) scan of the head. Extra-axial collections such as epidurals (*Fig. 377.4*) and subdural hematomas (*Fig. 377.5*) will appear as biconvex ("lens-shaped") and crescentic hyperdensities, respectively. Axial findings will also be apparent. Cerebral contusions will manifest as hypodense areas of edema (*Fig. 377.6*); intraparenchymal hemorrhages (*Fig. 377.7*) and diffuse axonal injuries will appear as small hemorrhagic lesions of white matter, the

latter typically found at the gray-white junction of the cerebral hemispheres; and subarachnoid hemorrhages appear as a collection of hyperdense fluid in the brain sulci, fissures, and cisterns (*Fig. 377.8*). Computed tomography is also very helpful in identifying any midline shift, or change in ventricular size indicating mass effect or obstruction of ventricular drainage.

Computed tomography can also identify skull fractures (*Fig. 377.9*), but may miss horizontal fractures that are parallel to the CT image cuts. Skull radiographs may be considered for identifying skull fractures, and have the benefit of exposing a child to less than 5% of the radiation required for a head CT scan. However, skull radiographs provide no information about the presence of ICIs. It is critical to recognize that the absence of a skull fracture does not rule out the possibility of an ICI. Skull radiographs are also limited by the fact that their interpretation is significantly dependent on the skill, experience, and expertise of the person reading the x-ray. Therefore the sensitivity of skull radiographs for detecting skull fractures will vary from institution to institution. A skull radiograph may be considered as a screening tool if CT scan is not readily available, or resources for sedation for younger, non-compliant children are unavailable. The presence of a skull fracture should prompt further evaluation for ICI.

Although CT scans can reliably identify intracranial injuries, they are not indicated, nor should not be obtained, for every pediatric patient who presents with a head injury. No single sign or symptom is a good predictor of an ICI, and imaging a child based on the presence of only one of these factors may result in a large number of unnecessary tests. The radiation exposure of a CT scan, particularly in children, may increase the risk of subsequent brain malignancies. There are also the risks associated with sedation in children who are unable to remain still for the CT scan. It is therefore incumbent upon clinicians to be able to identify patients who are at high or low risk for ICI. High risk patients warrant prompt imaging, while low risk patients can be initially managed more conservatively.

Figure 377.8
Subarachnoid Hemorrhage. Diffuse, acute subarachnoid hemorrhage, with an intraventricular bleed and left parietal skull fracture, due to non-accidental trauma in a 6 week old (Image courtesy of Kathleen McCarten, MD)

Guidelines published by the American Academy of Pediatrics (AAP) suggest that high risk signs and symptoms of ICI include depressed mental status, focal neurologic deficit, signs of depressed or basilar skull fracture, seizure, irritability, acute skull fracture, bulging fontanelle, significant scalp hematoma in children under 2 years, vomiting five or more times or for more than 6 h, and loss of consciousness for 1 min or longer. Children less than 2 years of age also warrant closer attention given that they may present with more subtle findings and are more likely than their older counterparts to have an ICI and be asymptomatic.

Recent literature has suggested that if a patient fulfills certain criteria, they can be considered low risk, have imaging deferred, and be managed conservatively (*Fig. 377.10*). Although the absence of these symptoms makes a significant ICI unlikely, the presence of one of these findings does not necessarily mean that imaging is required. The only findings that immediately prompt CT imaging are a GCS of less than 14, other signs of altered mental status, a palpable skull fracture, or signs of basilar skull fracture. The risk of a clinically important ICI in the presence of any of these findings are 4.3–4.4%. If any of the other signs or symptoms are present, or there are any concerning historical features (e.g. occipital, parietal or temporal scalp hematoma; severe mechanism of injury;

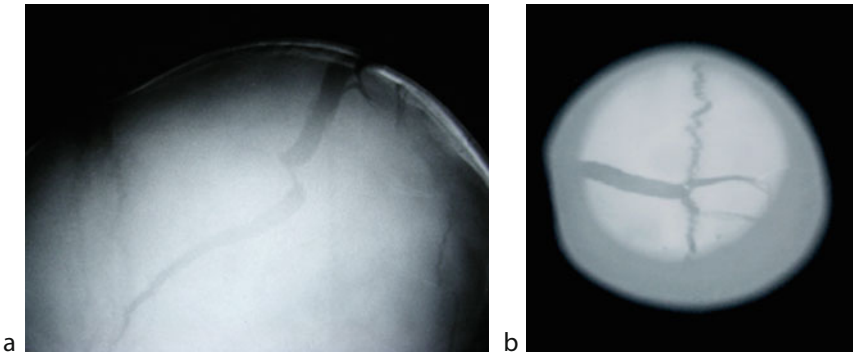

Figure 377.9
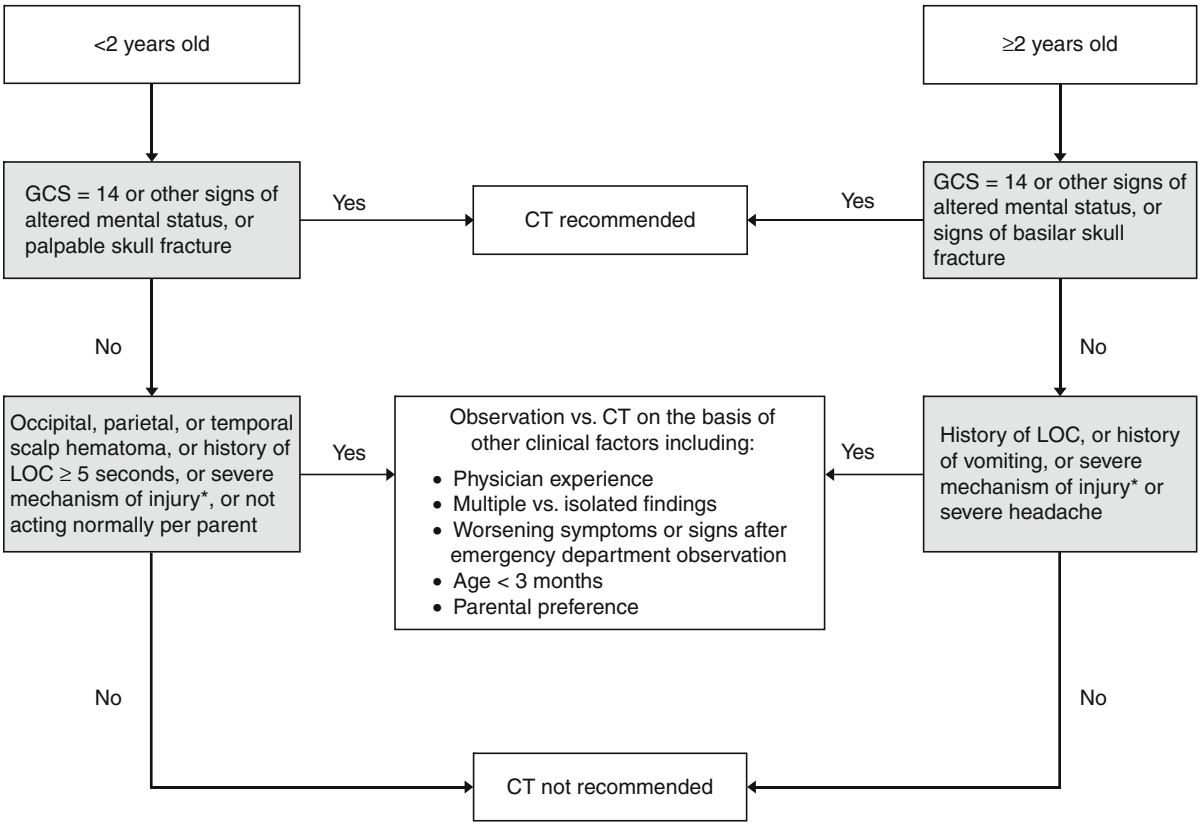
Skull Fracture. Plain radiographic and computed tomographic images of a large parietal skull fracture due to a fall in a 4 month old (Images courtesy of Kathleen McCarten, MD)



*Severe mechanism of injury: motor vehicle crash with patient ejection, death of another passenger, or rollover; pedestrian or bicyclist without helmet struck by a motorized vehicle; falls of more than 0.9 m (3 feet) if < 2 years old, or more than1.5 m (5 feet) if ≥ 2 years old; or head struck by a high-impact object.

Figure 377.10
Suggested CT algorithm for children with GCS scores of 14–15 after head trauma (Adapted from Kuppermann N et al. 2009)

severe headache; history of vomiting), the decision to observe or image should be based on clinical factors such as physician experience, multiple vs. isolated findings, worsening of symptoms during period of observation, age < 3 months, and parental preference.

Magnetic resonance imaging (MRI) is another option for neuroimaging a child with a head injury. While MRI has the benefits of not exposing the patient to ionizing radiation and more detailed image quality, there are several disadvantages to MRI. Although there is some evidence that MRI is as accurate as CT for the detection of hyperacute hemorrhage (i.e. < 6 h), MRI tends to be less accessible than CT, is more time consuming and will likely require prolonged sedation for uncooperative children. This is especially problematic for patients who require urgent neurosurgical intervention. When such injuries are suspected, immediate head CT is the imaging modality of choice.

In infants with open fontanelles, head ultrasound may identify large intracranial hemorrhages, dilated ventricles, or midline shift. However, this modality is limited by its dependence on user proficiency as well as its inability to visualize the entire intracranial vault. Additionally, ultrasound does not reliably detect acute cerebral hemorrhage. Therefore, ultrasound should not be considered a reliable means of excluding intracranial injury.

A concussion is a clinical diagnosis which should be considered in patients who have experienced a closed head injury, do not have an apparent ICI, but have signs and symptomatology consistent with concussion, as described in the signs and symptoms section. Conventional neuroimaging with CT scans and standard MRI do not reveal any structural abnormalities in concussed patients. Detailed neuropsychological testing is not necessary in the acute phase of diagnosing a concussion, but may be

useful for eliciting more subtle sequelae of the event at a later time.

Differential Diagnosis

Head trauma can cause a variety of different injuries. The scalp can be lacerated or contused, and may present differently depending on the layer of the scalp affected (Fig. 377.11). Scalp hematomas can form anywhere from hours to days after the injury, and may last anywhere from days to weeks. A subgaleal hematoma occurs when blood accumulates below the galea and above the periosteum. It is usually fluctuant and boggy, and may cross suture lines. A cephalohematoma is a collection of blood below the periosteum and above the skull. Cephalohematomas will not cross suture lines, and tend to be more tense and firm. Due to the high degree of vascularity of the scalp, lacerations may bleed profusely. As a result, scalp lacerations and hematomas may be associated with a large degree of blood loss sufficient to result in tachycardia or hypotension, especially in infants.

Scalp hematomas in infants and young children are also significant because they are associated with an increased risk of underlying skull fractures and ICI. A high level of suspicion is warranted during a child's first year of life, as the skull is thinner during this time. The parietal bones are most commonly fractured, followed by the temporal and occipital bones, and finally the frontal bone. A linear fracture is the most commonly occurring fracture. Basilar skull fractures, most often involve the petrous portion of the temporal bone, but can also involve the occipital, sphenoid and/or ethmoid bone. They are relatively uncommon, but may involve damage to blood vessels and nerves when the foramen magnum is involved, as well as the cranial nerves to which the basilar skull is in close proximity. Depressed skull fractures require evaluation for an associated ICI, and may need neurosurgical intervention to repair the fracture.

Intracranial injuries may occur after a head injury and can be life threatening. Epidural hematomas are as common in children as in adults. They frequently occur in association with a skull fracture and meningeal artery or vein bleeding. Subdural hematomas, on the other hand, are more common in adults than children. The mechanism is usually acceleration-deceleration, resulting in tearing of the bridging veins. Acute interhemispheric subdural hematomas may occur in infants who have suffered a shaking injury, or a young child with an impact injury from abuse. Subarachnoid hemorrhages occur after blunt trauma to the head, or after experiencing shear forces that tear the small vessels of the pia mater.

In addition to intracranial blood collections, children may incur cerebral contusions, which are bruises of the cerebral cortex. An intraparenchymal hematoma may occur as a complication of the contusion, potentially causing impaired blood flow or even mass effect. Severe acceleration-deceleration or angular rotational forces may cause diffuse axonal injury (DAI), which are shear injuries of the axons and associated vasculature causing diffuse primary injury to the white matter tracts of the brain. Diffuse brain swelling may also occur. It is often due to multiple factors, including cytotoxic and/or vasogenic edema. These factors are the result of either a primary brain injury, or are a manifestation of hypoxia and hypoperfusion due to secondary brain injuries.

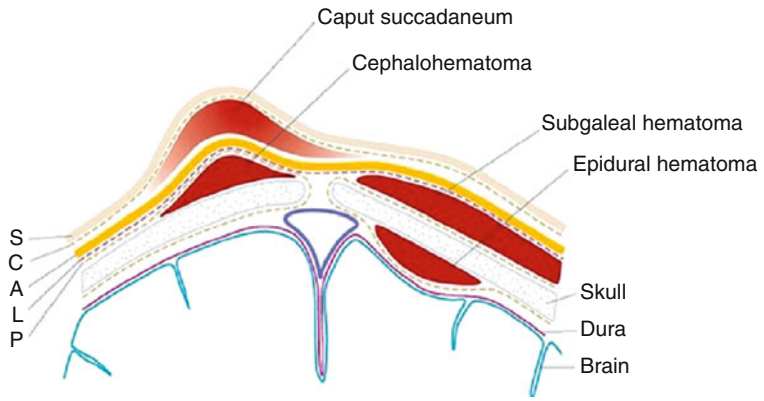


Figure 377.11
Layers of the scalp (Kim and Taragin, 2009)

When no intracranial pathology is readily identified, symptomatic patients may have a concussion, which is often described as any alteration in mental status. Patients with a concussion may or may not experience a loss of consciousness. Symptoms of concussion include confusion, headache, dizziness, nausea, vomiting, and amnesia. Although a CT scan may not reveal any injury, an MRI may reveal abnormalities in cerebrovascular autoregulation, subtle evidence of brain contusion, or diffuse axonal injury. Abnormalities on neuropsychological testing are frequently found with concussions. If the aforementioned symptoms of confusion, headache, dizziness, nausea, vomiting, amnesia, or neuropsychological deficits persist for weeks or months after the acute event, post-concussion syndrome should be considered, as discussed in more detail in the prognosis section.

Another significant complication post-concussion is "second impact syndrome". This is a rare event in which a patient who has experienced a recent concussion suffers a subsequent minor head injury, leading to uncontrolled cerebral edema and either death or severe morbidity. The exact mechanism is not completely understood, but it has been suggested that the second impact exacerbates a state of abnormal cerebrovascular autoregulation and cerebral metabolism caused by the first impact, thus causing the potentially fatal cerebral swelling.

Treatment

Initial management of patients who have experienced a head injury should always begin with assessment and management of airway, breathing and circulation. Cervical spine precautions should be maintained if there are any complaints of cervical spine pain, any neurologic symptoms or deficits, as well as in the context of severe mechanisms of injury, such as fall from heights or significant motor vehicle accidents. A preliminary assessment of neurologic status should also be completed to ensure that there are no signs of impending cerebral herniation. If such signs are present, treatment for increased ICP and neurosurgical consultation and intervention should be immediately instituted.

Treatment of impending cerebral herniation includes endotracheal intubation; optimizing oxygenation and ventilation; and obtaining intravenous access and administering isotonic crystalloid solutions to normalize and maintain mean arterial pressure, and ultimately cerebral perfusion pressure.

Elevating the head of the bed to 30° and maintaining the head and neck in a midline position facilitates downward drainage of cerebral spinal fluid and improves venous drainage from the head. Mild hypocarbia due to moderate hyperventilation results in reflex vasoconstriction of the cerebral arteries, thereby decreasing intracranial blood volume and lowering ICP. Continuous end-tidal CO_2 monitoring is necessary to avoid the extremes of ventilation, both of which may be harmful. Overventilation results in excessive vasoconstriction, impeding cerebral blood flow and decreasing cerebral perfusion pressure. Hypoventilation results in vasodilation and increases ICP. A patient's PCO_2 should be maintained between 30 and 35 mmHg. Sedation and/or paralysis should be considered to minimize patient agitation and prevent choking on an endotracheal tube, both of which increases intrathoracic pressure, obstructs venous drainage from the brain, and aggravates ICP.

Intravenous mannitol decreases intravascular volume and reduces ICP by increasing serum osmolarity. The increased serum osmolarity draws fluid into the intravascular space, which then expands the circulating volume, decreases blood viscosity, and improves cerebral blood flow. Additionally, water is drawn out of neurons and the interstitial space, thereby decreasing the volume occupied by the brain and interstitial fluid and reducing ICP. Mannitol is best administered as a bolus because a prolonged continuous infusion of mannitol would have the opposite effect. When given as an infusion, mannitol molecules would cross into the cerebral interstitial space and cause water retention in the brain, thereby increasing cerebral edema and increasing ICP. A mannitol bolus rapidly exerts its effect, decreasing ICP within minutes. It is important to balance the therapeutic effects of mannitol with its potential for adverse effects. Mannitol's diuretic effects can cause hypovolemia, ultimately resulting in decreased cerebral blood flow. It is therefore best to reserve mannitol for impending cerebral herniation. An alternative to mannitol for decreasing ICP is hypertonic saline. It also increases serum osmolarity and produces the same effects, but does not have a diuretic effect and may be helpful when circulatory status is tenuous.

Seizures should be aggressively treated because they can exacerbate intracranial pressure and cerebral metabolic demands, both of which increase cerebral blood flow and, ultimately, intracranial pressure. Choice of antiepileptic medication should be based on the patient's respiratory and hemodynamic status. Benzodiazepines may be used to treat acute seizure activity. Phenytoin or fosphenytoin are frequently used for seizure prophylaxis in patients with intracranial hemorrhages.

Neurosurgical consultation and intervention will ultimately be required in patients with increased ICP. This may include the placement of an intracranial drain or

pressure monitor so that ICP can be closely monitored and CSF removed as necessary. A burr hole may be performed to relieve impending herniation, but may be of low yield since most causes of increased ICP in children are due to diffuse brain swelling, rather than a focal space-occupying hemorrhage causing mass effect. A burr hole is also a procedure that should only be performed by clinicians with the appropriate expertise, and after all medical options have been exhausted. Another potential means of relieving increased ICP in infants may be to tap the ventricles through an open fontanelle or suture. This procedure should also only be performed by clinicians with the appropriate expertise, and when all other medical options have failed. Tapping the ventricles will, by necessity, cause damage to the brain parenchyma, and runs the risk of causing other life threatening complications.

Fortunately, most patients who experience minor closed head injuries do not require anything more than supportive measures and symptomatic treatment. If a patient has a laceration, ample irrigation and wound closure is often adequate. Hematomas do not require any intervention beyond assuring that the patient is hemodynamically stable. Additionally, patients and parents should be educated about the possibility that the hematomas may continue to expand over the next few days, and may persist for even up to a few weeks. Patients less than 2 years of age with isolated skull fractures should have follow up arranged so that they can be re-evaluated for the development of a growing skull fracture or a leptomeningeal cyst (*Fig. 377.12*).

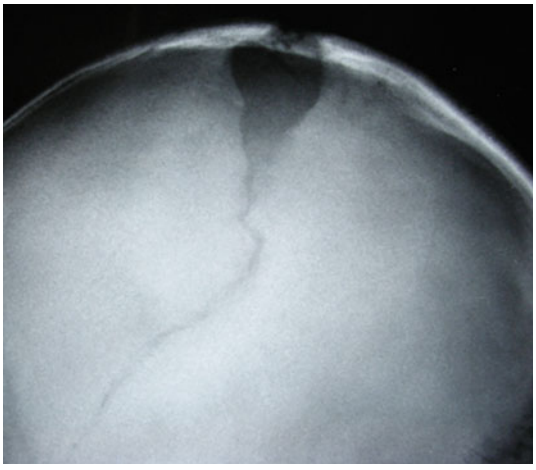

Figure 377.12
Leptomeningeal Cyst. Large "growing skull fracture," 2 months after the initial fracture seen in *Fig. 377.9* (Image courtesy of Kathleen McCarten, MD)

Most patients with concussions can be safely managed on an out-patient basis. Observation and/or hospitalization may be considered for patients with severe headache, dizziness, nausea, or vomiting. If a concussion is managed as out-patient, it is imperative to instruct the patient and parents on the signs of ICI that should prompt immediate medical re-evaluation, as well as recommendations on how and when to return to activity and play. Patients who return to activity too soon after an initial insult put themselves at risk for both second impact syndrome, and potential aggravation and persistence of concussion symptoms.

Patients should not return to activity until their symptoms have resolved. The most widely used guidelines for when patients may resume normal activity is a consensus statement by the International Symposia on Concussion in Sport. The guiding principle is that of "physical and cognitive rest until symptoms resolve and then a graded program of exertion prior to medical clearance and return to play". There is a stepwise escalation of activity during which a patient must be asymptomatic before progressing to a higher level of exertion (*Table 377.2*). Each step should take at least 24 h, which means that the entire process may take as little as 1 week. If a patient experiences post-concussive symptoms at any point, they must drop back to the previous level of exertion and may attempt to progress again after another 24 h period. Although there are specific circumstances in which adult athletes may return to play on the same day of injury, same-day return to play is not recommended for the adolescent or pediatric athlete. A more conservative approach is recommended for this population because children may have different physiological responses and require longer recovery periods compared to adults. There are also concerns that children and adolescents may exhibit a delay in onset of concussive symptoms or neuropsychological deficits that may not be evident at the time of injury that would have indicated that same-day return to play was inappropriate. Comprehensive neuropsychological testing may be useful in this context to assist decision-making regarding the appropriate time for concussed athletes to safely return to play.

Prognosis

Prognosis varies greatly depending on the underlying pathology. Isolated scalp hematomas are often benign, but may appear to grow bigger over time as clotted blood begins to liquefy and the hematoma becomes boggy. Parents should be counseled to expect this development approximately 5–7 days after the injury.

Table 377.2
Graduated Return to Play Protocol

Rehabilitation stage	Functional exercise at each stage of rehabilitation	Objective of each stage
1. No activity	Complete physical and cognitive rest	Recovery
2. Light aerobic exercise	Walking, swimming or stationary cycling keeping intensity <70% MPHR; no resistance training	Increase HR
3. Sport-specific exercise	Skating drills in ice hockey, running drills in soccer; no head impact activities	Add movement
4. Non-contact training drills	Progression to more complex training drills, e.g. passing drills in football and ice hockey; may start progressive resistance training	Exercise, coordination, and cognitive load
5. Full contact practice	Following medical clearance, participate in normal training activities	Restore confidence and asses functional skills by coaching staff
6. Return to play	Normal game play	

Complications arising from skull fractures depend on which part of the skull is damaged. Basilar skull fractures carry the risk of intracranial infection due to potential involvement of mastoid air cells or paranasal sinuses. Temporal bone fractures may also result in facial nerve injury or damage to inner ear structures, such as the ossicles or labyrinth, leading to hearing problems. A rare but significant injury that may result are intimal tears of the carotid artery which could lead to intracranial aneurysms or stroke. Prognosis is best for patients with basilar skull fractures who have a normal neurologic exam, no identified intracranial abnormality, and no evidence of CSF leak. The presence of any of those factors require more aggressive management to identify and prevent the discussed complications.

A complication of isolated skull fractures unique to children less than 2 years of age are growing fractures, which are caused by leptomeningeal cysts. The two terms are often used interchangeably, as the former cannot occur without the development of the latter. Leptomeningeal cysts develop when there is a dural tear associated with the skull fracture, allowing the arachnoid tissue and subarachnoid CSF to herniate out through the dural defect. The resulting cyst prevents the bone from properly reapproximating and healing, thereby exacerbating the defect, causing erosion of the fracture site, and thus resulting in the "growing fracture". The intracranial contents herniate out because of the pressure caused by the rapid rate of brain growth and expansion unique to this age group, which exceeds the rate at which the fracture heals. Growing skull fractures involving the basilar skull may present as exophthalmos due to cranial nerve impingement. They may present weeks or months after the time of injury, and may present as a boggy or pulsatile soft tissue mass, or palpable bony defect. Since growing fractures require neurosurgical repair, children less than 2 years of age with an isolated skull fracture should have follow up arranged, where they can be re-evaluated for this complication.

Prognosis of patients with intracranial injuries is highly variable. In general, prognosis correlates with the patient's neurologic status on presentation, severity of the lesion, and the presence or absence of other lesions. Patients with secondary systemic insults also have worse prognosis, as factors such as hypotension and hypoxia may exacerbate secondary brain injury. Patients with intraparenchymal hematomas often have poor outcome, compared to patients with small petechial hemorrhages, who may recover with little sequelae. Patients with DAI and diffuse brain swelling tend to do poorly, although children often have better outcomes than adults in both cases. In DAI, mortality rates range from 10% to 15%, with persistent neurologic dysfunction in 30% to 40% of survivors. Patients with SAH have been shown to have mortality rates as high as 24%, and 24% of survivors have poor neurologic outcomes.

Patients with epidural hematomas tend to do comparatively better than patients with SAHs. Mortality rates for epidural hematomas range from 0% to 10%, with up to 15% of survivors with poor neurologic outcomes. Although the general rule of presenting neurologic status correlating with outcome applies to these patients, many patients who present with coma or nonreactive pupils have a moderate or good neurologic outcome after surgical intervention.

Patients with subdural hematomas, on the other hand, do not fare as well. Mortality rates are as high as 10% to 20%, and persistent neurologic sequelae are common amongst survivors. However, like patients with epidural hematomas, those with subdural hematomas who initially

present very poorly may still recover and have moderate or good functional outcomes. A small percentage of patients who are managed conservatively and do not undergo an operation to drain their subdural hematoma may go on to develop chronic subdural hematoma that may be associated with seizures or developmental delay.

Although concussions may occur in the absence of clearly visible pathology, they can cause longstanding sequelae. Post-concussion syndrome may develop, consisting of a constellation of symptoms in the areas of cognitive, somatic, and/or affective and emotional complaints. Cognitive complaints would include decreased memory, attention, and concentration; somatic complaints include headache, fatigue, and dizziness; and affective and emotional complaints include depression, irritability, and anxiety. They can last any where from weeks to even months after the initial injury. Although patients with a lower GCS on presentation have been reported to have more symptoms at 6 weeks after injury, there is discussion regarding whether social and personal factors post-injury may also contribute to the persistence of symptoms.

Prevention

It is difficult to prevent or ameliorate the potentially devastating sequelae of head injuries. Therefore, primary prevention of head injuries is paramount and the best method of decreasing the costs and burdens of head injuries. Pediatricians can play an important role in preventing head injuries in children on multiple levels. Interactions with families provide opportunities to strongly encourage the use of helmets for common outdoor activities, including bicycling, skiing, and snowboarding. Physicians can also facilitate prevention at the community level by advocating for the implementation of playground safety standards, as well as modifications to unsafe pedestrian physical environments. And finally, physicians can support legislature that would enforce these protective measures and help to ameliorate the burden of disease brought upon by head injuries.

378 Headache and Head Pain

Christine A. Matarese · Kenneth J. Mack

Headache is a common childhood complaint. Headaches can be divided into the primary headache disorders, such as migraine, and the secondary headache disorders, which are due to an underlying disorder.

Primary Headache Disorders in Children

Migraine

Migraines are severe, often bilateral, throbbing headaches frequently located in the temples or frontal head regions. Migraine occurs in 2–5% of preschool children, 10% of school-aged children, and 20–30% of teenage girls. Approximately 20% of migraine patients experience their first attack when younger than 5 years of age.

Symptoms of migraine vary with the age of the child. In preschool children, migraine often consists of episodes involving an ill, pale appearance, abdominal pain, vomiting, and the need to sleep. Pain may be expressed by irritability, crying, rocking, or seeking a dark room in which to sleep. Five- to 10-year-old patients with migraine tend to experience bilateral frontal, temporal, or retro-orbital headache with associated nausea, abdominal cramping, vomiting, photophobia, phonophobia, and a need to sleep. Parents may describe these children as pale with dark circles under the eyes. Older children tend to present with a unilateral, temporal headache and the location and intensity of pain often change within or between attacks.

Migraine can occur with or without aura. Only 10–20% of children with migraine experience an aura, often for the first time after the age of 8 years. The aura usually precedes the headache by less than 30 min and lasts for 5–20 min. The aura may present without headache. Children often are unaware or unable to describe their aura. The visual aura is the most common form in children, consisting of blurred vision, fortification spectra (zigzag lines), scotomata (field defects), scintillations, black dots, kaleidoscopic patterns of various colors, micropsia, macropsia (distortion of size), and metamorphopsia ("Alice in Wonderland" syndrome). Visual auras often are reported as moving or changing shapes; other auras include attention loss, confusion, amnesia, agitation, aphasia, ataxia, dizziness, vertigo, paresthesia, or hemiparesis. Aura symptoms vary widely within and between attacks.

The headaches can last 60 min to 48 h, but usually last less than 4 h. Some young patients report short headaches lasting 10–20 min. The severity of childhood headache often is milder than adult migraines. The headache phase can be associated with cold extremities, nausea, anorexia, vomiting, diarrhea or constipation, dizziness, chills, excessive sweating, ataxia, numbness, photophobia, phonophobia, memory loss, or confusion. Often the patient cannot concentrate or function effectively during or immediately after episodes. Relief typically is associated with sleep. After the headache phase, the patient may feel either elated and energized or more typically exhausted and lethargic. This stage of migraine may last from hours to days.

Migraine is associated with a variety of comorbid conditions. Psychiatric symptoms such as depression, panic attacks, anxiety disorders, or phobia may be present. Epilepsy and migraine often occur within the same individual, although most patients with migraines do not have seizures. Migraineurs are more prone to motion sickness than patients without migraine. Intermittent vertigo is found frequently in patients with migraine. There is a higher cardiovascular reactivity to postural changes in patients with migraine and this may result in dizziness. Migraines are also associated with sleep disturbances and ice cream headache in some patients.

Types of Migraine

Status migrainosus is a severe form of migraine in which the headache attack is continuous for longer than 72 h. Patients usually have a preexisting migraine history. In those who vomit, rehydration is often the necessary first step. One often effective treatment can be intravenous (IV) fluids, and antiemetic, and dihydroergotamine (DHE).

Familial hemiplegic migraine is an autosomal-dominant form of migraine with aura. Patients have a prolonged hemiplegia that can be accompanied by numbness, aphasia, and confusion. The hemiplegia may

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_378,

precede, accompany, or follow the headache, and symptoms may last for hours to days. The headache usually is contralateral to the hemiparesis. Some familial hemiplegic migraine is associated with cerebellar ataxia. Other types of severe familial hemiplegic migraine may present with coma, fever, and meningismus. Some forms of familial hemiplegic migraine respond to acetazolamide or calcium channel blockers. Structural lesions, vasculitis, cerebral hemorrhage, brain tumor, mitochondrial myopathy, encephalopathy, alternating hemiplegia, and lactic acidosis need to be considered in the differential diagnosis.

Basilar-type migraine is a subtype of migraine with aura, and is observed mostly in adolescent and young adult females. Headache pain may be located in the occipital area. Basilar-type migraine is characterized by disturbances in function believed originating from the brain stem, occipital cortex, and cerebellum. The occipital headache must have at least two of the following aura symptoms: dysarthria, vertigo, tinnitus, hyperacusia, diplopia, bi-field visual symptoms, ataxia, and decreased level of consciousness or bilateral paresthesias. A history of typical migraine exists in many families. Some patients experience basilar migraine attacks intermingled with typical migraine attacks.

Benign paroxysmal vertigo of childhood is a condition characterized by brief episodes of vertigo, disequilibrium, and nausea, usually found in children aged 2–6 years. The patient may have nystagmus within but not between the attacks. The child does not have hearing loss, tinnitus, or loss of consciousness. Symptoms usually last only a few minutes. These children often develop a more common form of migraine as they mature. Brain magnetic resonance imaging (MRI) can be obtained to exclude posterior fossa abnormalities, especially if abnormalities in the neurologic exam are found between episodes.

Acute confusional migraine is characterized by transient episodes of amnesia, acute confusion, agitation, lethargy, and dysphasia. This form of migraine is often precipitated by minor head trauma. The child may have a receptive or expressive aphasia, and the confusional state may either precede or follow the headache. Some children also experience recurrent episodes of confusion. The patient usually recovers within hours. The child may not have a history of headache but usually develops typical migraine attacks when older. It is important to exclude intoxications, encephalitis, structural lesions, and seizures (*Table 378.1*).

Migraine-associated *cyclic vomiting syndrome* is characterized by recurrent periods of intense vomiting separated by symptom-free intervals. Many patients with cyclic vomiting have regular or cyclic patterns of illness. Symptoms usually have a rapid onset at night or in the early morning and last 6–48 h. Associated symptoms include abdominal pain, nausea, retching, anorexia, pallor, lethargy, photophobia, phonophobia, and headache. The headache may not appear until the child is older. Migraine-associated cyclic vomiting syndrome usually begins when the patient is a toddler and resolves in adolescence or early adulthood; it rarely begins in adulthood. More females than males are affected by cyclic vomiting. Usually a family history of migraines in the parents or siblings is present. These children often experience severe fluid and electrolyte disturbances that require intravenous fluid therapy. Migraine-associated cyclic vomiting

Table 378.1
Suggested acute treatment options for pediatric migraine

Medication	Typical dose	Side effects
Ibuprofen	10 mg/kg/dose	Stomach irritation
Paracetamol (acetominophen)	10–15 mg/kg/dose	Liver toxicity with overdose
Naproxen sodium	5 mg/kg/dose	Stomach irritation
Sumatriptan (other triptans also available)	Children over the age of 10 years and 50 kg typically tolerate 25–100 mg oral, or 20 mg nasal: Children between the age of 6–10 years should first start with the 5 mg nasal spray form	Paresthesias, chest tightness, worsening headache

Drug dose available form:
Acetaminophen 10–15 mg/kg per dose tabs 80 mg, 160 mg, 325 mg; syrup 160 mg/tsp
Ibuprofen 10 mg/kg per dose tabs 200 mg, 400 mg, 600 mg, 800 mg; chewable tablets 50 mg, 100 mg; syrup 100 mg/tsp
Naproxen sodium 5 mg/kg per dose tab 220 mg (OTC); Tab 250 mg, 375 mg, 500 mg
5-HT Agonists (Triptans):
Sumatriptan tabs 25 mg, 50 mg, 100 mg; subcutaneous injection 6 mg; nasal spray 5 mg, 20 mg
Zolmitriptan 2.5 mg, 5 mg; disintegrating tabs 2.5 mg

syndrome is a diagnosis of exclusion. Other causes of cyclic vomiting include gastrointestinal disorders (malrotation), neoplasms, urinary tract disorders, metabolic, endocrine, and mitochondrial disorders.

In *abdominal migraine*, the patient may suffer from recurrent bouts of generalized abdominal pain with nausea and vomiting, but often with no headache present. The episodes are often relieved by sleep and later the child awakens feeling better. Abdominal migraine may alternate with typical migraine and can lead to typical migraine as the child matures. These children respond to migraine prophylactic medication.

Paroxysmal torticollis of infancy is an uncommon disorder characterized by repeated episodes of head tilting associated with nausea, vomiting, and headache. Attacks usually occur in infants and may last from minutes to days. Posterior fossa abnormalities should be considered in the differential diagnosis. Recent data has linked these symptoms to mutations in the CACNA1A gene in some patients.

Acephalgic migraine of childhood (migraine sine hemicrania) is characterized by a migraine aura without headache, usually visual auras, and a female predominance. A family history of migraine is frequent.

Evaluation and Diagnosis of Migraine

No specific diagnostic tests for migraine exist and the diagnosis is made through the history, physical exam, and clinical judgment. The child with migraine should have a normal general physical examination and a normal detailed neurologic examination. Only a small percentage of headache patients require further laboratory and radiologic studies. An imaging study should be considered in patients with a history of seizures, recent head trauma, significant change in the headache, or evidence of focal neurologic deficits or papilledema upon physical examination. No absolute rules exist in the evaluation of the headache patient; the need for a neuroimaging study ultimately is based on clinical judgment. Electroencephalography (EEG) is not useful in the routine evaluation of headache patients. It should be considered in patients with an atypical migraine aura, episodic loss of consciousness, or symptoms suggestive of a seizure disorder. Lumbar puncture is indicated if meningitis, encephalitis, subarachnoid hemorrhage, or high–low pressure syndromes are considered. Patients in whom elevated intracranial pressure is suggested or with focal neurologic deficits should undergo a neuroimaging study prior to a lumbar puncture.

Treatment and Prognosis

The treatment of migraine headaches should emphasize identification of environmental trigger factors, pain control at the time of the headache, and preventative medication. The treatment of children with mild, infrequent attacks consists primarily of rest, trigger avoidance, and analgesics. The patient and parents benefit from a simple explanation of the headache pain and reassurance that it is not caused by a brain tumor or other life-threatening condition. A regular bedtime, regular meal schedules, and avoidance of overloading the child's schedule with activities are important. Helping the child recognize migraine triggers is helpful but often difficult. It is important that the patient has realistic expectations; identifying and avoiding triggers reduces the frequency of migraine headache but does not eliminate headaches.

Psychological triggers include stress, anxiety, worry, depression, and bereavement. Emphasizing to the patient and family that migraine is not an imagined or psychological illness is important. Stress is not the sole cause of the headaches, although it makes migraines more difficult to manage. Physiological triggers include fever or illness, missing a meal, fatigue, and sleep deprivation. Environmental triggers of migraine include fluorescent light, bright light, flickering light, fatigue, barometric pressure changes, high altitude, strong odors, computer screens, or rapid temperature changes. Some patients report that complex visual patterns like stripes, checks, or zigzag lines may trigger migraines. Physical exertion can trigger childhood migraine. Some migraineurs report that they are more likely to get a headache after participating in sports or being extremely active. Minor head trauma (e.g., being hit in the head with a ball, falling on one's head) also may result in a migraine attack. Travel or motion may cause migraine, particularly in young children.

At the time of the headache, advise the child to lie down in a cool, dark, quiet room and fall asleep. Sleep is the most potent antimigraine treatment. Some patients find that ice or pressure on the affected area of pain can alleviate pain temporarily. Nonsteroidal anti-inflammatory drugs (NSAIDs) are effective if taken at an appropriate dosage during the aura or early headache phase. Gastric stasis occurs in migraine patients and causes delay in absorption of oral medications. Occasionally, carbonated beverages may improve absorption. Nonpharmacologic treatment modalities such as self-relaxation, biofeedback, and self-hypnosis may be reasonable alternatives to pharmacologic treatment in managing childhood migraine, particularly in adolescents.

Prophylactic or preventative medications are taken on a daily basis to reduce the frequency or severity of headaches and associated symptoms. A good response to prophylactic medications is often considered a 50% reduction in the frequency or severity of attacks. Consider the use of prophylactic drugs for children with frequent (>2 per week), prolonged, and disabling migraine attacks that do not adequately respond to other treatments. Often, several weeks are necessary before therapeutic gains are observed with prophylactic medications. Possible preventative medications include amitriptyline, propranolol, gabapentin, valproate, topiramate, flunarizine, verapamil, and riboflavin.

Migraines may change in frequency as children move into adulthood. In one of the few longitudinal studies of childhood migraine patients, children with migraine were followed for 40 years. The average onset of the migraines occurred at 6 years. During puberty or young adulthood, 62% of the children were migraine free for at least 2 years, ~33% of these children regained regular attacks after an average of 6 migraine-free years, and a surprising 60% of the original 73 children still had migraines after 30 years, while 22% of the subjects never had a migraine-free year. Of those patients who became parents, 52% have at least one child in their present or previous families who developed recurrent migrainous headache.

Chronic Daily Headache

Chronic daily headache is a disorder where the diagnosis is based on the presence of headache for greater than or equal to 15 headache days in 1 month, over a period of three consecutive months, with no underlying organic pathology. The headaches last for more than 4 hours per day. This headache disorder tends to affect teenagers and adults, but can occur in preteens. It can occur in up to 4% of young women and up to 2% of young men, with similar prevalence rates seen in studies from Asia, Europe, and the United States.

Silberstein and others have defined four different categories of chronic daily headache based upon symptoms. These include transformed or chronic migraine, chronic tension type headache, new daily persistent headache, and hemicrania continua. Many teenage patients with chronic daily headache have a past history of episodic migraine. The transformation to a chronic migraine may occur over a period of weeks to months, or it may occur abruptly over a matter of hours. Approximately a quarter of teenagers with chronic daily headache will have no significant past headache history and an infection such as mononucleosis or a minor head injury may incite a new daily persistent headache. A smaller number of patients will have a history of tension type headaches prior to their chronic daily headache.

Most commonly, the youngster with chronic daily headache will complain of at least two types of headaches. Prominent are severe intermittent headaches that are migraine-like. They tend to be pan-cephalic or frontal in location. The severe headaches will be described as throbbing, severe, crushing, knife like, or hatchet like. They are often associated with nausea during the most severe times, and the patient will frequently have photophobia, phonophobia, and osmophobia. For this more severe headache pain, sleep will sometimes help, but they will still have persistent headache when they awaken. The frequency of these severe headaches will vary with the individual. The severe episodes typically occur multiple times a week.

In addition to these severe intermittent headaches, the patient with chronic daily headache will often complain of a continuous headache that is present 24 h a day, 7 days a week. This continuous headache may wax and wane in severity, often being worse either in the morning or at the end of the school day. The characteristics of the all-the-time headache pain are similar to the episodes of severe headaches, only much less intense. Some patients may also describe this all-the-time headache as having features of a tension type headache, with the pain being band-like or crushing rather than throbbing.

Headache is not the only symptom in chronic daily headache; it is really a multi-symptom complex. Sleep is disrupted in at least two thirds of the patients who have chronic daily headache. Typically, the headache syndrome will not resolve until the sleep is improved.

Many chronic daily headache patients also complain of dizziness which is associated with feeling weak, unsteady, and with blurry or loss of vision. This is often positional, and may involve syncope or near syncope several minutes after standing. There is typically no vertigo, except during severe headache episodes. The dizziness is particularly prominent in the morning. A difference in blood pressure or pulse rate between sitting and standing may be noted and the patient often experiences mild symptoms of this dizziness if stood up for several minutes in the office. One may see either a significant tachycardia with standing (postural orthostatic tachycardia syndrome) and/or a decrease in the systolic blood pressure with standing.

Mood problems and anxiety also frequently coexist with chronic daily headache. The mood problems may precede or follow the onset of the headache. Both the symptoms of headache and mood need to be addressed.

If there are significant problems with mood and anxiety, it is difficult to control the headaches until these symptoms are improved. Other frequent comorbid symptoms include nonspecific abdominal pain, back pain, neck pain, and diffuse muscle and joint pain and often no additional organic etiology is found to explain these additional pain symptoms. There are important environmental factors that play a role in these headaches. There is an interesting seasonal variability in the degree of chronic daily headache symptoms. Most patients will do better in the summertime and frequently have a worsening of their headaches at the start of the school year, and school absence can be a significant problem.

Evaluation

Neuroimaging studies will be normal in the overwhelming majority of chronic daily headache patients. Occasionally in these patients, white matter abnormalities, arachnoid cysts, or pineal cysts will be seen that are generally believed to be of no clinical significance to the chronic daily headache. If a patient has had a significant history of head or neck trauma, particularly at the onset of the chronic daily headache, then an MR angiogram (MRA) of the neck should also be considered to rule out a possible carotid dissection. When pseudotumor cerebri is a strong consideration, then a magnetic resonance venography (MRV) should also be considered since sinus thrombosis can cause elevated intracranial pressure. Serum studies to consider include evaluation of the thyroid, sedimentation rate, and ANA. Many patients will transition from a headache-free period or episodic migraines to chronic migraines during an infection so consideration should be given to serology for Epstein-Barr virus, West Nile virus, and other viral or bacterial infections.

Treatment and Prognosis

Chronic daily headache is difficult to control and it typically takes weeks to months to effect a change in headache control. The cornerstones of therapy are education, preventative medications, and attention to environmental trigger factors. It is difficult for many families to comprehend that the head pain can persist for such a long time, that there are no abnormalities showing up on diagnostic testing, and that the medications they are prescribed are not immediately effective. It is thus useful to spend adequate time with the patient and family discussing the role of medications, when not to use pain relievers, the role of non-medication approaches (such as biofeedback or physical therapy), and what the family should expect in the short and long term. After 1 month of an effective therapy, a reasonable expectation would be to have less frequent severe headache episodes, and a decrease in the intensity of the all-the-time, 24/7 headache. It is rare to see complete resolution of the headaches after a short period of time. Once a trend toward improvement is seen, the dose of medication is adjusted for optimal control of the headaches, and the patient is continued on the preventative for at least 6 months of good (but rarely complete) symptom control. It is not unusual to make frequent adjustments in management initially, and it may take months before matching up the right preventative medication or the right therapeutic approach with the individual patient.

Preventative medications are traditionally used in episodic migraines to reduce the frequency of the migraine headaches. However, in chronic daily headache, a reasonable therapeutic goal would be to make the severe intermittent headaches less frequent, and to make the all-the-time headache less intense. The most published experience of preventatives in chronic migraine or chronic daily headache is the use of medicines that work on the serotonergic system or the anticonvulsants. Unfortunately, there have been few prospective randomized controlled studies in children to give us guidance as to what is the most effective or safe medication to use in chronic daily headache (*Table 378.2*).

Studies in adults and children have shown that tricyclic antidepressants, such as amitriptyline, are helpful in chronic daily headache. Consideration needs to be given to follow electrocardiogram (EKG) changes, as this drug may prolong the QT interval. Weight gain is a significant concern in teenage patients with these medicines, and it affects some children more than others. Amitriptyline can also be helpful for sleep onset. Other tricyclics, such as nortriptyline or protriptyline, may cause less sedation.

Other serotonergic agents such as the selective serotonin reuptake inhibitors (SSRIs) have also shown to be effective in some adults with chronic headache. The SSRIs seem to be less effective than the tricyclics for pain control, although they are more helpful in children for their positive effects on mood. In select patients, the use of an SSRI can be very useful.

Studies in headache patients have shown anticonvulsants are also useful. Valproate, topiramate, and gabapentin have been used. Choice of rational pharmacotherapy to treat the patient's other problems is ideal. Antidepressants can address underlying mood disorders as well as sleep problems. Beta-blockers can make depression worse; however, they may be helpful for patients with

Table 378.2
Migraine and chronic daily headache: suggested preventive agents

Medication	Typical target dose	Side effects/monitoring
Amitriptyline	0.5–3 mg/kg/day; patients metabolize at different rates; need for 25–150 mg/day	EKG and drug levels at higher doses; weight gain
Topiramate	1–2 mg/kg/day; 50–200 mg/day	Decreased appetite; difficulty thinking and word finding, kidney stones, decreased sweating
Propranolol	1–2 mg/kg/day; 60–120 mg/day	Occasional exercise intolerance; irritability; nightmares; asthma
Verapamil	1–6 mg/kg/day; 80–480 mg/day	Constipation; dizziness; need to follow PR and QT intervals on EKG
Gabapentin	10–40 mg/kg/day; 300–3,600 mg/day	Tiredness; swelling
Valproate	10–30 mg/kg/day; 250–1,000 mg/day	Weight gain; teratogenic; rare liver and pancreatic problems

a postural orthostatic tachycardia syndrome. Calcium channel blockers are useful for patients who also have hypertension, but cause constipation and orthostatic hypotension. If the patient needs to lose weight, topiramate is a good choice, although this may result in mental clouding. The use of botulinum toxin shows promise as well.

Hemicrania continua is a rare headache syndrome, occurring in approximately 1% of chronic daily headache patients. It is a persistent unilateral headache pain. The pain may be characterized by a stabbing sensation, and may be associated with autonomic changes. It is important to recognize this entity since these patients may respond to daily doses of indomethacin to ameliorate this condition.

Pain control at the time of the headache is a very difficult problem for patients. Analgesics that are typically effective for episodic migraine headaches are not very effective for chronic migraine or chronic daily headaches. Most patients report that pain relievers are not effective for the all-the-time, 24/7 headache. It is reasonable to discourage patients from trying to use analgesics to treat the all-the-time headache, since this may result in analgesic overuse and a potential analgesic rebound headache. Combating rebound from those substances is part of the treatment. Medications implicated in this overuse syndrome include most OTC analgesics and decongestants, opioids, butalbital, isometheptene, benzodiazepines, ergotamine, and triptans.

In contrast, for the more severe intermittent headache episodes with migrainous qualities, analgesics should be considered. Approaches can include the use of migraine pain relievers such as triptans, indomethacin or other nonsteroidal anti-inflammatory agents. Compounds that contain caffeine, barbiturates, opiates, or that have a high potential for rebound should be limited or avoided. Patients typically find that when the preventative medication starts working, the pain analgesics will become more effective. Additional treatment strategies include dihydroergotamine, IV valproate, or steroids. Non-pharmacological approaches to the headaches are also very important. Because of the chronic nature of the pain, some patients will benefit with a consultation with a psychologist to at least be introduced to the techniques of relaxation therapy and biofeedback. Many of the patients have been ill for months to years and have become physically "deconditioned." Starting a reconditioning exercise program is very important. Patients should be encouraged to start slowly. For the most severely affected patients, begin with 10 min of aerobic exercise a day and then increase the time by 10% a week. There is limited data looking at the outcome of chronic daily headache in children. The average duration in childhood is unknown, but it is not unusual to see children who have chronic daily headaches persisting for months to years.

Tension Type Headache

Migraine and tension type headache are the most common types of headache in children and adolescents. The actual prevalence of tension type headache in children is uncertain because it varies with the defining criteria, but studies have reported anywhere from 0.9% to 73% of affected children. Age of onset has been reported in studies as between 5 and 12 years. The headaches tend to occur more frequently in females during adolescence and genetics plays less of a role in this disorder than in migraine. The pathophysiology is incompletely understood but may involve trigeminal activation. The headaches are characterized by a variable intensity, bilateral, dull, pressure pain with occasional associated phonophobia that lasts

minutes to days. There are three subtypes defined by the International Headache Society classification. Episodic tension type headache may be infrequent (less than 1 day per month) or frequent (1–14 days per month) and chronic tension type headache occurs 15 or more days per month. Diagnosis is based on the clinical history and a normal neurologic exam, including vital signs and funduscopic exam. The differential diagnosis is broad and includes a variety of organic disorders such as infection, malformation, bleed, and systemic disorders. The value of neuroimaging in the presence of a typical history and normal neurologic exam is low, but is recommended if there is vomiting, a history of trauma, seizure or an abnormality on exam. Tension type headache or medication overuse headache may progress into chronic daily headache. Treatment of episodic tension type headache involves reassurance, stress reduction, psychological and cognitive behavioral therapies, and appropriate use of an acute analgesic medication, such as a nonsteroidal anti-inflammatory drug. Treatment of chronic tension type headache may involve the above in addition to a prophylactic medication such as an antidepressant.

Trigeminal Autonomic Cephalgias

Trigeminal autonomic cephalgias refer to a group of headaches that are characterized by repetitive, brief episodes of severe unilateral pain associated with ipsilateral autonomic features including rhinorrhea, nasal congestion, lacrimation, and conjunctival injection. They include cluster headache, paroxysmal hemicrania, and SUNCT syndrome (short-lasting unilateral neuralgiform headache with conjunctival injection and tearing). They each differ in the duration, frequency, and rhythmicity of attacks. All are more common in adults and have rarely been reported in children.

Cluster Headache

Cluster headache is the most common trigeminal autonomic cephalgia. The prevalence in adults is less than 1% and has a male predominance. The prevalence in childhood and adolescence has been estimated to be 0.1%. Studies have noted childhood onset at ages between 5 and 19 years. The pathophysiology is not completely understood but theories involve hypothalamic activation and neurogenic inflammation. Symptoms include several bouts per day, generally with circadian rhythmicity, lasting weeks of severe unilateral orbital, supraorbital, or temporal head pain lasting 15 min to 3 h with associated unilateral autonomic features and associated restlessness. Children may experience thrashing about or emotional outbursts secondary to the severe pain. There are episodic (most common) and chronic forms and a familial predisposition. Diagnosis is made clinically but a head computed tomography or magnetic resonance imaging should be performed to exclude an underlying brain lesion. The differential diagnosis includes other trigeminal autonomic cephalgias and an underlying brain lesion. Treatment involves preventative medications such as verapamil and acute treatment such as oxygen, triptans or steroids. The patient should be cautioned against triggers, such as smoke and alcohol.

Paroxysmal Hemicrania and SUNCT Syndrome

Paroxysmal hemicrania is rare in children. Attacks are shorter (minutes), more frequent, and less severe than in cluster headaches. These headaches are exceptionally responsive to treatment with indomethacin. SUNCT syndrome is also rare in children. Attacks are very short in duration (seconds to minutes), triggered by touching the face or chewing, have limited associated autonomic features, and occur up to hundreds of times per day.

Ice Pick Headaches

Ice pick headaches are a benign primary headache disorder characterized by sudden ice pick–like pains. These pains may last for seconds to minutes, typically occur at different parts of the child's head, and are often seen in patients prone to migraines. They are fairly infrequent and most often do not require treatment. There are case reports of these headaches responding to indomethicin.

Secondary Causes of Headache in Children

Cerebral Venous Sinus Thrombosis

Cerebral venous sinus thrombosis is a serious disorder that frequently presents with headache. Diagnosis and treatment may be delayed secondary to its varied clinical presentation unless it is considered and investigated as a potential etiology. The annual incidence in a multicenter

Canadian registry of children 18 years of age and younger was 0.67/100,000. In children, there is no female predominance as is seen in young adults. Risk factors and presenting symptoms are related to age. Neonates are most commonly affected and risk factors include hypoxic encephalopathy or other perinatal complications, infection, and dehydration. In children, risk factors include acute or chronic systemic illnesses, anemia, infection (especially of the head and neck), prothrombotic states, and dehydration.

The clinical presentation in neonates includes seizures and diffuse neurologic signs. In children it may include headache, changes in mental status, papilledema, emesis, and focal neurologic signs. Headache is the most frequent symptom. The headache onset is generally acute to subacute and the intensity moderate to severe. The pain is typically continuous and localized, exacerbated by recumbency and Valsalva maneuvers and unrelieved by analgesics. Neuroimaging should be performed and include head magnetic resonance imaging (MRI) and magnetic resonance venography (MRV) because head computed tomography (CT) may be normal in about 30% of patients. This will demonstrate an absence of blood flow in the cerebral veins. Treatment involves antithrombotic therapy utilizing intravenous heparin followed by warfarin for several months. In cases of extensive thrombosis, thrombolytic therapy and mechanical thrombectomy may be considered. Outcomes vary from resolution with normal neurologic function in about half to neurologic sequelae (motor, cognitive, speech) and death.

Pseudotumor Cerebri (Idiopathic Intracranial Hypertension)

Idiopathic intracranial hypertension is a syndrome of increased intracranial pressure with normal neuroimaging studies, normal CSF composition, and elevated CSF pressure. In adults, it is frequently associated with obese females of childbearing age. In children, however, it is less frequently associated with obesity and female gender. Symptoms include those of elevated intracranial pressure, headache, nausea, vomiting, and visual disturbances. Headache is the most common presenting symptom and may be daily, pulsatile, and exacerbated by supine positioning. Infants with headache may present more subtly with only changes in sleep and behavior. Neurological exam may demonstrate cranial nerve palsies, especially abducens palsy and papilledema. Papilledema is considered a characteristic finding; however, it may not be seen in infants because of their unfused sutures, and is an inconsistent finding in children and adolescents. Associated factors to inquire about in the history include the use of acne medications, antibiotics, and oral contraceptives.

Diagnosis is one of exclusion and is based upon the 1985 Modified Dandy Criteria: an awake and alert patient, signs/symptoms of increased ICP, absence of localizing findings on neurologic exam except for abducens nerve palsy, normal CSF findings except for increased pressure (>250 mm water), absence of ventricular system anomaly on imaging studies, and lack of other cause identified. Neuroimaging should be performed to evaluate for mass lesions causing obstructive hydrocephalus or dural venous sinus thrombosis. A lumbar puncture should be performed after a mass lesion has been ruled out by imaging to evaluate for increased intracranial pressure. Treatment in children may involve acetazolamide, corticosteroids, serial lumbar punctures, lumboperitoneal shunting or optic nerve sheath fenestration. Patients should be referred to an ophthalmologist for an exam including visual field testing and continued visual monitoring as visual loss is a complication. Outcome is generally favorable.

Chiari Malformations

Headaches may be a presenting symptom of a Chiari I malformation. There are four types of Chiari malformations but because the other malformations are generally evident at birth, a type I malformation is the most likely to be discovered in childhood. Type I Chiari malformation refers to the downward displacement of the cerebellar tonsils through the foramen magnum. It may be associated with obstructive hydrocephalus and syringomyelia. The incidence is unknown because many patients are asymptomatic and remain undiagnosed. Headache is a common presenting symptom and may be exacerbated by Valsalva maneuver or physical exertion. The head pain may be located in various areas and may occur multiple times daily and last seconds to minutes. Presenting complaints may also include neck pain, sensory, motor, or gait impairments, or oropharyngeal dysfunction. Neurologic exam findings may include scoliosis, abnormal deep tendon reflexes, and cranial nerve deficits. Diagnostic testing should include magnetic resonance imaging of the brain, including the posterior fossa, craniovertebral junction, and upper cervical levels. Surgical treatment for children presenting with headache is generally controversial but may include suboccipital craniectomy and cervical laminectomy.

Trauma

Epidural Hematoma

Trauma is a common cause of injury and loss of consciousness in children and may be associated with a potentially life-threatening epidural hematoma. In an epidural hematoma, there is hemorrhage, commonly from the middle meningeal artery, and accumulation of blood between the dura mater and the skull. This blood initially strips the dura away from the skull, causing pain and eventually exerts mass effect on the brain which can lead to herniation and death. Thus it is important to quickly recognize the symptoms and efficiently manage children with epidural hematoma who may present with headache.

Risk factors include falls, motor vehicle accidents, direct head injuries, and skull fractures. Patients may experience an asymptomatic, lucid interval following the initial injury, and then develop headache with associated nausea, vomiting, and altered mental status. Late and ominous findings indicating compression of the brain stem include focal neurologic findings, pupillary changes, bradycardia, hypertension, and respiratory depression. Clinical presentation varies with age. In newborns, epidural hematomas may complicate delivery and may present with seizures, hypotonia and pallor. Older children may present with headache, nausea, and vomiting several hours following a head injury associated with loss of consciousness. Diagnosis is via head CT which demonstrates a convex, hyperdense mass that generally does not cross suture lines. Treatment depends on the physical exam and head CT findings. Surgical management involves hematoma evacuation and nonsurgical management involves serial imaging and observation. Outcome can be favorable with prompt diagnosis and surgical management.

Subdural Hematoma

Subdural hematomas result from venous tearing and hemorrhage into the potential space located between the dura and arachnoid. Risk factors include falls, motor vehicle accidents, and trauma. Infants are predisposed to subdural hematomas because they have relatively larger heads, subdural spaces, and weaker neck muscles compared with older patients. Other predisposing factors include a history significant for a bleeding disorder, an arachnoid cyst, or shunted hydrocephalus. Onset of symptoms may be delayed days to weeks due to the relatively lower-pressure venous system. Infants may present with a bulging fontanelle and irritability. Young children may present with seizures, increasing head circumference, hypotonia, and focal neurologic signs. Non-accidental trauma should be considered in the differential diagnosis of a young child with a subdural. Associated factors may include retinal hemorrhages, bruises, fractures, or a previous history of abuse. Older children may present with altered mental status, headache, and vomiting. Late findings indicating compression of the brain stem include focal neurologic findings, pupillary changes, bradycardia, hypertension, and respiratory depression.

Diagnosis of subdural hematoma is by head computed tomography (CT) which demonstrates a concave, hyperdense mass which crosses suture lines. Additional studies to consider in a child with a subdural hematoma include a blood count, coagulation studies, funduscopic exam and skeletal survey. Treatment depends on the physical exam and head CT findings and outcome varies. Surgical management involves hematoma evacuation or shunt placement and nonsurgical management may involve serial imaging, observation, and intracranial pressure monitoring.

Meningitis

Meningitis refers to inflammation of the tissues surrounding the brain and spinal cord. Etiology includes bacteria, viruses, fungi, and parasites.

Bacterial Meningitis

Bacterial meningitis is life threatening and the most common causative agents depend on patient factors such as age, immunization status, and presence of underlying predisposing factors. Risk factors include living in an endemic area, immunocompromise, lack of immunization against Haemophilus influenza type b or *Streptococcus pneumoniae*, recent infection (especially upper respiratory, ear, or sinus), head trauma, ventricular shunts, or cochlear implants.

The most common etiologic organism varies with age and location. In neonates, group B streptococci, Listeria monocytogenes, and gram negative enteric bacilli (*Escherichia coli,* Klebsiella, *Enterobacter*, *Salmonella*) are common agents. Worldwide, *S. pneumoniae*, *N. meningitides*, and *H. influenza* type b are common causes of bacterial meningitis in young children and *S. pneumoniae* and *N. meningitides* are common in older children. Clinical features and exam findings may include headache, fever, neck stiffness, photophobia, altered mental status, nausea,

vomiting, irritability, seizures, cranial nerve palsies, petechiae, and purpura.

Evaluation should include CSF cell count, differential, glucose, protein, culture and serum blood count, differential, glucose, culture and possibly neuroimaging. Imaging should be performed prior to lumbar puncture if there is concern for increased intracranial pressure that may result in herniation during the lumbar puncture. Disease progression may be fulminant so empiric antibiotic therapy may need to precede lumbar puncture and imaging; however, a blood culture should be obtained initially.

CSF findings include pleocytosis with neutrophil predominance, elevated protein, decreased glucose, and a positive gram stain. A positive CSF culture is diagnostic as is a positive blood culture in the setting of CSF pleocytosis. Complications include shock, increased intracranial pressure, seizures, and subdural effusions and abscesses. Treatment should be initiated empirically while awaiting culture results and then altered if necessary when a specific organism is identified. Recommendations for empirical therapy of bacterial meningitis by the Infectious Disease Society of America include vancomycin plus a third-generation cephalosporin for children older than 1 month. Adjunctive dexamethasone use to decrease the inflammatory response is recommended in infants and children with *H. influenzae* type b meningitis and should be given prior to the initiation of antimicrobials and continued for 2–4 days. Outcomes vary but persistent neurologic sequelae are not uncommon following bacterial meningitis.

Viral Meningitis

Viral meningitis is more common than bacterial meningitis in children. It is also known as aseptic meningitis and refers to an inflammation of the meninges without evidence of bacteria in the CSF. Various infectious agents such as enterovirus, herpesvirus, arbovirus, influenza, and rabies may be responsible but non-polio enteroviruses are the most common cause of viral encephalitis in the United States. Worldwide, there is a diverse range of pathogens that may cause viral encephalitis. Arboviruses have a global distribution but are found primarily in tropical regions. West Nile virus is an arbovirus that is found in North America. Pediatric West Nile Virus may present with a febrile illness and may include meningitis, encephalitis, and a poliomyelitis-like illness.

Clinical presentation may include fever, headache, nausea, vomiting, photophobia, and change in mental status. Young children may present with fever, irritability, rash or seizures. Common etiologies include group B coxsackieviruses and echoviruses. Evaluation should include lumbar puncture and CSF analysis to rule out a bacterial etiology. Pleocytosis is seen and may be neutrophilic initially and then become more lymphocytic. Treatment is supportive and prognosis is generally favorable.

Brain Tumors

Headache may be the presenting symptom of a brain tumor in children. Brain tumors are the most common solid organ cancer and second to leukemia as the most common overall cancer in children. Presenting signs and symptoms vary with the age of the child and with the location of the tumor but frequently include headache (especially nocturnal or early morning), nausea, vomiting, unsteadiness, seizures, behavior changes, papilledema, and focal neurological deficits. The majority of childhood brain tumors are located infratentorially. Location of the tumor determines clinical presentation. For example, brainstem gliomas may present with cranial neuropathies due to their compression of exiting cranial nerves. Cerebellar astrocytomas and medulloblastomas may present with ataxia due to their location in the cerebellum as well as symptoms of increased intracranial pressure because of fourth ventricular compression. Ependymomas tend to arise from the floor of the fourth ventricle, which is near the vomiting center, and may present with nausea, vomiting, or obstructive hydrocephalus. Supratentorial midline tumors such as craniopharyngiomas and gliomas may present with visual deficits, eye movement abnormalities, neuroendocrine dysfunction, and behavioral and appetite changes due to their location near the optic chiasm and pituitary gland.

Headache is a common complaint in children and deciding which children to image can be challenging. Recent studies have investigated clinical predictors of underlying brain tumor in children presenting with headache and found that a headache that causes nocturnal awakening or is present upon awakening as well as a negative family history of migraine were predictors of underlying brain tumor. Additional predictors include headache duration of less than 6 months, vomiting, seizures, confusion, and an abnormal neurological exam. Diagnosis is via neuroimaging with and without the use of contrast. Magnetic resonance imaging is generally preferred over computed tomography because the posterior fossa is better visualized. Treatment depends on the histological diagnosis, tumor location, and age of the child but

may involve surgery, chemotherapy, radiation, and other modalities such as anticonvulsant medications or bone marrow or stem cell reconstitution. Prognosis varies with tumor type.

Vascular Malformations

Cerebral vascular malformations include venous angiomas, arteriovenous malformations, capillary telangiectasias, and cavernous malformations. Venous angiomas are the most common and are usually benign. Clinical presentation may include headache as well as dizziness, incoordination, seizures, motor or sensory deficits. Diagnosis is via magnetic resonance imaging and treatment is conservative. Capillary telangiectasias are usually asymptomatic and may be found incidentally on neuroimaging studies.

Cavernous malformations and arteriovenous malformations are more likely to cause neurologic symptoms. Cavernous malformations may be sporadic or familial. Clinical presentation may include headache, hemorrhage, seizure, or focal neurologic sign. Diagnosis is via magnetic resonance imaging and treatment depends on symptoms and location but may involve surgical resection, or stereotactic radiosurgery.

Arteriovenous malformations involve a loss of the normal vascular organization. They consist of abnormal collections of dilated arteries and veins in the brain parenchyma. The most common presenting sign is hemorrhage but additional presentations include headache, seizures, and neurologic deficits. Hemorrhagic strokes are relatively common in children and may be due to an underlying arteriovenous malformation. Diagnosis is via neuroimaging, including computed tomographic angiography which provides vascular detail or magnetic resonance imaging/angiography which provide visualization of surrounding structures. Angiography is the gold standard however, because it allows for visualization of the lesion and is useful in the assessment of hemorrhage risk. Treatment depends on many factors and may include surgical resection, radiosurgery, or embolization.

Brain Abscess

Brain abscesses are generally uncommon in children but may develop in children with predisposing factors. Studies have identified congenital heart disease, otitis media, sinus or intracranial infections, intracranial hardware, skull fractures, intracranial surgery and immunosuppression (organ transplantation, chemotherapy, HIV) as predisposing factors for brain abscess development. Pathogenesis involves the invasion of microorganisms (bacteria, fungi, parasites) into the brain parenchyma and can result from direct extension, hematogenous spread, or penetrating trauma. Infants being treated for meningitis may present with a bulging fontanelle and increased head circumference. Older children may present with more obvious signs including vomiting, fever, headache, photophobia, mental status changes, seizure, and focal neurologic signs such as hemiparesis or visual field deficits. Early diagnosis and treatment leads to improved outcome. A brain abscess should be considered in a child with a history of congenital heart disease, immunosuppression, recent neurosurgical procedure or ear or sinus infection presenting with new onset headache, seizure, or focal neurologic sign. Neuroimaging with contrast should be performed and will demonstrate an enhancing rim around an area of decreased attenuation. Treatment generally involves monitoring with frequent brain imaging, several weeks of antibiotics and possible surgical intervention. Outcome may include hydrocephalus, seizures, developmental delay, neurologic deficits, or death.

Hydrocephalus

Hydrocephalus is due to the accumulation of cerebrospinal fluid (CSF) secondary to an imbalance in its production and reabsorption. This may result from increased CSF production, decreased absorption or obstruction to flow, which is the most common cause. This increased pressure results in dilatation of the ventricular system, affects its lining and the surrounding white matter. Congenital hydrocephalus may be a result of intrauterine infection, toxin exposure, or central nervous system (CNS) tumor or malformation. Acquired hydrocephalus may be the result of CNS infection, hemorrhage, or tumor, causing ventricular obstruction. Signs and symptoms include an increase in head circumference, headache (especially morning), nausea, vomiting and changes in vital signs, level of consciousness, and papilledema. Acute hydrocephalus presents more obviously than chronic hydrocephalus, as the system has time to adjust to the changes. Diagnosis can be made by neuroimaging including cranial ultrasound in infants or head computed tomography or magnetic resonance imaging. Treatment depends on the underlying cause but may involve CSF drainage and shunt placement. Complications of shunts include mechanical malfunction and infection. Headache is a frequent complaint in patients with shunts and should raise the suspicion for shunt malfunction or infection. Prognosis depends on

cause, time to treatment, and complications but may include seizures and developmental delay. Prognosis in untreated hydrocephalus is poor and may include death.

379 Pediatric Neurorehabilitation

Michelle A. Miller

Overview

Pediatric rehabilitation involves those measures taken to decrease the functional impact of a disease process or trauma on that child and the family. It includes the family unit at its core and integrates the child's developmental levels into its expectations. The chapters in this section have discussed the wide variety of neurological findings in children, how to establish the diagnosis when possible, prognosis, and treatment approaches. This chapter will outline the common impairments associated with neurological disease and trauma and how they might be addressed.

Disability

The World Health Organization has defined disability as being "an umbrella term covering impairment, activity limitations, and participation restrictions." Impairment is that area of body function or structure which has a deficit. This would include weakness, a visual field cut, or aphasia, for example. Activity limitations refer to difficulty with performing a specific task because of the impairment. With the examples above, this could include walking, reading, or talking, respectively. Finally, participation restrictions put this in the context of society and how the child is affected within typical life situations. Therefore, the child who has difficulty walking may not be able to walk to school any longer and the child with a visual field cut and/or aphasia may not be able to order food at a restaurant because he is unable to read the menu or voice his choices. Disability may be temporary as in the case of a child with Guillain–Barre syndrome, who has a full recovery or chronic such as for the child with cerebral palsy (CP). Regardless of whether the child is born with a disability or acquires it later in life, the child and the family are forever changed.

Historical Perspective

Children with disabilities have not always been treated kindly in history. In Ancient Greece, Aristotle proposed "death for the deformed child." Later, Jesus, Buddha, Confucius, and Mohamed all extolled concern for all humankind whether disabled or not. In the Middle Ages, disabled children were tolerated as long as they could work. However, the Roman Catholic Church then began to switch its stand from "children of innocence" to "products of the devil." The time of the Inquisition saw many deaths as they were viewed as people without souls or witches. These beliefs continued into the 1600s when, for example, a Massachusetts General Court in 1641 pronounced that "the birth of a defective or abnormal child was always suspect, reflecting either God's wrath or the work of the devil." In the 1800s, individuals with disabilities were often indentured servants or held in jail. Perspectives began to change when philanthropists such as DuPont, Frick, Watson, Carnegie, and others supported the formation of custodial care institutions in 1923 to shelter and care for those individuals who were felt to be unable to manage in the general society. Attitudes continued to switch with the advent of the polio epidemics. The onset of modern-day rehabilitation was further sparked by the returning, injured veterans of World War II and the Vietnam War. Many countries have now adapted policies of inclusion and advocated for the removal of architectural and philosophical barriers to those with disabilities. Pediatricians should be aware of those resources in their community to support and enhance the lives of disabled children.

The Rehabilitation Evaluation

The medical diagnosis relies on a thorough history and physical examination with appropriate testing as indicated. Treatment is focused on curing or alleviating the medical problem. The rehabilitation evaluation documents the functional consequences of that medical diagnosis. All of the child's impairments are considered and placed in the context of how they are able to perform age appropriate tasks such as talking, feeding, dressing, toileting, walking, and playing.

If the disease or trauma cannot be cured through medical or surgical intervention, then therapy is instituted to minimize the impairment. For example, glasses are

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_379,

provided for a child with a visual acuity deficit, or a weak muscle can be strengthened. In some cases, the impairment is permanent and cannot be minimized. The physician must then evaluate those skills that are intact and use them to adapt to the environment.

Case Example

A 4-year-old boy has been diagnosed with spinal muscular atrophy (SMA) type II. He is inquisitive and social, but limited in his interactions by his inability to get his body from point A to point B. Working with a therapist and a durable medical equipment specialist, he learned how to operate a power wheelchair. After obtaining the power wheelchair, he was able navigate around his preschool class, talk with friends, and explore the environment. His intact capabilities included his normal cognition, inquisitiveness, and social skills. By increasing his mobility, he was able to take advantage of new learning opportunities through increased interactions with his peers and his classroom.

Rehabilitation of the Brain

The brain has a prolonged developmental course with synaptic proliferation, pruning, and myelination proceeding into the 2nd and 3rd decades of life. With this understanding, it is hypothesized that the brain has a certain degree of plasticity to recover from injury and regain function. The brain may be injured as the result of trauma or illness. It may not form correctly during gestation. The lesions may be static as in cerebral palsy or traumatic brain injury (TBI) or may be progressive as with the leukodsytrophies (see Chap. 366, "Acute, Subacute and Progressive Encephalopathies" by G. Gascon).

The leading cause of mortality in children in developed countries is traumatic brain injury (TBI). For those who survive, there may be a high associated morbidity. Luckily, the majority of TBI is mild and often classified as concussion. These injuries are the ones most likely to present to the pediatrician's office. A careful neurologic examination is warranted to evaluate for any focal deficits. Most commonly the child presents with complaints of headaches, body pain, mood/behavioral changes, fatigue, and difficulties in school. Treatment tends to be symptomatic with the addition of medication to help with sleep if warranted. A period of cognitive rest is recommended until the headaches and fatigue have improved. This may mean temporary absence from school, a decrease in reading workload, and postponing any school testing. At home, television watching and computer use may need to be curtailed. Typically, children can return to school and sedentary activities within a week. When the child is involved in sports, they should not resume play until symptoms have resolved and neuropsychological testing as may be available by ImPACT or CogSport have returned to baseline. Alternative testing may include paper and pencil tests such as trail making, digit symbol substitution, and the Stroop word color tests (*Fig. 379.1*).

General conditioning and noncontact sports–related skills should be practiced first. Children should not progress to contact skills or actual play until they can perform all skills without symptoms. Guidelines for return to play have been well described in the Consensus Statement on Concussion in Sport 3rd International Conference on Concussion in Sport Held in Zurich, November 2008. Studies have shown that higher-level balance skills even with a mild brain injury may be impaired for up to 3 months following the injury (see Chap. 377, "Head Injury in Children" by Daniel Tsze and Tom Chun for further detail).

A rare, but deadly complication after concussion, second impact syndrome, may occur in some children and

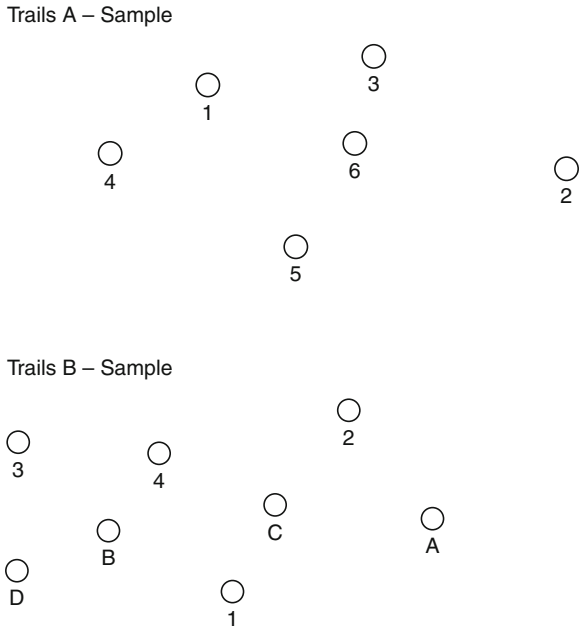

Figure 379.1
Examples of trail-making tests A and B. Individuals must connect the circles sequentially by number for trails A and by alternating the number and alphabet for trails B. Time for completion of the test is standardized

adolescents. In a child who has not fully recovered from a concussion, a second seemingly minor head trauma may result in severe brain swelling. On CT, diffuse brain swelling is noted that may lead to brain herniation and death.

For children who sustain a moderate to severe TBI, the rehabilitation plan is more complex and intense. Impairments may include eye muscle weakness, vision loss, facial weakness, hearing loss, dysphagia, sensory loss, weakness, balance difficulties, behavioral changes, and cognitive changes especially involving attention, memory, and organization. If the severe TBI was the result of a motor vehicle collision, there may be associated bony or peripheral nerve injuries adding to the impairment (see Chap. 377, "Head Injury in Children" by Daniel Tsze and Tom Chun for further details). Rehabilitation starts with preventing secondary injury. As complications following the injury increase, the prognosis for functional recovery declines. In the acute setting, the goals include maintaining limb range of motion, managing spasticity, managing pain, preventing skin pressure injury, managing agitation, and improving awareness of self and the environment. The stages of recovery from a brain injury are nicely described by the Ranchos Los Amigos Scale (*Table 379.1*). Education of the family and the child, as possible, with respect to the injury and typical course of recovery are of paramount importance.

Therapies typically involve physical therapy, occupational therapy, speech therapy, psychology, and rehab nursing at a minimum. Children and families receive significant benefit when therapeutic recreation, a school teacher, a nutritionist, and a massage therapist are included. These therapies will focus on strengthening muscles that are weak, improving or maintaining range of motion, evaluating and strengthening oral musculature and control to help with swallowing, improving balance, and working on functional skills. These could include sitting, transferring from sit to stand, walking, toileting skills, eating, dressing, bathing, talking, hand writing, and social interaction.

Bracing to decrease spasticity, maintain range of motion, support a weak limb, or correct a deformity may be needed. For example, a child with spastic hemiplegia following a TBI may benefit from an ankle foot orthosis (AFO) to help clear his foot and control his knee while walking (*Fig. 379.2*).

Medications such as Botulinum toxin, baclofen, diazepam, and dantrolene sodium may be employed to help with spasticity not responding to physical measures. However, their benefit must be weighed against the possible side effects including increased somnolence, decreased

Table 379.1
Rancho Los Amigos cognitive scale

Level	Description	Detail
I	No response to tactile, auditory, or visual stimulus	
II	Generalized reflex response to pain	Decorticate or decerebrate posture, physiologic changes or vocalization with often the same response regardless of the stimulus.
III	Localized response	Blinks to light, turns toward/away from sound, responds to physical discomfort, and has inconsistent response to commands.
IV	Confused/agitated	Alert, very active, aggressive, or bizarre behaviors, performs motor activities but behavior is nonpurposeful, extremely short attention span, generalized agitation.
V	Confused/non-agitated	Gross attention to environment, highly distractible, requires continual redirection, difficulty learning new tasks, agitated by too much stimulation or specific irritant. May engage in social conversation but with inappropriate verbalizations.
VI	Confused/appropriate	Inconsistent orientation to time and place, retention span/recent memory impaired, begins to recall past, consistently follows simple directions, and has goal-directed behavior with assistance.
VII	Automatic/appropriate	Performs daily routine in highly familiar environment in a non-confused but automatic robot-like manner. Skills noticeably deteriorate in unfamiliar environment. Lacks realistic planning for own future.
VIII	Purposeful/appropriate

seizure threshold, and increased muscle weakness. Assistive devices such as a walker, cane, crutches, or a wheelchair can enhance mobility. Often, the physical impairments have a good recovery with return of ambulatory abilities and self-care skills at or near baseline. However, cognitive impairments may have a much greater functional impact. Speech therapists can work on memory and organizational skills. Medications can be used to help with secondary attention deficits. However, a full battery of neuropsychological testing gives the best input to a child's areas of strengths and weaknesses. This information should be shared with the schools to facilitate school reentry and develop plans for education. In the United States, Individualized Education Plans (IEPs) are developed based on the results of a multifactored evaluation (MFE) which assesses physical and cognitive function within the school. They may include therapy services in the school to promote attainment of school-related activities such as computer access or opening containers in the lunchroom. Typical modifications recommended for the TBI population with significant impairments include a copy of the teacher's notes, a smaller classroom setting, dismissal from class early to allow safe navigation of the hallways, an extra set of books to be kept at home, an aide to keep a child on task or find his way through the school, reduction in homework load to assess mastery of the topic as opposed to busy work, multiple-choice testing instead of essay questions, a quiet setting with extra time for testing as well as accessible transportation to and from school. If a child's needs are not as complex, a 504 plan for in-classroom or school accommodations would allow a child access to use an elevator, for example, while healing from a fractured leg. It provides accommodations to a child in the regular classroom setting as opposed to a special education setting.

As the child progresses from the acute stage of recovery to subacute and chronic stages, a pediatrician should watch for signs of depression. Often, the full impact of the injury does not strike the child until months after discharge from the hospital. As they become more aware of their deficits and limitations, the child may become depressed or angry. Ongoing counseling can be beneficial either at the school or in a private setting. Children may also present to their pediatrician with an apparent worsening of their physical or cognitive skills. This is not uncommon with typical viral illnesses, although the pediatrician should ask about any further head trauma, seizure activity, or signs of hydrocephalus.

Other causes of brain injury such as stroke or brain tumor often present with more focal areas of deficit related to the area of the brain involved. (Please refer to Chap. 376, "Cerebrovascular Disorders in Children" by Steve Roach for further discussion.) The rehabilitation approach is similar with a close evaluation of the impairment and the resulting functional impact of that impairment. For a child with severe aphasia, an assistive communication device may be warranted. Additional education may need to be provided to the child and family if there is likelihood for additional strokes or recurrence of the brain tumor in the future. If the tumor is malignant, then acute goals may need to be tempered with future prognosis. A child who regains walking ability may still need a wheelchair due to fatigue from chemotherapy or progression of the disease.

An earlier presentation of brain injury is represented in the cerebral palsy population. The etiologies of cerebral palsy (CP) are varied, but by definition the insult to the brain must be nonprogressive, occur in the developing fetal or infant brain, and result in motor and postural impairments. (Please refer to the chapters on Chap. 359, "Congenital Brain Malformations and Hydrocephalus" by John Gaitanis and Chap. 360, "Neonatal Neurological Disorders" by William Brown and Mara Coyle Brown for further discussion.) CP is

the most common motor disability of childhood. Its classification is based on the anatomic distribution of weakness and the movement disorder. Children may be hemiplegic, diplegic, triplegic, or quadriplegic. Triplegia has also been described as hemiplegia on diplegia in that both lower limbs are involved as well as an upper limb. Movement patterns include spastic, dystonic, athetoid, choreiform, ataxic, hypotonic, and mixed forms. Purely hypotonic cerebral palsy is rare. Infants typically present hypotonic at birth and later develop spasticity, choreoathetosis, or ataxia as their neurologic system matures.

Early diagnosis of CP allows for early therapeutic intervention and assessment for associated disorders such as visual deficits, hearing impairment, seizure disorder, speech delay, swallowing and motility disorders, hip subluxation/dislocation, scoliosis, and cognitive impairments. Hearing impairment in CP is relatively rare except in children with congenital TORCH (toxoplasmosis, rubella, cytomegalovirus, and herpes) infections or a history or kernicterus. Visual deficits are varied and may include more severe impairments such as cortical blindness or retinopathy of prematurity (ROP) to the less severe such as amblyopia or strabismus. Early treatment with laser therapy for ROP to eye patching or glasses for amblyopia or strabismus, for example, can have a profound impact on future function. Infants with swallowing or oral motor dysfunction may need feeding tubes to allow for adequate nutrition and to decrease the risk of aspiration and pneumonia. Early, progressive hip subluxation may require surgical intervention such as a hip adductor tenotomy to prevent dislocation of the femoral heads (*Fig. 379.3*).

In addition to assessment and treatment of the associated disorders to help prevent or decrease further functional impairment, rehabilitation includes therapies such as physical therapy, occupational therapy, and speech therapy. These therapies may address management of spasticity, strengthening, range of motion, and developmental milestones. Constraint-induced therapy may be employed to force use of the weak upper limb. The nonaffected upper limb is immobilized so that the child is forced to use the weaker limb. Studies are ongoing to determine which children may respond best to this type of therapy. Other therapies which have been reported beneficial include aquatic therapy, hippotherapy, and acupuncture. Bracing may help to correct and/or support joint position altered by spasticity and weakness. Medications to decrease spasticity may also be indicated to improve function or decrease pain. Adaptive equipment such as walkers, crutches, and wheelchairs help with mobility. Other types of equipment such as bath chairs and lifts help to alleviate caregiver burden and improve safety especially as a more severely impaired child grows. Adaptive equipment may also include augmentative or assistive communication devices, utensils with built-up handles or straps for self-feeding, and dressing aids (*Fig. 379.4*). Technology has progressed so that children may access environmental control units to turn on lights, computers, or televisions.

Figure 379.3
Note the bilateral coxa valga, shallow acetabuli, and hip subluxation which are common in the nonambulatory child with CP

Figure 379.4
With the use of a mouth stick with a pen attached, this young man who is quadriplegic is able to write his name

As the child with CP ages, other medical concerns may arise. A child with hemiplegia may develop a significant leg length discrepancy that not only affects gait, but also may cause a scoliosis if left untreated. Children who are nonambulatory often develop a progressive scoliosis. In addition, they are at high risk for osteoporosis and resultant fractures. Children may have early onset of puberty and referral to an endocrinologist is warranted. As adults, these children often complain of cervical pain, back pain, hip pain, and hand parasthesias. Competitive employment of adults with cerebral palsy in a European population–based study was only 29% compared to 82% of the control group. Proposed reasons for the difference included cognitive impairment, difficulties with accessibility, attitudes toward individuals with CP, poor social skills, and employment policies.

Rehabilitation of the Spinal Cord

There are many processes which can affect spinal cord function acutely including traumatic spinal cord injury, transverse myelitis, infarct, tumor, and epidural hematoma. These all present with some degree of loss of sensation and motor function and if untreated, may progress. History and physical examination and an MRI will differentiate most of these cases.

Even with appropriate treatment, residual impairment is likely. These impairments include decreased or absent sensation, paralysis, neurogenic bladder, and neurogenic bowel. Acute medical complications include hypercalcemia, renal calculi, urinary tract infection, constipation, ileus, autonomic dysreflexia, pressure ulcers, spasticity, pneumonia in children with cervical or high thoracic injury, and difficulties with temperature regulation. Autonomic dysreflexia (AD) may occur in a child with an injury at the T6 level or higher. When there is a noxious stimulus below the level of injury, there is an increase in sympathetic activity leading to hypertension due to vasoconstriction below the level of injury. The central nervous system responds with increased vagal tone and resultant bradycardia. If untreated, this can be fatal with extreme hypertension. Symptoms include a pounding headache, flushing, and sweating above the level of injury, and "goose" flesh. When symptoms arise, have the child sit up immediately and then search for the cause. Symptoms will resolve with removal of the noxious stimuli. The most common causes are an over distended bladder and constipation. Other causes include tight-fitting clothing, fracture below the level of injury, and appendicitis, for example. If the cause cannot be determined quickly, nitropaste is effective in bringing blood pressure down and can be removed quickly to prevent hypotension when the noxious stimulus is removed. Parents and children at risk should be taught the signs and symptoms of AD and how to respond. Deep venous thrombosis (DVT) and pulmonary embolism (PE) are not as common in children who are prepubertal, but may occur not only in the legs, but also around deep lines. Symptoms may include calf swelling or tenderness, tachycardia, chest pain, or irritability. Usual presentation is within the first few weeks following the spinal cord injury. Doppler ultrasound will confirm the diagnosis of DVT and spiral CT or VQ scan will confirm the diagnosis of PE. Low-molecular-weight heparin or warfarin treatment of the PE and/or DVT should continue for 3–6 months. Factor anti-Xa levels and INR should be followed to measure therapeutic dosing for low-molecular-weight heparin and warfarin, respectively. Complications include bleeding and heparin-induced thrombocytopenia.

Subacute and long-term medical complications include latex allergy, pressure ulcers, heterotopic ossification, scoliosis, syrinx, and osteoporosis. The incidence of latex allergy has been reported to be 6–18% in children after spinal cord injury. Heterotopic ossification (*Fig. 379.5*) occurs most commonly around the hips

Figure 379.5
Heterotopic ossification noted near the left ASIS

and shoulders and should be aggressively treated with nonsteroidal anti-inflammatory drugs such as indocin and range of motion. Scoliosis occurs in the growing child whose primary means of mobility is in a wheelchair. Bracing may help to slow the progression of the curve, but it will not cure it. A referral to orthopedic surgery is recommended for appropriate timing of spinal fusion if needed.

Rehabilitation focuses on recognizing and treating the medical complications, education of the family and child regarding the injury and resultant effects, and addressing the impairments. Sensory loss may reverse with time. However, in the meantime, children are taught to visually inspect skin for injury daily and to test water temperature, for example, to prevent a burn of insensate areas. There may be associated neuropathic pain which may respond to medications such as gabapentin, pregabalin, or amitryptiline. Pressure relief should be performed every 15 min while awake and every 2 h when asleep by weight shifting or turning to prevent pressure ulcers in those without any sensation. Areas at highest risk in infants are the occiput and sacrum. In older children, the sacrum, ischii, lateral epicondyles, and malleoli are high risk areas.

Weakness can be treated with exercise, electric stimulation, and bracing to improve function. Ventilatory support, biPAP, or CPAP may be needed by children with injuries at the C5 level and higher. The level of injury will determine the eventual functional capabilities of the child. Neurological classification of the injury in the United States is determined by the American Spinal Injury Association guide (◉ *Fig. 379.6*). In general, children at a C7 level and below can be independent with mobility and basic self-care skills at the wheelchair level. Children with a functional level of L3 and below should be able to ambulate with assistive devices. Newer technology has included robotic exoskeletons to assist with walking, but these are not currently available to children due to the size and weight.

Spasticity often interferes with function and may cause pain and decreased range of motion. However, it may also provide stability as in the case of a paraplegic who uses that spasticity to stand. Therefore, treatment of spasticity must take into account function. Initial treatment includes stretching, bracing, and modalities such as superficial heat. When these do not adequately control the spasticity, medications may be beneficial. For focal spasticity, botulinum toxin injections may be helpful. If the spasticity is more widespread, options include baclofen, diazepam, dantrolene, tizanidine, and clonidine. The side effects and efficacy must be evaluated for each medication prior to initiation.

Initially following the injury, bladder and bowel function stops. The bladder is flaccid, and incontinence is usually due to overflow. Overdistention of the bladder is common and can cause a secondary injury to the bladder wall. With aggressive fluid resuscitation, a Foley catheter is the best management of the bladder. As fluids become more balanced, children should be switched to an intermittent catheterization program. Children can be taught to self-cath by age 5. The goals of the bladder program include preventing kidney injury, preventing urinary tract infections, and continence. As the child recovers from the initial insult, the bladder may become spastic. In this case, children will void small amounts frequently. A urinary tract infection should be ruled out as this will cause a similar voiding pattern. Baseline studies should include a renal ultrasound and a voiding cystourethrogram (VCUG). Urodynamic studies may be performed at a later date when bladder function has stabilized. Oxybutynin is an effective treatment for a spastic bladder. In children with recurrent urinary tract infections, prophylactic antibiotics may be indicated. The leading cause of death in individuals with a spinal cord injury prior to the introduction of bladder catheterization was renal failure.

Bowel function is similarly disrupted. Initially, an ileus is common and the anal sphincter may be flaccid. As spinal reflexes return, anal sphincter tone returns, but gastric motility continues to be very slow. Medications are used to assist with peristalsis and elimination from the rectal vault at a specific time to allow for continence. Medications to assist with peristalsis include stimulants such as senna, bisacodyl, milk of magnesia, and hyperosmolar agents such as polyethylene glycol (Miralax). Rectal agents include bisacodyl suppositories, therevac mini enemas, enemas, and/or rectal stimulation. The program must fit in with the child's lifestyle and knowing their premorbid elimination pattern may be helpful. Generally, the goal is to have a bowel movement daily following the rectal program.

The impact of a spinal cord injury on a child and family is life altering. A psychologist can be very helpful in helping a child and the family deal with the feelings and adjustment to a potentially new way of life. Depression in the weeks to months following the injury is very common.

Myelomeningocele presents with many of the same issues as spinal cord injury although the pattern of weakness and sensory loss may be patchy. In addition, children often have a Chiari malformation and associated hydrocephalus (◉ *Fig. 379.7*).

Therefore, children may have cognitive impairments in addition to the sensory, motor, and bladder/bowel

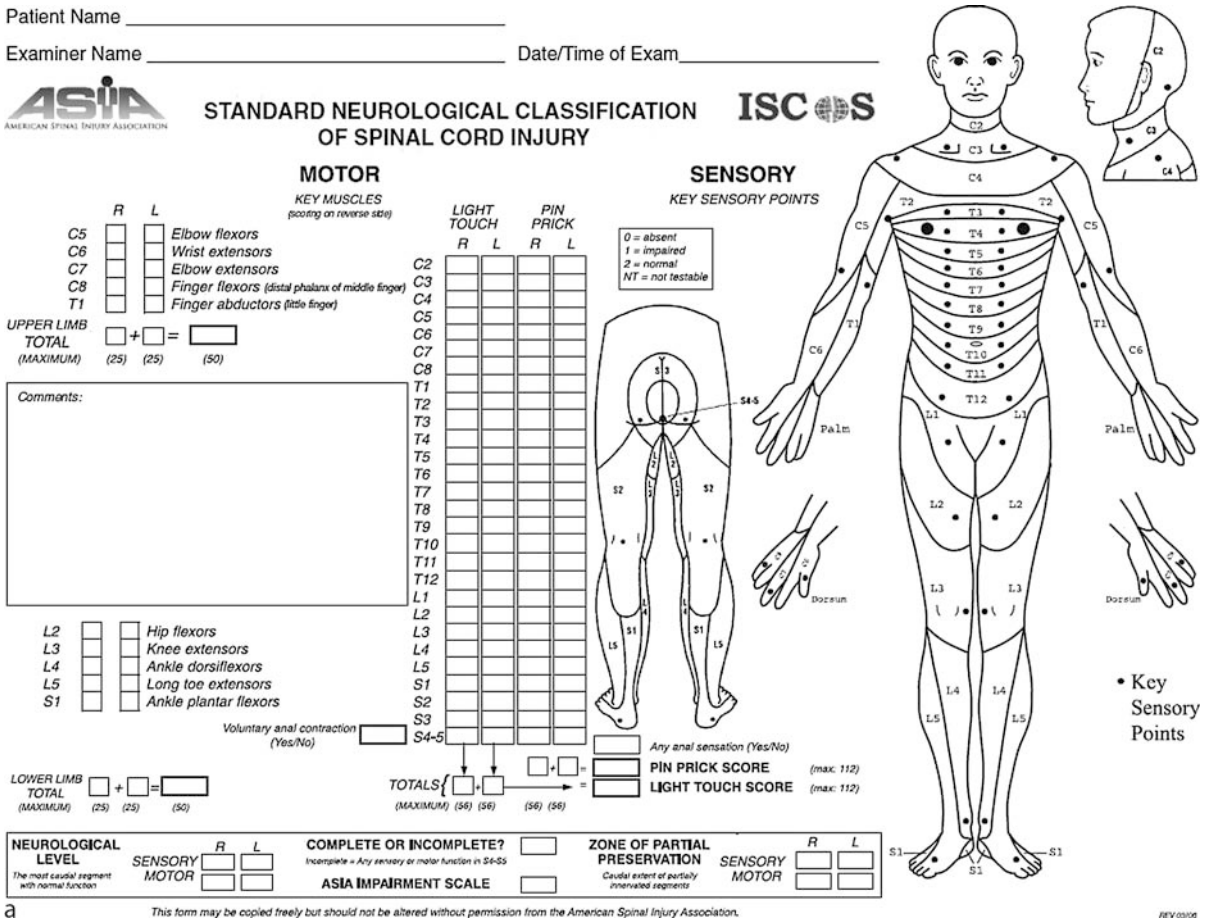

Figure 379.6
(Continued)

Muscle grading

0 Total paralysis

1 Palpable or visible contraction

2 Active movement, full range of motion, gravity eliminated

3 Active movement, full range of motion, against gravity

4 Active movement, full range of motion, against gravity and provides some resistance

5 Active movement, full range of motion, against gravity and provides normal resistance

5* Muscle able to exert, in examiner's judgement, sufficient resistance to be considered normal if identifiable inhibiting factors were nor present

NT not testable. Patient unable to reliably exert effort or muscle unavailable for testing due to factors such as immobilization, pain on effort or contracture.

Asia impairment scale

☐ A = Complete: No motor or sensory function is preserved in the sacral segments S4-S5.

☐ B = Incomplete: Sensory but not motor function is preserved below the neurological level and includes the sacral segments S4-S5.

☐ C = Incomplete: Motor function is preserved below the neurological level, and more than half of key muscles below the neurological level have a muscle grade less than 3.

☐ D = Incomplete: Motor function is preserved below the neurological level, and at least half of key muscles below the neurological level have a muscle grade of 3 or more.

☐ E = Normal: Motor and sensory function are normal.

Clinical syndromes (Optional)

☐ Central cord
☐ Brown-sequard
☐ Anterior cord
☐ Conus medullaris
☐ Cauda equina

Steps in classification

The following order is recommended in determining the classification of individuals with SCI.

1. Determine sensory levels for right and left sides.
2. Determine motor levels for right and left sides.
   Note: In regions where there is no myotome to test, the motor level is presumed to be the same as the sensory level.
3. Determine the single neurological level.
   This is the lowest segment where motor and sensory function is normal on both sides, and is the most cephalad of the sensory and motor levels determined in steps 1 and 2.
4. Determine whether the injury is Complete or Incomplete (sacral sparing).
   If voluntary anal contraction = No AND all S4-5 sensory scores = 0
   And any anal sensation = No, then injury is COMPLETE.
   Otherwise injury is incomplete.
5. Determine ASIA Impairment Scale (AIS) Grade:

Is injury Complete?
NO ↓ — If YES, AIS = A Record ZPP (For ZPP record lowest dermatome or myotome on each side with some (non-zero score) preservation)

Is injury motor incomplete?
YES ↓ — If No, AIS = B (Yes = voluntary anal contraction OR motor function more than three levels below the motor level on a given side.)

Are at least half of the key muscles below the (single) neurological level graded 3 or better?

NO ↓ AIS = C

YES ↓ AIS = D

If sensation and motor function is normal in all segments, AIS = E
Note: AIS E is used in follow up testing when an individual with a documented SCI has recovered normal function. If at initial testing no deficits are found, the individual is neurologically intact: the ASIA Impairment Scale does not apply.

b

Figure 379.6
Neurological classification of spinal cord injury

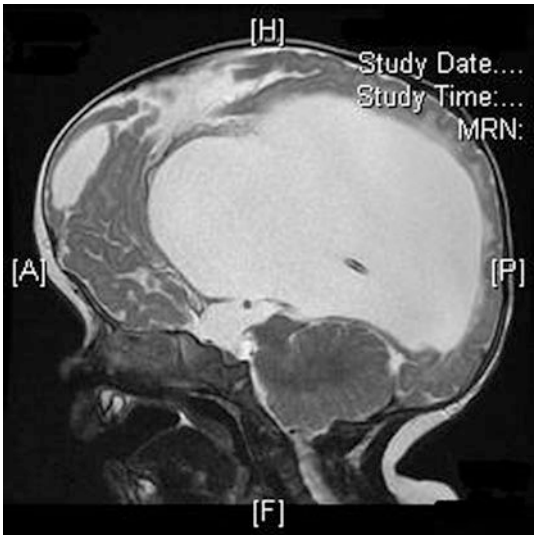

Figure 379.7
Note the Chiari II malformation with the cerebellar tonsils herniating through the foramen magnum and the severe hydrocephalus

dysfunction. Medical complications may include shunt failure and tethered cord in addition to those listed above for spinal cord injury. The incidence of latex allergy in this population has been reported to be as high as 72%. Obesity is also prevalent in children with myelomeningocele. Dietary guidelines include a diet low in fat and carbohydrates and high in protein and fiber. Caloric intake should be decreased by 10–20% of typical recommendations for children.

Rehabilitation of Peripheral Nervous System

Disorders of the peripheral nervous system may be due to trauma such as a brachial plexus injury, autoimmune response such as Guillain–Barre Syndrome (GBS), or due to hereditary diseases such as Charcot–Marie Tooth (CMT) disease. In addition, there are a number of neuropathies that may be caused by medications or developmental disorders such as hypomyelination. These conditions may have a favorable prognosis such as brachial plexus injury or GBS or be slowly progressive such as CMT (Please see Chap. 375, "Parainfectious and Autoimmune Disorders" by Tanuja Chitnis).

Birth brachial plexus injury results typically from shoulder dystocia during delivery. The infant often has an increased birth weight and becomes stuck under the pelvic brim. There may be an associated clavicle fracture. The infant often does not move the upper limb initially. Immobilization of the shoulder by pinning the sleeve of the infant's shirt to the shirt is recommended to allow the clavicle to heal and to prevent further injury to the arm. Gentle range of motion to the shoulder, elbow, and wrist should begin at 2 weeks of age. Most commonly the upper trunks of the plexus are involved (Erb's palsy, C5–C6 nerve roots); less commonly the lower trunks (Klumpke's palsy, C8–T1 nerve roots). In severe injuries, the complete plexus is involved. An EMG at 6–8 weeks of age can delineate the areas of injury and any reinnervation that may have occurred. If a nerve root avulsion or neurotmesis (complete disruption of the nerve and myelin sheath) is revealed by MRI of the cervical spine and cord, referral to neurosurgery at 4–6 months of age is recommended for a primary repair. For all other cases which demonstrate evidence of recovery, therapy includes range of motion, activities to facilitate use of the affected limb and possibly electrical stimulation if tolerated. As the child develops, there may be imbalances in muscle strength leading to joint contractures at the shoulder or elbow. These may respond to stretching, serial casting, or surgery. Bracing may be helpful with maintaining range of motion at the elbow.

Guillain–Barre syndrome presents with ascending sensory loss and weakness in the limbs. It may be demyelinating or axonal. The axonal variant tends to have a poorer prognosis for recovery. Rehabilitation includes strengthening weak muscles, treating neuropathic pain, and teaching adaptive techniques for self-care skills and mobility until strength improves. Endurance is the last area to recover and often rest breaks are required upon return to school and home activities.

The progressive neuropathies often require bracing to support weak muscles to allow for continued functioning. Daily stretching and range of motion exercises will help to preserve joint mobility. Adaptive techniques and equipment help with energy conservation. Continued reevaluation of functional capabilities is required to adjust bracing and equipment as needed. Therapeutic exercise should be within tolerance and never to the point of fatigue.

Rehabilitation of Conversion Reaction

Some children may present to their pediatrician or the hospital with symptoms such as weakness, difficulty walking, pseudoseizures, sensory abnormalities, or pain that

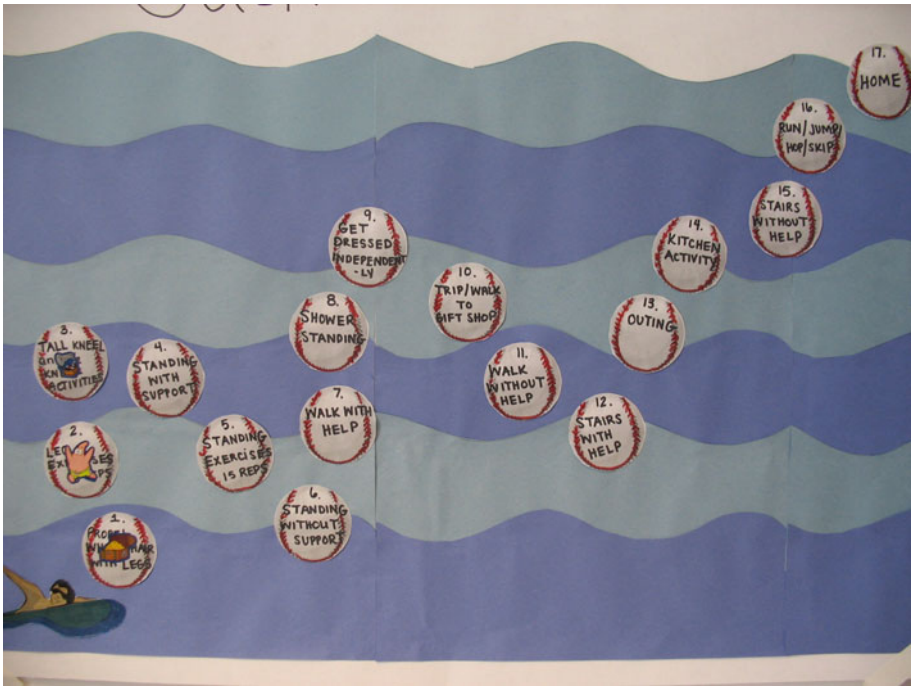

Figure 379.8
Example of a goal mountain for a child who has difficulty walking

upon further evaluation do not have an organic basis. The diagnosis of conversion reaction is given when other plausible etiologies have been ruled out. Conversion reaction is classified as one of the somatoform disorders. It is felt to be the body's subconscious response to a stressor or stressors. Children may or may not be aware of the stressor and classically do not demonstrate concern for their impairment – "la belle indifference." These children are often very intelligent, high achievers, and set very high expectations for themselves. Females tend to be at higher risk for this disorder than males. Early diagnosis and treatment is key to a favorable prognosis.

In many cases, the pediatrician may be able to simply give reassurance that the symptoms will resolve quickly and parents should downplay or ignore the symptoms. It is very beneficial to explain the diagnosis to parents so that they do not inadvertently reinforce the symptoms. However, giving the diagnosis to the child is often counterproductive as children feel that others think they are making up the symptoms or are crazy. A referral for counseling is helpful in teaching children coping techniques for stress.

When this approach is not enough, there are two different treatment approaches: psychiatric intervention and physical rehabilitation. If the conversion reaction has a physical manifestation such as a gait abnormality, for example, a structured rehabilitation program may be beneficial. However, parents must have accepted the diagnosis and agreed to the program for the best results. Treatment is aimed at a systematic reacquisition of skills to meet the expected functional outcome; walking normally, for example. The program is kept very structured and children receive positive reinforcement only when they have achieved the individual goals set for them on their goal mountain (*Fig. 379.8*).

Symptoms are largely ignored and children may not progress up the goal mountain until the goal is performed correctly on two consecutive therapies. In addition to the physical therapy, children receive daily counseling with a psychologist to evaluate stressors and teach coping techniques. Parents also participate in counseling for education regarding the disorder and how to address any regression once children return home. Oftentimes, children require ongoing counseling after discharge from the rehabilitation program. Good prognostic indicators include early diagnosis and good family support. Poor prognostic factors include longer duration of symptoms, history of sexual abuse, and family denial of diagnosis.

Endocrine Disorders

Khalid Hussain

380 Introduction to Endocrine Disorders

Khalid Hussain

Background to Hormone Physiology

The endocrine system uses the internal secretion of hormones to convey messages to target cells via cognate receptors. Hormones are defined as chemical messengers that are released into the blood stream that then act on distant target tissues. Hormones can also bind to receptors on cells that are expressed close to the site of release. When hormones act on neighboring non-hormone-producing cells, the action is called "paracrine." The synthesis of hormones occurs in specialized cells designed for that specific purpose. Hormones must be able to travel in the blood stream and diffuse in effective concentrations into tissues.

Many protein hormones such as growth hormone, prolactin, insulin, and glucagon are produced in dedicated cells by standard protein synthetic mechanisms common to all cells. These secretory cells usually contain specialized secretory granules designed to store large amounts of hormone and to release the hormone in response to specific signals. For example in the case of steroid hormones, the precursor is cholesterol which is modified by various chemical reactions to form glucocorticoids, androgens, and estrogens, and their biologically active derivatives.

Hormones are synthesized in response to biochemical signals generated by various modulating systems. Many of these systems are specific to the effects of the hormone product. For example, parathyroid hormone synthesis is regulated by the concentration of ionized calcium, whereas gonadal, adrenal, and thyroid hormone synthesis is regulated by the signals from the hypothalamic-pituitary axis. Specialized cells in the hypothalamus and pituitary monitor the circulating hormone concentrations and secrete trophic hormones that activate specific pathways for hormone synthesis and release. Typical examples are luteinizing hormone (LH), follicle-stimulating hormone (FSH), thyroid-stimulating hormone (TSH), and adrenocorticotropic hormone (ACTH). In the case of the thyroid gland, hypothalamic TSH-releasing hormone (TRH) stimulates TSH secretion from the anterior pituitary. TSH then initiates TH synthesis and release from the thyroid gland. TRH and TH inputs regulate the hypothalamic-pituitary-thyroid axis (see *Fig. 380.1*).

Hormones may be fully active when released into the circulation or may require activation in specific cells to produce their biological effects. These activation steps are often highly regulated. For example, the T4 released from the thyroid cell is a prohormone that must undergo a specific deiodination to form active 3,5,3 triiodothyroxine (T3). This deiodination reaction can occur in target tissues such as the central nervous tissue.

Hormones produce their effects by interacting with cell surface receptors. Others (such as steroid and thyroid hormones) must enter the cell to bind to cytosolic or nuclear receptors. Receptor proteins may be localized in the cell membrane, cytoplasm, or nucleus. Membrane-associated receptors usually consist of extracellular sequences that recognize and bind ligand, transmembrane anchoring hydrophobic sequences, and intracellular

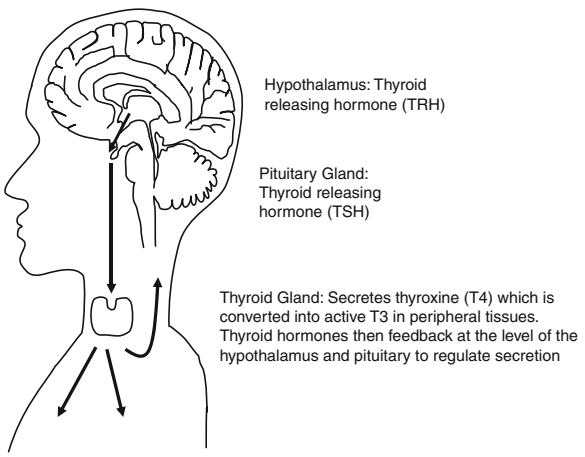

Figure 380.1
Summary of thyroid hormone secretion: Thyroid hormone (TH) plays an important role in development, growth, and cellular metabolism. TH production is controlled by a complex mechanism of positive and negative regulation. Hypothalamic TSH-releasing hormone (TRH) stimulates TSH secretion from the anterior pituitary. TSH then initiates TH synthesis and release from the thyroid gland. Serum concentrations of T_4 and its biologically active form T_3 are maintained in a narrow range by the ability of thyroid hormone (TH) to limit its own production by negative feedback at the hypothalamic TSH-releasing hormone (TRH) neuron and pituitary thyrotroph

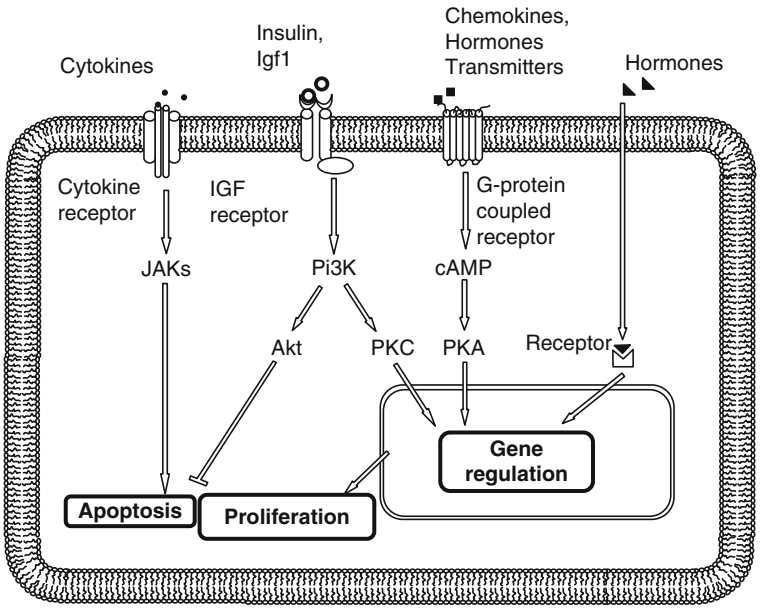

Figure 380.2

An outline of cell signaling pathways; cytokines, hormones, and transmitters interact with corresponding receptors and the signal is transduced through various pathways. Some hormones, for example, estrogen enter the cell through the membrane and interact with a receptor. Janus kinase (JAK) is a family of intracellular non-receptor tyrosine kinases that transduce cytokine-mediated signals via the JAK-STAT pathway. Phosphoinositide 3-kinases (PI 3-kinases or PI3Ks) are a family of related intracellular signal transducer enzymes capable of phosphorylating the 3 position hydroxyl group of the inositol ring of phosphatidylinositol. AKT protein family, whose members are also called protein kinases B (PKB), plays an important role in mammalian cellular signaling. Cyclic adenosine monophosphate (cAMP, cyclic AMP, or 3′-5′-cyclic adenosine monophosphate) is a second messenger important in many biological processes

sequences which initiate intracellular signaling. Intracellular signaling is mediated by soluble second messengers (such as cyclic AMP) or by activation of intracellular signaling molecules (such as signal transducers and activators of transcription protein (STAT) proteins). Receptor-dependent activation of heterotrimeric G-protein comprising ά, β, and γ subunits may either induce or suppress effector enzymes or ion channels. Several growth factors or hormone receptors (insulin) behave as intrinsic tyrosine kinases or activate intracellular protein tyrosine kinases. *Figure 380.2* shows an outline of the various receptors involved in hormonal signaling.

Introduction to Endocrine Disorders

A large number of childhood endocrine disorders may present to the pediatrician. Thus it is important for the pediatrician to have an understanding of the common endocrine problems so that a prompt diagnosis can be made or the patient can be appropriately referred. Conditions such as short stature and diabetes mellitus are some of the most common endocrine problems observed in the childhood period.

Common causes of short stature presenting to the pediatrician include familial short stature and idiopathic short stature. On the other hand, diabetes mellitus is one of the most common chronic pediatric diseases. Type 1 diabetes mellitus is the leading form of diabetes in young white people, especially those of northern European ancestry. Type 2 diabetes mellitus is now on the increase in the pediatric population on a worldwide scale.

The endocrine section of this book contains chapters on growth, puberty, disorders of sexual development (DSD), adrenal, thyroid, and pituitary and calcium disorders. There are separate chapters on diabetes mellitus section and hypoglycemia. Each chapter is clinically orientated to provide the practicing clinician with a thorough knowledge of the clinical problem. There are clear guidelines on investigation and patient management. In addition, each chapter provides a state-of-the-art overview of the recent research advances in the relevant field.

381 Disorders of Calcium Homeostasis

Ravi Chetan · Assunta Albanese

Physiology of Bone and Calcium Metabolism

The metabolism of calcium and bone are closely linked. Ninety-nine percent of the total body calcium is present in the skeleton; the remaining 1% is labile between bone, extracellular and intracellular fluid. The total serum calcium concentrations range from 2.2 to 2.6 mmol/L. At a physiologic pH (7.4) 40% of total calcium is bound to albumin, 10% exists as complexes with bicarbonate/phosphate/citrate, and 50% is free ionized calcium. The normal range for ionized calcium in blood plasma is 1–1.25 mmol/L. Ionized calcium has the primary regulatory role, it is in turn the regulated component. The homeostasis of calcium (Ca^{2+}) is intimately linked to that of magnesium (Mg^{2+}) and phosphorus. Dietary intake, fecal and urinary excretion, and bone turnover need to be balanced. Phosphorus is more widely distributed with 85% in bones as hydroxyapatite and 15% as a component of phospholipids, phosphoproteins, and nucleic acids. In blood, phosphorus exists in two ionic forms HPO_4^{2-} and $H_2PO_4^{-}$, together called inorganic phosphorus (P_i), and normal plasma or serum phosphorus concentration changes during life with the highest levels been found in neonates. Homeostasis of phosphorus is done mainly by the kidneys.

The plasma levels of calcium and phosphorus are subject to regulation by the interaction of three hormones – parathormone (PTH), vitamin D (as 1,25-dihydroxyvitamin D), and calcitonin (CT) – acting on three organs, bone, intestines, and kidneys. The influences of other hormones, notably sex steroids, growth hormone, and thyroxine and several novel gene products involved in this homeostasis are becoming clear.

Pathophysiology: Disorders of calcium and bone metabolism are common and best understood by examining changes in: parathyroid hormone, 1,25-dihydroxyvitamin D, urinary excretion of calcium and phosphorus, and bone turnover.

Parathyroid Hormone (*PTH*) is an 84-amino-acid peptide secreted by parathyroid glands (usually 2 pairs) located at the back of the thyroid gland in the neck. PTH acting on bone and the kidney influences several changes that increase plasma levels of circulating calcium. Calcium in turn has a negative feedback role on parathyroid glands to suppress parathyroid hormone secretion; so there is a reciprocal relationship between circulating levels of PTH and calcium. Extracellular ionized Ca^{2+} acts on calcium sensing receptor (CaSR) on the surface of parathyroid cells to detects and respond to very small changes in the Ca^{2+}concentration. The same sensor also regulates the responses of thyroid C-cells, which secrete CT in direct relationship to extracellular Ca^{2+}, and on the distal renal tubules where calcium excretion is regulated, and in several other tissues

The effects of PTH are mediated by a specific receptor called PTH receptor. A protein that is similar to PTH, known as parathyroid hormone-related peptide (PTHrP), is secreted and acts locally (paracrine/intracrine) within the bone. PTHrP is also secreted by many tumors (thus causing hypercalcemia). PTHrP acts on the same receptor as PTH. The receptor is thus known as the PTH/PTHrP receptor. Both CaSR and PTH/PTHrP receptor belong to the family of G-protein receptors that act via adenylate cyclase systems. The main effects of PTH are stimulating renal reabsorption of calcium, inhibiting renal reabsorption of phosphate, stimulating bone resorption, and inhibiting bone formation and mineralization. PTH also stimulates synthesis of Calcitriol. The net effect is an increase in serum Ca^{2+} and decrease in serum phosphorus.

Vitamin D is a secosterol present in humans in two forms: vitamin D3 or cholecalciferol (endogenously synthesized or ingested from animal sources) and vitamin D2 or ergocalciferol (ingested from plant sources). Their relative distribution ratio is 2:1. Cholecalciferol is synthesized in skin from the cholesterol metabolite 7-dehydrocholesterol under the influence of ultraviolet radiation. Vitamin D2 (ergocalciferol) is produced by ultraviolet irradiation of the plant sterol – ergosterol. Both forms of vitamin D are further activated by similar sequential hydroxylation at carbon position 25 (in the liver) and 1 (in the kidneys) give the Vit D-hormone – 1,25-dihydroxyvitamin D (Calcitriol). Hydroxylation also

Abdelaziz Y. Elzouki (ed.), *Textbook of Clinical Pediatrics*, DOI 10.1007/978-3-642-02202-9_381,

renders water solubility. Hepatic hydroxylation is dependent entirely on the amount of native vitamin D (D2 & D3) available; hence, laboratory measurements of 25-hydroxyvitamin D are good indicators of body vitamin D status. C-1 hydroxylation of 25-hydroxyvitamin D in the kidneys is self regulated by levels of 1,25-dihydroxyvitamin D and by PTH (and therefore indirectly by plasma Ca^{2+} levels). C-1 hydroxylation of 25-hydroxyvitamin D also occurs in lymphocytes, macrophages and monocytes; this is unregulated and potentially can lead to toxic levels of 1,25-dihydroxyvitamin D in certain situations resulting in hypercalcemia. The role of 1,25-dihydroxyvitamin D in Calcium regulation is fourfold. (A) It increases active absorption of Ca^{2+} from intestine. Fifteen to twenty percent of dietary calcium is usually absorbed; this is increased during periods of accelerated skeletal growth, pregnancy, and lactation. 1,25-dihydroxyvitamin D increases the permeability of brush border for uptake of Ca^{2+} from the luminal surface by increasing the Calcium-binding Proteins (CaBP) which facilitate Ca^{2+} transfer across the basolateral surface if the luminal epithelial cells and enhancing Mg^{2+} absorption (Magnesium is important for PTH secretion and action). Vitamin D acts synergistically with PTH on bone to increase bone resorption and restore normal Ca^{2+} levels. This is done by inducing macrophages to change into osteoclasts. It increases bone mineralization, possibly by both enhancing osteoblasts activity and increasing extracellular supply of calcium and phosphate in the osteoid matrix. It has no direct action on the kidney but, as mentioned above, it auto-regulates 1-α hydroxylase activity and hence its own synthesis. It should be noted that when vitamin D levels are low there will be a compensatory increase in PTH levels and thus severe (symptomatic) hypocalcemia is most unlikely.

Calcitonin is secreted by the parafollicular C-cells of thyroid in response to hypercalcemia. Its actions largely oppose the effects of PTH to decrease plasma Ca by impairing osteoclast formation and osteolytic activity and increased urinary excretion of calcium. It is of questionable importance in physiological regulation of calcium in post-natal life, but may have a role to play in fetal bone mineralization. It is a useful marker in Multiple Endocrine Neoplasia-2 and is used therapeutically to reduce plasma Ca^{2+} when there is hypercalcemia.

Urinary excretion of Phosphorus: Phosphorus homeostasis is mainly achieved by the kidneys. 90% of dietary phosphorus is freely filtered across the glomerulus. Of this, 90% is reabsorbed in the proximal tubule and 10% in the distal tubule. HPO_4^{2-} mostly undergoes active reabsorption while $H_2PO_4^-$ is passively reabsorbed. When the glomerular filtration rate is normal the amount of phosphate reabsorbed in the proximal tubules determines the serum phosphate concentration. PTH is the primary phosphaturic hormone; it dramatically inhibits reabsorption of Pi from proximal renal tubules. PTH simultaneously enhances active Ca^{2+} reabsorption from ascending limb of loop of Henle and distal convoluted tubule. Serum Pi levels and vitamin D also influence the homeostasis of phosphorus.

Three novel genes viz. phosphate-regulating endopeptidase (PHEX) gene at locus Xp22.2-p22.1, Fibroblast-Growth-Factor-23 (FGF-23) gene at locus 12p13.3, and the klotho gene (KL) on locus 13q12 play important roles in the regulation of Pi homeostasis. The PHEX gene encodes an endopeptidase, predominantly expressed in bone and teeth, but not in kidney. FGF-23 codes for a peptide that is a substrate of this endopeptidase. Cleaved FGF-23 fragments promote renal reabsorption of Pi. Klotho generates the FGF-23 receptor and is essential for endogenous FGF-23 function.

Active reabsorption of the filtered load of Pi across renal tubules is via Sodium-phosphate co-transporters (NaPi). Three sodium–phosphorus cotransporters are expressed in proximal tubule cells. NaPi-I and NaPi-II are located in the apical membrane, whereas NaPi-III is expressed in the basolateral membrane. In proximal tubule cells (and in enterocytes), the activity of NaPi-II limits transepithelial phosphate transport.

Determining the renal reabsorption of phosphate: The proportion of filtered phosphate which is not reabsorbed is represented by the ratio of the phosphate clearance to the glomerular filtration rate, and an approximate value for the latter can be obtained from the endogenous-creatinine clearance. The phosphate/creatinine clearance ratio (C_p/C_{cr}) is calculated as: (urine phosphate $\times$ plasma creatinine) $\div$ (plasma phosphate $\times$ urine creatinine). The tubular reabsorption of phosphate (TRP) is then calculated:-TRP = $(1 - C_p/C_{cr}) \times 100$. Normal levels: $C_p/C_{cr} = 0.02 - 0.22$. TRP = 78–98%.

Alternatively using the nomogram of Walton and Bijvoet renal phosphate threshold (TRP) normalized for the glomerular filtration rate (TRP = TMP/GFR) can be calculated. The normal range is 2.5–4.2 mg/100 ml.

The TMP (maximal reabsorption rate for Pi) is variable and is regulated by diet and the calcitropic hormones. TMP is reduced by high dietary phosphorus intake. PTH and CT both increase Pi excretion while 1,25-dihydroxyvitamin D decreases excretion. A low TRP in the hypophosphatemic patient indicates an appropriate renal response to hypophosphatemia, and usually implicates gastrointestinal loss or intracellular shift. A high TRP

in hypophosphatemia is indicative of increased renal excretion (secondary to a PTH-mediated mechanism, Fanconi syndrome, X-linked or autosomal dominant hypophosphatemic rickets, or oncogenic rickets/osteomalacia).

Urinary excretion of Calcium: Calcium (>90%) is reabsorbed passively by the proximal tubule and Loop of Henle. This can be inhibited by frusemide. Less than 10% of filtered load is actively reabsorbed in the distal tubule which is hormonally regulated; inhibited by CT, stimulated by PTH while vitamin D has small stimulatory effect). Klotho stimulates calcium reabsorption in the distal convoluted tubule by deglycosylating and stabilizing the epithelial calcium channel TRPV5 on the surface of cellular membrane. Distal tubular reabsorption of Ca^{2+} is stimulated by thiazides.

Bone turnover: Bone tissue is in constant state of flux with the extracellular fluid. Bone formation and resorption are part of a continuous remodeling process taking place on the bone surface of microscopic units called osteons. Annually 25% of trabecular and 3% of cortical bone undergoes turnover. Three types of cell produce and maintain bone. Osteoblasts (bone-forming cells) work at bone surfaces and secrete osteoid (unmineralized collagen). They modulate the crystallization of hydroxyapatite and influence the activity of osteoclasts. Osteoclasts (bone-resorbing cells) are responsible for the resorption of bone. They are necessary for the repair of bone surfaces and the remodeling of bone. Osteocytes are mature osteoblasts which have become embedded within the mineralized regions of bone. They are involved in the sensing and translation of information about the internal bone environment.

Markers of bone formation: Osteocalcin is a noncollagenous protein (gamma-carboxyglutamate) found in bone and dentin, secreted by osteoblasts and thought to play a role in mineralization and calcium ion homeostasis. Osteocalcin may also function as a negative regulator of bone formation, although its exact role is unknown. Osteocalcin is used as a preliminary biomarker of the effectiveness of a given drug on bone formation. P1NP (N-propeptide of type I collagen) is a marker of newly formed collagen. Alkaline phosphatase (ALPL) comprises a group of enzymes that catalyze the hydrolysis of phosphate esters in an alkaline environment, generating organic radical and inorganic phosphate. In mammals, there are four alkaline phosphatase isoenzymes: placental, placental-like (germ cell), intestinal, and tissue-non-specific (liver/bone/kidney). All four isoenzymes are anchored to the outer surface of the plasma membrane by a covalently attached glycosylphosphatidylinositol (GPI) anchor. Human alkaline phosphatases have four metal binding sites: two for zinc, one for magnesium, and one for calcium ion. The tissue-non-specific isoenzyme (ALPL) plays a role in skeletal mineralization. Defective ALPL leads to Hypophosphatasia. Conversely in other cause of defective mineralization ALPL levels are elevated. ALPL is also elevated during periods of rapid bone growth, e.g., infancy and puberty.

Markers of bone resorption: Biochemical markers of bone resorption are substances formed during modification of bone collagen (collagen type I) and released into the blood when osteoclasts degrade bone matrix. Breakdown products of collagen include deoxypyridinoline and pyridinoline and their associated cross-link telopeptides at C- and N- terminals (NTX and CTX). Antibody assays against these proteins therefore provide information about osteoclast activity and collagen breakdown. Despite some derived from collagen breakdown in other tissues as well the collagen cross-link deoxypyridinoline appears to be the marker with least contribution from non-osseous tissues. C-telopeptide-related octapeptide is another assay that identifies an aminoacid sequence of collagen type I involved in the formation of intermolecular cross-links.

Hypocalcemia

Definition

Hypocalcemia is total serum calcium of less than 2.1 mmol/L in children, less than 2 mmol/L in term neonates, and less than 1.75 mmol/L in preterm neonates

In the fetus plasma Ca^{2+} is maintained up to 0.5 mmol/l higher than in the mother. There is active transport of Ca^{2+} across the placenta. Fetal bones have high rate of Ca^{2+} accretion, the highest rates are seen in the late third trimester. Preterm birth thus significantly reduces this. At birth, Ca^{2+} levels drop physiologically for 24–48 h with a nadir around 2.0 mmol/l. Plasma Ca^{2+} levels are then maintained by a physiological temporary suspension of bone uptake.

Etiology

Causes of hypocalcemia can be considered in two groups.

Neonatal Hypocalcemia: Early neonatal hypocalcemia (within 48–72 h of birth) and late neonatal hypocalcemia (usually 3–7 days after birth; can occur as late as 6 weeks of age). A higher risk of early neonatal hypocalcemia is seen in low birth weight babies – 30% of

infants <1,500 g have hypocalcemia, preterm infants born <32 weeks gestation, infants of diabetic mothers, and infants affected by with birth asphyxia. The mechanisms of early onset hypocalcemia are not entirely understood and might be due to delay response to the rise in PTH following "physiological" postnatal hypocalcemia. It often corrects itself spontaneously but calcium supplementation can be needed. In infants of diabetic mothers, maternal magnesium depletion might lead to fetal hypomagnesemia that induces functional hypoparathyroidism and hypocalcemia in the infant. Late neonatal hypocalcemia may be due to (a) exogenous high phosphate load: Hypocalcemia is caused by feeding with phosphate-rich milk, e.g., whole cow's milk has 7 times the phosphate load of breast milk (956 v 140 mg/L), (b) magnesium deficiency, (c) transient hypoparathyroidism of newborn, (d) hypoparathyroidism due to other causes, (e) maternal hyperparathyroidism, (f) maternal vitamin D deficiency, and (g) in association with gentamicin use, especially with once-every-24-hour dosing schedule.

Maternal vitamin D deficiency and hypoparathyroidism can present at any time after birth.

Childhood Hypocalcemia is best considered in three groups. (1) Parathyroid disorders and Hypocalcemia due to reduced PTH secretion or impaired PTH action. (2) Vitamin D disorders: vitamin D deficiency, impaired vitamin D metabolism, or impaired Renal Function. (3) Abnormally active Calcium Sensing Receptor, i.e., Familial Hypercalciuric Hypocalcemia.

Clinical Approach to Hypocalcemia

Hypocalcemia is often asymptomatic and comes to notice by a low serum/plasma calcium level on a blood test done for some other reason. When symptoms occur they include: tetany, stridor, paraesthesia (especially in hands and feet), and focal or generalized seizures. Trousseau's sign (carpal spasm on inflating the sphygmomanometer cuff) and Chvostek's sign (facial and eyelid twitching induced by a sharp tap on the facial nerve) may be elicited. The ECG may show a prolonged QTc interval. Chronic hypocalcemia may manifest with cataracts/calcification of the lens, papilloedema, enamel hypoplasia, and calcification in basal ganglia/frontal lobe seen on CT scan. In infants with hypocalcemia secondary to vitamin D deficiency cardiomyopathy may also occur. Some syndromes associated with hypocalcemia have characteristic dysmorphic features, e.g., Williams syndrome.

Initial investigations include: plasma calcium, phosphate and magnesium, alkaline phosphatase, albumin, creatinine, serum PTH level, and plasma level of 25-OH vitamin D. [Calculate corrected Calcium using the formula: *corrected calcium (mmol/L) = uncorrected calcium (mmol/L) + 0.02 × (40-albumin)*]. Serum should be stored for later measurement of 1,25-dihydroxyvitamin D if indicated. Urine for calcium, phosphate, creatinine. X-ray of wrist + hand (or knee + chest in infants and toddlers) for suspected rickets or skeletal survey for other suspected bone abnormalities.

The above plasma and urine investigations might need to be performed in the child's parents.

From these initial investigations it is useful to categorize the cause of hypocalcemia according to PTH results: (a) If undetectable or low PTH: *Hypoparathyroidism, hypomagnesemia* are most likely causes. (b) Normal PTH: *Abnormal CaSR*. (c) High PTH: *Vitamin D deficiency/impaired metabolism, pseudohypoparathyroidism, osteopetrosis, renal failure*.

Treatment of Hypocalcemia

Severe/Symptomatic Hypocalcemia is treated using IV Calcium. Dose is 0.11 mmol/kg of Ca^{2+} given slowly over 5–10 min. This dose can be repeated if symptoms do not abate. Alternatively use a continuous infusion of Ca^{2+} 0.5–1.0 mmol/kg in 24 h. This can be added to the maintenance fluid. (Maximum dose is 8.8 mmol/24 h.) Switch to oral calcium supplements as soon as possible. Parenteral preparations available include: 10% solution of Calcium gluconate contains 0.22 mmol Ca^{2+}/ml). The maximum volume per dose is 20 ml of 10% Calcium gluconate. 10% Calcium chloride injection is also available containing 680 micromol of Ca^{2+}/ml.

Asymptomatic/mild hypocalcemia is treated by the oral route. Oral calcium dose is 0.25 mmol/kg 4 times-a-day for neonates and children up to 5 years age; from 5 to 12 years age, 0.2 mmol/kg 4 times-a-day; and for those >12 years, 10 mmol 4 times-a-day.

The dose is adjusted depending on response. Common preparations include Calcium Sandoz® syrup – a mixture of calcium salts providing 2.7 mmol of Ca^{2+}/5 ml. and Sandocal® effervescent tablets provide 400 mg or 1,000 mg (equivalent to 10 mmol of Ca^{2+} or 25 mmol of Ca^{2+}, respectively).

Magnesium can be used if response to calcium alone is poor or if hypomagnesemia is present. Twenty percent magnesium sulfate contains 0.8 mmol/ml of Mg^{2+}, while 50% magnesium sulfate contains 2 mmol/ml of Mg^{2+}). The dose of Mg^{2+} is 0.4 mmol/kg for neonates, 0.2 mmol/kg for ages 1 month–12 years, and 4 mmol for children

age >12 years. Magnesium sulfate can be given as deep IM injection or as IV infusion over at least 10 min after diluting it to a 10% solution with 5% or 10% Dextrose or 0.45% or 0.9% sodium chloride solution.

Vitamin D *and not one of its analogues* is used to treat hypocalcemia due to vitamin D deficiency. Vitamin D analogues are used to treat hypoparathyroidism and pseudohypoparathyroidism.

Practice points: (1) Vitamin D deficiency is the commonest cause of hypocalcemia in childhood, outside of the neonatal period. (2) Vitamin D deficiency must first be eliminated or corrected before the other causes of hypocalcemia can be diagnosed. (3) Hypocalcemia can result from vitamin D deficiency without rickets and without raised phosphates and PTH values. (4) Adequate blood and urine samples should be collected and stored before commencing treatment.

Hypocalcemia with Low PTH Level = Hypoparathyroidism

Definition

Hypoparathyroidism is a rare condition caused by a group of heterogeneous conditions in which hypocalcemia and hyperphosphatemia occur as a result of deficient parathyroid hormone (PTH) secretion or the absence of parathyroid glands. Primary hypoparathyroidism can be congenital or acquired. In neonatal period hypoparathyroidism can be transient.

Etiology

Transient Neonatal Hypoparathyroidism: PTH secretion is normally suppressed in the fetus because of high placental transfer of calcium, particularly in the third trimester. At birth cord clamping abruptly stops calcium transfer; serum calcium concentrations decrease rapidly and PTH secretion is triggered. Prolonged delay in parathyroid response causes a transient hypoparathyroidism. Preterm infants are at increased risk, and up to 50% of very low birth weight infants may have hypocalcemia. Infants of diabetic mothers may be born prematurely, and also have hypomagnesemia resulting from maternal magnesuria accompanying glucosuria. Low serum magnesium impairs PTH release and action. Maternal hyperparathyroidism causes more prolonged suppression of PTH secretion in the neonate.

Clinical Symptoms and Signs

Hypocalcemia with its clinical manifestations are the presenting features; in addition specific craniofacial features and assessment of cardiac and renal systems are necessary to exclude a syndromic cause. Similarly, autoimmune hypoparathyroidism can occur as an isolated endocrine condition or with other glandular deficiencies in APS1, requiring evaluation of other endocrine dysfunction. Long term effects of hypoparathyroidism may involve teeth (poor enamel), nails, hair, and skin, and there may be calcium deposits or kidney stones. Anxiety and depression may be present as low calcium and/or low PTH levels are linked to emotions. There may also be problems with memory and general fogginess. Fatigue and muscle weakness is common.

Isolated Inherited Hypoparathyroidism: These conditions are inherited as autosomal dominant (AD), recessive (AR), or X-linked modes. Several genes are involved. Human PTH gene is located at 11p15. Several inherited mutations lead to isolated defects in synthesis and secretion of PTH. In X-linked recessive hypoparathyroidism, the mutant gene (Xq26–27) is most likely involved in parathyroid gland development. Autosomal recessive loss of function of GCM2 (glial cells missing-2) and GCMB (glial cells missing-B) gene impairs normal parathyroid gland embryology and is responsible for isolated hypoparathyroidism. Gain-of-function mutations in the calcium-sensing receptor (CASR) gene (3q13.3–q21) cause autosomal dominant hypocalcemia. The serum PTH levels are normal; this is discussed in the next section.

The investigation of hypoparathyroidism is as discussed for hypocalcemia.

Treatment of Hypoparathyroidism

The goal of treatment in hypoparathyroidism is threefold: to raise the serum calcium to alleviate acute symptoms and this is then maintained at the lower limit of normal range (2.00–2.12 mmol); to prevent the complications of chronic hypocalcemia; and to prevent the key complication of vitamin D intoxication (hypercalcemia and hypercalciuria) with its adverse effects on the renal and central nervous system.

Calcium is administered both for acute treatment and maintenance as detailed in the treatment of hypocalcemia.

Vitamin D is preferably given as calcitriol (0.25–0.5 μg/day) or as alphacalcidol (dose 15–50 ng/kg/day). Calcitriol is preferred because of its potency and rapid onset and offset of action. Alphacalcidol is rapidly

converted to 1,25-dihydroxyvitamin D in vivo and has the same potency and rapidity of action. Cholecalciferol and ergocalciferol are both more cumulative and therefore potentially more toxic.

Monitoring is done by measurements of serum and urine calcium. 24 h urine calcium excretion is high when treatment is started, even before normocalcemia is achieved, and nephrocalcinosis is a risk. Ultrasound monitoring is necessary. If despite adequate calcium supplements and calcitriol the serum calcium levels are not normalized, thiazides are used in symptomatic patients to reduce urinary calcium excretion.

The elevated serum phosphate levels usually need no active treatment; with the correction of serum calcium there is a decline in phosphate. Phosphate-binding agents such as aluminum hydroxide are occasionally helpful in reducing hyperphosphatemia in initial stages of therapy. Human recombinant PTH has become available but is currently not licensed for the treatment of hypoparathyroidism. Hypoparathyroidism is one of the few endocrinopathies for which hormone-replacement therapy is not readily available. For an excellent review of the current status of replacement therapy see reference.

Hypomagnesemia

Definition

Serum levels of magnesium are in the range of 0.65–1.0 mmol/L. Lower levels constitute hypomagnesemia. Magnesium is a ligand for CaSR. Hypomagnesemia both blunts the release of PTH and also its action. Therefore hypocalcemia secondary to hypomagnesemia can only be corrected once magnesium levels are normalized.

Etiology

The main congenital causes of hypomagnesemia are inherited intestinal absorption defect or a renal tubular reabsorption defect. Acquired causes include any malabsorption, malnutrition, and renal tubular damage (e.g., Cisplatinum).
