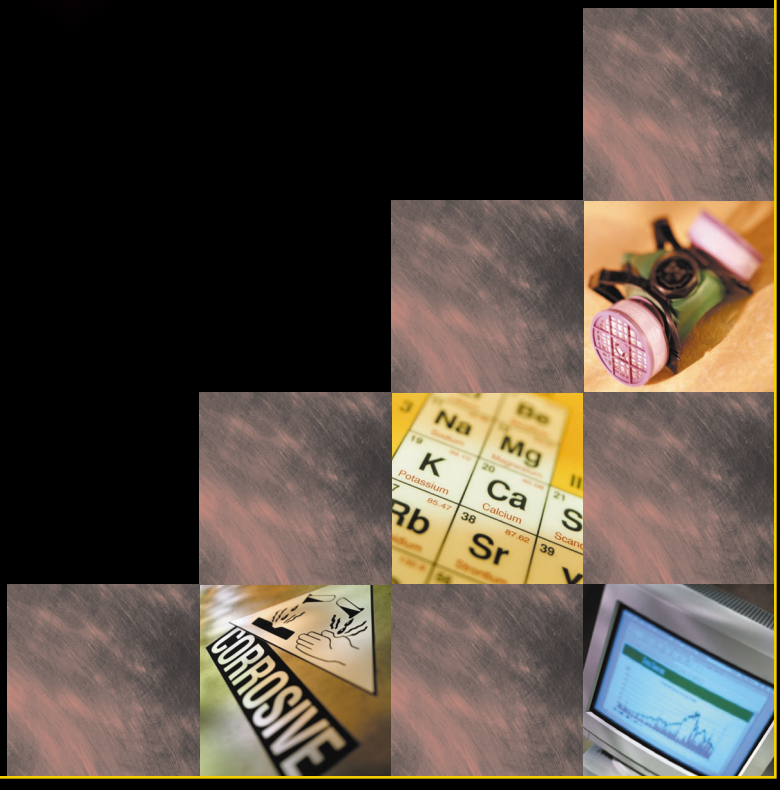
National Safety Council®

Fundamentals of Industrial Hygiene

5th Edition

Barbara A. Plog

Patricia J. Quinlan



Fundamentals of Industrial Hygiene

Fifth Edition

OCCUPATIONAL SAFETY AND HEALTH SERIES

The National Safety Council Press' Occupational Safety and Health Series is composed of materials written to help readers establish and maintain safety, health, and environmental programs. These books contain the latest information on establishing priorities, collecting and analyzing data to help identify problems, and developing methods and procedures to reduce or eliminate illness and incidents, thus mitigating injury and minimizing economic loss resulting from these events.

- *Accident Prevention Manual for Business & Industry*—4 volume set
  1. Administration & Programs
  2. Engineering & Technology
  3. Security Management
  4. Environmental Management
- *Study Guide: Accident Prevention Manual for Business & Industry: Administration & Programs and Engineering & Technology*
- *Occupational Health & Safety*
- *Fundamentals of Industrial Hygiene*
- *Study Guide: Fundamentals of Industrial Hygiene*

In addition to the Occupational Safety and Health Series, some recent NSC Press additions include:

- *Authentic Involvement*
- *Pocket Guide to Safety Essentials*
- *Injury Facts (*formerly *Accident Facts®)* published annually
- *Safety Culture and Effective Safety Management*
- *Safety Through Design*
- *On-Site Emergency Response Planning Guide*
- *Safety and Health Classics*
- *Lockout/Tagout: The Process of Controlling Hazardous Energy*
- *Supervisors' Safety Manual*
- *Out in Front: Effective Supervision in the Workplace*

Fundamentals of Industrial Hygiene
Fifth Edition

Editor-in-Chief: Barbara A. Plog, MPH, CIH, CSP
Editor: Patricia J. Quinlan, MPH, CIH
Project Editor: Jodey B. Schonfeld
Associate Editor: Patricia M. Dewey

NATIONAL SAFETY COUNCIL MISSION STATEMENT

The mission of the National Safety Council is to educate and influence society to adopt safety, health, and environmental policies, practices, and procedures that prevent and mitigate human suffering and economic losses arising from preventable causes.

DISCLAIMER

Although the information and recommendations contained in this publication have been compiled from sources believed to be reliable, the National Safety Council makes no guarantee as to, and assumes no responsibility for, the correctness, sufficiency, or completeness of such information or recommendations. Other or additional safety measures may be required under particular circumstances.

Foreword

The National Safety Council was chartered on the belief that information and planning are the keys to safety. For those beginning their careers or experienced safety and health professionals, *Fundamentals of Industrial Hygiene* continues to be the acclaimed standard of information for occupational and industrial hygiene professionals.

I encourage all employers, as well as safety and health professionals, to share the Council's commitment to preventing injury and illness and protecting people from hazards in the workplace. Fulfilling this commitment requires accurate, up-to-date information—the kind of comprehensive and current information contained in the fifth edition of the National Safety Council's *Fundamentals of Industrial Hygiene*. Written and edited by prominent industrial hygienists, occupational safety professionals and noted physicians, *Fundamentals of Industrial Hygiene* provides a useful guide to assist the reader, regardless of his or her knowledge base, to recognize, evaluate and control hazards in any type of workplace.

Throughout my own career, I have often referred to the most current edition of *Fundamentals of Industrial Hygiene* for valuable guidance. While at the Occupational Safety and Health Administration, I used earlier editions of *Fundamentals* to obtain in-depth knowledge and insight related to specific occupational environments, processes and procedures. Today, the book remains an indispensable tool to me and to National Safety Council staff, volunteers, members, chapters and affiliates in designing safety and health programs that are grounded in current scientific knowledge and real-life experience.

Whether establishing priorities, collecting and analyzing data, developing procedures to mitigate loss and suffering, or as a simple reference tool, *Fundamentals of Industrial Hygiene* assists every reader in the establishment of safety and health programs that are the foundation of our mission—preventing injury and illness, wherever they may occur.

Alan C. McMillan
President, National Safety Council

Preface

The fifth edition of *Fundamentals of Industrial Hygiene* comes at a time of continuing congressional activity that seeks to regulate how the federal Occupational Safety and Health Administration (OSHA) promulgates and enforces standards for health and safety in U.S. workplaces.

The words of then-OSHA head Joseph Dear to the American Industrial Hygiene Conference in Kansas City, Missouri, on May 24, 1995, still hold true, that OSHA strives to "guarantee that each worker who leaves for work in the morning arrives home safely each night." (*The Synergist*, American Industrial Hygiene Association, Volume 6, Number 6–7, p. 10, June/July, 1995.)

It is also clear the fundamental principles of industrial hygiene deserve more emphasis than at any time before.

This edition of *Fundamentals of Industrial Hygiene* presents original new chapters on Particulates (Chapter 8), Dilution Venilation of Industrial Workplaces (Chapter 20), Respiratory Protection (Chapter 22), The Occupational Medicine Physician (Chapter 25), and The Occupational Health Nurse (Chapter 26). All other chapters have been extensively updated and revised.

The primary purpose of this book is to provide a reference for those who have either an interest in or a direct responsibility for the recognition, evaluation, and control of occupational health hazards. Thus, it is intended to be of use to industrial hygienists, industrial hygiene students, physicians, nurses, safety personnel from labor and industry, labor organizations, public service groups, government agencies, and manufacturers. Others who may find this reference helpful include consultants, architects, lawyers, and allied professional personnel who work with those engaged in business, industry, and agriculture. It is hoped that this book will be of use to those responsible for planning and carrying out programs to minimize occupational health hazards.

An understanding of the fundamentals of industrial hygiene is very important to anyone involved in environmental, community, or occupational health. This manual should be of help in defining the magnitude and extent of an industrial hygiene problem; it should help the reader decide when expert help is needed.

Fundamentals of Industrial Hygiene is also intended to be used either as a self-instructional text or as a text for an industrial hygiene fundamentals course, such as the ones offered by the National Safety Council, various colleges and universities, and professional organizations.

The increase in the number and complexity of substances found in the workplace—substances that may spill over into the community environment—makes

imperative the dissemination, as efficiently and conveniently as possible, of certain basic information relating to occupational health hazards and resultant occupational diseases.

The book is organized into seven parts; each can stand alone as a reference source. For that reason, we have permitted a certain amount of redundancy.

Part One introduces the subject areas to be covered, in an overview of the fundamentals of industrial hygiene.

Part Two includes chapters on the fundamental aspects of the anatomy, physiology, hazards, and pathology of the lungs, skin, ears, and eyes. This background lays the groundwork for understanding how these organ systems interrelate and function.

Part Three is concerned with the recognition of specific environmental factors or stresses. The chemical substances, physical agents, and biological and ergonomic hazards present in the workplace are covered. The basic concepts of industrial toxicology are also presented in this section. Anticipation of these hazards is the desired result.

Part Four describes methods and techniques of evaluating the hazard. Included is one of the more important aspects of an industrial hygiene program: the methods used to evaluate the extent of exposure to harmful chemical and physical agents. Basic information is given on the various types of instruments available to measure these stresses and on how to use the instruments properly to obtain valid measurements.

Part Five deals with the control of the environmental hazards. Although industrial hygiene problems vary, the basic principles of health hazard control, problem-solving techniques, and the examples of engineering control measures given here are general enough to have wide application. To augment the basics, specific information is covered in the chapters on industrial ventilation.

Part Six is directed specifically to people responsible for conducting and organizing occupational health and safety programs. The fundamental concepts of the roles of the industrial hygienist, the occupational health nurse, the safety professional, and the occupational medicine physician in implementing a successful program are discussed in detail. Particular attention is paid to a discussion of the practice of industrial hygiene in the public and private sectors and to a description of the professional certification of industrial hygienists.

Part Seven contains up-to-date information on government regulations and their impact on the practice of industrial hygiene.

Appendix A provides additional resources. One of the most difficult parts of getting any project started is finding sources of help and information. For this reason, we have included a completely updated and comprehensive annotated bibliography and a listing of professional and service organizations, government agencies, and other resources.

Other appendixes include the ACGIH Threshold Limit Values (TLVs®) and Biological Exposure Indices (BEIs®), a review of mathematics, instructions on conversion of units, and a glossary of terms used in industrial hygiene, occupational health, and pollution control. An extensive index is included to assist the reader in locating information in this text.

We would like to gratefully acknowledge the work of the contributors to previous editions of the *Fundamentals of Industrial Hygiene*.

First Edition

1—Fundamental Concepts of Industrial Hygiene—Julian B. Olishifski, PE
2—Solvents and Health in the Occupational Environment— Donald R. McFee, ScD3—Pneumoconiosis-Producing Dusts—Fred Cook, MS
4—Industrial Dermatitis—Charles W. Wyman, BS
5—Industrial Noise—Herbert T. Walworth, MS

6—Basic Concepts of Ionizing Radiation Safety—E. L. Alpaugh, PE
7—Nonionizing Radiation: Lasers, Microwaves, Light—Julian B. Olishifski, PE
8—Effects of Temperature Extremes—E. L. Alpaugh, PE
9—Ergonomics Stresses: Physical and Mental—Julian B. Olishifski, PE
10—Evaluating the Hazard—J. B. Olishifski, PE
11—Toxicology—J. B. Olishifski, PE
12—General Methods of Control—J. B. Olishifski, PE
13—Respiratory Protective Equipment—A. M. Lundin, BS
14—Industrial Ventilation—W. G. Hazard, AM
15—General Ventilation and Special Operations—W. G. Hazard, AM
20—Setting Up an Industrial Hygiene Program—Julian B. Olishifski, PE
21—Sources of Information on Industrial Hygiene—Julian B. Olishifski, PE

Second Edition
1—Fundamental Concepts—Julian B. Olishifski, PE
2—The Lungs—Julian B. Olishifski, PE
3—The Skin—Julian B. Olishifski, PE
4—The Ear—Julian B. Olishifski, PE
5—The Eyes—Julian B. Olishifski, PE
6—Solvents—Donald R. McFee, ScD
7—Particulates— Edwin L. Alpaugh, PE
8—Industrial Dermatoses—Larry L. Hipp
9—Industrial Noise—Julian B. Olishifski, PE
10—Ionizing Radiation—C. Lyle Cheever, MS, MBA
11—Nonionizing Radiation—Edward J. Largent and Julian B. Olishifski, PE
12—Temperature Extremes—Edwin L. Alpaugh, PE
13—Ergonomics—Bruce A. Hertig
14—Biological Hazards—Alvin L. Miller, PhD, CIH and Anne C. Leopold
15—Industrial Toxicology—Ralph G. Smith and Julian B. Olishifski, PE
16—Evaluation— Edward R. Hermann, CE, PhD, PE, CIH and Jack E. Peterson, PhD, PE, CIH
17—Methods of Evaluation—Julian B. Olishifski, PE
18—Air-Sampling Instruments—Julian B. Olishifski, PE
19—Direct-Reading Gas and Vapor Monitors—Joseph E. Zatek, CSP, CIH, CHCM, CHM
20—Methods of Control—Julian B. Olishifski, PE
21—Industrial Ventilation—Willis G. Hazard, AM
22—General Ventilation—Willis G. Hazard, AM
23—Respiratory Protective Equipment—Allen M. Lundin, BS
24—Governmental Regulations—M. Chain Robbins, BS, MPH, CSP, PE
25—The Industrial Hygienist—Clyde M. Berry
26—The Safety Professional—Willis T. McLean
27—The Occupational Physician—Carl Zenz, MD, ScD
28—The Occupational Health Nurse—Jeanette M. Cornyn
29—Industrial Hygiene Program—Edward J. Largent and Julian B. Olishifski, PE
30—Sources of Information—Julian B. Olishifski, PE and Robert Pedroza

Third Edition
1—Overview of Industrial Hygiene—Barbara Plog, MPH, CIH, CSP
2—The Lungs—George S. Benjamin, MD, FACS
3—The Skin—James S. Taylor, MD
4—The Ears—George S. Benjamin, MD, FACS
5—The Eyes—George S. Benjamin, MD, FACS
6—Solvents—Donald R. McFee, ScD, CIH, PE, CSP; Peter Zavon, CIH
7—Particulates—Theodore J. Hogan, PhD, CIH

8—Industrial Dermatoses—James S. Taylor, MD
9—Industrial Noise—John J. Standard, MS, MPH, CIH, CSP
10—Ionizing Radiation—C. Lyle Cheever, MS, MBA
11—Nonionizing Radiation—Larry E. Anderson, PhD
12—Temperature Extremes—Theodore J. Hogan, PhD, CIH
13—Ergonomics—Karl H. E. Kroemer, PhD
14—Biological Hazards—Alvin L. Miller, PhD, CIH; Cynthia S. Volk
15—Industrial Toxicology—Carl Zenz, MD, ScD
16—Evaluation—Edward R. Hermann, CE, PhD, PE, CIH; Jack E. Peterson, PhD, PE, CIH
17—Methods of Evaluation—Julian B. Olishifski, MS, PE, CSP
18—Air-Sampling Instruments—Maureen A. Kerwin (now Maureen A. Huey), MPH
19—Direct-Reading Gas and Vapor Monitors—Joseph E. Zatek, CSP, CIH, CHCM, CHM
20—Methods of Control—Julian B. Olishifski, MS, PE, CSP
21—Industrial Ventilation—D. Jeff Burton, PE, CIH
22—General Ventilation —D. Jeff Burton, PE, CIH
23—Respiratory Protective Equipment—Craig E. Colton, CIH
24—The Industrial Hygienist—Barbara A. Plog, MPH, CIH, CSP
25—The Safety Professional—Fred A. Manuele, PE, CSP
26—The Occupational Physician—Carl Zenz, MD
27—The Occupational Health Nurse—Larry Hannigan, RN
28—The Industrial Hygiene Program—Maureen A. Kerwin (now Maureen A. Huey), MPH
29—Computerizing an Industrial Hygiene Program—Adrienne Whyte, PhD
30—Governmental Regulations—M. Chain Robbins, BS, MPH, CSP, PE
31—Occupational Safety and Health: The Federal Regulatory Program—A History—Benjamin W. Mintz

Fourth Edition
1—Overview of Industrial Hygiene—Barbara A. Plog, MPH, CIH, CSP
2—The Lungs—George S. Benjamin, MD, FACS
3—The Skin and Occupational Dermatoses—James S. Taylor, MD
4—The Ears—George S. Benjamin, MD, FACS, and Barry J. Benjamin, MD, FACS
5—The Eyes—George S. Benjamin, MD, FACS
6—Industrial Toxicology—Richard Cohen, MD, MPH, and Kameron Balzer, CIH
7—Gases, Vapors, and Solvents—George S. Fulton, MS, CIH
8—Particulates—Theodore J. Hogan, PhD, CIH
9—Industrial Noise—John Standard, MS, MPH, CIH, CSP
10—Ionizing Radiation—C. Lyle Cheever, MS, MBA
11—Nonionizing Radiation—Gordon Miller, CIH
12—Thermal Stress—Thomas E. Bernard, PhD, CIH
13—Ergonomics—Karl H. E. Kroemer, PhD
14—Biological Hazards—A. Lynn Harding, MPH, Diane O. Fleming, PhD, and Janet M. Macher, ScD, MPH
15—Evaluation—Elizabeth R. Gross, CIH, Elise Pechter, CIH
16—Air-Sampling—Maureen A. Huey, MPH, CIH
17—Direct-Reading Instruments for Gases, Vapors, and Particulates—Rolfe M.A. Hahne, PhD, CIH
18—Methods of Control—Susan M. Raterman, CIH, REPA
19—Local Exhaust Ventilation of Industrial Occupancies—D. Jeff Burton, PE, CIH, CSP

20—General Ventilation of Industrial Occupancies—D. Jeff Burton, PE, CIH, CSP
21—General Ventilation of Nonindustrial Occupancies—D. Jeff Burton, PE, CIH, CSP
22—Respiratory Protection—Craig E. Colton, CIH
23—The Industrial Hygienist—Jill Niland, MPH, CIH, CSP
24—The Safety Professional—Peter B. Rice, CIH, CSP
25—The Occupational Physician—Carl Zenz, MD
26—Occupational Health Nursing—Barbara J. Burgel, RN, MS, COHN
27—The Industrial Hygiene Program—Maureen A. Huey, MPH
28—Computerizing an Industrial Hygiene Program—Adrienne A.Whyte, PhD
29—Governmental Regulations—Gabriel J. Gillotti, PE
30—Occupational Safety and Health: The Federal Regulatory Program—A History—Benjamin W. Mintz
Appendix A—Deborah Gold, MPH, and Donna Iverson
Appendix E—European Union Initiatives in Occupational Health and Safety—Robin S. Coyne, CIH, ROH, LIH

We would also like to thank Ron Miller and George Kraficsin, who reviewed material for the fifth edition: special thanks to Patty Quinlan and Jodey Schonfeld, whose excellent work, tireless attention to technical detail, and professionalism, helped to make this edition the best yet.

And finally, this book is dedicated to my family, Michael and Max, who again supported having "the book" in our lives over the past two years; and my mother and father, Doris and Henry Plog; and to the working women and men who are, after all, the point of it all.

Because this manual will be revised periodically, contributions and comments from readers are welcome.

BARBARA A. PLOG, MPH, CIH, CSP
EDITOR IN CHIEF
DECEMBER 2001

Contributors

John R. Balmes, MD, is a Professor of Medicine at the University of California, San Francisco (UCSF) where he is the Chief of the Division of Occupational and Environmental Medicine at San Francisco General Hospital, Director of the Occupational Medicine Residency program, and an Attending Physician on the Pulmonary/Critical Care Service at San Francisco General Hospital. Dr. Balmes leads an active research program involving controlled human exposure studies of the respiratory effects of ambient air pollutants in his Human Exposure Laboratory at the UCSF Lung Biology Center. He also collaborates on several epidemiological projects involving the effects of air pollution on respiratory health at the University of California-Berkeley where he is Director of the Northern California Center for Occupational and Environmental Health.

Thomas E. Bernard, PhD, CIH, joined the University of South Florida faculty in 1989. He offers classes in the industrial hygiene program with major responsibilities for ergonomics, physical agents and controls. His active research programs involve the evaluation of heat stress and strain, the role of clothing in heat stress assessment, and ergonomics. He also tries to promote the practice of industrial hygiene through active participation in professional associations. Previously, he worked for Westinghouse Electric Corporation and the United States Bureau of Mines.

Barbara J. Burgel, RN, MS, COHN-S, FAAN, is a Clinical Professor and Adult Nurse Practitioner in the Department of Community Health Systems at the University of California San Francisco School of Nursing. Ms. Burgel has taught in the Occupational Health Nursing graduate program since 1981. Ms. Burgel is currently providing clinical care and ergonomic interventions to Asian immigrant garment workers in a free clinic in the Oakland, California, Chinatown district.

C. Lyle Cheever CIH-ret, MS, MBA, is retired from Argonne National Laboratory where his work from 1957 to 1998 included project manager for decommissioning of radioactive materials facilities, radioactive and hazardous waste manager, associate director of Occupational Health and Safety, and Industrial Hygiene supervisor.

Richard Cohen, MD, MPH, is a Clinical Professor of Medicine at the University of California, San Francisco. He also lectures at Stanford University School of Medicine. Dr. Cohen is board certified in both Occupational Medicine and

General Preventive Medicine. He has been a member of the CAL/OSHA PEL Advisory Committee and is a Fellow in the American College of Occupational and Environmental Medicine. He provides expertise in industrial toxicology and occupational medicine to industry, particularly in the pharmaceutical, biotechnology and electronics sectors.

Craig E. Colton, CIH, is a Certified Industrial Hygienist in the Regulatory Affairs and Training group of the 3M Occupational Health and Environmental Safety Division with 22 years of experience specializing in respiratory protection. His responsibilities as a senior technical service specialist include conducting workplace protection factor studies on 3M respirators, monitoring and responding to regulatory affairs related to respiratory protection, and providing technical assistance to respirator users. Before joining the 3M staff, he was an instructor at the OSHA Training Institute where he was course chair for respiratory protection. He also quantitatively fit tested OSHA personnel. Colton has also taught continuing education courses for the University of North Carolina and University of California-Berkeley. He is a past chair of the AIHA Respiratory Protection Committee, and America's Section of the International Society for Respiratory Protection, and was a member of the ANSI Z88.12 subcommittee for Respiratory Protection for Infectious Aerosols. He is currently a member of the ANSI Z88 Committee for Respiratory Protection.

Marjorie De Groot received her Masters Degree in Audiology from the University of Colorado in 1985. She has worked in various medical settings performing both diagnostic and rehabilitative audiology. Currently Ms. De Groot is employed at the San Francisco General Occupational Health Service as director of the Hearing Conservation Program. She is a member of the American Academy of Audiology, the California Academy of Audiology and the National Hearing Conservation Association.

Diane O. Fleming, Ph.D, CBSP (ABSA), became active in biosafety and infection-control in the late 1970s at Wright State University in Ohio, as Chairman of their Institutional Biosafety Committee. She served as Biosafety Officer and Assistant Director of Safety for the Johns Hopkins University and Medical Center, and as Biosafety Manager for Frederick Cancer Research and Development Center, Sterling Drug, and Merck & Co, Inc.. Dr. Fleming is now an independent biosafety consultant for academic, government and industrial clients. She is the past-president of ABSA and two local affiliates, ChABSA and MABSA. From 1990–97, she was Chairman of the ASM subcommittee on Laboratory Safety. Diane has published articles in peer-reviewed journals and chapters in books dealing with biosafety. She is co-editor of the third edition of *Biological Safety: Principles and Practices,* published by the ASM.

Gabriel J. Gillotti is the Director of the Voluntary Programs and Outreach Unit in the U.S. Department of Labor's Region IX Office of OSHA located in San Francisco, California. Mr. Gillotti received a Bachelor of Science degree in Civil Engineering and a Bachelor of Arts degree in Mathematics in 1959 from the University of Notre Dame, Notre Dame, Indiana. He spent four years as a construction engineer for the California Department of Water Resources working on the California Aqueduct system, followed by a number of years as a safety engineer with the California State Division of Industrial Safety and the Boeing Company. In 1970, he joined the U.S. Department of Labor as an industry representative on a Task Force assigned the responsibility to draft and publish safety and health standards and compliance regulations under the Construction Safety and the OSHA Acts of 1969 and 1970 respectively. Since 1971 he has been an adminis-

trator in the San Francisco Regional Office. Currently, as the Director of the Voluntary Programs and Outreach office, he and his staff are responsible for interacting with the public and private sector via speech-making, external training, engaging in partnerships, support Voluntary Protection Programs and other outreach initiatives. Over those 30 years, Mr. Gillotti has made hundreds of presentations and presented papers before local, national, and international groups on the subject of workplace safety and health. Mr. Gillotti is a Registered Professional Engineer in California. He is also the recipient of a Distinguished Career Service award from the Secretary of Labor.

Deborah Gold is a Senior Industrial Hygienist at Cal/OSHA. She is a member of the ACGIH and the APHA.

Elizabeth Gross is Director of Environmental Health and Safety at Dana-Farber Cancer Institute in Boston, a biomedical research and clinical facility. Prior to working at Dana-Farber, she was Assistant Industrial Hygienist at Harvard University. In both capacities, she has evaluated and helped control a broad range of potential exposures to workers. In addition, Ms. Gross is a Visiting Lecturer at both Harvard and Boston University Schools of Public Health, where she lectures on Fundamentals of Industrial Hygiene, Laboratory, Hospital, and Office Health and Safety. She has also been an active participant in the American Industrial Hygiene Association, the Harvard School of Public Health Industrial Hygiene Program Advisory Board, the American Board of Industrial Hygiene, the Academy of Industrial Hygiene, and the Joint Industrial Hygiene Ethics Education Committee. She is a CIH, has an MS in Industrial Hygiene from Harvard School of Public Health, an MA from the University of California-Berkeley, and a BA from the University of Michigan.

Rolf M.A. Hahne, PhD, CIH, is Director, Environmental Health Laboratory and Lecturer, Department of Environmental Health, School of Public Health and Community Medicine, University of Washington. He received his BS from Stanford University, an MA from Columbia University, and a PhD from the University of Wisconsin. He has been working in industrial hygiene and environmental health for 29 years in both the public and private sectors, including work with the Dow Chemical Company, Pan American World Airways, the University of Iowa, and the University of Washington.

S. Katharine Hammond, PhD, CIH, is Professor of Environmental Health Sciences at the University of California-Berkeley School of Public Health. Dr. Hammond directs the industrial hygiene program at University of California-Berkeley. She is a chemist; her research focuses on exposure assessment for epidemiological studies. She has developed new methods for collecting and analyzing chemicals in the workplace and assessing exposures without airborne measurements. Among the major research projects are the relationship between diesel exhaust and lung cancer among railroad workers; the rates of spontaneous abortion among women who work in wafer fabricating clean rooms and their exposures to a variety of chemical, physical and ergonomic agents; respiratory health effects of automobile assembly work; methods to reduce workers' exposure to lead during bridge rehabilitation; unintended consequences of environmental regulations on occupational exposures; environmental tobacco smoke exposure in the workplace and elsewhere.

A. Lynn Harding, B.Sc., MPH, CBSP (ABSA), is an independent biosafety consultant, has extensive experience working with corporate and academic institutions to develop, implement, and evaluate biosafety programs, facilities, and

training materials. Prior to consulting, she was the Director of the Biological Safety Office and Acting Director of the Environmental Health and Safety Department at Harvard University. Early in her career she worked at several Harvard teaching hospitals, MIT, and the Wright Fleming Institute of Microbiology in London on research associated with nosocomial infections, bacterial vaccine development and folic acid metabolism. An active member of the American Biological Safety Association, she has also served on EPA and RAC taskforces associated with infectious waste and animal and plant containment. She has published on subjects such as laboratory acquired infections, biosafety in research laboratories, infections associated with *Hemophilus influenzae,* and the development of research tools to study nosocomial infections.

Michael J. Horowitz, MS, CIH, is a District Manager for the California OSHA program. He has been an industrial hygienist with Cal/OSHA for the past 12 years. He is also a second-generation industrial hygienist.

Donna Iverson earned a Bachelor of Arts degree in Geography at the University of California-Berkeley. This has served her well in mapping the dangers and pitfalls inherent in the world of Occupational Safety and Health. She was University of California-Berkeley's Labor Occupational Health Program Librarian for 10 years, and is currently in charge of scheduling and logistics for LOHP's Lead-Safe Schools Training Project.

Sarah Jewell, MD, MPH, is board-certified in Internal Medicine and Occupational/Environmental Medicine. She is an Assistant Clinical Professor of Medicine at the University of California, San Francisco and is the Medical Director of the Occupational Health Service at San Francisco General Hospital.

Rick Kelly MS, CIH, is a Certified Industrial Hygienist. He provides limited consultation services, especially training, course development and writing, such as the "Particulates" chapter, in this edition. In his professional capacity, he provides industrial hygiene services to the Chemistry and Material Sciences and Decontamination and Demolition organizations at Lawrence Livermore National Laboratories.

Prior to this post, Rick was the Supervisor of Industrial Hygiene and Safety at the University of California at Berkeley. He was also the founder and interim director of an EPA-grant initiated health and safety training program at the University of California-Berkeley Extension. He is widely recognized as an expert on peroxidizable chemicals and perchlorate-contaminated ventilation system testing and demolition.

Peggy F. Kivel, CIH, is a Certified Industrial Hygienist with more than 18 years of experience in the field of industrial hygiene. She has served as the Regional Manager for IHI Environmental in the San Francisco Bay Area for the past 12 years. Ms. Kivel has extensive experience in the areas of worker exposure assessments, indoor air quality investigations and hazardous materials management. Prior to working at IHI Environmental, Ms. Kivel was a Staff Industrial Hygienist at IBM Corporation in San Jose, California, providing support for major manufacturing, development and research divisions. She has a Bachelor of Arts degree from the University of California-Berkeley.

Karl H. E. Kroemer, CPE, Ph.D. (Dr.-Ing.) 1965, MS (Dipl.-Ing.) 1960, BS (Vordiplom) 1957, all from the Technical University Hanover, Germany, is Professor Emeritus of Industrial and Systems Engineering, Virginia Tech, Director, Ergonomics Research Institute, Inc. He is a Certified Professional

Ergonomist, CPE. Fellow, HFES and ES; a member of the AIHA; and an honorary member, International Society for Occupational Ergonomics and Safety. He has written more than 200 publications and obtained two patents. His international consulting experience includes work in engineering anthropometry, applied physiology, biomechanics, human factors engineering, and office ergonomics.

Janet Macher ScD, MPH, is an air pollution research specialist with the California Department of Health Services. She has a Master's Degree from the University of California and doctorate from Harvard University with emphasis on industrial hygiene, public health, and microbiology. Dr. Macher studies engineering measures to control airborne infectious and hypersensitivity diseases, evaluates methods to collect and identify airborne biological material, and participates in investigations of bioaerosol-related illnesses in the state of California.

Barbara Materna, PhD, CIH, has provided industrial hygiene expertise within governmental public health programs at the state and local level since 1981. She is currently Chief of the Occupational Lead Poisoning Prevention Program in the Occupational Health Branch, California Department of Health Services. Her work has been focused on preventing occupational health problems including perchloroethylene exposure in dry cleaning, toxic exposures in wildland firefighting, injuries among refuse collectors, pesticide illness, and occupational lead poisoning. Dr. Materna is also interested in occupational health and safety issues among small business employers, intervention effectiveness, and construction health and safety.

H.J. (Hank) McDermott CIH, CSP, PE, currently is the Team Leader, Occupational Safety & Health, Chevron Research & Technology Co., Richmond, California. He has more than 30 years of safety and industrial hygiene experience in industry and the U.S. Air Force, where he served as a bioenvironmental engineering officer. He has a Bachelor of Science degree in Civil Engineering from the University of Delaware, an Master of Science in Civil Engineering from Northwestern, and an Master of Art in Public Administration from the University of New Mexico. He is the author of the *Handbook of Ventilation for Contaminant Control* (3rd edition), published by the American Conference of Governmental Industrial Hygienists, and is a Fellow of the American Industrial Hygiene Association.

Benjamin W. Mintz is now Professor of Law, Columbus School of Law, the Catholic University of America. He was previously and relevantly Associate Solicitor for Occupational Safety and Health at the U.S. Department of Labor. He published a book, *OSHA: History, Law and Policy* and a number of other articles on OSHA. He is a graduate of the Columbia Law School and also has a rabbinical degree from Yeshivah University.

Linda Morse, MD, is board certified in Occupational Medicine and Chief of Occupational Health Services for Kaiser Permanente San Francisco. She is a Fellow of the American College of Occupational and Environmental Medicine and co-editor of *Occupational Injuries—Evaluation, Management and Prevention,* published by Mosby in 1995. She has lectured and written widely on diverse topics including firefighter health and safety, cumulative trauma disorders of the neck and upper extremity, and the role of the treating physician in the workers' compensation system, and is an Assistant Clinical Professor of Medicine at the University of California, San Francisco, Medical Center.

Jill Niland has more than 20 years of experience in industrial hygiene and occupational health. She is principal consultant and partner in CDIC Chicago, an occupational safety and health consulting firm, which focuses on training,

auditing and program development using new technologies. Previously she was senior industrial hygiene consultant at the National Safey Council in Itasca, Illinois, where she was also an associate editor of the 4th edition of *Fundamentals of Industrial Hygiene*. In prior positions at Zurich American Insurance, and at Alexander and Alexander, an insurance broker, she provided industrial hygiene services to clients in a wide variety of industries. Ms. Niland received a Bachelor of Arts degree from Cornell University, Ithaca, New York, and a Masters in Public Health degree from the University of Illinois in Chicago.

Elise Pechter, CIH, is a Certified Industrial Hygienist who works for the Occupational Health Surveillance Program at the Massachusetts Department of Public Health. In this capacity she coordinates intervention activities in response to work-related asthma, teen injuries, and acute chemical poisonings, integrating occupational health into public health. A member of ACGIH, NEAIHA, and APHA, Ms. Pechter is on the executive board of the Harriet Hardy Institute, member of the Health/Technical committee of MassCOSH, and chair of the Advisory Board for the Work Environment Justice Fund. In addition, Elise works on several other projects: occupational cancer prevention in an NCI funded small business intervention project, identifying occupational asthma triggers, and providing health and safety training for vocational teachers at an annual conference.

Barbara A Plog, MPH, CIH, CSP, is a Certified Industrial Hygienist and a Certified Safety Professional and has been in the field of occupational health for 20 years. She is the Director of the Continuing Professional Education Program of the Center for Occupational and Environmental Health (COEH) at the University of California-Berkeley School of Public Health. COEH is a NIOSH Education and Research Center. Ms Plog is a Lecturer in the School of Public Health's industrial hgyiene program and an assistant clinical professor at the University of California-San Francisco School of Nursing's Occupational Health Nursing program. She teaches Industrial Hygiene and Occupational Safety to graduate students in industrial hygiene and occupational health nursing. She also serves as the Associate Director for Technical Services for the Labor Occupational Health Program and is the Technical Director and Principal Investigator for the Lead-Safe Schools Program. She holds a Masters of Public Health Degree in Industrial Hygiene from the University of Illinois School of Public Health. Before coming to the University of California-Berkeley in 1987, Ms. Plog was manager of Occupational Health at the National Safety Council for five years. She is editor-in-chief of the 1,000-plus page textbook, *Fundamentals of Industrial Hygiene,* 3rd, 4th, and 5th editions.

Patricia J. Quinlan, CIH, is a Certified Industrial Hygienist in the Division of Occupational and Environmental Medicine at the University of California, San Francisco. She also holds an appointment as Associate Clinical Professor, in the Department of Community Health Systems, School of Nursing, University of California-San Francisco. Patricia has been active in the field of industrial hygiene for 20 years. She has been with University of California-San Francisco since 1987. Prior to University of California-San Francisco, she was the industrial hygienist for the Labor Occupational Health Program at University of California-Berkeley, from 1982–1987. She is a Certified Industrial Hygienist (CIH) and has been active in a number of committees of the AIHA and APHA Occupational Health Section. She is a member of the California OSHA Statewide Advisory and Airborne Contaminants Advisory Committees.

Susan M. Raterman, CIH, is the founder and President of The Raterman Group, Ltd., an industrial hygiene and environmental hazard consulting firm. The Raterman Group, Ltd. specializes in the areas of comprehensive industrial

hygiene consulting, asbestos and lead hazard assessments and remediation oversight, and indoor air and water quality evaluations. Ms. Raterman provides management and technical expertise in industrial hygiene and environmental health to clients in the commercial, industrial and public sectors. Additionally, she provides compliance program development and training, and expert testimony and litigation support to clients on environmental issues. Ms. Raterman is Certified in the Comprehensive Practice of Industrial Hygiene by the American Industrial Hygiene Association, and is an Illinois Environmental Protection Agency Licensed Industrial Hygienist. She is also a Registered Environmental Property Assessor with the National Registry of Environmental Professionals, and is an Illinois Department of Public Health Licensed Asbestos Building Inspector/Management Planner and Asbestos Project Designer. She attained a Master of Science Degree in Environmental Health Engineering from Northwestern University in Evanston, Illinois, and a Bachelor of Arts in Biology from St. Louis University in St. Louis, Missouri. Ms. Raterman is member of the Advisory Council of Robert D. McCormick School of Engineering and Applied Science of Northwestern University. She is a member of the American Industrial Hygiene Association, the American Board of Industrial Hygiene, the International Facility Management Association, and is on the Board of Directors for Chicago Real Estate Executive Women.

Pete Rice, CIH, has 25 years of experience in developing, implementing, and supervising environmental and occupational safety and industrial hygiene programs. He has participated in the recognition, evaluation, and control of safety and health practices and procedures on hundreds of various industrial, construction, and waste cleanup projects involving chemical, physical, biological, ergonomic, and safety hazards. In addition, Mr. Rice has been partly responsible for developing Cal/OSHA health standards for respiratory protection, ventilation, hazard communication, and asbestos. Mr. Rice most recently managed Harding Lawson Associates' domestic and international Safety and Industrial Hygiene Programs. Mr. Rice currently serves as the Director for Environmental, Health and Safety Services for ClickSafety (www.clicksafety.com). A leader in distance occupational safety and health learning, Mr. Rice teaches industrial hygiene and safety at the university level (University of California-Berkeley) and has trained numerous industrial hygienists and safety professionals. He formerly acted as the senior technical industrial hygienist, safety professional, and chief training officer for Cal/OSHA. He is Certified Industrial Hygienist - American Board of Industrial Hygiene 1981, No. 2156 Certified Safety Professional - Board of Certified Safety Professionals 1984, No. 7287 Registered Environmental Health Specialist - California 1977, No. 4265 Registered Environmental Assessor - California 1989, No.01050 California Community College Instructor Credential MS, Environmental and Occupational Health and Safety, California State University, Northridge, 1977, Bachelor of Science, Environmental Health and Biology, California State University, Northridge, 1976.

James S. Taylor, MD, is Head, Section of Industrial Dermatology, Cleveland Clinic Foundation. He is a graduate of the Indiana University School of Medicine, completed his dermatology residency at the Cleveland Clinic, is certified by the American Board of Dermatology and previously served as an industrial dermatologist with NIOSH. He is a member of the North American Contact Dermatitis Group, the National Occupational Research Agenda Allergic and Irritant Dermatitis Panel, the AMA Committee to Revise the *Guides to the Evaluation of Permanent Impairment*, and the Board of Directors of the American Academy of Dermatology. He is past president of the American Contact Dermatitis Society, is the author of 185 scientific publications and serves as a consultant to industry and government.

Vic Toy is a program manager for Global Occupational Health Services for the IBM Corporation. He has been involved with managing industrial hygiene programs and services, setting corporate policies and practices, and most recently, with the implementation of a global occupational health and safety management system. His background spans 20 years of diverse industrial hygiene experience in government and industry. He has delivered a number of presentations at professional meetings and has lectured at San Jose State University and University of California-Berkeley's Labor Occupational Health Program. He is a Fellow of the American Industrial Hygiene Association and a past President of the Academy of Industrial Hygiene. Mr. Toy holds a Bachelor of Science degree in Environmental Sciences from the University of California at Berkeley and a Masters in Public Health in Industrial Hygiene from the University of Michigan. He is certified in Comprehensive Practice by the American Board of Industrial Hygiene and in Management Aspects by the Board of Certified Safety Professionals.

Michael Yost, MS, PhD, is an Associate Professor in the Department of Environmental Health at the University of Washington, as well as the Director of the Industrial Hygiene and Safety program. His interests include optical remote sensing of chemicals in the environment, and physical agents, such as noise, vibration, and nonionizing radiation, in the workplace. Prior to joining the University of Washington in 1993, Dr. Yost was a Research Industrial Hygienist and a Lecturer in the School of Public Health at the University of California-Berkeley. He also served as a Reader at University of California-Berkeley's Department of Electrical Engineering and Computer Sciences. Dr. Yost's current research projects focus on developing novel tools for environmental and occupational exposure assessment. These projects include the development of a workplace open-path Fourier transform infra-red spectroscope, measurements of pesticide spray aerosols using light detection and ranging, occupational exposures to electromagnetic fields, and noise and vibration exposures in forestry workers.

Allison S. Zaum, OD, MPH, CIH (retired), received a Doctor of Optometry degree from the School of Optometry at the University of California-Berkeley, in 1998. Prior to becoming an optometrist, she worked for many years as an industrial hygienist, both in the pharmaceutical industry and in the semiconductor industry. She received a Masters in Public Health. in Environmental Health Sciences from the School of Public Health at the University of California-Berkeley in 1981, and was certified in Comprehensive Practice by the American Board of Industrial Hygiene. Her undergraduate education was at Brandeis University, where she received a Bachelor of Arts in Biology in 1979. Dr. Zaum currently is in private practice.

History and Development

Part I

Chapter 1

Overview of Industrial Hygiene

by Barbara A. Plog, MPH, CIH, CSP

Industrial hygiene is that science and art devoted to the anticipation, recognition, evaluation, and control of those environmental factors or stresses arising in or from the workplace that may cause sickness, impaired health and well-being, or significant discomfort among workers or among the citizens of the community. Industrial hygienists are occupational health professionals who are concerned primarily with the control of environmental stresses or occupational health hazards that arise as a result of or during the course of work. The industrial hygienist recognizes that environmental stresses may endanger life and health, accelerate the aging process, or cause significant discomfort.

The industrial hygienist, although trained in engineering, physics, chemistry, environmental sciences, safety, or biology, has acquired through postgraduate study or experience a knowledge of the health effects of chemical, physical, biological, and ergonomic agents. The industrial hygienist is involved in the monitoring and analysis required to detect the extent of exposure, and the engineering and other methods used for hazard control.

Evaluation of the magnitude of work-related environmental hazards and stresses is done by the industrial hygienist, aided by training, experience, and quantitative measurement of the chemical, physical, ergonomic, or biological stresses. The industrial hygienist can thus give an expert opinion as to the degree of risk the environmental stresses pose.

Industrial hygiene includes the development of corrective measures in order to control health hazards by either reducing or eliminating the exposure. These control procedures may include the substitution of harmful or toxic materials with less dangerous ones, changing of work processes to eliminate or minimize work exposure, installation of exhaust ventilation systems, good housekeeping (including appropriate waste disposal methods), and the provision of proper personal protective equipment.

An effective industrial hygiene program involves the anticipation and recognition of health hazards arising from work operations and processes, evaluation and measurement of the

magnitude of the hazard (based on past experience and study), and control of the hazard.

Occupational health hazards *may mean conditions that cause legally compensable illnesses, or may mean any conditions in the workplace that impair the health of employees enough to make them lose time from work or to cause significant discomfort. Both are undesirable. Both are preventable. Their correction is properly a responsibility of management.*

PROFESSIONAL ETHICS

In late 1994, the four major U.S. industrial hygiene organizations gave final endorsements to a revised Code of Ethics for the Practice of Industrial Hygiene. These organizations are the American Conference of Governmental Industrial Hygienists (ACGIH), the American Academy of Industrial Hygiene (AAIH), the American Board of Industrial Hygiene (ABIH), and the American Industrial Hygiene Association (AIHA).

The new code defines practice standards (Canons of Ethical Conduct) and applications (interpretive guidelines). The Canons of Ethical Conduct are as follows:

Industrial Hygienists shall practice their profession following recognized scientific principles with the realization that the lives, health, and well-being of people may depend upon their professional judgment and that they are obligated to protect the health and well-being of people.

Industrial Hygienists shall counsel affected parties factually regarding potential health risks and precautions necessary to avoid adverse health effects.

Industrial Hygienists shall keep confidential personal and business information obtained during the exercise of industrial hygiene activities, except when required by law or overriding health and safety considerations.

Industrial Hygienists shall avoid circumstances where a compromise of professional judgment or conflict of interest may arise.

Industrial Hygienists shall perform services only in the areas of their competence.

Industrial Hygienists shall act responsibly to uphold the integrity of the profession.

The interpretive guidelines to the Canons of Ethical Conduct are a series of statements that amplify the code (Figure 1–1).

The Occupational Health and Safety Team

The chief goal of an occupational health and safety program in a facility is to prevent occupational injury and illness by anticipating, recognizing, evaluating, and controlling occupational health and safety hazards. The medical, industrial hygiene, and safety programs may have distinct, additional program goals but all programs interact and are often considered different components of the overall health and safety program. The occupational health and safety team consists, then, of the industrial hygienist, the safety professional, the occupational health nurse, the occupational medicine physician, the employees, senior and line management, and others depending on the size and character of the particular facility. All team members must act in concert to provide information and activities, supporting the other parts to achieve the overall goal of a healthy and safe work environment. Therefore, the separate functions must be administratively linked in order to effect a successful and smoothly run program.

The first vital component to an effective health and safety program is the commitment of *senior management* and *line management*. Serious commitment is demonstrated when management is visibly involved in the program both by management support and personal compliance with all health and safety practices. Equally critical is the assignment of the authority, as well as the responsibility, to carry out the health and safety program. The health and safety function must be given the same level of importance and accountability as the production function.

The function of the *industrial hygienist* has been defined above. (Also see Chapter 23, The Industrial Hygienist.) The industrial hygiene program must be made up of several key components: a written program/policy statement, hazard recognition procedures, hazard evaluation and exposure assessment, hazard control, employee training, employee involvement, program evaluation and audit, and recordkeeping. (See Chapter 27, The Industrial Hygiene Program, for further discussion.)

The *safety professional* must draw upon specialized knowledge in the physical and social sciences. Knowledge of engineering, physics, chemistry, statistics, mathematics, and principles of measurement and analysis is integrated in the evaluation of safety performance. The safety professional must thoroughly understand the factors contributing to accident occurrence and combine this with knowledge of motivation, behavior, and communication in order to devise methods and procedures to control safety hazards. Because the practice of the safety professional and the industrial hygienist are so closely related, it is rare to find a safety professional who does not practice some traditional industrial hygiene and vice versa. At times, the safety and industrial hygiene responsibilities may be vested in the same individual or position. (See Chapter 24, The Safety Professional.)

The *occupational health nurse* (OHN) is the key to the delivery of comprehensive health care services to workers. Occupational health nursing is focused on the promotion, protection, and restoration of workers' health within the context of a safe and healthy work environment. The OHN provides the critical link between the employee's health status, the work process, and the determination of employee ability to do the job. Knowledge of health and safety regulations, workplace hazards, direct care skills, counseling, teaching, and program management are but a few of the key knowledge areas for the OHN, with strong communication

Code of Ethics for the Practice of Industrial Hygiene

Objective

These canons provide standards of ethical conduct for Industrial Hygienists as they practice their profession and exercise their primary mission, to protect the health and well-being of working people and the public from chemical, microbiological, and physical health hazards present at, or emanating from, the workplace.

Canons of ethical conduct

CANON 1

Industrial Hygienists shall practice their profession following recognized scientific principles with the realization that the lives, health, and well-being of people may depend upon their professional judgment and that they are obligated to protect the health and well-being of people.

INTERPRETIVE GUIDELINES

- Industrial Hygienists should base their professional opinions, judgments, interpretations of findings, and recommendations upon recognized scientific principles and practices which preserve and protect the health and well-being of people.
- Industrial Hygienists shall not distort, alter, or hide facts in rendering professional opinions or recommendations.
- Industrial Hygienists shall not knowingly make statements that misrepresent or omit facts.

CANON 2

Industrial Hygienists shall counsel affected parties factually regarding potential health risks and precautions necessary to avoid adverse health effects.

INTERPRETIVE GUIDELINES

- Industrial Hygienists should obtain information regarding potential health risks from reliable sources.
- Industrial Hygienists should review the pertinent, readily available information to factually inform the affected parties.
- Industrial Hygienists should initiate appropriate measures to see that the health risks are effectively communicated to the affected parties.
- Parties may include management, clients, employees, contractor employees, or others, dependent on circumstances at the time.

CANON 3

Industrial Hygienists shall keep confidential personal and business information obtained during the exercise of industrial hygiene activities, except when required by law or overriding health and safety considerations.

INTERPRETIVE GUIDELINES

- Industrial Hygienists should report and communicate information which is necessary to protect the health and safety of workers and the community.
- If their professional judgment is overruled under circumstances where the health and lives of people are endangered, Industrial Hygienists shall notify their employer, client, or other such authority, as may be appropriate.
- Industrial Hygienists should release confidential personal or business information only with the information owners express authorization, except when there is a duty to disclose information as required by law or regulation.

CANON 4

Industrial Hygienists shall avoid circumstances where a compromise of professional judgment or conflict of interest may arise.

INTERPRETIVE GUIDELINES

- Industrial Hygienists should promptly disclose known or potential conflicts of interest to parties that may be affected.
- Industrial Hygienists shall not solicit or accept financial or other valuable consideration from any party, directly or indirectly, which is intended to influence professional judgment.
- Industrial Hygienists shall not offer any substantial gift, or other valuable consideration, in order to secure work.
- Industrial Hygienists should advise their clients or employer when they initially believe a project to improve industrial hygiene conditions will not be successful.
- Industrial Hygienists should not accept work that negatively impacts the ability to fulfill existing commitments.
- In the event that this Code of Ethics appears to conflict with another professional code to which Industrial Hygienists are bound, they will resolve the conflict in the manner that protects the health of affected parties.

CANON 5

Industrial Hygienists shall perform services only in the areas of their competence.

INTERPRETIVE GUIDELINES

- Industrial Hygienists should undertake to perform services only when qualified by education, training, or experience in the specific technical fields involved, unless sufficient assistance is provided by qualified associates, consultants, or employees.
- Industrial Hygienists shall obtain appropriate certifications, registrations, and/or licenses as required by federal, state, and/or local regulatory agencies prior to providing industrial hygiene services, where such credentials are required.
- Industrial Hygienists shall affix or authorize the use of their seal, stamp, or signature only when the document is prepared by the Industrial Hygienist or someone under their direction and control.

CANON 6

Industrial Hygienists shall act responsibly to uphold the integrity of the profession.

INTERPRETIVE GUIDELINES

- Industrial Hygienists shall avoid conduct or practice which is likely to discredit the profession or deceive the public.
- Industrial Hygienists shall not permit use of their name or firm name by any person or firm which they have reason to believe is engaging in fraudulent or dishonest industrial hygiene practices.
- Industrial Hygienists shall not use statements in advertising their expertise or services containing a material misrepresentation of fact or omitting a material fact necessary to keep statements from being misleading.
- Industrial Hygienists shall not knowingly permit their employees, employers, or others to misrepresent the individuals' professional background, expertise, or services which are misrepresentations of fact.
- Industrial Hygienists shall not misrepresent their professional education, experience, or credentials.

Figure 1–1. The joint Code of Ethics for the Practice of Industrial Hygiene endorsed by the AIHA, the ABIH, the AAIH, and the ACGIH. (From *ACGIH Today!* 3(1), January 1995.) These guidelines may be supplemented when necessary, as ethical issues and claims arise.

skills of the utmost importance. OHNs deliver high-quality care at worksites and support the primary prevention dictum that most workplace injuries and illnesses are preventable. If injuries occur, OHNs use a case-management approach to return injured employees to appropriate work on a timely basis. The OHN often functions in multiple roles within one job position, including clinician, educator, manager, and consultant. (See Chapter 26, The Occupational Health Nurse.)

The *occupational medicine physician* has acquired, through graduate training or experience, extensive knowledge of cause and effect relationships of chemical, physical, biological, and ergonomic hazards, the signs and symptoms of chronic and acute exposures, and the treatment of adverse effects. The primary goal of the occupational medicine physician is to prevent occupational illness and, when illness occurs, to restore employee health within the context of a healthy and safe workplace. Many regulations provide for a minimum medical surveillance program and specify mandatory certain tests and procedures.

The occupational medicine physician and the occupational health nurse should be familiar with all jobs, materials, and processes used. An occasional workplace inspection by the medical team enables them to suggest protective measures and aids them in recommending placement of employees in jobs best suited to their physical capabilities. (See discussion of the Americans with Disabilities Act in Chapter 26, The Occupational Health Nurse.)

Determining the work-relatedness of disease is another task for the occupational medicine physician. The industrial hygienist provides information about the manufacturing operations and work environment of a company to the medical department as well. In many cases it is extremely difficult to differentiate between the symptoms of occupational and nonoccupational disease. The industrial hygienist supplies information on the work operations and their associated hazards and enables the medical department to correlate the employee's condition and symptoms with potential workplace health hazards.

The *employee* plays a major role in the occupational health and safety program. Employees are excellent sources of information on work processes and procedures and the hazards of their daily operations. Industrial hygienists benefit from this source of information and often obtain innovative suggestions for controlling hazards.

The *safety and health committee* provides a forum for securing the cooperation, coordination, and exchange of ideas among those involved in the health and safety program. It provides a means of involving employees in the program. The typical functions of the safety and health committee include, among others, to examine company safety and health issues and recommend policies to management, conduct periodic workplace inspections, and evaluate and promote interest in the health and safety program. Joint labor–management safety and health committees are often used where employees are represented by a union. The committee meetings also present an opportunity to discuss key industrial hygiene program concerns and to formulate appropriate policies.

FEDERAL REGULATIONS

Before 1970, government regulation of health and safety matters was largely the concern of state agencies. There was little uniformity in codes and standards or in the application of these standards. Almost no enforcement procedures existed.

On December 29, 1970, the Occupational Safety and Health Act, known as the OSHAct, was enacted by Congress. Its purpose was to "assure so far as possible every working man and woman in the nation safe and healthful working conditions and to preserve our human resources." The OSHAct sets out two duties for employers:

- Each employer shall furnish to each employee a place of employment, which is free from recognized hazards that are causing or are likely to cause death or serious harm to their employees.
- Each employer shall comply with occupational safety and health standards under the Act.

For employees, the OSHAct states that "Each employee shall comply with occupational safety and health standards and all rules, regulations, and orders issued pursuant to the Act which are applicable to his own actions and conduct."

The Occupational Safety and Health Administration (OSHA) came into official existence on April 28, 1971, the date the OSHAct became effective. It is housed within the U.S. Department of Labor. The OSHAct also established the National Institute for Occupational Safety and Health (NIOSH), which is housed within the Centers for Disease Control and Prevention (CDC). The CDC is part of the U.S. Public Health Service.

OSHA was empowered to promulgate safety and health standards with technical advice from NIOSH. OSHA is empowered to enter workplaces to investigate alleged violations of these standards and to perform routine inspections. Formal complaints of standards violations may be made by employees or their representatives. The OSHAct also gives OSHA the right to issue citations and penalties, provide for employee walkarounds or interview of employees during the inspection, require employers to maintain accurate records of exposures to potentially hazardous materials, and to inform employees of the monitoring results. OSHA is also empowered to provide up to 50/50 funding with states that wish to establish state OSHA programs that are at least as effective as the federal program. As of this date, there are 23 approved state plans and approved plans from Puerto Rico and the Virgin Islands.

NIOSH is the principal federal agency engaged in occupational health and safety research. The agency is responsible for identifying hazards and making recommendations for

regulations. These recommendations are called Recommended Exposure Limits (RELs). NIOSH also issues criteria documents and health hazard alerts on various hazards and is responsible for testing and certifying respiratory protective equipment.

Part of NIOSH research takes place during activities called *Health Hazard Evaluations*. These are on-the-job investigations of reported worker exposures that are carried out in response to a request by either the employer or the employee or employee representative. In addition to its own research program, NIOSH also funds supportive research activities at a number of universities, colleges, and private facilities.

NIOSH has training grant programs in colleges and universities across the nation. These are located at designated Education and Research Centers (ERCs). ERCs train occupational medicine physicians, occupational health nurses, industrial hygienists, safety professionals, ergonomists, and others in the safety and health field. They also provide continuing professional education for practicing occupational health and safety professionals. (See Chapter 28, Government Regulations, and Chapter 29, History of the Federal Occupational Safety and Health Administration, for a full discussion of federal agencies and regulations.)

ENVIRONMENTAL FACTORS OR STRESSES

The various environmental factors or stresses that can cause sickness, impaired health, or significant discomfort in workers can be classified as chemical, physical, biological, or ergonomic.

Chemical hazards. These arise from excessive airborne concentrations of mists, vapors, gases, or solids in the form of dusts or fumes. In addition to the hazard of inhalation, some of these materials may act as skin irritants or may be toxic by absorption through the skin.

Physical hazards. These include excessive levels of nonionizing radiation (see Chapter 10), ionizing radiation (see Chapter 11), noise (see Chapter 9), vibration, and extremes of temperature (see Chapter 12) and pressure.

Ergonomic hazards. These include improperly designed tools, work areas, or work procedures. Improper lifting or reaching, poor visual conditions, or repeated motions in an awkward position can result in accidents or illnesses in the occupational environment. Designing the tools and the job to fit the worker is of prime importance. Engineering and biomechanical principles must be applied to eliminate hazards of this kind (see Chapter 13).

Biological hazards. These are any living organism or its properties that can cause an adverse response in humans. They can be part of the total environment or associated with a particular occupation. Work-related illnesses due to biological agents have been widely reported, but in many workplaces their presence and resultant illness are not well recognized. It is estimated that the population at risk for occupational biohazards may be several hundred million workers worldwide (see Chapter 14).

Exposure to many of the harmful stresses or hazards listed can produce an immediate response due to the intensity of the hazard, or the response can result from longer exposure at a lower intensity.

In certain occupations, depending on the duration and severity of exposure, the work environment can produce significant subjective responses or strain. The energies and agents responsible for these effects are called environmental stresses. An employee is most often exposed to an intricate interplay of many stresses, not to a single environmental stress.

Chemical Hazards

The majority of occupational health hazards arise from inhaling chemical agents in the form of vapors, gases, dusts, fumes, and mists, or by skin contact with these materials. The degree of risk of handling a given substance depends on the magnitude and duration of exposure. (See Chapter 15, Evaluation, for more details.)

To recognize occupational factors or stresses, a health and safety professional must first know about the chemicals used as raw materials and the nature of the products and by-products manufactured. This sometimes requires great effort. The required information can be obtained from the Material Safety Data Sheet (MSDS) (Figure 1–2) that must be supplied by the chemical manufacturer or importer for all hazardous materials under the OSHA hazard communication standard. The MSDS is a summary of the important health, safety, and toxicological information on the chemical or the mixture ingredients. Other stipulations of the hazard communication standard require that all containers of hazardous substances in the workplace be labeled with appropriate warning and identification labels. See Chapter 28, Government Regulations, and Chapter 29, History of the Federal Occupational Safety and Health Administration, for further discussion of the hazard communication standard.

If the MSDS or the label does not give complete information but only trade names, it may be necessary to contact the manufacturer to obtain this information.

Many industrial materials such as resins and polymers are relatively inert and nontoxic under normal conditions of use, but when heated or machined, they may decompose to form highly toxic by-products. Information about these hazardous products and by-products must also be included in the company's hazard communication program.

Breathing of some materials can irritate the upper respiratory tract or the terminal passages of the lungs and the air sacs, depending upon the solubility of the material. Contact of irritants with the skin surface can produce various kinds of dermatitis.

The presence of excessive amounts of biologically inert gases can dilute the atmospheric oxygen below the level required to maintain the normal blood saturation value for oxygen and disturb cellular processes. Other gases and vapors can prevent the blood from carrying oxygen to the tissues or interfere with its transfer from the blood to the tissue, thus producing chemical asphyxia or suffocation. Carbon monoxide and hydrogen cyanide are examples of chemical asphyxiants.

Some substances may affect the central nervous system and brain to produce narcosis or anesthesia. In varying degrees, many solvents have these effects. Substances are often classified, according to the major reaction they produce, as asphyxiants, systemic toxins, pneumoconiosis-producing agents, carcinogens, irritant gases, and so on.

SOLVENTS

This section discusses some general hazards arising from the use of solvents; a more detailed description is given in Chapter 7, Gases, Vapors, and Solvents.

Solvent vapors enter the body mainly by inhalation, although some skin absorption can occur. The vapors are absorbed from the lungs into the blood and are distributed mainly to tissues with a high content of fat and lipids, such as the central nervous system, liver, and bone marrow. Solvents include aliphatic and aromatic hydrocarbons, alcohols, aldehydes, ketones, chlorinated hydrocarbons, and carbon disulfide.

Occupational exposure can occur in many different processes, such as the degreasing of metals in the machine industry and the extraction of fats or oils in the chemical or food industry, dry cleaning, painting, and the plastics industry.

The widespread industrial use of solvents presents a major problem to the industrial hygienist, the safety professional, and others responsible for maintaining a safe, healthful working environment. Getting the job done using solvents without hazard to employees or property depends on the proper selection, application, handling, and control of solvents and an understanding of their properties.

A working knowledge of the physical properties, nomenclature, and effects of exposure is absolutely necessary in making a proper assessment of a solvent exposure. Nomenclature can be misleading. For example, benzine is sometimes mistakenly called benzene, a completely different solvent. Some commercial grades of benzine may contain benzene as a contaminant.

Use the information on the MSDS (Figure 1–2) or the manufacturer's label for the specific name and composition of the solvents involved.

The severity of a hazard in the use of organic solvents and other chemicals depends on the following factors:

- ➢ How the chemical is used
- ➢ Type of job operation, which determines how the workers are exposed
- ➢ Work pattern
- ➢ Duration of exposure
- ➢ Operating temperature
- ➢ Exposed liquid surface
- ➢ Ventilation rates
- ➢ Evaporation rate of solvent
- ➢ Pattern of airflow
- ➢ Concentration of vapor in workroom air
- ➢ Housekeeping

The hazard is determined not only by the toxicity of the solvent or chemical itself but by the conditions of its use (who, what, how, where, and how long).

The health and safety professional can obtain much valuable information by observing the manner in which health hazards are generated, the number of people involved, and the control measures in use.

After the list of chemicals and physical conditions to which employees are exposed has been prepared, determine which of the chemicals or agents may result in hazardous exposures and need further study.

Dangerous materials are chemicals that may, under specific circumstances, cause injury to persons or damage to property because of reactivity, instability, spontaneous decomposition, flammability, or volatility. Under this definition, we will consider substances, mixtures, or compounds that are explosive, corrosive, flammable, or toxic.

Explosives are substances, mixtures, or compounds capable of entering into a combustion reaction so rapidly and violently as to cause an explosion.

Corrosives are capable of destroying living tissue and have a destructive effect on other substances, particularly on combustible materials; this effect can result in a fire or explosion.

Flammable liquids are liquids with a flash point of 100 F (38 C) or less, although those with higher flash points can be both combustible and dangerous.

Toxic chemicals are gases, liquids, or solids that, through their chemical properties, can produce injurious or lethal effects on contact with body cells.

Oxidizing materials are chemicals that decompose readily under certain conditions to yield oxygen. They may cause a fire in contact with combustible materials, can react violently with water, and when involved in a fire can react violently.

Dangerous gases are those that can cause lethal or injurious effects and damage to property by their toxic, corrosive, flammable, or explosive physical and chemical properties.

Storage of dangerous chemicals should be limited to one day's supply, consistent with the safe and efficient operation of the process. The storage should comply with applicable local laws and ordinances. An approved storehouse should be provided for the main supply of hazardous materials.

For hazardous materials, MSDSs can be consulted for toxicological information. The information is useful to the medical, purchasing, managerial, engineering, and health and safety departments in setting guidelines for safe use of these materials. This information is also very helpful in an emergency. The information should cover materials actually

Material Safety Data Sheet

May be used to comply with OSHA's Hazard Communication Standard, 29 CFR 1910.1200. Standard must be consulted for specific requirements.

in use and those that may be contemplated for early future use. Possibly the best and earliest source of information concerning such materials is the purchasing agent. Thus, a close liaison should be set up between the purchasing agent and health and safety personnel so that early information is available concerning materials in use and those to be ordered, and to ensure that MSDSs are received and reviewed for all hazardous substances.

TOXICITY VERSUS HAZARD

The toxicity of a material is not synonymous with its hazard. *Toxicity* is the capacity of a material to produce injury or harm when the chemical has reached a sufficient concentration at a certain site in the body. *Hazard* is the probability that this concentration in the body will occur. This degree of hazard is determined by many factors or elements. (See Chapter 6, Industrial Toxicology.)

The key elements to be considered when evaluating a health hazard are as follows:

- ➢ What is the route of entry of the chemical into the body?
- ➢ How much of the material must be in contact with a body cell and for how long to produce injury?
- ➢ What is the probability that the material will be absorbed or come in contact with body cells?
- ➢ What is the rate of generation of airborne contaminants?
- ➢ What control measures are in place?

The effects of exposure to a substance depend on dose, rate, physical state of the substance, temperature, site of absorption, diet, and general state of a person's health.

Physical Hazards

Problems caused by such things as noise, temperature extremes, ionizing radiation, nonionizing radiation, and pressure extremes are physical stresses. It is important that the employer, supervisor, and those responsible for safety and health be alert to these hazards because of the possible immediate or cumulative effects on the health of employees.

NOISE

Noise (unwanted sound) is a form of vibration conducted through solids, liquids, or gases. The effects of noise on humans include the following:

- ➢ Psychological effects (noise can startle, annoy, and disrupt concentration, sleep, or relaxation)
- ➢ Interference with speech communication and, as a consequence, interference with job performance and safety
- ➢ Physiological effects (noise-induced hearing loss, or aural pain when the exposure is severe)

Damage risk criteria. If the ear is subjected to high levels of noise for a sufficient period of time, some loss of hearing may occur. A number of factors can influence the effect of the noise exposure:

- ➢ Variation in individual susceptibility
- ➢ Total energy of the sound
- ➢ Frequency distribution of the sound
- ➢ Other characteristics of the noise exposure, such as whether it is continuous, intermittent, or made up of a series of impacts
- ➢ Total daily duration of exposure
- ➢ Length of employment in the noise environment

Because of the complex relationships of noise and exposure time to threshold shift (reduction in hearing level) and the many contributory causes, establishing criteria for protecting workers against hearing loss is difficult. However, criteria have been developed to protect against hearing loss in the speech-frequency range. These criteria are known as the Threshold Limit Values for Noise. (See Chapter 9, Industrial Noise, and Appendix B, The ACGIH Threshold Limit Values and Biological Exposure Indices, for more details.)

There are three nontechnical guidelines to determine whether the work area has excessive noise levels:

- ➢ If it is necessary to speak very loudly or shout directly into the ear of a person in order to be understood, it is possible that the exposure limit for noise is being exceeded. Conversation becomes difficult when the noise level exceeds 70 decibels (dBA).
- ➢ If employees say that they have heard ringing noises in their ears at the end of the workday, they may be exposed to too much noise.
- ➢ If employees complain that the sounds of speech or music seem muffled after leaving work, but that their hearing is fairly clear in the morning when they return to work, they may be exposed to noise levels that cause a partial temporary loss of hearing, which can become permanent with repeated exposure.

Permissible levels. The criteria for hearing conservation, required by OSHAct in 29 *CFR* 1910.95, establishes the permissible levels of harmful noise to which an employee may be subjected. The permissible decibel levels and hours (duration per day) are specified. For example, a noise level of 90 dBA is permissible for eight hours, 95 dBA for four hours, etc. (See Chapter 9, Industrial Noise, for more details.)

The regulations stipulate that when employees are subjected to sound that exceeds the permissible limits, feasible administrative or engineering controls shall be used. If such controls fail to reduce sound exposure within permissible levels, personal protective equipment must be provided and used to reduce sound levels to within permissible levels.

According to the Hearing Conservation Amendment to 29 *CFR* 1910.95, in all cases when the sound levels exceed 85 dBA on an eight-hour time-weighted average (TWA), a continuing, effective hearing conservation program shall be administered. The Hearing Conservation Amendment specifies the essential elements of a hearing conservation program. (See Chapter 9, Industrial Noise, for a discussion of noise and OSHA noise regulations.)

Administering a hearing conservation program goes beyond the wearing of earplugs or earmuffs. Such programs

can be complex, and professional guidance is essential for establishing programs that are responsive to the need. Valid noise exposure information correlated with audiometric tests results is needed to help health and safety and medical personnel to make informed decisions about hearing conservation programs.

The effectiveness of a hearing conservation program depends on the cooperation of employers, employees, and others concerned. Management's responsibility in such a program includes noise measurements, initiation of noise control measures, provision of hearing protection equipment, audiometric testing of employees to measure their hearing levels (thresholds), and information and training programs for employees.

The employee's responsibility is to properly use the protective equipment provided by management, and to observe any rules or regulations on the use of equipment in order to minimize noise exposure.

EXTREMES OF TEMPERATURE

Probably the most elementary factor of environmental control is control of the thermal environment in which people work. Extremes of temperature, or thermal stress, affect the amount of work people can do and the manner in which they do it. In industry, the problem is more often high temperatures rather than low temperatures. (More details on this subject are given in Chapter 12, Thermal Stress.)

The body continuously produces heat through its metabolic processes. Because the body processes are designed to operate only within a very narrow range of temperature, the body must dissipate this heat as rapidly as it is produced if it is to function efficiently. A sensitive and rapidly acting set of temperature-sensing devices in the body must also control the rates of its temperature-regulating processes. (This mechanism is described in Chapter 3, The Skin and Occupational Dermatoses.)

Heat stress is a common problem, as are the problems presented by a very cold environment. Evaluation of heat stress in a work environment is not simple. Considerably more is involved than simply taking a number of air-temperature measurements and making decisions on the basis of this information.

One question that must be asked is whether the temperature is merely causing discomfort or whether continued exposure will cause the body temperature to fall below or rise above safe limits. It is difficult for a person with only a clipboard full of data to interpret how another person actually feels or is adversely affected.

People function efficiently only in a very narrow body temperature range, a core temperature measured deep inside the body, not on the skin or at body extremities. Fluctuations in core temperatures exceeding 2 F below or 3 F above the normal core temperature of 99.6 F (37.6 C), which is 98.6 F (37 C) mouth temperature, impair performance markedly. If this five-degree range is exceeded, a health hazard exists.

The body attempts to counteract the effects of high temperature by increasing the heart rate. The capillaries in the skin also dilate to bring more blood to the surface so that the rate of cooling is increased. Sweating is an important factor in cooling the body.

Heatstroke is caused by exposure to an environment in which the body is unable to cool itself sufficiently. Heatstroke is a much more serious condition than heat cramps or heat exhaustion. An important predisposing factor is excessive physical exertion or moderate exertion in extreme heat conditions. The method of control is to reduce the temperature of the surroundings or to increase the ability of the body to cool itself, so that body temperature does not rise. In heatstroke, sweating may cease and the body temperature can quickly rise to fatal levels. It is critical to undertake emergency cooling of the body even while medical help is on the way. Studies show that the higher the body temperature on admission to emergency rooms, the higher the fatality rate. Heatstroke is a life-threatening medical emergency.

Heat cramps can result from exposure to high temperature for a relatively long time, particularly if accompanied by heavy exertion, with excessive loss of salt and moisture from the body. Even if the moisture is replaced by drinking plenty of water, an excessive loss of salt can cause heat cramps or heat exhaustion.

Heat exhaustion can also result from physical exertion in a hot environment. Its signs are a mildly elevated temperature, pallor, weak pulse, dizziness, profuse sweating, and cool, moist skin.

ENVIRONMENTAL MEASUREMENTS

In many heat stress studies, the variables commonly measured are work energy metabolism (often estimated rather than measured), air movement, air temperature, humidity, and radiant heat. See Chapter 12, Thermal Stress, for illustrations and more details.

Air movement is measured with some type of anemometer and the air temperature with a thermometer, often called a *dry bulb thermometer*.

Humidity, or the moisture content of the air, is generally measured with a psychrometer, which gives both dry bulb and wet bulb temperatures. Using these temperatures and referring to a psychrometric chart, the relative humidity can be established.

The term *wet bulb* is commonly used to describe the temperature obtained by having a wet wick over the mercury-well bulb of an ordinary thermometer. Evaporation of moisture in the wick, to the extent that the moisture content of the surrounding air permits, cools the thermometer to a temperature below that registered by the dry bulb. The combined readings of the dry bulb and wet bulb thermometers are then used to calculate percent relative humidity, absolute moisture content of the air, and water vapor pressure.

Radiant heat is a form of electromagnetic energy similar to light but of longer wavelength. Radiant heat (from such

sources as red-hot metal, open flames, and the sun) has no appreciable heating effect on the air it passes through, but its energy is absorbed by any object it strikes, thus heating the person, wall, machine, or whatever object it falls on. Protection requires placing opaque shields or screens between the person and the radiating surface.

An ordinary dry bulb thermometer alone will not measure radiant heat. However, if the thermometer bulb is fixed in the center of a metal toilet float that has been painted dull black, and the top of the thermometer stem protrudes outside through a one-hole cork or rubber stopper, radiant heat can be measured by the heat absorbed in this sphere. This device is known as a globe thermometer.

Heat loss. Conduction is an important means of heat loss when the body is in contact with a good cooling agent, such as water. For this reason, when people are immersed in cold water, they become chilled much more rapidly and effectively than when exposed to air of the same temperature.

Air movement cools the body by convection: The moving air removes the air film or the saturated air (which is formed very rapidly by evaporation of sweat) and replaces it with a fresh air layer capable of accepting more moisture from the skin.

Heat stress indices. The methods commonly used to estimate heat stress relate various physiological and environmental variables and end up with one number that then serves as a guide for evaluating stress. For example, the effective temperature index combines air temperature (dry bulb), humidity (wet bulb), and air movement to produce a single index called an effective temperature.

Another index is the wet bulb globe temperature (WBGT). The numerical value of the WBGT index is calculated by the following equations.

Indoors or outdoors with no solar loads:

$$WBGT_{in} = 0.7\ T_{nwb} + 0.3\ T_{gt}$$

Outdoors with solar load:

$$WBGT_{out} = 0.7\ T_{nwb} + 0.2\ T_{gt} + 0.1\ T_{db}$$

where

T_{nwb} = natural wet bulb temperature
T_{gt} = globe temperature
T_{db} = dry bulb temperature

In its *Criteria Document on Hot Environments* (see Bibliography), NIOSH states that when impermeable clothing is worn, the WBGT should not be used because evaporative cooling would be limited. The WBGT combines the effects of humidity and air movement, air temperature and radiation, and air temperature. It has been successfully used for environmental heat stress monitoring at military camps to control heat stress casualties. The measurements are few and easy to make; the instrumentation is simple, inexpensive, and rugged; and the calculations are straightforward. It is also the index used in the *ACGIH Threshold Limit Values* (TLVs®) *for Chemical Substances and Physical Agents and Biological Exposure Indices* (BEIs®) book (see Appendix B). The ACGIH recommends TLVs for continuous work in hot environments as well as when 25, 50, or 75 percent of each working hour is at rest. Regulating allowable exposure time in the heat is a viable technique for permitting necessary work to continue under heat-stress conditions that would be intolerable for continuous exposure. The NIOSH criteria document also contains a complete recommended heat stress control program including work practices.

Work practices include acclimation periods, work and rest regimens, distribution of work load with time, regular breaks of a minimum of one per hour, provision for water intake, protective clothing, and application of engineering controls. Experience has shown that workers do not stand a hot job very well at first, but develop tolerance rapidly through acclimation and acquire full endurance in a week to a month. (For more details, see Chapter 12, Thermal Stress, and the NIOSH criteria document.)

COLD STRESS

Generally, the answer to a cold work area is to supply heat where possible, except for areas that must be cold, such as food storage areas.

General hypothermia is an acute problem resulting from prolonged cold exposure and heat loss. If an individual becomes fatigued during physical activity, he or she will be more prone to heat loss, and as exhaustion approaches, sudden vasodilation (blood vessel dilation) occurs with resultant rapid loss of heat.

Cold stress is proportional to the total thermal gradient between the skin and the environment because this gradient determines the rate of heat loss from the body by radiation and convection. When vasoconstriction (blood vessel constriction) is no longer adequate to maintain body heat balance, shivering becomes an important mechanism for increasing body temperature by causing metabolic heat production to increase to several times the resting rate.

General physical activity increases metabolic heat. With clothing providing the proper insulation to minimize heat loss, a satisfactory microclimate can be maintained. Only exposed body surfaces are likely to be excessively chilled and frostbitten. If clothing becomes wet either from contact with water or due to sweating during intensive physical work, its cold-insulating property is greatly diminished.

Frostbite occurs when the skin tissues freeze. Theoretically, the freezing point of the skin is about 30 F (1 C); however, with increasing wind velocity, heat loss is greater and frostbite occurs more rapidly. Once started, freezing progresses rapidly. For example, if the wind velocity reaches 20 mph, exposed flesh can freeze within about 1 minute at 14 F (10 C). Furthermore, if the skin comes in direct contact with objects whose surface temperature is below the freezing point, frostbite can develop at the point of contact despite

warm environmental temperatures. Air movement is more important in cold environments than in hot because the combined effect of wind and temperature can produce a condition called *windchill*. The windchill index should be consulted by everyone facing exposure to low temperature and strong winds. (See Chapter 12, Thermal Stress.)

IONIZING RADIATION

A brief description of ionizing radiation hazards is given in this section; for a complete description, see Chapter 10, Ionizing Radiation.

To understand a little about ionization, recall that the human body is made up of various chemical compounds that are in turn composed of molecules and atoms. Each atom has a nucleus with its own outer system of electrons.

When ionization of body tissues occurs, some of the electrons surrounding the atoms are forcibly ejected from their orbits. The greater the intensity of the ionizing radiation, the more ions are created and the more physical damage is done to the cells.

Light consisting of electromagnetic radiation from the sun that strikes the surface of the earth is very similar to x-rays and gamma-radiation; it differs only in wavelength and energy content. (See description in Chapter 11, Nonionizing Radiation.) However, the energy level of sunlight at the earth's surface is too low to disturb orbital electrons, so sunlight is not considered ionizing even though it has enough energy to cause severe skin burns over a period of time.

The exact mechanism of the manner in which ionization affects body cells and tissue is complex. At the risk of oversimplifying some basic physical principles and ignoring others, the purpose of this section is to present enough information so the health and safety professional will recognize the problems involved and know when to call on health physicists or radiation safety experts for help.

At least three basic factors must be considered in such an approach to radiation safety:

- ➢ Radioactive materials emit energy that can damage living tissue.
- ➢ Different kinds of radioactivity present different kinds of radiation safety problems. The types of ionizing radiation we will consider are alpha-, beta-, x-ray, and gamma-radiation, and neutrons.
- ➢ Radioactive materials can be hazardous in two different ways. Certain materials can be hazardous even when located some distance away from the body; these are external hazards. Other types are hazardous only when they get inside the body through breathing, eating, or broken skin. These are called internal radiation hazards.

Instruments are available for evaluating possible radiation hazards. Meters or other devices are used for measuring radiation levels and doses.

Kinds of radioactivity. The five kinds of radioactivity that are of concern are alpha, beta, x-ray, gamma, and neutron. The first four are the most important because neutron sources usually are not used in ordinary manufacturing operations.

Of the five types of radiation mentioned, alpha-particles are the least penetrating. They do not penetrate thin barriers. For example, paper, cellophane, and skin stop alpha-particles.

Beta-radiation has considerably more penetrating power than alpha radiation. A quarter of an inch of aluminum can stop the more energetic betas. Virtually everyone is familiar with the penetrating ability of x rays and the fact that a barrier such as concrete or lead is required to stop them.

Gamma-rays are, for all practical purposes, the same as x rays and require the same kinds of heavy shielding materials.

Neutrons are very penetrating and have characteristics that make it necessary to use shielding materials of high hydrogen atom content rather than high mass alone.

Although the type of radiation from one radioactive material may be the same as that emitted by several other different radioactive materials, there may be a wide variation in energies.

The amount of energy a particular kind of radioactive material possesses is defined in terms of MeV (million electron volts); the greater the number of MeV, the greater the energy. Each radioactive material emits its own particular kinds of radiation, with energy measured in terms of MeV.

External versus internal hazards. Radioactive materials that emit x-rays, gamma-rays, or neutrons are external hazards. In other words, such materials can be located some distance from the body and emit radiation that produces ionization (and thus damage) as it passes through the body. Control by limiting exposure time, working at a safe distance, use of barriers or shielding, or a combination of all three is required for adequate protection against external radiation hazards.

As long as a radioactive material that emits only alpha-particles remains outside the body, it will not cause trouble. Internally, it is a hazard because the ionizing ability of alpha particles at very short distances in soft tissue makes them a veritable bulldozer. Once inside the body—in the lungs, stomach, or an open wound, for example—there is no thick layer of skin to serve as a barrier and damage results. Alpha-emitting radioactive materials that concentrate as persisting deposits in specific parts of the body are considered very hazardous.

Beta-emitters are generally considered an internal hazard although they also can be classed as an external hazard because they can produce burns when in contact with the skin. They require the same precautions as do alpha-emitters if there is a chance they can become airborne. In addition, some shielding may be required.

Measuring ionizing radiation. Many types of meters are used to measure various kinds of ionizing radiation. These

meters must be accurately calibrated for the type of radiation they are designed to measure.

Meters with very thin windows in the probes can be used to check for alpha-radiation. Geiger-Mueller and ionization chamber-type instruments are used for measuring beta-, gamma-, and x-radiation. Special types of meters are available for measuring neutrons.

Devices are available that measure accumulated amounts (doses) of radiation. Film badges are used as dosimeters to record the amount of radiation received from beta-, x-ray, or gamma-radiation and special badges are available to record neutron radiation.

Film badges are worn by a worker continuously during each monitoring period. Depending on how they are worn, they allow an estimate of an accumulated dose of radiation to the whole body or to just a part of the body, such as a hand or arm.

Alpha-radiation cannot be measured with film badges because alpha-particles do not penetrate the paper that must be used over the film emulsion to exclude light. (For more details on measurement and government regulations for ionizing radiation, see Chapter 10, Ionizing Radiation.)

NONIONIZING RADIATION

This is a form of electromagnetic radiation with varying effects on the body, depending largely on the wavelength of the radiation involved. In the following paragraphs, in approximate order of decreasing wavelength and increasing frequency, are some hazards associated with different regions of the nonionizing electromagnetic radiation spectrum. Nonionizing radiation is covered in detail by OSHAct regulations 29 *CFR* 1910.97, and in Chapter 11, Nonionizing Radiation.

Low frequency. Longer wavelengths, including powerline transmission frequencies, broadcast radio, and shortwave radio, can produce general heating of the body. The health hazard from these kinds of radiation is very small, however, because it is unlikely that they would be found in intensities great enough to cause significant effect. An exception can be found very close to powerful radio transmitter aerials.

Microwaves are found in radar, communications, some types of cooking, and diathermy applications. Microwave intensities may be sufficient to cause significant heating of tissues.

The effect is related to wavelength, power intensity, and time of exposure. Generally, longer wavelengths produce a greater penetration and temperature rise in deeper tissues than shorter wavelengths. However, for a given power intensity, there is less subjective awareness to the heat from longer wavelengths than there is to the heat from shorter wavelengths, because of the absorption of the longer wavelength radiation beneath the body's surface.

An intolerable rise in body temperature, as well as localized damage to specific organs, can result from an exposure of sufficient intensity and time. In addition, flammable gases and vapors can ignite when they are inside metallic objects located in a microwave beam.

Infrared radiation does not penetrate below the superficial layer of the skin, so its only effect is to heat the skin and the tissues immediately below it. Except for thermal burns, the health hazard of exposure to low-level conventional infrared radiation sources is negligible. (For information on possible damage to the eye, consult Chapter 11, Nonionizing Radiation.)

Visible radiation, which is about midway in the electromagnetic spectrum, is important because it can affect both the quality and accuracy of work. Good lighting conditions generally result in increased product quality with less spoilage and increased production.

Lighting should be bright enough for easy and efficient sight, and directed so that it does not create glare. Illumination levels and brightness ratios recommended for manufacturing and service industries are published by the Illuminating Engineering Society. (See Chapter 11, Nonionizing Radiation, for further information.)

One of the most objectionable features of lighting is glare (brightness in the field of vision that causes discomfort or interferes with seeing). The brightness can be caused by either direct or reflected light. To prevent glare, the source of light should be kept well above the line of vision or shielded with opaque or translucent material.

Almost as problematic is an area of excessively high brightness in the visual field. A highly reflective white paper in the center of a dark, nonreflecting surface or a brightly illuminated control handle on a dark or dirty machine are two examples.

To prevent such conditions, keep surfaces uniformly light or dark with little difference in surface reflectivity. Color contrasts are acceptable, however.

Although it is generally best to provide even, shadow-free light, some jobs require contrast lighting. In these cases, keep the general (or background) light well diffused and glareless and add a supplementary source of light that casts shadows where needed.

Ultraviolet radiation in industry can be found around electrical arcs, and such arcs should be shielded by materials opaque to ultraviolet. The fact that a material can be opaque to ultraviolet has no relation to its opacity to other parts of the spectrum. Ordinary window glass, for instance, is almost completely opaque to the ultraviolet in sunlight although transparent to the visible wavelengths. A piece of plastic dyed a deep red-violet may be almost entirely opaque in the visible part of the spectrum and transparent in the near-ultraviolet spectrum.

Electric welding arcs and germicidal lamps are the most common strong producers of ultraviolet radiation in industry. The ordinary fluorescent lamp generates a good deal of ultraviolet inside the bulb, but it is essentially all absorbed by the bulb and its coating.

The most common exposure to ultraviolet radiation is from direct sunlight, and a familiar result of overexposure—one that is known to all sunbathers—is sunburn. Most people are familiar with certain compounds and lotions that reduce the effects of the sun's rays, but many are unaware that some industrial materials, such as cresols, make the skin especially sensitive to ultraviolet rays. After exposure to cresols, even a short exposure in the sun usually results in a severe sunburn.

Lasers emit beams of coherent radiation of a single color or wavelength and frequency, in contrast to conventional light sources, which produce random, disordered light wave mixtures of various frequencies. The laser (an acronym for light amplification by stimulated emission of radiation) is made up of light waves that are nearly parallel to each other, all traveling in the same direction. Atoms are "pumped" full of energy, and when they are stimulated to fall to a lower energy level, they give off radiation that is directed to produce the coherent laser beam. (See Chapter 11, Nonionizing Radiation, for more details.)

The maser, the laser's predecessor, emits microwaves instead of light. Some companies call their lasers "optical masers." Because the laser is highly collimated (has a small divergence angle), it can have a large energy density in a narrow beam. Direct viewing of the laser source or its reflections should be avoided. The work area should contain no reflective surface (such as mirrors or highly polished furniture) because even a reflected laser beam can be hazardous. Suitable shielding to contain the laser beam should be provided. The OSHAct covers protection against laser hazards in its construction regulations.

Biological effects. The eye is the organ that is most vulnerable to injury by laser energy because the cornea and lens focus the parallel laser beam on a small spot on the retina. The fact that infrared radiation of certain lasers may not be visible to the naked eye contributes to the potential hazard.

Lasers generating in the ultraviolet range of the electromagnetic spectrum can produce corneal burns rather than retinal damage, because of the way the eye handles ultraviolet light. (See Chapter 11, Nonionizing Radiation.)

Other factors that affect the degree of eye injury induced by laser light are as follows:

- ➢ Pupil size (the smaller the pupil diameter, the less laser energy reaches the retina)
- ➢ The ability of the cornea and lens to focus the incident light on the retina
- ➢ The distance from the source of energy to the retina
- ➢ The energy and wavelength of the laser
- ➢ The pigmentation of the eye of the subject
- ➢ The location on the retina where the light is focused
- ➢ The divergence of the laser light
- ➢ The presence of scattering media in the light path

A discussion of laser beam characteristics and protective eyewear can be found in Chapter 11.

EXTREMES OF PRESSURE

It has been recognized from the beginning of caisson work (work performed in a watertight structure) that people working under pressures greater than normal atmospheric pressure are subject to various health effects. *Hyperbaric* (greater than normal pressure) environments are also encountered by divers who work under water, whether by holding the breath while diving, breathing from a self-contained underwater breathing apparatus (SCUBA), or by breathing gas mixtures supplied by compression from the surface.

Occupational exposures occur in caisson or tunneling operations, where a compressed gas environment is used to exclude water or mud and to provide support for structures. Humans can withstand large pressures if air has free access to lungs, sinuses, and the middle ear. Unequal distribution of pressure can result in barotrauma, a kind of tissue damage resulting from expansion or contraction of gas spaces within or adjacent to the body, which can occur either during compression (descent) or during decompression (ascent).

The teeth, sinuses, and ears are often affected by pressure differentials. For example, gas spaces adjacent to tooth roots or fillings may be compressed during descent. Fluid or tissue forced into these spaces can cause pain during descent or ascent. Sinus blockage caused by occlusion of the sinus aperture by inflamed nasal mucosa prevents equalization of pressures.

Under some conditions of work at high pressure, the concentration of carbon dioxide in the atmosphere can be considerably increased so that the carbon dioxide acts as a narcotic. Keeping the oxygen concentration high minimizes this condition, but does not prevent it. The procedure is useful where the carbon dioxide concentration cannot be kept at a proper level.

Decompression sickness, commonly called the bends, results from the release of nitrogen bubbles into the circulation and tissues during decompression. If the bubbles lodge at the joints and under muscles, they cause severe cramps. To prevent this, decompression is carried out slowly and by stages so that the nitrogen can be eliminated slowly, without forming bubbles.

Deep-sea divers are supplied with a mixture of helium and oxygen for breathing, and because helium is an inert diluent and less soluble in blood and tissue than is nitrogen, it presents a less formidable decompression problem.

One of the most common troubles encountered by workers under compressed air is pain and congestion in the ears from inability to ventilate the middle ear properly during compression and decompression. As a result, many workers subjected to increased air pressures suffer from temporary hearing loss; some have permanent hearing loss. This damage is believed to be caused by obstruction of the eustachian tubes, which prevents proper equalization of pressure from the throat to the middle ear.

The effects of reduced pressure on the worker are much the same as the effects of decompression from a high pressure. If

pressure is reduced too rapidly, decompression sickness and ear disturbances similar to the diver's conditions can result.

Ergonomic Hazards

Ergonomics literally means the study or measurement of work. It is the application of human biological science in conjunction with the engineering sciences to achieve the optimum mutual adjustment of people to their work, the benefits being measured in terms of human efficiency and well-being. The topic of ergonomics is covered briefly here. (For more details, see Chapter 13, Ergonomics.)

The ergonomics approach goes beyond productivity, health, and safety. It includes consideration of the total physiological and psychological demands of the job on the worker.

In the broad sense, the benefits that can be expected from designing work systems to minimize physical stress on workers are as follows:

- ➢ Reduced incidence of repetitive motion disorders
- ➢ Reduced injury rate
- ➢ More efficient operation
- ➢ Fewer accidents
- ➢ Lower cost of operation
- ➢ Reduced training time
- ➢ More effective use of personnel

The human body can endure considerable discomfort and stress and can perform many awkward and unnatural movements for a limited period of time. However, when awkward conditions or motions are continued for prolonged periods, they can exceed the worker's physiological limitations. To ensure a continued high level of performance, work systems must be tailored to human capacities and limitations.

Ergonomics considers the physiological and psychological stresses of the task. The task should not require excessive muscular effort, considering the worker's age, sex, and state of health. The job should not be so easy that boredom and inattention lead to unnecessary errors, material waste, and accidents. Ergonomic stresses can impair the health and efficiency of the worker just as significantly as the more commonly recognized environmental stresses.

The task of the design engineer and health and safety professional is to find the happy medium between "easy" and "difficult" jobs. In any human–machine system, there are tasks that are better performed by people than by machines and, conversely, tasks that are better handled by machines.

Ergonomics deals with the interactions between humans and such traditional environmental elements as atmospheric contaminants, heat, light, sound, and tools and equipment. People are the monitoring link of a human–machine environment system.

In any activity, a person receives and processes information, and then acts on it. The receptor function occurs largely through the sense organs of the eyes and the ear, but information can also be conveyed through the senses of smell, touch, or sensations of heat or cold. This information is conveyed to the central mechanism of the brain and spinal cord, where the information is processed to arrive at a decision. This can involve the integration of the information, which has already been stored in the brain, and decisions can vary from automatic responses to those involving a high degree of reasoning and logic.

Having received the information and processed it, the individual then takes action (control) as a result of the decision, usually through muscular activity based on the skeletal framework of the body. When an individual's activity involves the operation of a piece of equipment, the person often forms part of a "closed-loop servosystem," displaying many of the feedback characteristics of such a system. The person usually forms the part of the system that makes decisions, and thus has a fundamental part to play in the efficiency of the system.

BIOMECHANICS–PHYSICAL DEMANDS

Biomechanics can be a very effective tool in preventing excessive work stress. *Biomechanics* means the mechanics of biological organisms. It deals with the functioning of the structural elements of the body and the effects of external and internal forces on the various parts of the body.

Cumulative effects of excessive ergonomic stress on the worker can, in an insidious and subtle manner, result in physical illnesses and injuries such as "trigger finger," tenosynovitis, bursitis, carpal tunnel syndrome, and other cumulative trauma disorders.

Cases of excessive fatigue and discomfort are, in many cases, forerunners of soreness and pain. By exerting a strong distracting influence on a worker, these stresses can render the worker more prone to major accidents. Discomfort and fatigue tend to make the worker less capable of maintaining the proper vigilance for the safe performance of the task.

Some of the principles of biomechanics can be illustrated by considering different parts of the human anatomy, such as the hand.

Hand anatomy. The flexing action in the fingers is controlled by tendons attached to muscles in the forearm. The tendons, which run in lubricated sheaths, enter the hand through a tunnel in the wrist formed by bones and ligaments (the carpal tunnel) and continue on to point of attachment to the different segments, or phalanges, of the fingers (Figure 1–3).

When the wrist is bent toward the little finger side, the tendons tend to bunch up on one side of the tunnel through which they enter the hand. If an excessive amount of force is continuously applied with the fingers while the wrist is flexed, or if the flexing motion is repeated rapidly over a long period of time, the resulting friction can produce inflammation of the tendon sheaths, or tenosynovitis. This can lead to a disabling condition called carpal tunnel syndrome. (See Chapter 13, Ergonomics.)

The palm of the hand, which contains a network of nerves and blood vessels, should never be used as a hammer or

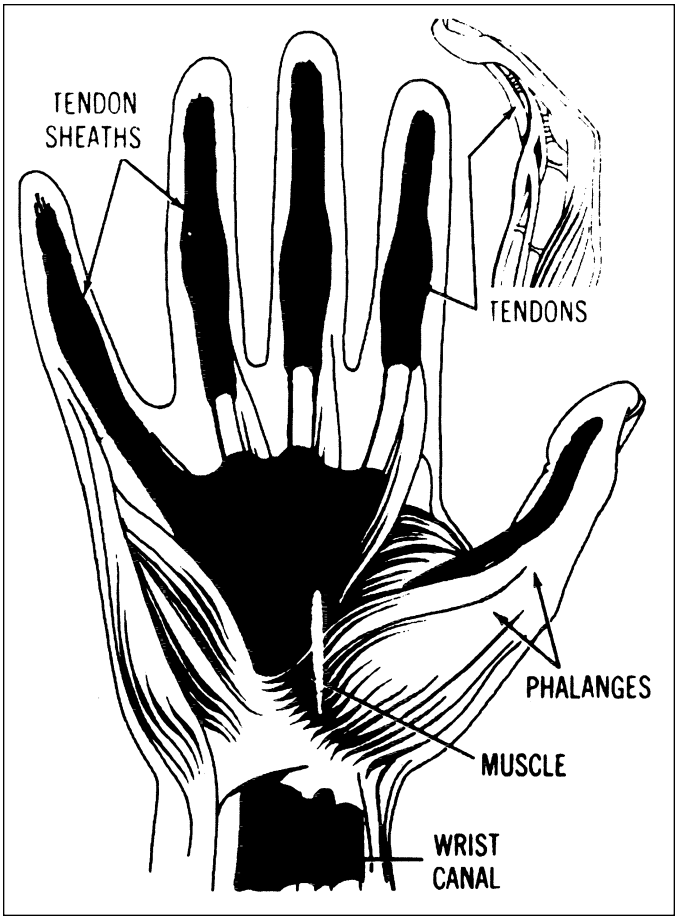

Figure 1–3. Diagram of hand anatomy.

subjected to continued firm pressure. Repetitive or prolonged pressure on the nerves and blood vessels in this area can result in pain either in the palm itself or at any point along the nerve pathways up through the arm and shoulder. Other parts of the body, such as the elbow joints and shoulders, can become painful for similar reasons.

Mechanical vibration. A condition known to stonecutters as "dead fingers" or "white fingers" (Raynaud's phenomenon) occurs mainly in the fingers of the hand used to guide the cutting tool. The circulation in this hand becomes impaired, and when exposed to cold the fingers become white and without sensation, as though mildly frostbitten. The white appearance usually disappears when the fingers are warmed for some time, but a few cases are sufficiently disabling that the victims are forced to seek other types of work. In many instances both hands are affected.

The condition has been observed in a number of other occupations involving the use of vibrating tools, such as the air hammers used for scarfing metal surfaces, the air chisels for chipping castings in the metal trades, and the chain saws used in forestry. The injury is caused by vibration of the fingers as they grip the tools to guide them in performing their tasks. The related damage to blood vessels can progress to nearly complete obstruction of the vessels.

Prevention should be directed at reducing the vibrational energy transferred to the fingers (perhaps by the use of padding) and by changing the energy and frequency of the vibration. Low frequencies, 25–75 hertz, are more damaging than higher frequencies.

Lifting. The injuries resulting from manual handling of objects and materials make up a large proportion of all compensable injuries. This problem is of considerable concern to the health and safety professional and represents an area where the biomechanical data relating to lifting and carrying can be applied in the work layout and design of jobs that require handling of materials. (For more details, see Chapter 13, Ergonomics, and the *Application Manual for the Revised NIOSH Lifting Equation*.)

The relevant data concerning lifting can be classified into task, human, and environmental variables.

➢ *Task variables*
- Location of object to be lifted
- Size of the object to be lifted
- Height from which and to which the object is lifted
- Frequency of lift
- Weight of object
- Working position

➢ *Human variables*
- Sex of worker
- Age of worker
- Training of worker
- Physical fitness or conditioning of worker
- Body dimensions, such as height of the worker

➢ *Environmental variables*
- Extremes of temperature
- Humidity
- Air contaminants

Static work. Another very fatiguing situation encountered in industry, which unfortunately is often overlooked, is static, or isometric, work. Because very little outward movement occurs, it seems that no muscular effort is involved. Often, however, such work generates more muscular fatigue than work involving some outward movement. A cramped working posture, for example, is a substantial source of static muscular loading.

In general, maintaining any set of muscles in a rigid, unsupported position for long periods of time results in muscular strain. The blood supply to the contracted muscle is diminished, a local deficiency of oxygen can occur, and waste products accumulate. Alternating static and dynamic work, or providing support for partial relaxation of the member involved, alleviates this problem.

Armrests are usually needed in two types of situations. One is the case just mentioned—to relieve the isometric muscular work involved in holding the arm in a fixed, unsupported

position for long periods of time. The second case is where the arm is pressed against a hard surface such as the edge of a bench or machine. The pressure on the soft tissues overlaying the bones can cause bruises and pain. Padded armrests have solved numerous problems of both types (see Figure 1–4).

WORKPLACE DESIGN

Relating the physical characteristics and capabilities of the worker to the design of equipment and to the layout of the workplace is another key ergonomic concept. When this is done, the result is an increase in efficiency, a decrease in human error, and a consequent reduction in accident frequency. However, several different types of information are needed: a description of the job, an understanding of the kinds of equipment to be used, a description of the kinds of people who will use the equipment, and the biological characteristics of these people.

In general, the first three items—job, equipment, and users—can be defined easily. The biological characteristics of the users, however, can often be determined satisfactorily only from special surveys that yield descriptive data on human body size and biomechanical abilities and limitations.

Anthropometric data. Anthropometric data consist of various heights, lengths, and breadths used to establish the minimum clearances and spatial accommodations, and the functional arm, leg, and body movements that are made by the worker during the performance of the task.

BEHAVIORAL ASPECTS—MENTAL DEMANDS

One important aspect of industrial machine design directly related to the safety and productivity of the worker is the design of displays and controls.

Design of displays. Displays are one of the most common types of operator input; the others include direct sensing and verbal or visual commands. Displays tell the operator what the machine is doing and how it is performing. Problems of display design are primarily related to the human senses.

A machine operator can successfully control equipment only to the extent that the operator receives clear, unambiguous information, when needed on all pertinent aspects of the task. Accidents, or operational errors, often occur because a worker has misinterpreted or was unable to obtain information from displays. Displays are usually visual, although they also can be auditory (for example, a warning bell rather than a warning light), especially when there is danger of overloading the visual sensory channels.

Design of Controls. An operator must decide on the proper course of action and manipulate controls to produce any desired change in the machine's performance. The efficiency and effectiveness—that is, the safety with which controls can be operated—depend on the extent to which information on the dynamics of human movement (or biomechanics) has been incorporated in their design. This is particularly true whenever controls must be operated at high speed, against large resistances, with great precision, or over long periods of time.

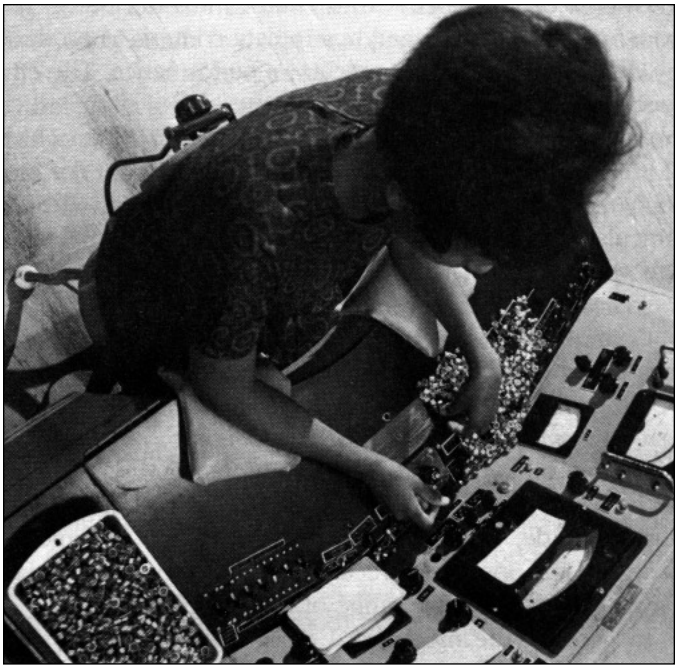

Figure 1–4. Worker uses pads to keep her forearm off the sharp table edge.

Controls should be designed so that rapid, accurate settings easily can be made without undue fatigue, thereby avoiding many accidents and operational errors. Because there is a wide variety of machine controls, ranging from the simple on–off action of pushbuttons to very complex mechanisms, advance analysis of the task requirements must be made. On the basis of considerable experimental evidence, it is possible to recommend the most appropriate control and its desirable range of operation.

In general, the mechanical design of equipment must be compatible with the biological and psychological characteristics of the operator. The effectiveness of the human–machine combination can be greatly enhanced by treating the operator and the equipment as a unified system. Thus, the instruments should be considered as extensions of the operator's nervous and perceptual systems, the controls as extensions of the hands, and the feet as simple tools. Any control that is difficult to reach or operate, any instrument dial that has poor legibility, any seat that induces poor posture or discomfort, or any obstruction of vision can contribute directly to an accident or illness.

Biological Hazards

Approximately 200 biological agents, such as infectious microorganisms, biological allergens, and toxins, are known to produce infections or allergenic, toxic, or carcinogenic reactions in workers. Most of the identified biohazardous agents belong to these groups:

- ➢ Microorganisms and their toxins (viruses, bacteria, fungi, and their products) resulting in infection, exposure, or allergy
- ➢ Arthropods (crustaceans, arachnids, insects) associated with bites or stings resulting in skin inflammation, systemic intoxication and transmission of infectious agents, or allergic response
- ➢ Allergens and toxins from higher plants, producing dermatitis, rhinitis, or asthma
- ➢ Protein allergens (such as urine, feces, hair, saliva, and dander) from vertebrate animals

Other groups with the potential to expose workers to biohazards include lower plants other than fungi (lichen, liverworts, ferns) and invertebrate animals other than arthropods (parasites such as protozoa, *Schistosoma*) and roundworms (*Ascaris*).

Workers engaging in agricultural, medical, and laboratory work have been identified as most at risk to occupational biohazards but many varied workplaces present the potential for such exposure. For example, at least 24 of the 150 zoonotic diseases known worldwide are considered to be a hazard for agricultural workers in North America. Risk of infection varies with the type and species of animal and geographic location. Disease may be contracted directly from animals, but more often it is acquired in the workplace environment. Controls include awareness of specific hazards, use of personal protective equipment, preventive veterinary care, worker education, and medical monitoring or prophylactic therapy, where appropriate.

The potential for exposure to occupational biohazards exists in most work environments. The following are but a few examples in very diverse workplaces:

- ➢ Workers maintaining water systems can be exposed to *Legionella pneumophila* and *Naegleria spp.*
- ➢ Workers associated with birds (parrots, parakeets, pigeons) in pet shops, aviaries, or on construction and public works jobs near perching or nesting sites can be exposed to *Chlamydia psittaci.*
- ➢ Workers in wood processing facilities can be exposed to endotoxins, allergenic fungi growing on timber, and fungi causing deep mycoses.
- ➢ Sewage and compost workers can be exposed to enteric bacteria, hepatitis A virus, infectious or endotoxin-producing bacteria, parasitic protozoa, and allergenic fungi.
- ➢ Health care workers, emergency responders, law enforcement officers, and morticians may be exposed to such bloodborne pathogens as hepatitis B (HBV), hepatitis C (HCV), and the human immunodeficiency virus (HIV) in addition to other biological hazards. (See Chapter 14, Biological Hazards.)

BUILDING-RELATED ILLNESSES DUE TO BIOLOGICAL HAZARDS

The sources of biological hazards may be fairly obvious in occupations associated with the handling of microorganisms, plants, and animals and in occupations involving contact with potentially infected people. However, recognizing and identifying biological hazards may not be as simple in other situations such as office buildings and nonindustrial workplaces. Building-related illness (BRI) is a clinically diagnosed disease in one or more building occupants, as distinguished from sick-building syndrome (SBS), in which building occupants' nonspecific symptoms cannot be associated with an identifiable cause. Certain BRI such as infectious and hypersensitivity diseases are clearly associated with biological hazards, but the role of biological materials in SBS is not as well understood.

The conditions and events necessary to result in human exposure to bioaerosols are the presence of a reservoir that can support the growth of microorganisms or allow accumulation of biological material, multiplication of contaminating organisms or biological materials in the reservoir, generation of aerosols containing biological material, and exposure of susceptible workers. (See Chapter 14, Biological Hazards, for a full discussion.)

INDUSTRIAL SANITATION—WATER SUPPLY

The requirements for sanitation and personal facilities are covered in the OSHAct safety and health regulations 29 *CFR* 1910, Subpart J—General Environmental Controls. The OSHAct regulations for carcinogens require special personal health and sanitary facilities for employees working with potentially carcinogenic materials.

Potable water should be provided in workplaces when needed for drinking and personal washing, cooking, washing of foods or utensils, washing of food preparation premises, and personal service rooms.

Drinking fountain surfaces must be constructed of materials impervious to water and not subject to oxidation. The nozzle of the fountain must be located to prevent the return of water in the jet or bowl to the nozzle orifice. A guard over the nozzle prevents contact with the nozzle by the mouth or nose of people using the drinking fountain.

Potable drinking water dispensers must be designed and constructed so that sanitary conditions are maintained; they must be capable of being closed and equipped with a tap. Ice that comes in contact with drinking water must be made of potable water and maintained in a sanitary condition. Standing water in cooling towers and other air-moving systems should be monitored for legionella bacteria. (See Chapter 14, Biological Hazards, for details.)

Outlets for nonpotable water, such as water for industrial or firefighting purposes, must be marked in a manner that indicates clearly that the water is unsafe and is not to be used as drinking water. Nonpotable water systems or systems carrying any other nonpotable substance should be constructed so as to prevent backflow or backsiphonage.

HARMFUL AGENTS–ROUTE OF ENTRY

In order to exert its toxic effect, a harmful agent must come into contact with a body cell and must enter the body via inhalation, skin absorption, or ingestion.

Chemical compounds in the form of liquids, gases, mists, dusts, fumes, and vapors can cause problems by inhalation (breathing), absorption (through direct contact with the skin), or ingestion (eating or drinking).

Inhalation

Inhalation involves airborne contaminants that can be inhaled directly into the lungs and can be physically classified as gases, vapors, and particulate matter including dusts, fumes, smokes, aerosols, and mists.

Inhalation, as a route of entry, is particularly important because of the rapidity with which a toxic material can be absorbed in the lungs, pass into the bloodstream, and reach the brain. Inhalation is the major route of entry for hazardous chemicals in the work environment.

Absorption

Absorption through the skin can occur quite rapidly if the skin is cut or abraded. Intact skin, however, offers a reasonably good barrier to chemicals. Unfortunately, there are many compounds that can be absorbed through intact skin.

Some substances are absorbed by way of the openings for hair follicles and others dissolve in the fats and oils of the skin, such as organic lead compounds, many nitro compounds, and organic phosphate pesticides. Compounds that are good solvents for fats (such as toluene and xylene) also can be absorbed through the skin.

Many organic compounds, such as TNT, cyanides, and most aromatic amines, amides, and phenols, can produce systemic poisoning by direct contact with the skin.

Ingestion

In the workplace, people can unknowingly eat or drink harmful chemicals. Toxic compounds can be absorbed from the gastrointestinal tract into the blood. Lead oxide can cause serious problems if people working with this material are allowed to eat or smoke in work areas. Thorough washing is required both before eating and at the end of every shift.

Inhaled toxic dusts can also be ingested in hazardous amounts. If the toxic dust swallowed with food or saliva is not soluble in digestive fluids, it is eliminated directly through the intestinal tract. Toxic materials that are readily soluble in digestive fluids can be absorbed into the blood from the digestive system.

It is important to study all routes of entry when evaluating the work environment—candy bars or lunches in the work area, solvents being used to clean work clothing and hands, in addition to airborne contaminants in working areas. (For more details, see Chapter 6, Industrial Toxicology.)

TYPES OF AIRBORNE CONTAMINANTS

There are precise meanings of certain words commonly used in industrial hygiene. These must be used correctly in order to understand the requirements of OSHAct regulations, effectively communicate with other occupational health professionals, recommend or design and test appropriate engineering controls, and correctly prescribe personal protective equipment. For example, a fume respirator is worthless as protection against gases or vapors. Too often, terms (such as gases, vapors, fumes, and mists) are used interchangeably. Each term has a definite meaning and describes a certain state of matter.

States of Matter

Matter is divided into dusts, fumes, smoke, aerosols, mists, gases, and vapors. These are discussed in the following sections.

DUSTS

These are solid particles generated by handling, crushing, grinding, rapid impact, detonation, and decrepitation (breaking apart by heating) of organic or inorganic materials, such as rock, ore, metal, coal, wood, and grain.

Dust is a term used in industry to describe airborne solid particles that range in size from 0.1–25 μm in diameter (1 μm = 0.0001 cm or 1/25,400 in.). Dusts more than 5 μm in size usually do not remain airborne long enough to present an inhalation problem (see Chapter 8, Particulates).

Dust can enter the air from various sources, such as when a dusty material is handled (as when lead oxide is dumped into a mixer or talc is dusted on a product). When solid materials are reduced to small sizes in processes such as grinding, crushing, blasting, shaking, and drilling, the mechanical action of the grinding or shaking device supplies energy to disperse the dust.

Evaluating dust exposures properly requires knowledge of the chemical composition, particle size, dust concentration in air, how it is dispersed, and many other factors described here. Although in the case of gases, the concentration that reaches the alveolar sacs is nearly like the concentration in the air breathed, this is not the case for aerosols or dust particles. Large particles, more than 10 μm aerodynamic diameter, can be deposited through gravity and impaction in large ducts before they reach the very small sacs (alveoli). Only the smaller particles reach the alveoli. (See Chapter 2, The Lungs, for more details.)

Except for some fibrous materials, dust particles must usually be smaller than 5 μm in order to penetrate to the alveoli or inner recess of the lungs.

A person with normal eyesight can detect dust particles as small as 50 μm in diameter. Smaller airborne particles can be detected individually by the naked eye only when strong light is reflected from them. Particles of dust of respirable size (less than 10 μm) cannot be seen without the aid of a microscope, but they may be perceived as a haze.

Most industrial dusts consist of particles that vary widely in size, with the small particles greatly outnumbering the large ones. Consequently (with few exceptions), when dust is noticeable in the air near a dusty operation, probably more invisible dust particles than visible ones are present. A

process that produces dust fine enough to remain suspended in the air long enough to be breathed should be regarded as hazardous until it can be proved safe.

There is no simple one-to-one relationship between the concentration of an atmospheric contaminant and duration of exposure and the rate of dosage by the hazardous agent to the critical site in the body. For a given magnitude of atmospheric exposure to a potentially toxic particulate contaminant, the resulting hazard can range from an insignificant level to one of great danger, depending on the toxicity of the material, the size of the inhaled particles, and other factors that determine their fate in the respiratory system.

FUMES

These are formed when the material from a volatilized solid condenses in cool air. The solid particles that are formed make up a fume that is extremely fine, usually less than 1.0 μm in diameter. In most cases, the hot vapor reacts with the air to form an oxide. Gases and vapors are not fumes, although the terms are often mistakenly used interchangeably.

Welding, metalizing, and other operations involving vapors from molten metals may produce fumes; these may be harmful under certain conditions. Arc welding volatilizes metal vapor that condenses as the metal or its oxide in the air around the arc. In addition, the rod coating is partially volatilized. These fumes, because they are extremely fine, are readily inhaled.

Other toxic fumes, such as those formed when welding structures that have been painted with lead-based paints or when welding galvanized metal, can produce severe symptoms of toxicity rather rapidly unless fumes are controlled with effective local exhaust ventilation or the welder is protected by respiratory protective equipment.

Fortunately, most soldering operations do not require temperatures high enough to volatilize an appreciable amount of lead. However, the lead in molten solder pots is oxidized by contact with air at the surface. If this oxide, often called dross, is mechanically dispersed into the air, it can produce a severe lead-poisoning hazard.

In operations when lead dust may be present in air, such as soldering or lead battery-making, preventing occupational poisoning is largely a matter of scrupulously clean housekeeping to prevent the lead oxide from becoming dispersed into the air. It is customary to enclose melting pots, dross boxes, and similar operations, and to ventilate them adequately to control the hazard. Other controls may be necessary as well.

SMOKE

This consists of carbon or soot particles less than 0.1 μm in size, and results from the incomplete combustion of carbonaceous materials such as coal or oil. Smoke generally contains droplets as well as dry particles. Tobacco, for instance, produces a wet smoke composed of minute tarry droplets.

AEROSOLS

These are liquid droplets or solid particles of fine enough particle size to remain dispersed in air for a prolonged period of time.

MISTS

These are suspended liquid droplets generated by condensation of liquids from the vapor back to the liquid state or by breaking up a liquid into a dispersed state, such as by splashing, foaming, or atomizing. The term *mist* is applied to a finely divided liquid suspended in the atmosphere. Examples are the oil mist produced during cutting and grinding operations, acid mists from electroplating, acid or alkali mists from pickling operations, paint spray mist in painting operations, and the condensation of water vapor to form a fog or rain.

GASES

These are formless fluids that expand to occupy the space or enclosure in which they are confined. Gases are a state of matter in which the molecules are unrestricted by cohesive forces. Examples are arc-welding gases, internal combustion engine exhaust gases, and air.

VAPORS

These are the volatile form of substances that are normally in the solid or liquid state at room temperature and pressure. Evaporation is the process by which a liquid is changed into the vapor state and mixed with the surrounding atmosphere. Solvents with low boiling points volatilize readily at room temperature.

In addition to the definitions concerning states of matter that are used daily by industrial hygienists, terms used to describe degree of exposure include the following:

- ppm: parts of vapor or gases per million parts of air by volume at room temperature and pressure
- mppcf: millions of particles of a particulate per cubic foot of air
- mg/m^3: milligrams of a substance per cubic meter of air
- f/cc: fibers of a substance per cubic centimeter of air

The health and safety professional recognizes that air contaminants exist as a gas, dust, fume, mist, or vapor in the workroom air. In evaluating the degree of exposure, the measured concentration of the air contaminant is compared to limits or exposure guidelines that appear in the published standards on levels of exposure (see Appendix B).

Respiratory Hazards

Airborne chemical agents that enter the lungs can pass directly into the bloodstream and be carried to other parts of the body. The respiratory system consists of organs contributing to normal respiration or breathing. Strictly speaking, it includes the nose, mouth, upper throat, larynx, trachea, and bronchi (which are all air passages or airways) and the lungs, where oxygen is passed into the blood and carbon dioxide is given off. Finally, it includes the

diaphragm and the muscles of the chest, which perform the normal respiratory movements of inspiration and expiration. (See Chapter 2, The Lungs.)

All living cells of the body are engaged in a series of chemical processes; the sum total of these processes is called metabolism. In the course of its metabolism, each cell consumes oxygen and produces carbon dioxide as a waste product.

Respiratory hazards can be broken down into two main groups:

- ➢ Oxygen deficiency, in which the oxygen concentration (or partial pressure of oxygen) is below the level considered safe for human exposure
- ➢ Air that contains harmful or toxic contaminants

OXYGEN-DEFICIENT ATMOSPHERES

Each living cell in the body requires a constant supply of oxygen. Some cells are more dependent on a continuing oxygen supply than others. Some cells in the brain and nervous system can be injured or die after 4–6 min without oxygen. These cells, if destroyed, cannot be regenerated or replaced, and permanent changes and impaired functioning of the brain can result from such damage. Other cells in the body are not as critically dependent on an oxygen supply because they can be replaced.

Normal air at sea level contains approximately 21 percent oxygen and 79 percent nitrogen and other inert gases. At sea level and normal barometric pressure (760 mmHg or 101.3 kPa), the partial pressure of oxygen would be 21 percent of 760 mm, or 160 mm. The partial pressure of nitrogen and inert gases would be 600 mm (79 percent of 760 mm).

At higher altitudes or under conditions of reduced barometric pressure, the relative proportions of oxygen and nitrogen remain the same, but the partial pressure of each gas is decreased. The partial pressure of oxygen at the alveolar surface of the lung is critical because it determines the rate of oxygen diffusion through the moist lung tissue membranes.

Oxygen-deficient atmospheres may exist in confined spaces as oxygen is *consumed* by chemical reactions such as oxidation (rust, fermentation), *replaced* by inert gases such as argon, nitrogen, and carbon dioxide, or *absorbed* by porous surfaces such as activated charcoal.

Deficiency of oxygen in the atmosphere of confined spaces can be a problem in industry. For this reason, the oxygen content of any tank or other confined space (as well as the levels of any toxic contaminants) should be measured before entry is made. Instruments are commercially available for this purpose. (See Chapter 16, Air Sampling, Chapter 17, Direct-Reading Instruments for Gases, Vapors, and Particulates, and Chapter 22, Respiratory Protection, for more details.)

The first physiological signs of an oxygen deficiency (anoxia) are an increased rate and depth of breathing. A worker should never enter or remain in areas where tests have indicated oxygen deficiency without a supplied-air or self-contained respirator that is specifically approved by NIOSH for those conditions. (See Chapter 22, Respiratory Protection, for more details.)

Oxygen-deficient atmospheres can cause an inability to move and a semiconscious lack of concern about the imminence of death. In cases of abrupt entry into areas containing little or no oxygen, the person usually has no warning symptoms, immediately loses consciousness, and has no recollection of the incident if rescued in time to be revived. The senses cannot be relied on to alert or warn a person of atmospheres deficient in oxygen.

Oxygen-deficient atmospheres can occur in tanks, vats, holds of ships, silos, mines, or in areas where the air may be diluted or displaced by asphyxiating levels of gases or vapors, or where the oxygen may have been consumed by chemical or biological reactions.

Ordinary jobs involving maintenance and repair of systems for storing and transporting fluids or entering tanks or tunnels for cleaning and repairs are controlled almost entirely by the immediate supervisor. The supervisor should be particularly knowledgeable of all rules and precautions to ensure the safety of those who work in such atmospheres. Safeguards should be meticulously observed.

For example, there should be a standard operating procedure for entering tanks. Such procedures should be consistent with OSHAct regulations and augmented by in-house procedures, which may enhance the basic OSHAct rules. The American National Standards Institute (ANSI) lists confined space procedures in its respiratory protection standard and NIOSH has also issued guidelines for work in confined spaces including a criteria document for working in confined spaces (see Bibliography). Even if a tank is empty, it may have been closed for some time and developed an oxygen deficiency through chemical reactions of residues left in the tank. It may be unsafe to enter without proper respiratory protection.

THE HAZARD OF AIRBORNE CONTAMINANTS

Inhaling harmful materials can irritate the upper respiratory tract and lung tissue, or the terminal passages of the lungs and the air sacs, depending on the solubility of the material.

Inhalation of biologically inert gases can dilute the atmospheric oxygen below the normal blood saturation value and disturb cellular processes. Other gases and vapors may prevent the blood from carrying oxygen to the tissues or interfere with its transfer from the blood to the tissue, producing chemical asphyxia.

Inhaled contaminants that adversely affect the lungs fall into three general categories:

- ➢ Aerosols (particulates), which, when deposited in the lungs, can produce either rapid local tissue damage, some slower tissue reactions, eventual disease, or physical plugging
- ➢ Toxic vapors and gases that produce adverse reaction in the tissue of the lungs

➢ Some toxic aerosols or gases that do not affect the lung tissue locally but pass from the lungs into the bloodstream, where they are carried to other body organs or have adverse effects on the oxygen-carrying capacity of the blood cells

An example of an aerosol is silica dust, which causes fibrotic growth (scar tissue) in the lungs. Other harmful aerosols are fungi found in sugar cane residues, producing bagassosis.

An example of the second type of inhaled contaminant is hydrogen fluoride, a gas that directly affects lung tissue. It is a primary irritant of mucous membranes, even causing chemical burns. Inhalation of this gas causes pulmonary edema and direct interference with the gas transfer function of the alveolar lining.

An example of the third type of inhaled contaminant is carbon monoxide, a toxic gas passed into the bloodstream without harming the lung. The carbon monoxide passes through the alveolar walls into the blood, where it ties up the hemoglobin so that it cannot accept oxygen, thus causing oxygen starvation. Cyanide gas has another effect—it prevents enzymatic utilization of molecular oxygen by cells.

Sometimes several types of lung hazards occur simultaneously. In mining operations, for example, explosives release oxides of nitrogen. These impair the bronchial clearance mechanism so that coal dust (of the particle sizes associated with the explosions) is not efficiently cleansed from the lungs.

If a compound is very soluble—such as ammonia, sulfuric acid, or hydrochloric acid—it is rapidly absorbed in the upper respiratory tract and during the initial phases of exposure does not penetrate deeply into the lungs. Consequently, the nose and throat become very irritated.

Compounds that are insoluble in body fluids cause considerably less throat irritation than the soluble ones, but can penetrate deeply into the lungs. Thus, a very serious hazard can be present and not be recognized immediately because of a lack of warning that the local irritation would otherwise provide. Examples of such compounds (gases) are nitrogen dioxide and ozone. The immediate danger from these compounds in high concentrations is acute lung irritation or, possibly, chemical pneumonia.

There are numerous chemical compounds that do not follow the general solubility rule. Such compounds are not very soluble in water and yet are very irritating to the eyes and respiratory tract. They also can cause lung damage and even death under certain conditions. (See Chapter 6, Industrial Toxicology.)

THRESHOLD LIMIT VALUES

The ACGIH Threshold Limit Values® (TLVs®) are exposure guidelines established for airborne concentrations of many chemical compounds. The health and safety professional or other responsible person should understand something about TLVs and the terminology in which their concentrations are expressed. (See Chapter 15, Evaluation, Chapter 6, Industrial Toxicology, and Appendix B for more details.)

TLVs are airborne concentrations of substances and represent conditions under which it is believed that nearly all workers may be repeatedly exposed, day after day, without adverse effect. Control of the work environment is based on the assumption that for each substance there is some safe or tolerable level of exposure below which no significant adverse effect occurs. These tolerable levels are called Threshold Limit Values. In its Introduction, the ACGIH *Threshold Limit Values* (*TLVs®*) *for Chemical Subtances and Physical Agents and Biological Exposure Indices* (*BEIs®*) states that because individual susceptibility varies widely, a small percentage of workers may experience discomfort from some substances at concentrations at or below the threshold limit. A smaller percentage may be affected more seriously by aggravation of a preexisting condition or by development of an occupational illness. Smoking may enhance the biological effects of chemicals encountered in the workplace and may reduce the body's defense mechanisms against toxic substances.

Hypersusceptible individuals or those otherwise unusually responsive to some industrial chemicals because of genetic factors, age, personal habits (smoking and use of alcohol or other drugs), medication, or previous exposures may not be adequately protected from adverse health effects of chemicals at concentrations at or below the threshold limits.

These limits are not fine lines between safe and dangerous concentration, nor are they a relative index of toxicity. They should not be used by anyone untrained in the discipline of industrial hygiene.

The copyrighted trademark *Threshold Limit Value®* refers to limits published by ACGIH. The TLVs are reviewed and updated annually to reflect the most current information on the effects of each substance assigned a TLV. (See Appendix B and the Bibliography of this chapter.)

The data for establishing TLVs come from animal studies, human studies, and industrial experience, and the limit may be selected for several reasons. As mentioned earlier in this chapter, the TLV can be based on the fact that a substance is very irritating to the majority of people exposed, or the fact that a substance is an asphyxiant. Still other reasons for establishing a TLV for a given substance include the fact that certain chemical compounds are anesthetic or fibrogenic or can cause allergic reactions or malignancies. Some additional TLVs have been established because exposure above a certain airborne concentration is a nuisance.

The amount and nature of the information available for establishing a TLV varies from substance to substance; consequently, the precision of the estimated TLV continues to be subject to revision and debate. The latest documentation for that substance should be consulted to assess the present data available for a given substance.

In addition to the TLVs set for chemical compounds, there are limits for physical agents such as noise,

radiofrequency/microwave radiation, segmental vibration, lasers, ionizing radiation, static magnetic fields, light, near-infrared radiation, subradiofrequency (≤ 30 kHz) magnetic fields, subradiofrequency and static electric fields, ultraviolet radiation, cold stress, and heat stress. There are also biological exposure indices (BEIs®). (See Chapter 9, Industrial Noise, Chapter 11, Nonionizing Radiation, and Appendix B.)

The ACGIH periodically publishes a documentation of TLVs® in which it gives the data and information on which the TLV for each substance is based. This documentation can be used to provide health and safety professionals with insight to aid professional judgment when applying the TLVs.

The most current edition of the ACGIH *Threshold Limit Values* (*TLVs®*) *for Chemical Substances and Physical Agents and Biological Exposure Indices* (*BEIs®*) should be used. When referring to an ACGIH TLV, the year of publication should always preface the value, as in "the 2001 TLV for nitric oxide was 25 ppm." Note that the TLVs are not mandatory federal or state employee exposure standards, and the term *TLV* should not be used for standards published by OSHA or any agency except the ACGIH.

Three categories of Threshold Limit Values are specified as follows:

TIME-WEIGHTED AVERAGE (TLV–TWA)

This is the time-weighted average concentration for a conventional eight-hour workday and 40-hour workweek, to which it is believed that nearly all workers may be repeatedly exposed, day after day, without adverse effect.

SHORT-TERM EXPOSURE LIMIT (TLV–STEL)

This is the concentration to which it is believed workers can be exposed continuously for a short period of time without suffering from:

- Irritation
- Chronic or irreversible tissue damage
- Narcosis of sufficient degree to increase the likelihood of accidental injury, impair self-rescue, or materially reduce work efficiency and provided that the daily TLV–TWA is not exceeded

A STEL is a 15-min TWA exposure that should not be exceeded at any time during a workday, even if the eight-hour TWA is within the TLV-TWA. Exposures above the TLV-TWA up to the STEL should not be longer than 15 min and should not occur more than four times per day. There should be at least 60 min between successive exposures in this range.

The TLV–STEL is not a separate, independent exposure limit; it supplements the TWA limit when there are recognized acute effects from a substance that has primarily chronic effects. The STELs are recommended only when toxic effects in humans or animals have been reported from high short-term exposures.

Note: None of the limits mentioned here, especially the TWA–STEL, should be used as engineering design criteria.

CEILING (TLV–C)

This is the concentration that should not be exceeded during any part of the working exposure. To assess a TLV–C if instantaneous monitoring is not feasible, the conventional industrial hygiene practice is to sample during a 15-min period, except for substances that can cause immediate irritation with short exposures.

For some substances (such as irritant gases), only one category, the TLV–C, may be relevant. For other substances, two or three categories may be relevant, depending on their physiological action. If any one of these three TLVs is exceeded, a potential hazard from that substance is presumed to exist.

Limits based on physical irritation should be considered no less binding than those based on physical impairment. Increasing evidence shows that physical irritation can initiate, promote, or accelerate physical impairment via interaction with other chemical or biological agents.

The amount by which threshold limits can be exceeded for short periods without injury to health depends on many factors: the nature of the contaminant; whether very high concentrations, even for a short period, produce acute poisoning; whether the effects are cumulative; the frequency with which high concentrations occur; and the duration of such periods. All factors must be considered when deciding whether a hazardous condition exists.

Skin Notation

A number of the substances in the TLV list are followed by the designation *Skin*. This refers to potential significant exposure through the cutaneous route, including mucous membranes and the eyes, either by contact with vapors or, of probably greater significance, by direct skin contact with the substance. Vehicles such as certain solvents can alter skin absorption. This designation is intended to suggest appropriate measures for the prevention of cutaneous absorption.

Mixtures

Special consideration should be given in assessing the health hazards that can be associated with exposure to mixtures of two or more substances.

Federal Occupational Safety and Health Standards

The first compilation of the health and safety standards promulgated by OSHA in 1970 was derived from the then-existing federal standards and national consensus standards. Thus, many of the 1968 TLVs established by the ACGIH became federal standards or permissible exposure limits (PELs). Also, certain workplace quality standards known as ANSI maximal acceptable concentrations were incorporated as federal health standards in 29 *CFR* 1910.1000 (Table Z–2) as national consensus standards.

In adopting the ACGIH TLVs, OSHA also adopted the concept of the TWA for a workday. In general:

$$TWA = \frac{C_aT_a+C_bT_b+\ldots+C_nT}{8}$$

where T_a = the time of the first exposure period during the shift
C_a = the concentration of contaminant in period *a*
T_b = another time period during the shift
C_b = the concentration during period *b*
T_n = the *n*th or final time period in the shift
C_n = the concentration during period *n*

This simply provides a summation throughout the workday of the product of the concentrations and the time periods for the concentrations encountered in each time interval and averaged over an 8-hour standard workday.

EVALUATION

Evaluation can be defined as the decision-making process resulting in an opinion on the degree of health hazard posed by chemical, physical, biological, or ergonomic stresses in industrial operations. The basic approach to controlling occupational disease consists of evaluating the potential hazard and controlling the specific hazard by suitable industrial hygiene techniques. (See Chapter 15, Evaluation, for more details.)

Evaluation involves judging the magnitude of the chemical, physical, biological, or ergonomic stresses. Determining whether a health hazard exists is based on a combination of observation, interviews, and measurement of the levels of energy or air contaminants arising from the work process as well as an evaluation of the effectiveness of control measures in the workplace. The industrial hygienist then compares environmental measurements with hygienic guides, TLVs, OSHA PELs, NIOSH RELs, or reports in the literature.

Evaluation, in the broad sense, also includes determining the levels of physical and chemical agents arising out of a process to study the related work procedures and to determine the effectiveness of a given piece of equipment used to control the hazards from that process.

Anticipating and recognizing industrial health hazards involve knowledge and understanding of the several types of workplace environmental stresses and the effects of these stresses on the health of the worker. Control involves the reduction of environmental stresses to values that the worker can tolerate without impairment of health or productivity. Measuring and quantitating environmental stress are the essential ingredients for modern industrial hygiene, and are instrumental in conserving the health and well-being of workers.

Basic Hazard-Recognition Procedures

There is a basic, systematic procedure for recognizing and evaluating environmental health hazards, which includes the following questions:

- ➢ What is produced?
- ➢ What raw material is used?
- ➢ What materials are added in the process?
- ➢ What equipment is involved?
- ➢ What is the cycle of operations?
- ➢ What operational procedures are used?
- ➢ Is there a written procedure for the safe handling and storage of materials?
- ➢ What about dust control, cleanup after spills, and waste disposal?
- ➢ Are the ventilating and exhaust systems adequate?
- ➢ Does the facility layout minimize exposure?
- ➢ Is the facility well-equipped with safety appliances such as showers, masks, respirators, and emergency eyewash fountains?
- ➢ Are safe operating procedures outlined and enforced?
- ➢ Is a complete hazard communication program that meets state or federal OSHA requirements in effect?

Understand the industrial process well enough to see where contaminants are released. For each process, perform the following:

- ➢ For each contaminant, find the OSHA PEL or other safe exposure guideline based on the toxicological effect of the material.
- ➢ Determine the actual level of exposure to harmful physical agents.
- ➢ Determine the number of employees exposed and length of exposure.
- ➢ Identify the chemicals and contaminants in the process.
- ➢ Determine the level of airborne contaminants using air-sampling techniques.
- ➢ Calculate the resulting daily average and peak exposures from the air-sampling results and employee exposure times.
- ➢ Compare the calculated exposures with OSHA standards, the TLV listing published by the ACGIH, the NIOSH RELs, the hygienic guides, or other toxicological recommendations.

All of the above are discussed in detail in the following chapters.

Information Required

Detailed information should be obtained regarding types of hazardous materials used in a facility, the type of job operation, how the workers are exposed, work patterns, levels of air contamination, duration of exposure, control measures used, and other pertinent information. The hazard potential of the material is determined not only by its inherent toxicity, but also by the conditions of use (who uses what, where, and how long?).

To recognize hazardous environmental factors or stresses, a health and safety professional must first know the raw materials used and the nature of the products and by-products manufactured. Consult MSDSs for the substances.

Any person responsible for maintaining a safe, healthful work environment should be thoroughly acquainted with the concen-

trations of harmful materials or energies that may be encountered in the industrial environment for which they are responsible.

If a facility is going to handle a hazardous material, the health and safety professional must consider all the unexpected events that can occur and determine what precautions are required in case of an accident to prevent or control atmospheric release of a toxic material.

After these considerations have been studied and proper countermeasures installed, operating and maintenance personnel must be taught the proper operation of the health and safety control measures. Only in this way can personnel be made aware of the possible hazards and the need for certain built-in safety features.

The operating and maintenance people should set up a routine procedure (at frequent, stated intervals) for testing the emergency industrial hygiene and safety provisions that are not used in normal, ordinary facility or process operations.

Degree of Hazard

The degree of hazard from exposure to harmful environmental factors or stresses depends on the following:

- ➢ Nature of the material or energy involved
- ➢ Intensity of the exposure
- ➢ Duration of the exposure

The key elements to be considered when evaluating a health hazard are how much of the material in contact with body cells is required to produce injury, the probability of the material being absorbed by the body to result in an injury, the rate at which the airborne contaminant is generated, the total time of contact, and the control measures in use.

Air Sampling

The importance of the sampling location, the proper time to sample, and the number of samples to be taken during the course of an investigation of the work environment cannot be overstressed.

Although this procedure might appear to be a routine, mechanical job, actually it is an art requiring detailed knowledge of the sampling equipment and its shortcomings. The person taking the sample(s) needs to know where and when to sample; and how to weigh the many factors that can influence the sample results, such as ambient temperature, season of the year, unusual problems in work operations, and interference from other contaminants. The sample must usually be taken in the breathing zone of an employee (see Figure 1–5).

The air volume sampled must be sufficient to permit a representative determination of the contaminant to properly compare the result with the TLV or PEL. The sampling period must usually be sufficient to give a direct measure of the average full-shift exposure of the employees concerned. The sample must be sealed and identified if it is to be shipped to a laboratory so that it is possible to identify positively the time and place of sampling and the individual who took the sample.

Figure 1–5. Portable pump with intake positioned to collect continuous samples from the breathing zone of an employee. (Courtesy MSA)

Area samples, taken by setting the sampling equipment in a fixed position in the work area, are useful as an index of general contamination. However, the actual exposure of the employee at the point of generation of the contaminant can be greater than is indicated by an area sample.

To meet the requirement of establishing the TWA concentrations, the sampling method and time periods should be chosen to average out fluctuations that commonly occur in a day's work. If there are wide fluctuations in concentration, the long-term samples should be supplemented by samples designed to catch the peaks separately.

If the exposure being measured is from a continuous operation, it is necessary to follow the particular operator through two cycles of operation, or through the full shift if operations follow a random pattern during the day. For operations of this sort, it is particularly important to find out what the workers do when the equipment is down for maintenance or process change. Such periods are often also periods of maximum exposure. (See Chapter 16, Air Sampling.)

As an example of the very small concentrations involved, the industrial hygienist commonly samples and measures substances in the air of the working environment in concentrations ranging from 1 to 100 ppm. Some idea of the magnitude of these concentrations can be appreciated when one realizes that 1 inch in 16 miles is 1 part per million; 1 cent in $10,000, 1 ounce of salt in 62,500 pounds of sugar, and

1 ounce of oil in 7,812.5 gallons of water all represent 1 part per million.

OCCUPATIONAL SKIN DISEASES

Some general observations on dermatitis are given in this chapter, but more detailed information is given in Chapter 3, The Skin and Occupational Dermatoses. Occupational dermatoses can be caused by organic substances, such as formaldehyde, solvents or inorganic materials, such as acids and alkalis, and chromium and nickel compounds. Skin irritants are usually either liquids or dusts.

Types

There are two general types of dermatitis: primary irritation and sensitization.

PRIMARY IRRITATION DERMATITIS

Nearly all people suffer primary irritation dermatitis from mechanical agents such as friction, from physical agents such as heat or cold, and from chemical agents such as acids, alkalis, irritant gases, and vapors. Brief contact with a high concentration of a primary irritant or prolonged exposure to a low concentration causes inflammation. Allergy is not a factor in these conditions.

SENSITIZATION DERMATITIS

This type results from an allergic reaction to a given substance. The sensitivity becomes established during the induction period, which may be a few days to a few months. After the sensitivity is established, exposure to even a small amount of the sensitizing material is likely to produce a severe reaction.

Some substances can produce both primary irritation dermatitis and sensitization dermatitis. Among them are organic solvents, chromic acid, and epoxy resin systems.

Causes

Occupational dermatitis can be caused by chemical, mechanical, physical, and biological agents and plant poisons.

Chemical agents are the predominant causes of dermatitis in manufacturing industries. Cutting oils and similar substances are significant because the oil dermatitis they cause is probably of greater interest to industrial concerns than is any other type of dermatitis.

Detergents and solvents remove the natural oils from the skin or react with the oils of the skin to increase susceptibility to reactions from chemicals that ordinarily do not affect the skin. Materials that remove the natural oils include alkalis, soap, and turpentine.

Dessicators, hygroscopic agents, and anhydrides take water out of the skin and generate heat. Examples are sulfur dioxide and trioxide, phosphorus pentoxide, strong acids such as sulfuric acid, and strong alkalis such as potash.

Protein precipitants tend to coagulate the outer layers of the skin. They include all the heavy metallic salts and those that form alkaline albuminates on combining with the skin, such as mercuric and ferric chloride. Alcohol, tannic acid, formaldehyde, picric acid, phenol, and intense ultraviolet rays are other examples of protein-precipitating agents.

Oxidizers unite with hydrogen and liberate nascent oxygen on the skin. Such materials include nitrates, chlorine, iodine, bromine, hypochlorites, ferric chloride, hydrogen peroxide, chromic acid, permanganates, and ozone.

Solvents extract essential skin constituents. Examples are ketones, aliphatic and aromatic hydrocarbons, halogenated hydrocarbons, ethers, esters, and certain nitro compounds.

Allergic or anaphylactic proteins stimulate the production of antibodies that cause skin reactions in sensitive people. The sources of these antigens are usually cereals, flour, and pollens, but can include feathers, scales, flesh, fur, and other emanations.

Mechanical causes of skin irritation include friction, pressure, and trauma, which may facilitate infection with either bacteria or fungi.

Physical agents leading to occupational dermatitis include heat, cold, sunlight, x rays, ionizing radiation, and electricity. The x rays and other ionizing radiation can cause dermatitis, severe burns, and even cancer. Prolonged exposure to sunlight produces skin changes and may cause skin cancer.

Biological agents causing dermatitis can be bacterial, fungal, or parasitic. Boils and folliculitis caused by staphylococci and streptococci, and general infection from occupational wounds, are probably the best known among the bacterial skin infections. These can be occupationally induced infections.

Fungi cause athlete's foot and other types of dermatitis among kitchen workers, bakers, and fruit handlers; fur, hide, and wool handlers or sorters; barbers; and horticulturists. Parasites cause grain itch and often occur among handlers of grains and straws, and particularly among farmers, laborers, miners, fruit handlers, and horticulturists.

Plant poisons causing dermatitis are produced by several hundred species of plants. The best known are poison ivy, poison oak, and poison sumac. Dermatitis from these three sources can result from bodily contact with any part of the plant, exposure of any part of the body to smoke from the burning plant, or contact with clothing or other objects previously exposed to the plant.

Physical Examinations

Preplacement examinations help identify those especially susceptible to skin irritations. The examining physician should be given detailed information on the type of work for which the applicant is being considered. If the work involves exposure to skin irritants, the physician should determine whether the prospective employee has deficiencies or characteristics likely to predispose him or her to dermatitis (see Chapter 25, The Occupational Medicine Physician, for more details).

Preventive Measures

Before new or different chemicals are introduced in an established process, possible dermatitis hazards should be carefully considered. Once these hazards are anticipated, suitable engineering controls should be devised and built into the processes to avoid them.

The type, number, and amounts of skin irritants used in various industrial processes affect the degree of control that can be readily obtained, but the primary objective in every case should be to eliminate skin contact as completely as possible. The preventive measures discussed in Chapter 18, Methods of Control, can be adapted to control industrial dermatitis.

CONTROL METHODS

With employment in the United States shifting from manufacturing to the service sector, many workplaces today present nontraditional occupational health hazards. Industrial hygienists need to possess the skills to implement control methodology in both industrial settings and in workplaces such as laboratories, offices, health care facilities, and environmental remediation projects. Hazards can change with time as well, so that hazard control systems require continual review and updating.

Control methods for health hazards in the work environment are divided into three basic categories:

1. Engineering controls that engineer out the hazard, either by initial design specifications or by applying methods of substitution, isolation, enclosure, or ventilation. In the hierarchy of control methods, the use of engineering controls should be considered first.
2. Administrative controls that reduce employee exposures by scheduling reduced work times in contaminant areas (or during cooler times of the day for heat stress exposure, for example). Also included here is employee training that includes hazard recognition and specific work practices that help reduce exposure. (This type of training is required by law for all employees exposed to hazardous materials in the course of their work.)
3. Personal protective equipment the employees wear to protect them from their environment. Personal protective equipment includes anything from gloves to full body suits with self-contained breathing apparatus, and can be used in conjunction with engineering and administrative controls.

Engineering controls should be used as the first line of defense against workplace hazards wherever feasible. Such built-in protection, inherent in the design of a process, is preferable to a method that depends on continual human implementation or intervention. The federal regulations, and their interpretation by the Occupational Safety and Health Review commission, mandate the use of engineering controls to the extent feasible; if they are not sufficient to achieve acceptable limits of exposure, the use of personal protective equipment and other corrective measures may be considered.

Engineering controls include ventilation to minimize dispersion of airborne contaminants, isolation of a hazardous operation or substance by means of barriers or enclosures, and substitution of a material, equipment, or process to provide hazard control. Although administrative control measures can limit the duration of individual exposures, they are not generally favored by employers because they are difficult to implement and maintain. For similar reasons, control of health hazards by using respirators and protective clothing is usually considered secondary to the use of engineering control methods. (See Chapter 18, Methods of Control.)

Engineering Controls

Substituting or replacing a toxic material with a harmless one is a very practical method of eliminating an industrial health hazard. In many cases, a solvent with a lower order of toxicity or flammability can be substituted for a more hazardous one. In a solvent substitution, it is always advisable to experiment on a small scale before making the new solvent part of the operation or process.

A change in process often offers an ideal chance to improve working conditions as well as quality and production. In some cases, a process can be modified to reduce the hazard. Brush painting or dipping instead of spray painting minimizes the concentration of airborne contaminants from toxic pigments. Structural bolts in place of riveting, steam-cleaning instead of vapor degreasing of parts, and airless spraying techniques and electrostatic devices to replace hand-spraying are examples of process change. In buying individual machines, the need for accessory ventilation, noise and vibration suppression, and heat control should be considered before the purchase.

Noisy operations can be isolated from the people nearby by a physical barrier (such as an acoustic box to contain noise from a whining blower or a rip saw). Isolation is particularly useful for limited operations requiring relatively few workers or where control by any other method is not feasible.

Enclosing the process or equipment is a desirable method of control because it can minimize escape of the contaminant into the workroom atmosphere. Examples of this type of control are glove box enclosures and abrasive shot blast machines for cleaning castings.

In the chemical industry, isolating hazardous processes in closed systems is a widespread practice. The use of a closed system is one reason why the manufacture of toxic substances can be less hazardous than their use.

Dust hazards often can be minimized or greatly reduced by spraying water at the source of dust dispersion. "Wetting down" is one of the simplest methods for dust control. However, its effectiveness depends on proper wetting of the dust and keeping it moist. To be effective, the addition of a wetting agent to the water and proper and timely disposal of the wetted dust before it dries out and is redispersed may be necessary.

Ventilation

The major use of exhaust ventilation for contaminant control is to prevent health hazards from airborne materials. OSHA has ventilation standards for abrasive blasting, grinding, polishing and buffing operations, spray finishing operations, and open-surface tanks. For more details, see Chapter 19, Local Exhaust Ventilation, and Chapter 20, Dilution Ventilation of Industrial Workplaces.

A local exhaust system traps and removes the air contaminant near the generating source, which usually makes this method much more effective than general ventilation. Therefore, local exhaust ventilation should be used when exposures to the contaminant cannot be controlled by substitution, changing the process, isolation, or enclosure. Even though a process has been isolated, it still may require a local exhaust system.

General or dilution ventilation—removing and adding air to dilute the concentration of a contaminant to below hazardous levels—uses natural or forced air movement through open doors, windows, roof ventilators, and chimneys. General exhaust fans can be mounted in roofs, walls, or windows (see Chapters 19 and 20 for more details).

Consideration must be given to providing replacement air, especially during winter. Dilution ventilation is feasible only if the quantity of air contaminant is not excessive, and is particularly effective if the contaminant is released at a substantial distance from the worker's breathing zone. General ventilation should not be used where there is a major, localized source of contamination (especially highly toxic dusts and fumes). A local exhaust system is more effective in such cases.

Air conditioning does not substitute for air cleaning. Air conditioning is mainly concerned with control of air temperature and humidity and can be accomplished by systems that accomplish little or no air cleaning. An air-conditioning system usually uses an air washer to accomplish temperature and humidity control, but these air washers are not designed as efficient air cleaners and should not be used as such. (See Chapter 21, General Ventilation of Nonindustrial Occupancies.)

Processes in which materials are crushed, ground, or transported are potential sources of dust dispersion, and should be controlled either by wet methods or enclosed and ventilated by local exhaust ventilation. Points where conveyors are loaded or discharged, transfer points along the conveying system, and heads or boots of elevators should be enclosed as well as ventilated. (For more details, see Chapter 19, Local Exhaust Ventilation.)

Personal Protective Equipment

When it is not feasible to render the working environment completely safe, it may be necessary to protect the worker from that environment by using personal protective equipment. This is considered a secondary control method to engineering and administrative controls and should be used as a last resort.

Where it is not possible to enclose or isolate the process or equipment, ventilation or other control measures should be provided. Where there are short exposures to hazardous concentrations of contaminants and where unavoidable spills may occur, personal protective equipment must be provided and used.

Personal protective devices have one serious drawback: They do nothing to reduce or eliminate the hazard. They interpose a barrier between worker and hazard; if the barrier fails, immediate exposure is the result. The supervisor must be constantly alert to make sure that required protective equipment is worn by workers who need supplementary protection, as may be required by OSHA standards. (See Chapter 22, Respiratory Protection.)

Administrative Controls

When exposure cannot be reduced to permissible levels through engineering controls, as in the case of air contaminants or noise, an effort should be made to limit the employee's exposure through administrative controls.

Examples of some administrative controls are as follows:

- Arranging work schedules and the related duration of exposures so that employees are minimally exposed to health hazards
- Transferring employees who have reached their upper permissible limits of exposure to an environment where no further additional exposure will be experienced

Where exposure levels exceed the PEL for one worker in one day, the job can be assigned to two, three, or as many workers as needed to keep each one's duration of exposure within the PEL. In the case of noise, other possibilities may involve intermittent use of noisy equipment.

Administrative controls must be designed only by knowledgeable health and safety professionals, and used cautiously and judiciously. They are not as satisfactory as engineering controls and have been criticized by some as a means of spreading exposures instead of reducing or eliminating the exposure.

Good housekeeping plays a key role in occupational health protection. Basically, it is a key tool for preventing dispersion of dangerous contaminants and for maintaining safe and healthful working conditions. Immediate cleanup of any spills or toxic material, by workers wearing proper protective equipment, is a very important control measure. Good housekeeping is also essential where solvents are stored, handled, and used. Leaking containers or spigots should be fixed immediately, and spills cleaned promptly. All solvent-soaked rags or absorbents should be placed in airtight metal receptacles and removed daily.

It is impossible to have an effective occupational health program without good maintenance and housekeeping. Workers should be informed about the need for these controls. Proper training and education are vital elements for successful implementation of any control effort, and are required by law as part of a complete federal or state OSHA hazard communication program. (See Chapter 18, Methods of Control.)

SOURCES OF HELP

Specialized help is available from a number of sources. Every supplier of products or services is likely to have competent professional staff who can provide technical assistance or guidance. Many insurance companies that carry workers' compensation insurance provide industrial hygiene consultation services, just as they provide periodic safety inspections.

Professional consultants and privately owned laboratories are available on a fee basis for concentrated studies of a specific problem or for a facilitywide or companywide survey, which can be undertaken to identify and catalog individual environmental exposures. Lists of certified analytical laboratories and industrial hygiene consultants are available from the AIHA.

Many states have excellent industrial hygiene departments that can provide consultation on a specific problem. Appendix A, Additional Resources, contains names and addresses of state and national health and hygiene agencies. NIOSH has a Technical Information Center that can provide information on specific problems. Scientific and technical societies that can help with problems are listed in Appendix A. Some provide consultation services to nonmembers; they all have much accessible technical information. A list of organizations concerned with industrial hygiene is included in Appendix A.

SUMMARY

No matter what health hazards are encountered, the approach of the industrial hygienist is essentially the same. Using methods relevant to the problem, he or she secures qualitative and quantitative estimates of the extent of hazard. These data are then compared with the recommended exposure guidelines. If a situation hazardous to life or health is shown, recommendations for correction are made. The industrial hygienist's recommendations place particular emphasis on effectiveness of control, cost, and ease of maintenance of the control measures.

Anticipation, recognition, evaluation, and control are the fundamental concepts of providing all workers with a healthy working environment.

Anatomy, Physiology, and Pathology

Part II

Chapter 2

The Lungs

by George S. Benjamin, MD, FACS
revised by John Balmes, MD

The material in this chapter on human respiration is intended primarily for engineers and health and safety professionals who must evaluate and control industrial health hazards.

Establishing an effective industrial hygiene program calls for an understanding of the anatomy and physiology of the human respiratory system. The respiratory system is a quick and direct avenue of entry for toxic materials into the body because of its intimate association with the circulatory system and the constant need to oxygenate human tissue cells. Anything affecting the respiratory system, whether it is insufficient oxygen or contaminated air, can affect the entire human organism.

Humans can survive for weeks without food and for days without water, but for only a few minutes without air. Air must reach the lungs almost constantly so oxygen can be extracted and distributed via the blood to every body cell. The life-giving component of air is oxygen, which constitutes a little less than one-fifth of its volume.

All living cells of the body are engaged in a series of chemical processes. The total of these processes is metabolism. In the course of the body's metabolism, each cell consumes oxygen and produces carbon dioxide as a waste substance.

Each living cell in the body requires a constant supply of oxygen. Some cells, however, are more vulnerable than others; cells in the brain and heart may die after 4–6 minutes without oxygen. These cells can never be replaced, and permanent changes result from such damage. Other cells in the body are not so critically dependent on an oxygen supply because they are replaceable.

Thus, the respiratory system by which oxygen is delivered to the body and carbon dioxide removed is a very important part of the body. The respiratory system consists of all the organs of the body that contribute to normal respiration or breathing. Strictly speaking, it includes the nose, mouth, upper throat, larynx, trachea, and bronchi, which are all air passages or airways. It includes the lungs, where oxygen is passed into the blood and carbon dioxide is

given off. Finally, it includes the diaphragm and the muscles of the chest, which permit normal respiratory movements (Figure 2–1).

ANATOMY

The human respiratory system includes the nose, the pharynx, the larynx, the trachea, the bronchi, and the lungs. Each is discussed in the following sections.

Nose

The nose consists of an external and an internal portion. The external portion of the nose protrudes from the face and is highly variable in shape. The upper part of this triangular structure is held in a fixed position by the supporting nasal bones that form the bridge of the nose. The lower portion is movable because of its pliable framework of fibrous tissue, cartilage, and skin.

The internal portion of the nose lies within the skull between the base of the cranium and the roof of the mouth, and is in front of the nasopharynx (the upper extension of the throat). The skull bones that enter into the formation of the nose include the frontal, the sphenoid, the ethmoid, the nasal, the maxillary, the lacrimal, the vomer, and the palatine and inferior conchae.

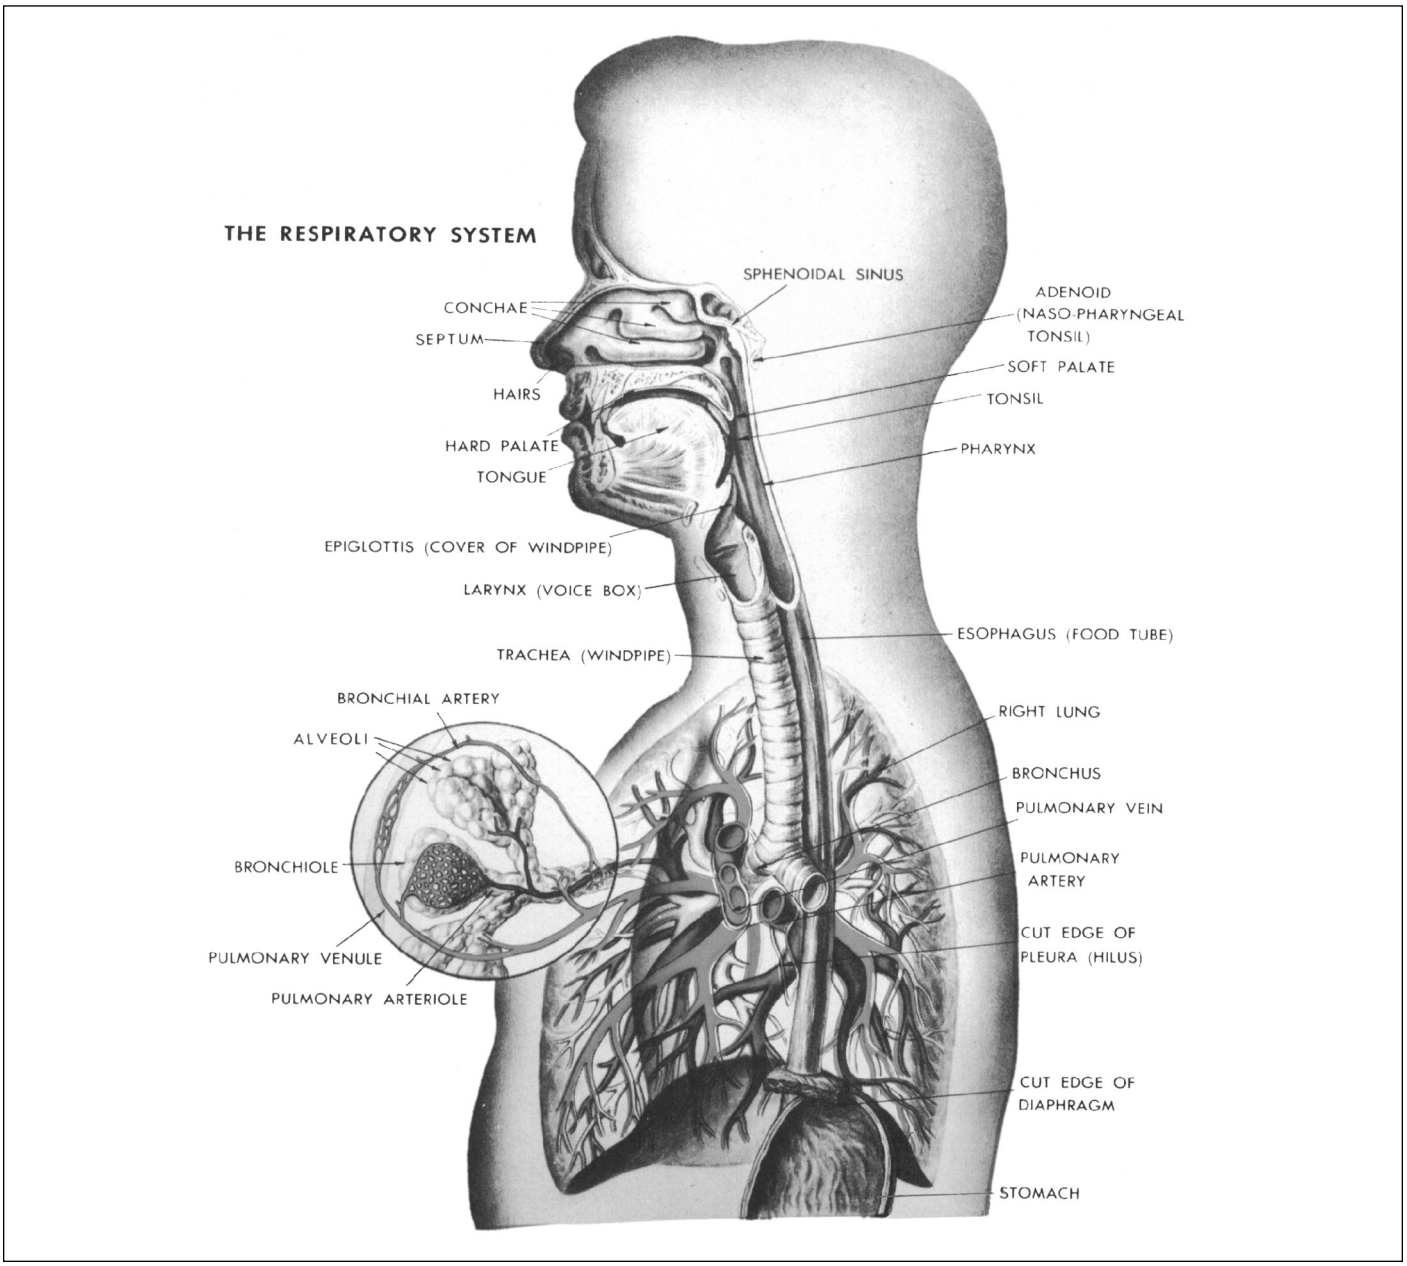

Figure 2–1. Schematic drawing of the respiratory system. (Reprinted with permission from *The Wonderful Human Machine.* Chicago: American Medical Association, 1971.)

The nasal septum is a narrow partition that divides the nose into right and left nasal cavities. In some people the nasal septum is markedly deflected to one side, causing the affected nasal cavity to be almost completely obstructed; this condition is called a deviated nasal septum.

The nasal cavities are open to the outside through the anterior nares (or nostrils); toward the rear, they open into the nasopharynx by means of the posterior nares, or conchae. The vestibule of each cavity is the dilated portion just inside the nostril. Toward the front, the vestibule is lined with skin and presents a ring of coarse hairs that serve to trap dust particles. Toward the rear, the lining of the vestibule changes from skin to a highly vascular ciliated mucous membrane, called the nasal mucosa, which lines the rest of the nasal cavity.

Extending into the nasal cavity from the base of the skull are large nerve filaments, which are part of the sense organ for smell. From these filaments, information on odors is relayed to the olfactory nerve, which goes to the brain.

TURBINATES

Near the middle of the nasal cavity and on both sides of the septum are a series of scroll-like bones called the conchae, or turbinates. The purpose of the turbinates is to increase the amount of tissue surface within the nose so that incoming air has a greater opportunity to be conditioned before it continues to the lungs.

Respiration begins with the nose, which is specially designed for the purpose, although there are times when you breathe through the mouth as well. When you perform any vigorous activity and begin to puff and pant, you are breathing rapidly through the mouth to provide the blood with the extra oxygen needed.

However, the mouth is not designed for breathing. You may have noticed this on cold days when you make a deliberate effort to keep your mouth tightly closed, because if you take air in through the mouth you can feel its coldness. Cold air passing through the mouth has no chance to become properly warmed. But cold as the air may be, you can breathe comfortably through the nose.

Air enters through the nares or nostrils, passes through a web of nasal hairs, and flows posteriorly toward the nasopharynx. The air is warmed and moistened in its passage and partially depleted of particles. Some particles are removed by impaction on the nasal hairs and at bends in the air path, and others by sedimentation.

In mouth breathing, some particles are deposited, primarily by impaction, in the oral cavity and at the back of the throat. These particles are rapidly passed to the esophagus (food tube) by swallowing.

MUCUS

The surfaces of the turbinates, like the rest of the interior walls of the nose, are covered with mucous membranes. These membranes secrete a fluid called mucus. The film of mucus is produced continuously and drains slowly into the throat. The mucus gives up heat and moisture to incoming air and serves as a trap for bacteria and dust in the air. It also helps dilute any irritating substances in the air.

The common cold involves an inflammation of the mucous membrane of the nose. It is characterized by an acute congestion of the mucous membrane and increased secretion of mucus. It is difficult to breathe through the nose because of the swelling of the mucous membrane and the accumulated secretions clogging the air passageway.

In cold weather, the membranes can increase the flow of mucus. If the atmosphere is unusually dry, as in an improperly heated building, the mucus may lose its moisture too rapidly and the membrane may become dry and irritated.

CILIA

In addition to the mucus, the membrane is coated with cilia, or hairlike filaments, that move in coordinated waves to propel mucus and trapped particles toward the nostrils. The millions of cilia lining the nasal cavity help the mucus clean the incoming air. When you breathe through the mouth, the protective benefits of the cilia and mucus are lost.

In summary, the nose serves not only as a passageway for air going to and from the lungs but also as an air conditioner and as the sense organ for smell. The importance of breathing through the nose is obvious as it moistens, filters, and warms or cools the air that is on its way to the lungs (Figure 2–2).

Throat

From the nasal cavity, air moves into the pharynx, or throat. Seven tubes enter the pharynx: the two from the nasal cavity, the eustachian tubes (which lead to the ears), the mouth cavity, the opening of the esophagus, and the opening of the trachea (windpipe).

PHARYNX

The pharynx, or throat, is a tubular passageway attached to the base of the skull and extending downward behind the nasal cavity, the mouth, and the larynx to continue as the esophagus. Its walls are composed of skeletal muscle and the lining consists of mucous membrane. The nasal passage joins the esophagus just behind the mouth. The union of the two passageways at this point makes it possible to breathe with reasonable comfort through the mouth when the nasal passages are blocked because of a cold or allergy.

NASOPHARYNX

The nasopharynx is the superior portion of the pharyngeal cavity; it lies behind the nasal cavities and above the level of the soft palate. This portion of the upper respiratory tract serves as a major defense against infectious organisms. Its ciliated mucosal lining is continuous with that of the nasal cavities. Immediately beneath the mucosa are collections of lymphoid tissue, the adenoids. The adenoids and tonsils, lower down in the throat, are part of the immune system and serve as a first defense against infectious organisms.

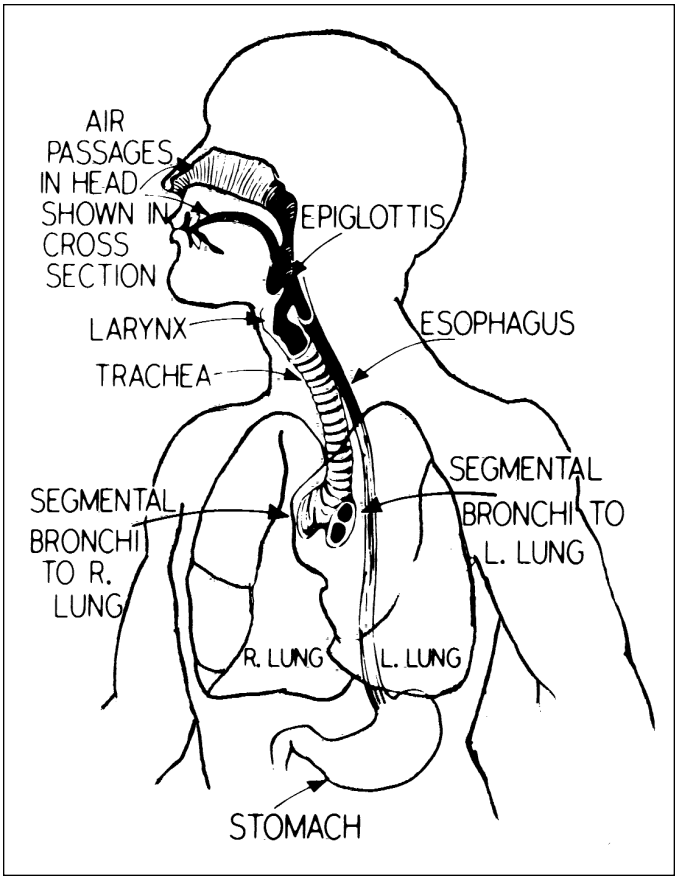

Figure 2–2. Parts of the human respiratory system. Air enters through the mouth and nose, passes down the trachea and into the lungs. (Reproduced with permission from *Emergency Care and Transportation of the Sick and Injured,* ed. 1. Chicago, IL, American Academy of Orthopaedic Surgeons, 1971.)

ESOPHAGUS AND TRACHEA

At the bottom of the throat are two passageways: the esophagus behind and the trachea in front. Food and liquids entering the pharynx pass into the esophagus, which carries them to the stomach. Air and other gases enter the trachea to go to the lungs.

EPIGLOTTIS

Guarding the opening of the trachea is a thin, leaf-shaped structure called the epiglottis (Figure 2–3). This structure helps food glide from the mouth to the esophagus.

Everyone is aware that swallowing food and breathing cannot take place at the same time without danger of choking. But nature has devised a way for food and air to use the same general opening, the pharynx, with only an occasional mix-up.

The incoming air travels through the nasal cavity and through the larynx by crossing over the path used by food on its way to the stomach. Similarly, food crosses over the route of air. When food is swallowed, the larynx rises against the base of the tongue to help seal the opening.

If food accidentally starts down the wrong way, into the lungs rather than the stomach, there are explosive protests from the lungs. Any contact of a sizable liquid or solid particle with the trachea sets off a cough, an explosive expulsion of air that blows it out again. A cough can be a very powerful force. A slight breathing in, closing of the glottis, buildup of pressure, and a sudden release of the trapped air are involved. Also, stimulation of the larynx can cause spasm of the vocal cords, with total obstruction of breathing.

Normally, swallowing blocks off the glottis, halts breathing briefly, and ensures correct division of air and food. However, an unconscious person may lack this automatic response, and if a drink is given, it may proceed straight into the lungs.

The diaphragm is sometimes subject to periodic spasms of contraction that enlarge the lung cavities and lead to a quick inrush of air. The vocal cords come together to stop the flow, and the air, so suddenly set into motion and so suddenly stopped, makes the sharp noise called the hiccup. Hiccups may be due to indigestion, overloaded stomach, irritation under the surface of the diaphragm, too much alcohol, or many other possible causes, including heart attacks.

Larynx

The larynx, or voice box, serves as a passageway for air between the pharynx and the trachea. It lies in the midline of the neck, below the hyoid bone and in front of the laryngopharynx. The unique structure of the larynx enables it to function somewhat like a valve on guard duty at the entrance to the windpipe, controlling air flow and preventing anything but air from entering the lower air passages. Exhalation of air through the larynx is controlled by voluntary muscles; thus, the larynx is the organ of voice.

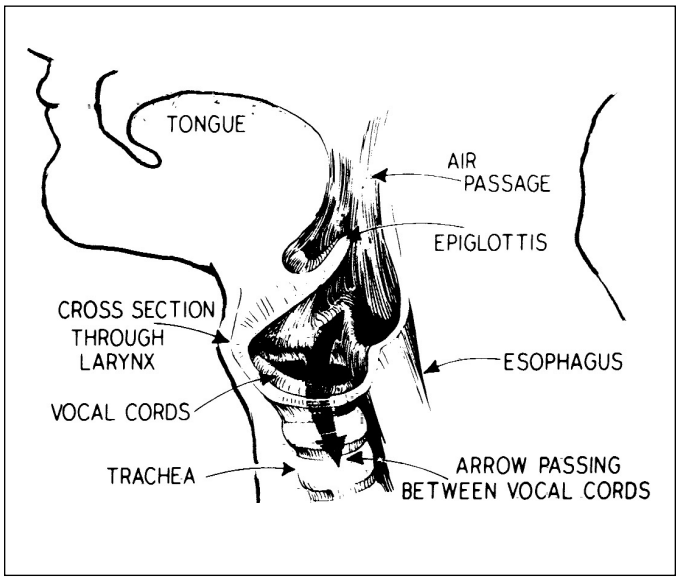

Figure 2–3. The anatomy of the neck: the epiglottis, larynx, vocal cords, trachea, and esophagus. (Reproduced with permission from *Emergency Care and Transportation of the Sick and Injured,* ed. 1. Chicago, IL, American Academy of Orthopaedic Surgeons, 1971.)

The larynx is a triangular box composed of nine cartilages joined together by ligaments and controlled by skeletal muscles. The larynx is lined with ciliated mucous membrane (except the vocal folds), and the cilia move particles upward to the pharynx.

VOCAL CORDS

The larynx is at the top of the windpipe, or trachea, which takes air to the lungs. Although incoming air passes through the boxlike larynx, it is actually air expelled from the lungs that makes voice sounds. In the front of the larynx, two folds of membranes, the vocal cords, are attached and held by tiny cartilages. Muscles attached to the cartilages move the vocal cords, which are made to vibrate by air exhaled from the lungs.

During ordinary breathing, the vocal cords are held toward the walls of the larynx so that air can pass without being obstructed. During speech, the vocal cords swing over the center of the tube and muscles contract to tense the vocal cords.

SPEECH

Sounds are created as air is forced past the vocal cords, making them vibrate. These vibrations make the sound. You can feel these vibrations by placing your fingers lightly on your larynx (Adam's apple) while speaking.

The vibrations are carried through the air upward into the pharynx, mouth, nasal cavities, and sinuses, which act as resonating chambers. The greater the force and amount of air from the lungs, the louder the voice. Pitch differences result from variations in the tension of the cords. The larger the larynx and the longer the cords, the deeper the voice. The average man's vocal cords are about 0.75 in. (1.9 cm) long. Shorter vocal cords give women higher-pitched voices. Words and other understandable sounds are formed by the tongue and muscles of the mouth.

Infections of the throat and nasal passages alter the shape of the resonating chambers and change the voice, roughening it so that it sounds hoarse. When the membranes of the larynx themselves are affected (laryngitis), speech may be reduced to a whisper. In whispering, the vocal cords are not involved; sound is produced by tissue folds, sometimes called false vocal cords, that lie just above the vocal cords themselves.

Trachea

The trachea or windpipe is a tube about 4.5 in. (11.5 cm) long and 1 in. (2.5 cm) in diameter, extending from the bottom of the larynx through the neck and into the chest cavity. At its lower end it divides into two tubes, the right and left bronchi. The esophagus, which carries food to the stomach, is immediately behind the trachea.

Rings of cartilage hold the trachea and bronchi open. If the head is tilted back, the tube can be felt as the fingers run down the front of the neck. The ridges produced by the alternation of cartilage and fibrous tissue are also felt, giving the tube a feeling of roughness.

The windpipe wall is lined with mucous membrane and with many hairlike cilia fanning upward toward the throat, moving dust particles that have been caught in the sticky membrane away from the lungs.

The path of the esophagus, which carries food to the stomach, runs immediately behind the trachea. At the point behind the middle of the breastbone, where the aorta arches away from the heart, the trachea divides into two branches: the right and the left bronchi.

Respiratory infections such as colds and sore throats may sometimes extend down into the trachea; they are then called tracheitis. Inflammation of the walls of these passages causes harsh breathing and deep cough.

Bronchi

The trachea divides into the right and left main stem bronchi under the sternum (breastbone), approximately where the second and third ribs connect to the sternum. Each bronchus enters the lung of its own side through the hilus (an opening through which vessels or nerves enter or leave an organ).

The right main stem bronchus is wider and shorter than the left. Its direction is almost identical to that of the trachea. That is why most aspirated material enters the right lung.

Each bronchus leads to a separate lung, and in doing so divides and subdivides into increasingly smaller, finer, and more numerous tubes, something like the branches of a tree; the whole structure is sometimes called the bronchial tree. In the larger branches there also is stiffening by rings of cartilage, but as the branches get smaller the cartilage diminishes to small plates and finally disappears.

The smaller branches of the bronchial tree, bronchioles, are another possible source of discomfort. The fine subdivisions of the air passages are lined by circular muscles, which through contraction or relaxation can alter the diameter, thus helping to control the flow of air through the lungs. Sometimes, as a result of infection or an allergic reaction to some foreign substance, there is a spasmodic contraction of the small muscles and a swelling of the mucous membrane of the bronchioles. The air passages narrow and airflow is reduced.

Lungs

There are two lungs, one on each side of the thoracic cage (Figure 2–4). The lungs are suspended within the thoracic cage by the trachea, by the arteries and veins running to and from the heart, and by pulmonary ligaments.

The lungs extend from the collarbone to the diaphragm, one on the right side of the body and one on the left. Taken together, they fill almost all of the thoracic cavity. The two lungs are not quite mirror images of each other. The right lung, slightly the larger of the two, is partially divided into three lobes; the left lung is divided into only two.

The mediastinum is the compartment between the left and right lung. It contains the heart, great vessels (aorta, vena cava, pulmonary veins, and arteries), nerves, trachea, main stem bronchi, and esophagus.

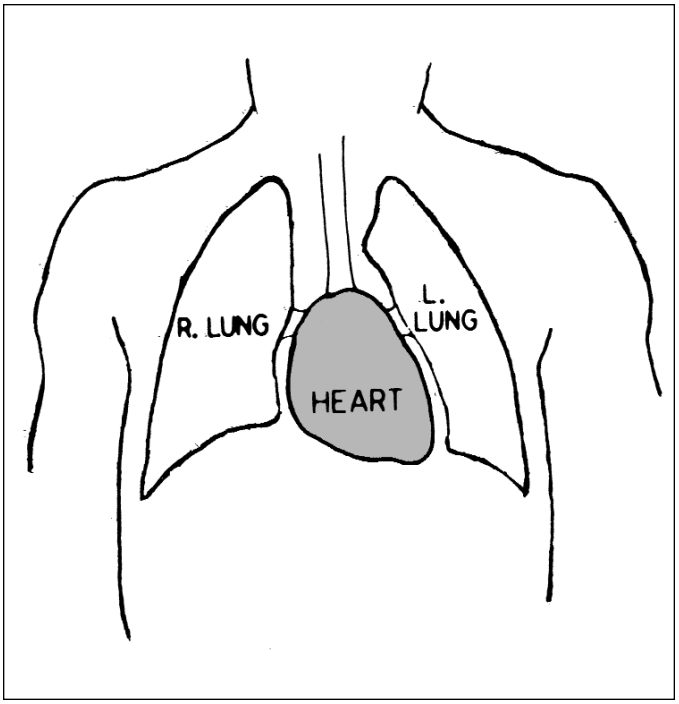

Figure 2–4. The relative size and spatial relationship of the human heart and lungs. (Reproduced with permission from *Emergency Care and Transportation of the Sick and Injured,* ed. 1. Chicago, IL, American Academy of Orthopaedic Surgeons, 1971.)

PLEURA

The lungs are covered by a double membrane. One, the pleural membrane, lies over the lungs; the other lines the chest cavity (Figure 2–5). They are separated by a thin layer of fluid that, during breathing, prevents the two membranes from rubbing against each other. Inflammation of the pleura can cause roughness and irritation, the condition called pleurisy.

The potential intrapleural space (between the two pleural layers) has a negative atmospheric pressure during inspiration (breathing in). An introduction of air between the pleural layers (pneumothorax) would decrease or disrupt this negative pressure and the lung would partially or totally collapse.

The tendency to collapse is counteracted by a pull in the opposite direction. The lung surface is held tenaciously to the chest wall not by physical bonds, but by the negative pressure of the intrapleural space. Normally, this negative pressure acts somewhat like a suction cup to pull the lung against the chest wall and keep it expanded.

ALVEOLI

Within a lung, the bronchi divide and subdivide, becoming smaller and smaller, until the branches reach a very fine size and are called bronchioles. *Acini* or terminal lung units are supplied by a terminal bronchiole from which multiple respiratory bronchioles branch off. The respiratory bronchioles lead into several ducts; each duct ends in a cluster of air sacs, which resemble a tiny bunch of grapes called alveoli (Figure 2–6).

The walls of the alveoli are two cells thick and oxygen can pass freely across those thin membranes. It can pass freely in both directions, of course, but the blood coming to the lungs has a lower partial pressure of oxygen than inspired air, so the net exchange is from the lungs to the bloodstream.

The human respiratory tract branches successively from the trachea to 25–100 million branches. These branches terminate in some 300 million air sacs, or alveoli. The cross section of the trachea is about 0.31 sq in. (2 cm^2) and the combined cross sections of the alveolar ducts, which handle about the same quantity of air, are about 8 ft^2 (8,000 cm^2).

The respiratory surface in the lungs ranges from about 300 ft^2 (28 m^2) at rest to about 1,000 ft^2 (93 m^2) at deepest inspiration. The membrane separating the alveolar air space from circulating blood may be only one or two cells thick. In the course of an eight-hour day of moderate work, a human breathes about 300 ft^3 (8.5 m^3) of air. Contrast the forced ventilation exposure of the large delicate lung surface with the

ambient air exposure of the skin, which has some 20 ft^2 (1.9 m^2) of surface and a thickness measured in millimeters. It is evident that the lungs represent by far the most extensive and intimate contact of the body with the ambient atmosphere.

The respiratory tract, with its successive branches and tortuous passageways, is a highly efficient dust collector. Essentially all particles entering the respiratory system larger than 4 or 5 micrometers (μm) are deposited in it. About half of those of 1-μm size appear to be deposited and the other half exhaled. The sites of deposition in the system are different for various sizes. Discussion of dust deposition in the respiratory system is simplified by the concept of equivalent size of particles. The equivalent size of a particle is the diameter of a unit density sphere, which has the same terminal settling velocity in still air as does the particle.

Particles greater than 2.5 or 3 μm equivalent size are deposited, for the most part, in the upper respiratory system—that is, the nasal cavity, the trachea, the bronchial tubes, and other air passages—whereas particles 2 μm in equivalent size are deposited about equally in the upper respiratory system and in the alveolar or pulmonary air spaces. Particles about 1 μm in equivalent size are deposited more efficiently in the alveolar spaces than elsewhere; essentially none are collected in the upper respiratory system. For more details, see Chapter 8, Particulates.

RESPIRATION

The process through which the body combines oxygen with food substances, and thus produces energy, is called metabolism (Figure 2–7). The term *respiration* refers to the tissue enzyme oxidation processes that use oxygen and produce carbon dioxide. More generally, this term designates the phases of oxygen supply and carbon dioxide removal. The following are the general subdivisions of the overall process:

- ➢ Breathing—movement of chest/lung complex to ventilate the alveoli
- ➢ External respiration—exchange of gas (oxygen and carbon dioxide) between lung (alveolar) air and blood
- ➢ Internal respiration—exchange of gas between tissue blood and the tissue cells
- ➢ Intracellular respiration—ultimate utilization of oxygen by the cells with the coincident release of carbon dioxide.

To a biochemist, *respiration* refers to the enzymatic processes in the tissues that use oxygen and produce carbon dioxide. The blood contains a chemical that is part protein and part iron pigment, called hemoglobin. The hemoglobin binds oxygen when the blood flows through regions where oxygen is plentiful—as in the alveoli—and releases it to tissues that are consuming oxygen. Similarly, the carbon dioxide produced when the body cells burn fuel is dissolved in the bloodstream as it flows through tissues where carbon dioxide is plentiful, and is released in the lungs, where carbon dioxide is comparatively scarce.

Carbon dioxide is always present in the atmosphere, but the proportion of carbon dioxide in air exhaled from the lungs is 100 times greater. The proportion of water vapor in air exhaled from the lungs is about 10 times greater than that of the normal atmosphere. Everyone has no doubt noticed the moisture that accumulates on a glass window when the nose and mouth are close to it. Breath appears as a white cloud on cold days because the low temperature of the air causes the exhaled water vapor to condense.

Gas Exchange

Gases diffuse rapidly from areas of higher to lower concentrations. The concentration of oxygen is higher in alveolar air than it is in the blood coming to the lungs from the right ventricle. Therefore, oxygen diffuses into the blood from the alveolar air. On the other hand, the concentration of oxygen is low in the cells of the body tissues and in tissue fluid; therefore, oxygen diffuses from the blood in the capillaries into the tissue fluid and into cells.

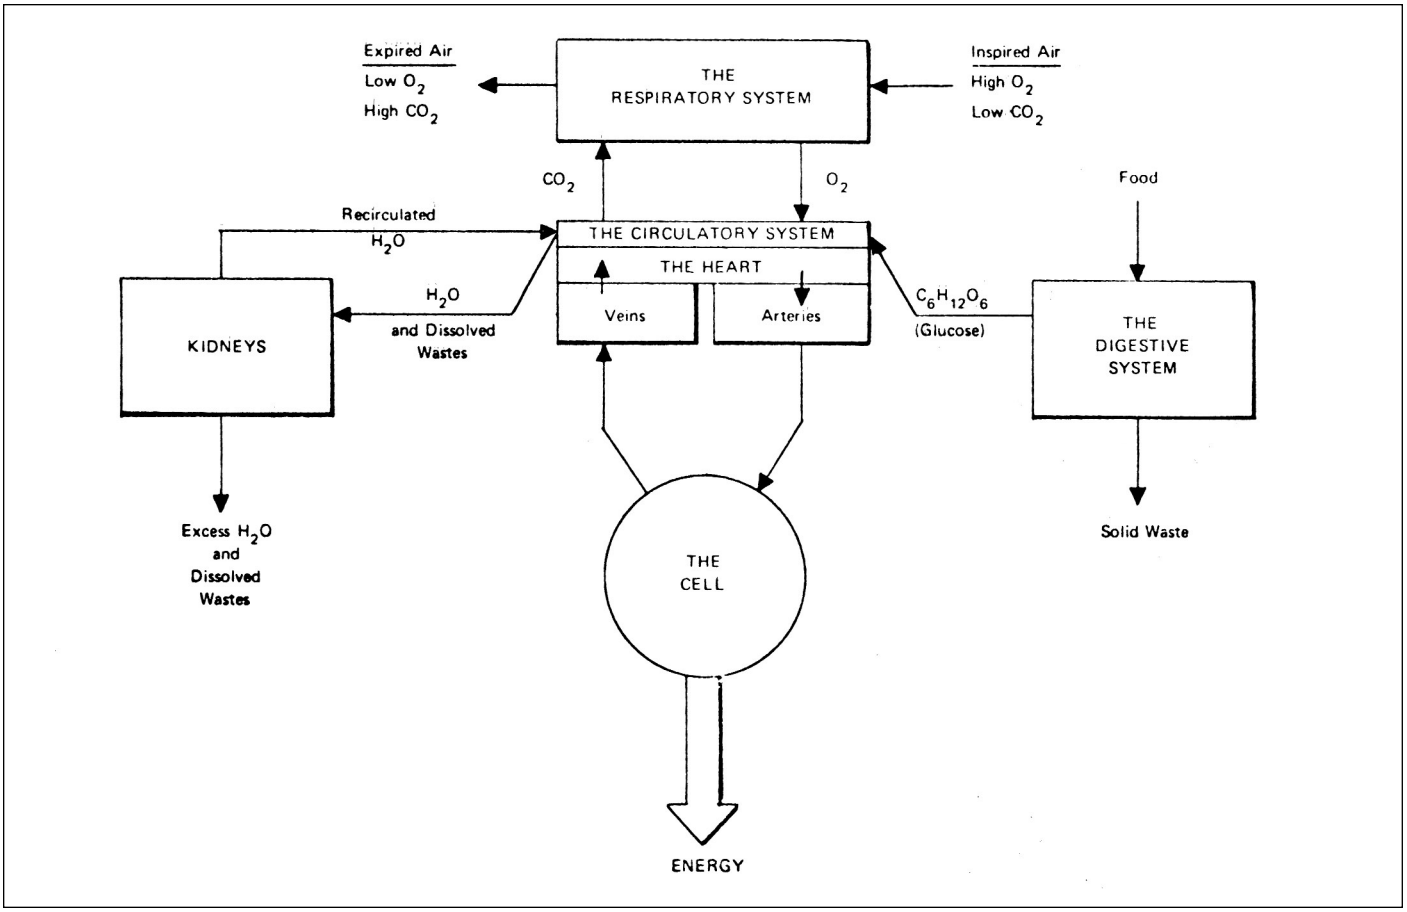

Figure 2–7. The conversion of food into energy (the metabolic process) is illustrated. (Reprinted from *A Guide to Industrial Respiratory Protection,* NIOSH Publication No. 76–189, 1976.)

EQUALIZING PRESSURES

If there is a pressure difference across a permeable membrane such as that separating the alveoli from the pulmonary capillaries, gas molecules pass from the high- to low-pressure region until the pressures are equalized (Figure 2–8).

The concentration of carbon dioxide in tissue cells and tissue fluid is higher than in the blood in capillaries. Therefore, carbon dioxide diffuses from tissue cells and tissue fluid into the blood. The concentration of carbon dioxide is higher in blood coming to the lungs from the right ventricle than it is in alveolar air; therefore, it diffuses from blood in pulmonary capillaries into the alveolar air.

On entering the bloodstream, both oxygen and carbon dioxide immediately go into simple physical solution in the plasma. However, because the plasma can hold only a small amount of gas in solution, most of the oxygen and carbon dioxide quickly enter into chemical combinations with other blood constituents.

OXYGEN TENSION

Only a small amount of oxygen is carried in solution in the plasma. However, it is this oxygen that exerts tension or pressure and is available for immediate diffusion when blood reaches the systemic capillaries (Figure 2–9). The remaining oxygen in the blood is combined with hemoglobin in the red blood cells to form oxyhemoglobin (HbO_2). This oxygen is given up readily by hemoglobin whenever the oxygen tension of plasma decreases, so that as oxygen diffuses from plasma in tissue capillaries it is replenished by more from oxyhemoglobin. Hemoglobin that has given up its load of oxygen is called *reduced* hemoglobin (Hb) (Figure 2–10). See Chapter 6, Industrial Toxicology, for more details.

In most people during routine activities, the depth and rate of breathing movements are regulated for the maintenance of carbon dioxide in the arterial blood. Low oxygen tension can stimulate breathing, but only when the oxygen content of the inspired gases is reduced to nearly half that in air at sea level. Oxygen partial pressure, except in some unusual circumstances, is usually high enough that breathing is regulated by the body requirements for carbon dioxide.

The oxygen content of lung air is determined by the oxygen content of the inspired gases, the flushing of the lungs required for carbon dioxide regulation, and the rate of oxygen uptake by the blood as it passes through the lungs.

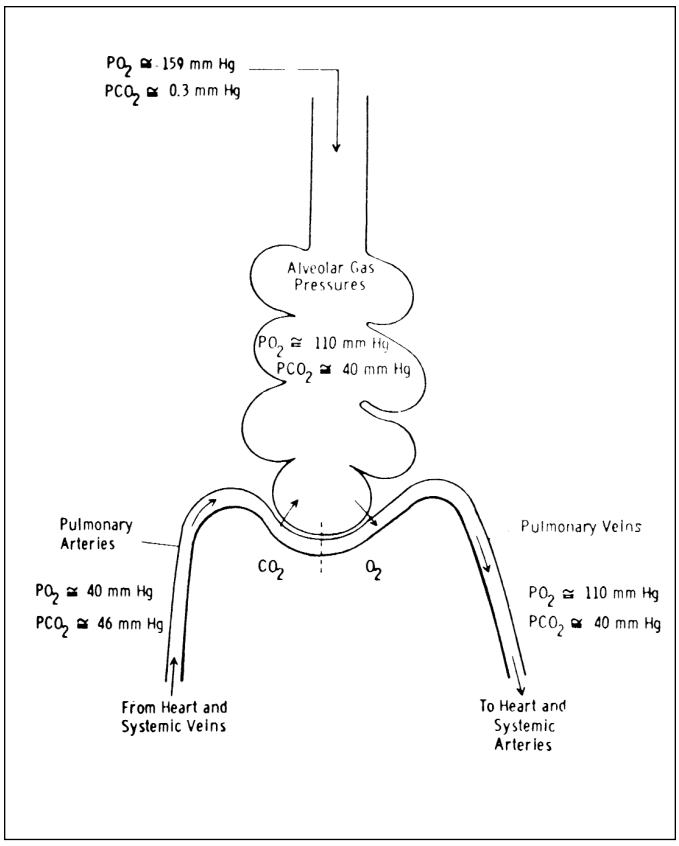

Figure 2–8. Partial pressures of various gases involved in the gas exchange in the lungs are shown. (Reprinted from *A Guide to Industrial Respiratory Protection,* NIOSH Publication No. 76–189, 1976.)

Mechanics of Breathing

Breathing is the act of taking fresh air into and expelling stale air from the lungs. Breathing is accomplished by changes in the size of the chest cavity. Twelve pairs of ribs surround and guard the lungs. The ribs are joined to the spine at the back and curve around the chest to form a cage. In front, the top seven pairs are connected to the sternum (breastbone). The next three pairs are connected to the rib above. The last two pairs, unconnected in front, are called floating ribs. The entire cage is flexible and can be expanded readily by special muscles. The rib cage forms the wall of the chest; the dome-shaped diaphragm forms the floor of the chest cavity. The diaphragm is attached to the breastbone in front, the spinal column in back, and the lower ribs on the sides.

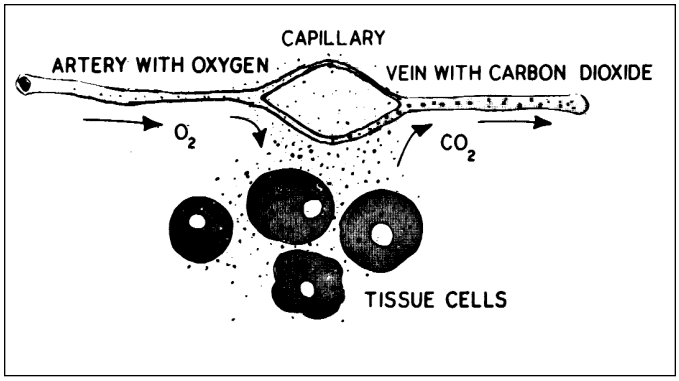

Figure 2–9. Exchange of oxygen and carbon dioxide between blood vessels, capillaries, and tissue cells. Oxygen passes from the blood to the capillaries to the tissue cells. Carbon dioxide passes from the tissue cells to the capillaries and into the blood. (Reproduced with permission from *Emergency Care and Transportation of the Sick and Injured,* ed. 2. Chicago, IL, American Academy of Orthopaedic Surgeons, 1977.)

Pressure Changes

The basic principle underlying the movement of any gas is that it travels from an area of higher pressure to an area of lower pressure, or from a point of greater concentration of molecules to a point of lower concentration. This principle applies not only to the flow of air into and out of the lungs but also to the diffusion of oxygen and carbon dioxide through alveolar and capillary membranes. The respiratory muscles and the elasticity of the lungs make the necessary changes in the pressure gradient possible, so that air first flows into the air passages and then is expelled.

Atmospheric pressure is the pressure exerted against all parts of the body by the surrounding air. It averages 760 mm of mercury (760 mmHg) at sea level. Any pressure that falls below atmospheric pressure is called a negative pressure and represents a partial vacuum.

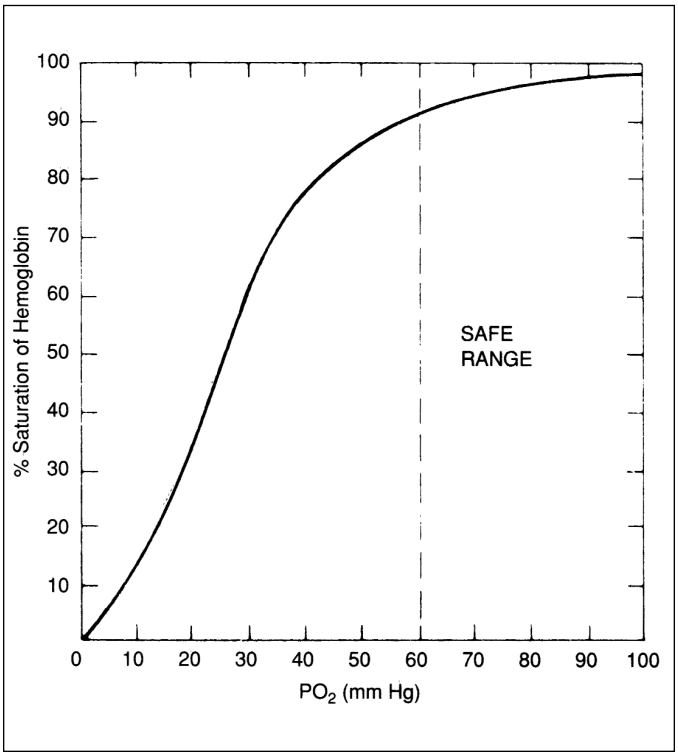

Figure 2–10. Percent saturation of hemoglobin with oxygen at various partial pressures is shown in the hemoglobin saturation curve. (Reprinted from *A Guide to Industrial Respiratory Protection,* NIOSH Publication No. 76–189, 1976.)

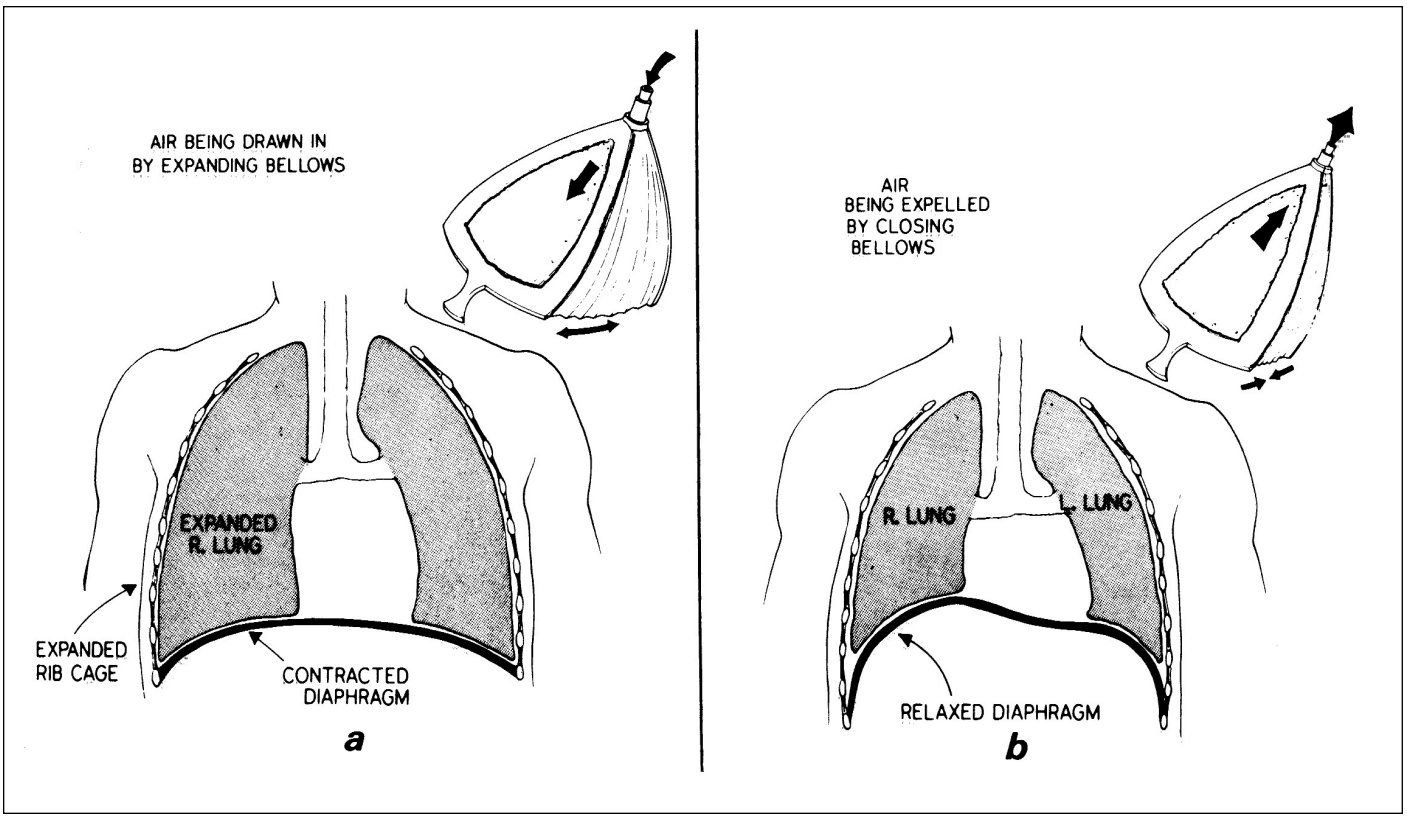

Figure 2–11. Inhalation is similar to the act of air entering a bellows. It occurs when the diaphragm contracts and the ribs expand. Exhalation is similar to the act of air leaving a bellows. It occurs when the diaphragm and ribs relax. (Reproduced with permission from *Emergency Care and Transportation of the Sick and Injured,* ed. 1. Chicago, IL, American Academy of Orthopaedic Surgeons, 1971.)

Intrapulmonic pressure is the pressure of air within the bronchial tree and the alveoli. During each respiratory cycle this pressure fluctuates below and above atmospheric pressure as air moves into and out of the lungs. Intrapulmonic pressure is below atmospheric pressure during inspiration, equal to atmospheric pressure at the end of inspiration, above atmospheric pressure during expiration, and again equal to atmospheric pressure at the end of expiration.

This series of changes in intrapulmonic pressure is repeated with each respiratory cycle. Whenever the size of the thoracic cavity remains constant for a few seconds, or in a position of rest, the intrapulmonic pressure is equal to atmospheric pressure.

Lungs have one way of filling themselves. Movement of the thoracic cage and the diaphragm permits air to enter the lungs. The thoracic cage is a semirigid bony case enclosed by muscle and skin. The diaphragm is a muscular partition separating the chest and abdominal cavities.

The chest cage can be compared to a bellows. The ribs maintain the shape of the chest bellows. The opening of the chest bellows is through the trachea. Air moves through the trachea to and from the lungs to fill and empty the air sacs (Figure 2–11). When a bellows is opened, the volume it can hold increases, causing a slight vacuum. This lowers the air pressure inside the bellows and causes the higher pressure outside the bellows to drive air through the opening, thereby filling the bellows.

When the air pressure inside equals the pressure outside, air stops moving into the bellows. Air will move from a high-pressure area to a low-pressure area until the pressure in both areas is equal. Therefore, as the bellows is closed, the pressure inside becomes higher than outside and air is expelled (Figure 2–11).

During inspiration (inhaling), the diaphragm and rib muscles contract. When the diaphragm contracts, it moves downward and enlarges the thoracic cavity from top to bottom. When the rib muscles contract, they raise the ribs. This enlarges the chest cavity (bellows) in all dimensions. This enlargement of the thoracic cavity reduces the pressure within the chest. The action is identical to that of opening a bellows. Air rushes into the lungs. Take a deep breath to see how the chest increases in size. This is the active muscular part of breathing.

During expiration (exhaling), the diaphragm and the rib muscles relax. As these muscles relax, the chest cavity decreases in size in all dimensions. As it does so, the air in the lungs is pressed into a smaller space, the pressure increases, and air is pushed out through the trachea. Decrease in size of the chest cavity after relaxation is accomplished largely by action of elastic tissue in the lung, which stretches for inhalation and recoils after muscular relaxation.

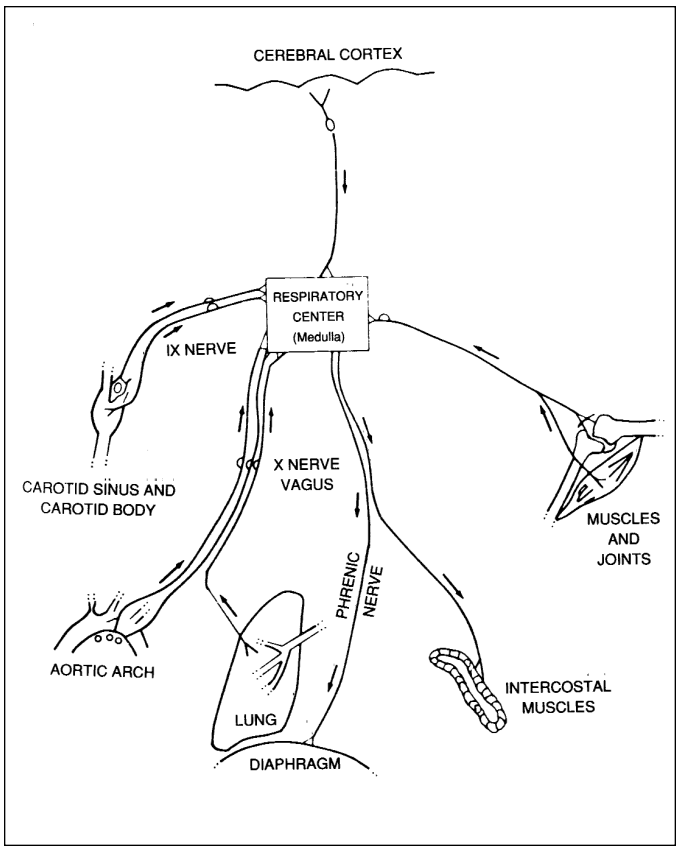

Figure 2–12. Normal rhythmic breathing is controlled by the requirement to ventilate the lungs to remove carbon dioxide as fast as it is produced by metabolic activity. The factors effective in controlling breathing are illustrated schematically. (Reprinted from Parker JF. *Bioastronautics,* 2nd ed. Washington, DC: National Aeronautics and Space Administration, 1973.)

Control of Breathing

Breathing is controlled by a series of respiratory centers in the nervous system. One center is in the medulla, the part of the brain at the top of the spinal cord (Figure 2–12).

Respiratory Center

Nerve impulses originating in the motor areas of the cerebral cortex and traveling to the respiratory center enable us to consciously alter the rate and the depth of breathing. For example, during speaking or singing, breath control is very important.

You can hold your breath voluntarily for a short period of time. However, voluntary control is limited, and the respiratory center will ignore messages from the cortex when breathing is necessary to meet the body's basic needs.

Carbon Dioxide

Breathing action can be triggered by the respiratory centers when the amount of carbon dioxide in the blood increases or when the oxygen level of the blood decreases.

If you hold your breath, carbon dioxide accumulates in the blood until, finally, it so strongly stimulates the respiratory control center of the brain that you are forced to breathe again. The length of time the breath can be held varies from 25 to 75 seconds; some people can hold their breath even longer.

Rate

Even in a relaxed state, you breathe in and out 10–14 times a minute, with each breath lasting 4–6 seconds. In a minute, 9–12 pt (4.3–5.7 L) of air are taken in. The fact is that the body has small reserves of oxygen; all of it is consumed within less than half a minute after the start of vigorous exertion. With such exertion, the need for air increases many times so that the breathing rate may speed up to one breath per second and a total intake of 31 gal (120 L) of air per minute.

In a normal day, you breathe some 3,300 gal (12,491 L) of air—enough to occupy a space of about 8 ft^3; in a lifetime, you will consume enough to occupy 13 million ft^3 (368,120 m^3) of space.

Lung Volumes and Capacities

For descriptive convenience the total capacity of the lung at full inspiration is divided into several functional subdivisions. These are illustrated in Figure 2–13.

The four primary lung volumes that do not overlap are as follows:

- ➢ Tidal volume (TV)—the volume of gas inspired or expired during each respiratory cycle
- ➢ Inspiratory reserve volume (IRV)—the maximal volume that can be forcibly inspired following a normal inspiration (from the end-inspiratory position)
- ➢ Expiratory reserve volume (ERV)—the maximum amount of air that can be forcibly expired following a normal expiration
- ➢ Residual volume (RV)—the amount of air remaining in the lungs following a maximum expiratory effort

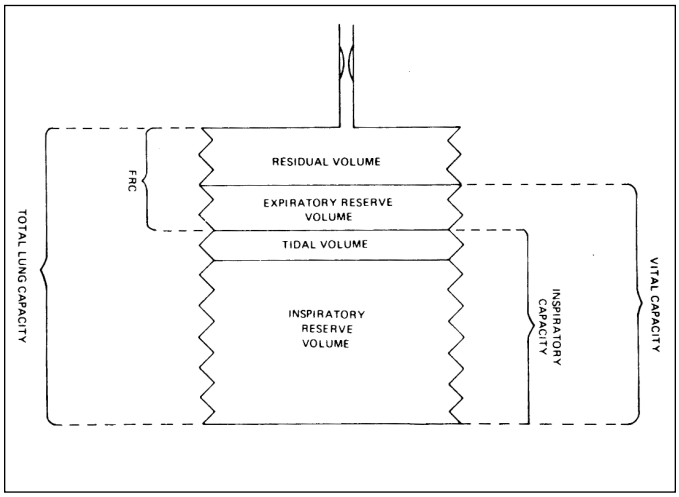

Figure 2–13. Inspiratory capacity and tidal capacity. (Reprinted from Parker JF. *Bioastronautics,* 2nd ed. Washington, DC: National Aeronautics and Space Administration, 1973.)

Each of the four following capacities includes two or more of the primary volumes:

- ➢ Total lung capacity (TLC)—the sum of all four of the primary lung volumes
- ➢ Inspiratory capacity (IC)—the maximum volume by which the lung can be increased by a maximum inspiratory effort from midposition
- ➢ Vital capacity (VC)—the maximum amount of air that can be exhaled from the lungs after a maximum inspiration (the sum of the inspiratory reserve volume, tidal volume, and expiratory reserve volume)
- ➢ Functional residual capacity (FRC)—the normal volume at the end of passive exhalation; that is, the gas volume that normally remains in the lung and functions as the residual capacity

In an ordinary inhalation the first air to enter the lungs is the air that was in the bronchi, throat, and nose—air that had left the lungs in the previous expiration but had not been pushed out as far as the outside world. Then, after an inspiration is complete, some of the fresh air that entered through the nostrils remains in the air passages; here it is useless, and is expired again before it can get to the lungs. The dead space represents the air passages between the nostrils and lungs. Fresh air actually entering the lungs with each breath may amount to no more than 21.4 $in.^3$ (350 cm^3). This represents only 1/18 of the lungs' total capacity and is called the tidal volume.

The partial replacement of the air in the lungs (alveolar air) by the shallow breathing we normally engage in is sufficient for ordinary purposes. We are quite capable of taking a deep inhalation of air as well, forcing far more into the lungs than would ordinarily enter. After about 30.5 $in.^3$ (500 cm^3) of air have been inhaled in a normal quiet breath, an additional 153 $in.^3$ (2,500 cm^3) can be sucked in. On the other hand, you can force 42.7 $in.^3$ (7,000 cm^3) of additional air out of the lungs after an ordinary quiet expiration is completed. By forcing all possible air out of the lungs and then drawing in the deepest possible breath, you can bring well over 1.7 ft^3 (4,000 cm^3) of new air into the lungs in one breath. This is the vital capacity.

Even with the utmost straining, the lungs cannot be completely emptied of air. After the last bit of breath has been forced out, about 73 $in.^3$ (1,200 cm^3) remain. This is the residual volume and is a measure of the necessary inefficiency of the lungs.

Vital lung capacity is measured by inhaling as deeply as possible and blowing out as much as possible into a spirometer. The quantity of expelled air varies with body size and age. A medium-sized man may have a vital capacity of 1.7–1.9 ft^3 (4,000–4,500 cm^3) between the ages of 20 and 40 years. However, as the elasticity of tissues decreases with age, the vital capacity diminishes and may be as much as 20 percent less at age 60 and 40 percent less at age 75.

Spirometry means measurement of air—the ventilatory capacity of the lungs. The spirometer achieves this by measuring volumes of air and relating them to time.

Change in the ability to move air into and out of the lungs in a normal manner results in what is called either obstructive or restrictive ventilatory defect, or a combination of the two. In diseases associated with an obstructive ventilatory defect, such as asthma or chronic obstructive pulmonary disease (COPD), there is reduction of air flow rates during and a prolongation of expiration. In diseases causing a restrictive ventilatory defect, such as the pneumoconioses (e.g., asbestosis, silicosis), there is a decreased ability to take a deep breath due to scarred (i.e., stiffer) lungs.

Forced vital capacity (FVC) is the maximal volume of air that can be exhaled forcefully after a maximal inspiration. For all practical purposes, the VC without forced effort and the FVC are identical in most people.

In the early detection of pneumoconiosis, the FVC is of variable use. In asbestosis, the FVC is regarded as a relatively sensitive indicator of early disease and may be impaired before there are radiographic abnormalities. Conversely, x-ray changes may be evident in silicosis while the FVC is still normal.

Forced expiratory volume in 1 second (s) (FEV_1) is the volume of air that can be forcibly expelled during the first second of expiration. With an obstructive ventilatory defect, the FEV_1 is decreased while the FVC is relatively preserved, leading to a decreased FEV_1/FVC ratio.

Forced expiratory flow (FEF) during the middle half of the FVC ($FEF_{25–75\%}$) can be defined as the average rate of flow during the middle two quarters of the forced expiratory effort. Compared with FEV_1, it may be more sensitive in detecting early airway obstruction and tends to reflect changes in airways less than 2 mm in diameter. Airborne substances are thought to exert their initial deleterious effects in these smaller bronchi and bronchioles. Smoking one cigarette can lower the $FEF_{25–75\%}$ for several hours.

Peak expiratory flow (PEF) is another measure of expiratory flow. PEF is the peak of the expiratory flow volume curve. The peak expiratory flow rate is the rate of maximal expiratory flow. The development of portable peak flow meters that directly measure flow rates has allowed workers to measure their lung function during and away from work. It has the advantages of sensitivity to early obstructive changes and ease of measurement.

HAZARDS

Let's look at some of the unhealthy conditions to which the lung is subject, the associated terminology, and some typical hazardous substances.

The membrane lining of the nasal passages can be affected by a number of causes. The resultant condition is called *rhinitis.* Inflammation in the larynx is called laryngitis; that of the bronchial tubes is called *bronchitis.* Constriction of the tube muscles in response to irritation, allergy, or other stimulus is called *asthma.*

In the lungs, a number of conditions can develop:

- ➢ *Atelectasis* means incomplete expansion of the lungs. It is caused by occlusion of a bronchus, perhaps by a plug of heavy mucus, with subsequent absorption of the air, or by external compression, as from a pleural effusion or a tumor. The atelectatic portion of the lung will allow blood to pass through without adding oxygen or removing carbon dioxide.
- ➢ The term *emphysema* derives from Greek words meaning *overinflated.* The overinflated structures are the alveoli. Cigarettte smoke and some occupational agents (e.g., coal dust, cadmium fumes) can cause destruction of alveolar walls that leads to emphysema. Chronic inflammation of the small and large airways (bronchiolitis, bronchitis) is also often present in patients with emphysema. The inflamed airways tend to become narrowed due to increased mucus production, swelling of the lining membrane, and enlargement (hypertrophy) of the surrounding muscle. Air flows into the alveoli easily but cannot flow out easily because of the narrowed diameter of the bronchioles. The patient can breathe in, but cannot breathe out efficiently; this leaves too much CO_2 in the lungs. As pressure builds up in the air cells, their thin walls are stretched to the point of rupture, so several air spaces communicate and the area of surfaces where gas exchange takes place is decreased.
- ➢ *Pleurisy* is caused when the outer lung lining (the visceral pleura) and the chest cavity's inner lining (the parietal pleura) lose their lubricating properties. The resultant friction causes irritation and pain. The thin, glistening layer of pleura that is inseparably bound to the lung has no pain fibers, but the opposing pleura is richly supplied. Normally the pleural layers glide over each other on a thin film of lubricating fluid. Disease may cause the pleura to become inflamed and adherent, or fluid may accumulate in the pleural space, separating the layers.
- ➢ *Pneumonitis* is any inflammation of the lung. It is essentially equivalent to the term *pneumonia,* which is usually reserved for infectious inflammation.
- ➢ *Bronchitis* is inflammation of the lining of the bronchial tubes. Chronic bronchitis means that the infection is persistent.
- ➢ *Pneumoconiosis* (dusty lung) is a general word for various pulmonary manifestations of dust inhalation, whether the dust is harmful or not. Two common forms of pneumoconiosis are silicosis and asbestosis. The typical pathological condition in harmful pneumoconiosis is the existence of fibrotic (scar) tissue in the alveolar sacs or at lymph nodes in the lungs. This fibrotic tissue, caused by some dust particles, reduces the efficiency of the lungs by making them less resilient and by reducing the effective working surface for gaseous exchange.

The fate of an inhaled air contaminant depends on its size, solubility, and chemical reactivity. As noted previously, larger particles tend to get deposited in the upper airways, trachea, and bronchi, while smaller particles (i.e., <3 μm in diameter) tend to deposit in the smaller airways and alveoli (the so-called deep lung). More soluble, reactive substances get absorbed onto the moist mucous membranes of the upper airways, trachea, and larger bronchi, leading to irritation and inflammation of these structures. Less soluble, reactive gases cause less irritation of the mucous membranes so that they cause less "warning" irritation of the mucous membranes. If any reactive substance is inhaled into the deep lung, then inflammation of the alveoli, or pneumonitis, can occur. If the chemical injury to the alveoli is severe enough, flooding of the alveoli with inflammatory material can occur, known as pulmonary edema. When there is pulmonary edema, gas exchange becomes markedly impaired.

Most of the particles that reach the deep lung (alveoli) are engulfed by cellls called macrophages (literally "big eaters") that migrate proximally to the airways and are either expectorated or swallowed or may enter the interstitial tissues. Once in the deep lung, however, chemical components in particles or in the vapor state can be absorbed into the bloodstream.

Inhaled contaminants that adversely affect the lungs fall into three general categories:

- ➢ Aerosols and dusts, which, when deposited in the lungs, may produce tissue reaction and/or disease
- ➢ Toxic gases that may produce direct tissue injury
- ➢ Toxic aerosols or gases that do not affect the lung tissue, but are passed from the lung into the bloodstream, where they are carried to other organs or have adverse effects on the oxygen-carrying capacity of the bloodstream (see Chapter 6, Industrial Toxicology)

Potential health hazards from dust occur on three levels. The inhalation of sufficient quantities of dust, regardless of its chemical composition, can cause a person to choke or cough; it can also accumulate in the lungs. Depending on its chemical composition, dust can cause an allergic or sensitization reaction in the respiratory tract. Depending on both its size and chemical composition, dust can, by physical irritation or chemical action, damage the airway and/or lung.

Fibrosis can be produced by certain insoluble and relatively inert fibrous (e.g., asbestos) and nonfibrous (e.g., silica) solid particulates found in industry. It is now thought that one of the prerequisites for particulate-induced bronchogenic carcinoma may be the insolubility of the particulate in the fluids and tissues of the respiratory tract. More insoluble particulates can reside in the lung long enough to induce tumors. A category of aerosol hazard, *bioaerosols,* includes certain bacteria and fungi that can cause an allergic-type inflammatory disease of the lungs called hypersensitivity pneumonitis. These microorganisms are found on moldy vegetative material such as silage, compost, and sugar cane.

Some of the reactive industrial gases and vapors of high solubility that can produce immediate irritation and inflammation of the entire respiratory tract include ammonia, hydrogen fluoride, and sulfur dioxide. Less soluble gases, such as nitrogen dioxide, phosgene, and ozone primarily

affect the deep lung (the bronchioles and the adjacent alveolar spaces) where they may produce pulmonary edema within a few hours.

Carbon monoxide (CO) is a toxic gas that is transferred from the lungs into the bloodstream but does not damage the lungs. Carbon monoxide passes through the alveolar walls into the blood, where it binds hemoglobin so it cannot accept oxygen, thus causing oxygen starvation.

Many metal oxides of submicron particle size (called fume) produce both immediate and long-term effects; the latter can occur in organs and tissues remote from the site of entry. For example, cadmium oxide fume inhaled at concentrations well above the Threshold Limit Value (TLV®) may produce immediate pulmonary edema that can be fatal; in addition, inhalation for many years of the fume at concentrations of a few multiples of the TLV can result in eventual renal injury and pulmonary emphysema.

Individual susceptibility to respiratory toxins is difficult to assess. In the occupational setting, workers exposed to the same environment for equal periods of time may develop different degrees of pulmonary disease. This can be due to the variation of the rate of clearance from the lung, the effect of cigarette smoking, coexistent pulmonary disease, and genetic factors.

NATURAL DEFENSES

The respiratory system has a rather complete set of mechanisms for shrugging off insults: the warming and humidifying effects of the nasal and throat passages (as defenses against very cold or overly dry air), the mucous lining, and physical impaction on the branching respiratory tree.

Because the mucous lining plays an important role in the cleansing of aerosols from the lungs, it deserves closer inspection. Cells in the trachea and bronchi produce mucus that is constantly being carried toward the mouth by tiny hairlike projections, called cilia, waving in synchrony. This moving blanket acts as a vehicle to carry foreign substances up and out of the system to the throat, where they can be expectorated or swallowed.

In a healthy lung, aerosols that get into a bronchiole can be carried back out of the system in a matter of hours. Given adequate recovery time (about 16 hours) after an eight-hour exposure to dust, the healthy lung can thus cleanse itself.

Other defense mechanisms include muscular contraction of the bronchial tubes upon irritation—this reaction restricts the airflow and thus minimizes intake of the irritating substance—and the cough and sneeze, which tend to rid the upper respiratory tract of irritants.

Thus far we have discussed only the defenses of the airways leading to the alveoli. In general, only very fine particles and gases reach the alveolar sacs. The larger the particle, the sooner it will be deposited through impaction or gravity on the lining of the airway tubes leading to the sacs.

In the case of gases, the concentration that reaches the alveolar sacs will be nearly the same as the concentration in the air breathed. With aerosols, this is not the case. Large particles, more than 10 μm, will be deposited long before they reach the alveoli, through gravity and impaction. Only the smaller particles will reach the alveoli. In the alveoli, Brownian movement of the particles results in deposition by diffusion.

Because only the small (fine) particles are likely to reach the alveoli in great quantities, and because the alveoli are the most important area in the lungs, it is clear that fine aerosols are potentially more harmful than larger aerosols. What happens to fine particles that do reach the alveolar sacs?

Particles deposited in the alveoli will be scavenged by macrophages, which are mobile white blood cells capable of ingesting particles. Once laden with foreign matter, these cells can do the following:

- ➢ migrate to the bronchioles, where the mucous lining carries them out of the system
- ➢ pass through the alveolar membrane into the lymph vessels associated with the blood capillaries
- ➢ be destroyed (if the contaminant is cytotoxic) and break up, releasing the particles back into the alveolar sac

If the particles are not removed by these means, they can form a deposit in and around the alveoli. Such deposits may or may not affect the health of the lungs over time.

All of the defense mechanisms are subject to some deterioration and slowing down with age or ill health. Thus, an older worker's lungs will not be cleaned as quickly or efficiently as those of a younger person. Also, some contaminants may impede the defense mechanisms themselves, increasing the rate of retention of the contaminant in the lungs.

AMA GUIDES FOR EVALUATING IMPAIRMENT

This section on determining the percent impairment is adapted from the American Medical Association's (AMA) *Guides to the Evaluation of Permanent Impairment* and is included to assist health and safety professionals in interpreting and understanding medical reports of workers' compensation cases.

This AMA publication assists physicians in evaluating permanent impairment of the respiratory system and the effect such impairment has on a person's ability to perform the activities of daily life. Permanent impairment of the respiratory system is not necessarily a static condition. A changing process can be present, so that it may be desirable to reevaluate the patient's impairment at appropriate intervals.

The measurable degree of dysfunction of the respiratory system does not necessarily parallel either the extent and severity of the anatomic changes of the lungs or the patient's own account of difficulties in carrying out the activities of daily life. Among the reasons for this phenomenon are the large pulmonary reserves normally present, existence of disease in other systems (particularly the cardiovascular system), wide variation in certain physiological measurements in normal individuals, and the patient's emotional response to respiratory disease or injury.

Many tests of pulmonary function have value and interest as guides to therapy and prognosis. For most patients, however, most of these are neither practical nor necessary for assignment to a particular class of impairment. Judicious interpretation of the results of ventilatory function tests and diffusion studies, combined with the clinical impression gained from weighing all the information gathered, should permit a physician to place the patient in the proper class of impairment.

Rating of Impairment

The classification of respiratory impairment is based primarily on spirometric tests of pulmonary function and diffusing capacity for carbon monoxide (D_{CO}).

Procedures useful in evaluating impairment of the respiratory system include but are not limited to complete history and physical examination with special reference to cardiopulmonary symptoms and signs; chest roentgenography (posteroanterior, PA) in full inspiration, lateral, and other procedures as indicated; hematocrit or hemoglobin determination; electrocardiogram, FEV_1, FVC, and D_{CO}; and other tests, such as blood gas and pulmonary exercise studies, as indicated.

Tests of Pulmonary Function—Ventilation

The tests of ventilatory function have certain limitations:

- ➢ They require maximal voluntary effort by the patient, who may be unable or reluctant to perform the tests as well as ventilatory capacity permits. For example, the performance may be affected by the patient's lack of understanding of the test; state of physical training; fear of cough, chest pain, hemoptysis, or worsening of dyspnea; motivation and cooperation; the effects of other illness, particularly heart disease; and the effects of certain temporary factors on the day of the test, such as the presence of a respiratory infection or bronchospasm.
- ➢ The results of these tests vary considerably among normal people of the same sex, age, and height.
- ➢ Infrequently, significant impairment of respiratory function can exist even though the patient can perform the tests of ventilatory function normally; that is, the bellows action of the lungs and thorax is normal, but there are abnormalities of pulmonary circulation or gas exchange that give rise to the impairment and necessitate other evaluation procedures.

Various types of spirometers are available that give a permanent record and that readily permit measurement of the FEV_1 and the FVC. These tests can be understood by patients after a short explanation and instruction period, but most patients must be encouraged to put forth their best effort. The FEV_1 and FVC should each be administered at least three times, with the best test result considered most representative of the patient's ability. The test should not be considered valid unless the best two curves agree within five percent.

If the forced expiratory volume test is interpreted as showing airflow obstruction, the test might be repeated 10–15 min after the patient has inhaled a nebulized bronchodilator. If there is at least 12-percent improvement in the performance of the test, the possible reversibility of the airway obstruction and, incidentally, the presumed efficiency of bronchodilator therapy are established. The patient's best test results before or after bronchodilation should be used in determining the degree of impairment.

Results of tests of ventilatory function should be expressed both in liters or liters per minute and as a percentage of the predicted normal. The FVC as a percentage of the predicted normal is taken as a measure of restrictive impairment. The ratio of actual FEV_1 to actual FVC is a criterion for diagnosing obstructive impairment, but the value of measured FEV_1 either by itself or as a percentage of predicted FEV_1 is considered the best measure of severity. Determination of exercise capacity and arterial blood-gas determinations are useful when a patient's symptoms do not correlate

Table 2–A. ***Terminology of Certain Pulmonary Function Measurements***

Terms Used	*Symbol*	*Description*	*Remarks*
Forced vital capacity	FVC	The largest volume of air measured on complete expiration after the deepest inspiration performed with expiration as forceful and rapid as possible (in liters).	This value should be ≥ the lower 95% confidence interval of the predicted value. A lower value suggests the presence of either an obstructive or restrictive ventilatory defect. If the FEV_1/FVC is >70%, then a restrictive defect is likely present.
Forced expiratory volume in one second	FEV_1	Volume of air exhaled during the performance of a forced expiratory maneuver in the first second (in liters).	
One-second forced expiratory volume expressed as a percentage of FVC	$\frac{FEV_1}{FVC} \times 100$	The observed FEV_1 expressed as a percentage of the observed FVC.	This value normally should exceed 70%. A lower value suggests the presence of some degree of obstructive airway disease.
Diffusing capacity for carbon monoxide	D_{CO}	The rate at which CO is transferred from the lungs to the blood (in mL/min/mmHg).	

well with spirometric studies. Diffusing capacity of carbon monoxide (single-breath D_{CO}) is available in most pulmonary function laboratories. It detects interference with transfer of gases across the alveolar membrane, as may occur in emphysema or interstitial fibrosis. Tables for "normal" values of FVC, FEV_1, FEV_1/FVC, and D_{CO} are given in the AMA *Guides to the Evaluation of Permanent Impairment.*

Quantitative exercise capacity measurements can be done using a treadmill or stationary bicycle. The primary exercise measurement used in respiratory impairment rating is the maximal oxygen consumption ($\dot{V}o_2max$). A patient's $\dot{V}o_2max$ provides a good estimate of the maximum workload that he/she can tolerate.

Determinations of partial pressures of oxygen and carbon dioxide in arterial blood, particularly before and after exercise, can be useful in certain cases. These measurements require arterial puncture, so they are not suitable for routine evaluation.

Other measurements of pulmonary function are available in specialized laboratories, but they are not sufficiently standardized for evaluation of impairment.

The *AMA Guides* classify respiratory impairment into four classes—none, mild, moderate, and severe—based on FVC, FEV_1, FEV_1/FVC, and D_{CO} or $\dot{V}o_2max$. Special criteria independent of pulmonary function are assigned to asthma, hypersensitivity pneumonitis, pneumoconiosis, or lung cancer. The 5th edition of the *AMA Guides* includes a new classification of impairment due to asthma that involves three different parameters: post-bronchodilator FEV_1, percent change in FEV_1 post-bronchodilator or degree of methacholine responsiveness (a measure of nonspecific airway hyperresponsiveness to noxious stimuli), and minimum medication needed to provide optimal control of the disease.

SUMMARY

The *nose* is an external organ lined by an extensive mucous membrane that warms, moistens, and filters inhaled air. It is the organ of smell.

The *pharynx* is located at the back of the nose and mouth, and above the larynx. It is a cylindrical tube that allows passage of food and air.

The *larynx, or* voice box, is an anterior structure in the neck. Its cartilaginous walls hold it open during inspiration and expiration.

The *trachea and bronchi* are airways lined with ciliated mucous membrane and have rings of cartilage to maintain patency. At midsternal level the trachea divides into two bronchi, one going to each lung. The left bronchus is longer and more horizontal than the right to accommodate the heart; consequently, inhaled foreign bodies find their way more easily into the right bronchus. These structures are the main sensory area for the initiation of the cough reflex. Their ciliated linings sweep mucus upward to the throat.

The *lungs* are two spongy cone-shaped organs that occupy the major portion of the thoracic cavity. The space between them is called the mediastinum, and contains the heart, blood vessels, and all tubes passing to and from the abdomen. The lungs are made up of acini or terminal lung units that contain a terminal bronchiole to which clusters of alveoli are connected by respiratory bronchioles.

The *alveoli* are clustered at the ends of the bronchioles like bunches of grapes. They have a rich blood supply from the pulmonary arteries, allowing close contact of blood and air, thus permitting the interchange of oxygen into the blood and carbon dioxide into the air.

The bronchioles, alveoli, and blood vessels are supported by elastic connective tissue, which, with lymphatic vessels, glands, and nerves, form the substance or interstitium of the lungs.

The vital capacity of the lungs is 3–4 L of air, but only half a liter is exchanged with each quiet respiration. As well as the gaseous exchange in the lungs, heat and moisture are lost from the body.

Spontaneous inspiratory nervous impulses arise from a center in the brain stem. This center is influenced by stimuli from many chemical and mechanical receptors. The stimulus for expiration is of a nervous origin and arises from stretching of the nerve endings in the alveolar wall. This stimulus cuts out the impulses that produced inspiration; by elastic recoil and relaxation of muscle, expiration is produced.

Human lungs are size-selective dust collectors. Only relatively small particles, generally those less than 2.5–3 μm in diameter, reach the alveolar spaces. The lungs have a very large surface, 300–1,000 ft^2 (28– 92 m^2) of very delicate tissue. This surface is exposed to contaminants in the air breathed. The lungs have good defenses against particulates; when unimpaired, these clearance mechanisms remove about 99 percent of the insoluble dust deposited in the lungs.

Chapter 3

The Skin and Occupational Dermatoses

by James S. Taylor, MD

Portions of this chapter in the first and second editions of this book were written by Julian B. Olishifsky and Larry L. Hipp.

The skin is the largest organ of the body. Its surface area is about 2 m^2 and in most places it is no more than 2 mm thick, yet its mass exceeds that of all other organs. Skin is a tough, flexible cover and is the first body barrier to make contact with a wide variety of industrial hazards. The skin is subject to attack from heat, cold, moisture, radiation, bacteria, fungi, and penetrating objects. Health and safety professionals should have a basic understanding of the anatomy, physiology, and defense mechanisms of the skin before recommending proper control measures.

The skin performs a number of important functions. Among these are protecting the body from invasion by microorganisms (fungi, bacteria, etc.), injury to vital internal organs, the rays of the sun, and the loss of moisture. The skin is also an organ of sensory perception; the sensations of pain, touch, itch, pressure, heat, cold, and warmth may be elicited in human skin.

Temperature regulation is yet another job performed by the skin. Blood vessels dilate (widen) when the body needs to lose heat or constrict (narrow) when the body must reduce the amount of heat loss through the skin.

When the surrounding air is comparatively warm, the skin is cooled by evaporation of moisture excreted by the sweat glands. There are between 2 and 3 million sweat glands over the surface of the body, excluding mucous membranes. The greatest concentration of sweat glands is on the palms of the hands and the soles of the feet. Their function depends on an intact nerve supply. Thermoregulatory sweating is controlled by a heat regulator in the brain. Emotions stimulate sweating primarily on the palms and soles.

The surface of the skin may look smooth, but if it is examined under a magnifying glass, countless ridges and valleys can be seen in which the many small openings of pores, hair follicles, and sweat glands are found (Figure 3–1). There are also different patterns of skin texture; compare the palm of the hand with the back of the hand, for example. The skin generally is soft, flexible, and elastic, particularly in young people.

A number of predisposing factors interact to determine the degree to which a person's skin responds to chemical, physical, and biological insults. These include type of skin (pigmentation, dryness, amount of hair), age, sex, season, previous skin diseases, allergies, and personal hygiene.

A worker's skin is very vulnerable to occupational hazards. Surveys indicate that dermatological conditions other than injuries are the second most common cause of all occupational diseases, accounting for 13 percent of all cases reported to the Bureau of Labor Statistics in 1997. Occupational skin disease is underreported and results in considerable lost time from work.

Although most occupational skin disorders are treated by primary care and occupational physicians, dermatologists are often consulted. Dermatology is the branch of medicine concerned with the diagnosis, treatment including surgery, and prevention of diseases of the skin, hair, and nails. Some dermatologists have had special training in occupational skin disorders.

Some disorders that are visible in the skin do not arise primarily in the skin but in other organs. Thus, the skin is an early warning system and its examination is very important in physical diagnosis, occasionally furnishing the first clue to identification of systemic diseases.

ANATOMY

Three distinct layers of tissue make up the skin; from the surface downward, they are the epidermis, the dermis, and the subcutaneous layer.

The thickness of the skin varies from 0.5 mm on the eyelid (the dermis is thinnest here) to 3–4 mm on the palms of the hands and soles of the feet (the epidermis is thickest here). Skin is also relatively thin in the skin folds: the axillae (armpits), under the breasts, the groin, and between the fingers and toes.

Epidermis

The top layer of the epidermis is composed of dead cells called the horny or keratin layer or the stratum corneum. This layer resists chemical attack fairly well, with the notable exception of alkali. It serves as the chief rate-limiting barrier against absorption of water and aqueous solutions, but offers little protection against lipid-soluble materials (such as organic solvents) or gases.

The horny layer gradually flakes off, or soaks off when wet. It is constantly being replaced by cells pushed toward the surface as new cells are formed in the deeper, germinative layer of the epidermis. This regenerative and sloughing characteristic serves to some extent as a protection against chemicals and microorganisms.

This constant shedding of flaky material goes mostly unnoticed unless a person has dandruff or must peel off insensate skin patches after a sunburn. Brisk rubbing with a towel peels off little rolls of material composed of dead outer skin cells that are never missed.

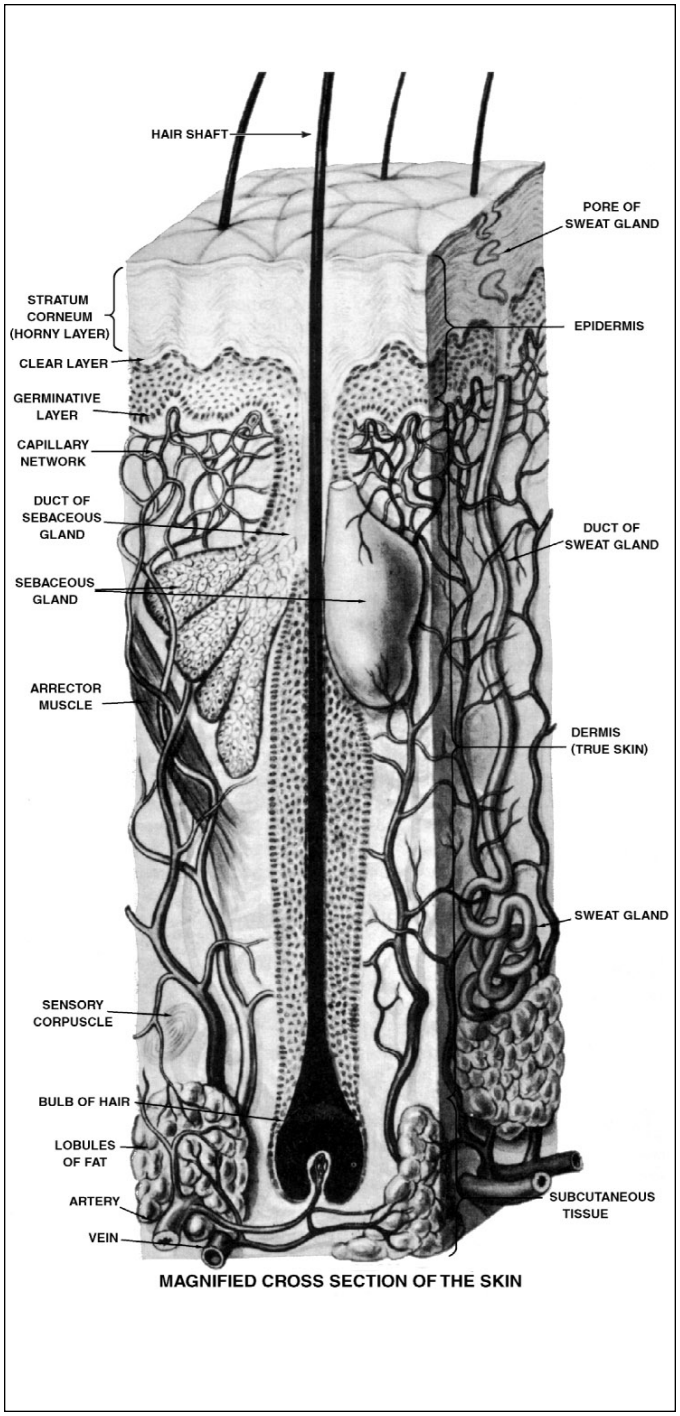

Figure 3–1. Magnified cross section of the skin. (Reprinted with permission of the AMA. *Today's Health Guide.* Chicago: AMA, 1965.)

There are three cell types in the epidermis:

- ➢ Keratinocytes, which make up the bulk of the epidermis, form from below and move up to become dead horny cells.
- ➢ Melanocytes, or pigment-forming cells, synthesize melanin (pigment) granules, which are then transferred to keratinocytes. The amount of melanin in keratinocytes determines the degree of pigmentation of skin

and hair. The absolute number of melanocytes in human skin is the same for all races. Differences in coloration among races result from differences in the number, size, degree of pigment formation, distribution, and rate of degradation of pigment granules within keratinocytes. Melanin proliferates under stimulus of certain wavelengths of sunlight and becomes visible as suntan or freckles. Moles are growths that contain melanin. Some people with little or no pigment in their skin have albinism, an inherited abnormality in which melanin (pigment) production is decreased. Vitiligo is a more common disorder in which loss of melanocytes also results in areas of cutaneous pigment loss. Some chemicals, such as phenolic germicides, can destroy pigment after occupational or environmental exposure.

➢ Langerhans' cells, located in the mid-epidermis, account for a relatively small percentage of all epidermal cells and play an important role in various immune processes, especially allergic contact dermatitis. Although the epidermis is an active tissue, it is not richly supplied with blood because blood vessels are absent. The blood supply to the epidermis is through the candelabra pattern of blood vessels in the upper dermal papillae (Figure 3–1).

The epidermis is thin enough that the nerve endings (Merkel cells) in the dermis are sufficiently close to the surface to supply the fine sense of touch. Some of this sensation is lost where areas of the skin are chronically subjected to friction, resulting in subsequent thickening of the epidermis that provides protection in the form of a callus.

Thus, the soles of the feet are commonly callused among those who habitually walk barefoot, as are the palms of the hands of those who do heavy work.

Dermis

Beneath the epidermis is the dermis, which is much thicker than the overlying epidermis, in most locations. It contains connective tissue composed of collagen elastic fibers and ground substance, is strong and elastic, and is the part of animal skins that makes leather when tanned. It is laced with blood vessels, nerve fibers, and receptor organs (for sensations of touch, pain, heat, and cold), and contains muscular elements, hair follicles, and oil and sweat glands (see Figure 3–1).

The dermis is tough and resilient, and is the main natural protection against trauma. When injured, it can form new tissue—a scar—to repair itself.

The top of the dermis is made up of a layer of tiny cone-shaped objects, called papillae. Thousands of papillae are scattered over the body. They are more numerous in areas such as the fingertips, where the skin appears to be more sensitive. Nerve fibers and special nerve endings are found in many of the papillae. As a result, the sense of touch is best developed in areas where papillae with nerve endings are most abundant.

The papillary layer fits snugly against the outer layer of skin, the epidermis, which has ridges corresponding to those of the papillae. The ridges prevent the skin layers from slipping against one another.

The ridges on the surfaces of the fingertips form the whorls, loops, and arches that make up fingerprints; dermatoglyphics is the study of the patterns of the ridges of the skin. Similar ridges appear on the soles of the feet. Because it is unlikely that two people will have the same pattern of ridges, fingertip patterns are used by the police to identify individuals.

The larger component of the dermis (reticular dermis) extends from the base of the papillary dermis to the subcutaneous fat. Muscle fibers are commonly seen in the reticular dermis on the face and neck.

Subcutaneous Layer

Beneath the dermis is a layer of subcutaneous tissue with fatty and resilient elements that cushions and insulates the skin above it. The distinguishing feature of the subcutaneous layer is the presence of fat. Also present are the lower parts of some eccrine and apocrine sweat glands and hairs, as well as hairs, nerves, blood and lymphatic vessels and cells, and fibrous partitions composed of collagen, elastic tissue, and reticulum. This layer links the dermis with tissue covering the muscles and bones.

Loss of subcutaneous fat and softer parts of the skin removes bouncy supporting material, and because the external skin does not shrink at the same rate, it tends to collapse and become enfolded in wrinkles.

Glands in the Skin

Two main types of glands are located in the dermis. One, already mentioned, is the sweat gland. Under the microscope it appears as a tightly coiled tube deep in the dermis with a corkscrew-like tubule that rises through the epidermis to the surface of the skin.

The second type is the sebaceous or oil gland, which is usually located in or near a hair follicle. Sebaceous glands are located in all parts of the skin except on the palms and soles. They are particularly numerous on the face and scalp.

Sweat Glands

Sweat glands excrete a fluid known as sweat, or perspiration. The working or secreting parts of the glands are intricately coiled tubules in the dermis. There are two kinds of sweat glands, which produce different kinds of sweat.

APOCRINE

One kind, called apocrine sweat, is not very important physiologically but has some social significance. Apocrine sweat glands open into hair follicles and are limited to a few regions of the body, particularly the underarm and genital areas. Apocrine sweat is sterile when excreted but decomposes when contaminated by bacteria from the skin surface, resulting in a strong and characteristic odor. The purpose of the many cosmetic underarm preparations is to remove these bacteria or block gland excretion.

ECCRINE

The other kind of sweat, called eccrine, is of great importance to our comfort and, in some cases, our lives. Multitudes of eccrine sweat glands are present everywhere in the skin except the lips and a few other areas. They are crowded in largest numbers into skin of the palms, soles, and forehead.

Eccrine sweat is little more than extremely dilute salt water. Its function is to help the body to dissipate excessive internal heat by evaporation from the surface of the skin.

Sebaceous Glands

There are many sebaceous (oil-secreting) glands in the skin. They are distributed over almost the entire body, and are most common in regions of the forehead, face, neck, and chest—the areas typically involved in common acne, a condition associated with cell-clogged sebaceous glands. The primary function of this oily substance, or sebum, is lubrication of the hair shaft and the horny surface layers of the skin. A certain amount of natural skin oil is necessary to keep skin and hair soft and pliable.

A strap of internal, plain, involuntary muscle tissue, the arrectores pilorum ("raiser of hair"), is located in the lower portion of the hair follicle below the sebaceous glands and originates in the connective tissue of the upper dermis. Goose bumps appear on the skin when these muscles attempt to produce heat.

Blood Vessels

The skin is richly supplied with small blood vessels. The blood supply in the skin accounts for the reddening of sunburn and the coloration of the fingers beneath the nails. Engorgement of the blood vessels accounts for the reddening of the skin when we blush.

Vascular birthmarks, such as hemangiomas, strawberry marks, and port wine stains, derive their coloration from unusually large numbers of tiny blood vessels concentrated in a small area of the skin.

Hair

Hair and nails are modified forms of skin cells containing keratin as their major structural material. Keratin is produced by the same processes that change living epidermal cells into dead, horny cells. However, hair and nails are made up almost entirely of keratin.

With the exception of the palms and soles, hair follicles populate the entire cutaneous surface, although in many areas they are so inconspicuous or vestigial that they are never noticed. Hair ranges in texture from the soft, almost invisible hair on the forehead to the long hair of the scalp and the short, stiff hair of the eyelashes.

Hair follicles develop as downgrowths of the epidermis. The hair then grows outward from the bottom of the follicle. Each hair has a root, which is anchored at the bottom of the follicle, and a shaft, which extends past the top of the follicle. The hair follicle enters the epidermis and passes deep into the dermis at an angle. The follicles of long hairs can extend into the subcutaneous layer. Sebaceous glands empty into the follicle. At the root of the hair is a cone-shaped papilla that is similar to the peg-like papillae that underlie the ridges of the fingers, palms, and soles.

The hair shaft is covered with tiny, overlapping scales. An inner layer of cells contains pigment that gives the hair its color. Most hair tips project from the skin at a slant. Minute arrectores pilorum muscles attached to the follicle have the fascinating ability to make the hair stand on end, as in goose bumps.

Hair follicles and the sweat glands also serve as routes for percutaneous absorption of chemicals. Physicians sometimes use this absorptive ability of the skin in administering certain drugs, such as nitroglycerine, scopolamine, estrogen, and nicotine. Some chemicals placed on the skin can be detected in the saliva a few minutes later. In the workplace the skin is a potential route of entry for a number of hazardous chemicals.

Nails

The fingernails and toenails, like hair, are specialized forms of the skin. The fully developed nail overlays a modified part of the dermis called the nail bed.

Nails are essentially the same in structure as hair. Like hair, nails also contain keratin, but nails are flat, hard plates. The living part of a nail lies in the matrix in back of the half-moon, or lunula. If the dead nail plate, which constitutes most of the visible part of the nail, is destroyed by injury, a new nail will grow if the matrix is intact.

The growth rate of nails varies and depends on such factors as the person's age and health. Nails grow faster in young people and grow slower with serious illnesses.

PHYSIOLOGY AND FUNCTIONS

The skin performs a number of important functions. It protects the body from invasion of bacteria, injury to vital internal organs, the rays of the sun, and the loss of moisture.

Temperature Regulation

For a discussion of the role of the skin heat regulation of the body, see Chapter 12, Thermal Stress.

Sweat

Sweat is produced constantly, usually in proportion to the temperature of the environment. In hot environments, the body must lose heat by evaporation, which is more effective than simple radiation. In cool, dry weather the amount of sweat produced is relatively small and the skin remains dry to the touch. We are not aware of sweating, so the small amount of sweat produced is called insensible perspiration.

When heat production of the body is increased or when the ambient temperature is unusually high, the sweat glands produce more perspiration. The rate of production outstrips

the rate of evaporation, particularly if humidity is high, because the rate of evaporation declines with the rise in humidity. Perspiration then collects on the body in visible drops and we are conscious of sweating.

However, heat is lost only when the sweat evaporates. All sweat glands are innervated by fibers of the sympathetic nervous system, ultimately controlled by the hypothalamus. Emotional stimulation from anxiety or fright may stimulate sweating in the palms and soles.

One way of increasing the rate at which water is evaporated from the body is to breathe rapidly, thus moving larger quantities of air from the moist surfaces of the mouth, throat, and lungs. Humans cannot do this in comfort, but it is the chief method of cooling available to dogs; in warm weather, dogs sit with mouth open, tongue extended, and pant.

Ultraviolet Light

Skin protects not only against mechanical shocks, but also against various forms of ultraviolet (UV) light. (See Chapter 11, Nonionizing Radiation, for a discussion of the forms.) Most animals are protected from sunlight by scales, hair, and feathers, which absorb the sun's rays without harm to themselves.

Humans have only the skin as protection from the sun's UV rays. Ultraviolet light energy produces chemical changes within the skin's cells; the effects vary with the time of the year, the geographic area, and the hour of the day.

Generally, after initial exposure to summer sun at midday, skin shows reddening or erythema, which may not appear for several hours. If the dose of sunlight is intense, the erythema may be followed by blistering and peeling of the outer layer of epidermal cells.

If the erythema is not severe, it fades in a few days and the skin gradually acquires a tan coloration (suntan). The tan color is produced by darkening of existing pigment (immediate pigment darkening) and by increase in pigment formation. When skin is exposed to the sun, it is believed that melanin pigment moves toward the surface of the skin and is replaced by new melanin in the lower cell layer. Along with pigmentation increase, the stratum corneum thickens to furnish additional protection against solar radiation injury. One or two weeks may be required to develop a suntan by moderate daily doses of sunlight; the tan fades if occasional exposure to sunlight is not continued.

As some protection against repeated UV light exposure, human skin is equipped with the capacity to form pigment (melanin), which absorbs UV light and thus acts as a protective umbrella over the regions beneath (delayed pigment darkening).

Solar UV radiation can induce actinic (solar) degeneration and skin cancer and is a major hazard of chronic sun exposure. Chronic exposure to artificial UV light in tanning salons may induce similar changes. Additionally, sunlight and artificial UV light may induce a number of abnormal cutaneous reactions in patients with certain hereditary or acquired diseases or in those taking certain medication. Photoaging and natural chronologic aging are different entities.

There is evidence now that the immune system of humans is affected by UV radiation and that environmental sources of radiation can have similar effects, such as contact photoallergy.

One beneficial normal effect of UV radiation on skin is the photochemistry that leads to the production of vitamin D_3. In most industrial countries, sufficient vitamin D is added to food to meet normal daily requirements.

Skin Absorption

A waxy type of mixture composed of sebum, breakdown products of keratin, and sweat, called the surface lipid film, coats the outer surface of the keratin layer, but there is no evidence that this normal coating has any barrier function.

The epidermis, especially the stratum corneum, acts as the major permeability barrier to the entry of foreign chemicals into the body. Overall, the skin is selectively permeable—more impermeable than permeable—and shows regional variation in absorptive capacity. Absorption of materials through the skin markedly increases when the continuity of the skin is disrupted by dermatitis, lacerations, or punctures. The hair follicles and sweat ducts may play only a minor role in skin absorption. However, they act as diffusion shunts—that is, relatively easy pathways through the skin for certain substances such as polar compounds, very large molecules that move across the stratum corneum very slowly, and pharmacologically active substances, especially in very hairy areas. After this initial phase, however, most of the percutaneous absorption of all substances takes place across the stratum corneum, which has a much greater surface area than that of the hair follicles and sweat ducts. Absorption of fat-soluble chemicals and oils can also occur via the hair follicle.

DEFENSE MECHANISMS

Anyone who works is a candidate for occupational skin disease, yet most workers are not affected by such disorders because the skin is a primary organ of defense. The skin is able to perform its many defense functions because of its location, structure, and physiological activity.

These are the specific defenses the skin has in terms of its protection against typical industrial hazards.

- ➢ *Bacteria:* The skin is a naturally dry terrain (except in places such as armpits and the groin, and during abnormal sweating) and has a normal contingent of bacteria that tends to destroy pathogenic bacteria. Free fatty acids in the surface oil also can have some antibacterial value. The immune defenses of the skin also defend against infections.
- ➢ *Sunlight:* The skin has two defenses: an increase in pigmentation, and thickening of the stratum corneum.
- ➢ *Primary irritants:* The skin resists acids but offers much less protection against organic and inorganic alkalis.

Sweat can act as a diluent to decrease the effect of water-soluble toxins. Conversely, it enhances hydration and maceration of the barrier, thereby promoting percutaneous absorption.

- ➢ *Injury:* The skin's resilience, especially of the dermis, provides a measure of resistance to forceful impact. The cutaneous nerves also provide information about the state of the external environment through sensations of touch and temperature.
- ➢ *Excessive increase or decrease in body heat:* The body's thermoregulatory mechanisms include the activity of sweat glands and blood vessels.
- ➢ *The absorption of chemicals through the skin:* This is where the most important function is performed. The skin is a flexible body envelope and the epidermal barrier, especially the stratum corneum, provides a significant blockade against water loss from the body and penetration of the skin by chemical agents.

DEFINITIONS AND INCIDENCE OF OCCUPATIONAL SKIN DISORDERS

A dermatosis is any abnormal condition of the skin, ranging from the mildest redness, itching, or scaling to an eczematous (superficial inflammation), ulcerative (ulcer-forming), acneiform (resembling acne), pigmentary (abnormal skin color), granulomatous (tumor-like mass, nodule), or neoplastic (new, abnormal tissue growth) disorder. Occupational dermatoses include any skin abnormalities resulting directly from or aggravated by the work environment. *Dermatitis* is a more limited term referring to any inflammation of the skin, such as contact dermatitis or cement dermatitis.

Occupational skin diseases can occur in workers of all ages and in any work setting, and cause a great deal of illness, personal misery, and reduced productivity. Although the frequency of occupational skin disease often parallels the level of hygiene practiced by employers, occupational skin diseases are largely preventable. Many consider this type of disease trivial and insignificant, but occupational skin disorders can result in complex impairment. Data compiled by the U.S. Bureau of Labor Statistics (BLS) for 1991 indicate that approximately 94 percent (5,977,400) of all occupational disorders are injuries and almost 6 percent (368,300) are diseases. Because large surface areas of skin are often directly exposed to the environment, the skin is particularly vulnerable to occupational insults. Although complete data on the extent and cost of dermatological injuries are not available, the National Institute for Occupational Safety and Health (NIOSH) estimated in 1986 that skin injuries may account for 23–35 percent of all injuries. An estimated 1–1.65 million dermatological injuries may occur annually, with an estimated annual rate of skin injury of 1.4–2.2 per 100 full-time workers. The highest percentage is due to lacerations and punctures (82 percent) followed by burns (chemical and other, 14 percent) (Table 3–A).

Table 3–A. ***Occupational Dermatological Injuries in the United States, 1983***

Type of Injury	*No.*	*(%)*
Lacerations and punctures	253,141	(82.3)
Burns (nonchemical)	36,477	(11.9)
Abrasions	10,576	(3.4)
Burns (chemical)	6,828	(2.2)
Cold injuries	566	(0.2)
Radiation injuries	135	(0.04)
Total	307,723	(100.0)

(Reported by the Supplementary Data System of the Bureau of Labor Statistics from 29 participating states.)

In the mid-1950s, skin disorders other than injuries accounted for 50–70 percent of all occupational diseases. This figure has been gradually decreasing and was 13 percent, or 57,900 cases, in 1997. NIOSH attributes the decline of skin diseases since then to a continuing trend toward automation, enclosure of industrial process, and educational efforts. Despite these figures, dermatitis is the second most common cause of reported occupational disease in the United States. National data indicate that as many as 20–25 percent of all occupational skin diseases involve lost time from work, with an average of 11 workdays lost per case. California and South Carolina have reported similar data based on workers' compensation claims. The results of two studies show a serious underreporting of occupational disease of all types, which may mean that the true incidence is 10 to 50 times greater than that reported by the BLS.

NIOSH has included work-related dermatological conditions on its list of 10 leading work-related diseases and injuries in the United States (Table 3–B). Reasons include the fact that 10–15 percent of requests NIOSH receives for health hazard evaluation involve skin complaints and the fact that the economic impact of dermatological conditions is substantial. The annual cost resulting from lost worker productivity, medical care, and disability payments has been estimated to range between $222 million and $1 billion.

Table 3–C gives incidence of occupational dermatoses (disease) by industry group for the United States in 1997. The highest incidence was in agriculture (226 cases per 100,000 full-time workers). The most hazardous industrial processes for skin disorders are as follows:

- ➢ Use of cutting oils and coolants in machine tool operation
- ➢ Plastics manufacturing
- ➢ Rubber manufacturing
- ➢ Food processing
- ➢ Leather tanning and finishing
- ➢ Agriculture
- ➢ Metal plating and cleaning
- ➢ Construction
- ➢ Printing
- ➢ Forest products manufacturing

Table 3–B. *The 10 Leading Work-Related Diseases and Injuries in the United States, 1982*

Occupational lung diseases: asbestos, byssinosis, silicosis, coal worker's pneumoconiosis, lung cancer, occupational asthma	**Disorders of reproduction:** infertility, spontaneous abortion, teratogenesis
Musculoskeletal injuries: disorders of the back, trunk, upper extremity, neck, lower extremity, traumatically induced Raynaud's phenomenon	**Neurotoxic disorders:** peripheral neuropathy, toxic encephalitis, psychoses, extreme personality changes (exposure-related)
Occupational cancers (other than lung): leukemia, mesothelioma, cancers of the bladder, nose, and liver	**Noise-induced loss of hearing**
Severe occupational traumatic injuries: amputations, fractures, eye loss, lacerations, and traumatic deaths	**Dermatological conditions:** dermatoses, burns (scalding), chemical burns, contusions (abrasions)
Cardiovascular diseases: hypertension, coronary artery disease, acute myocardial infarction	**Psychological disorders:** neuroses, personality disorders, alcoholism, drug dependency

The conditions listed under each category are to be viewed as selected examples, not comprehensive definitions of the category, and are *not* in order of incidence or importance.

NIOSH developed a suggested list of the 10 leading work-related diseases and injuries. Three criteria were used to develop the list: (1) the frequency of occurrence of the disease or injury; (2) its severity in the individual case; and (3) its amenability to prevention.

Table 3–C. *Numbers and Incidence of Occupational Skin Diseases by Major Industry, 1997*

Industry	*No. of Cases*	*Incidence**
Agriculture/forestry/fishing	3,000	226
Manufacturing	26,000	139
Services	15,600	61
Transportation/utilities	3,200	52
Mining	300	51
Construction	1,800	35
Wholesale/retail trade	7,600	34
Finance/insurance/real estate	500	7
Total	57,900	67

* Per 100,000 full-time workers per year.

DIRECT CAUSES OF OCCUPATIONAL SKIN DISEASE

There are unlimited substances and conditions capable of inducing a skin disorder in the workplace. Each year, new causes are reported and most can be classified under one of the following five broad headings:

- ➢ Chemical
- ➢ Mechanical
- ➢ Physical
- ➢ Biological
- ➢ Botanical

Chemical

Organic and inorganic chemicals are the predominant causes of dermatoses in the work environment (Table 3–D). The list of such chemicals is endless because each year additional agents capable of injuring the skin are added. Chemical agents may be divided into two groups: primary irritants and sensitizers.

PRIMARY IRRITANTS

These are likely to affect most people; some actually affect everyone. These agents react on contact. The reaction alters the chemistry of the skin by dissolving a portion of it by precipitating the protein of the cells, or by some other chemical reaction. The result can range from tissue destruction (chemical burn) to inflammation (dermatitis) depending on the strength of the agent and the duration of the exposure.

Primary irritants damage skin because they have an innate chemical capacity to do so. Many irritants are water-soluble and thus react with certain components of the skin. The water-insoluble compounds, including many solvents, react with the lipid (fatty) elements within skin. The precise mechanism of primary irritation on the skin is not known, but some useful generalizations explain the activity of groups of materials in the irritant category. About 80 percent of all occupational dermatoses are caused by primary irritants. Dermatitis caused by a primary irritant is referred to as irritant contact dermatitis because the skin irritation is normally confined to the area of direct contact.

Most inorganic and organic acids act as primary irritants. Certain inorganic alkalis, such as ammonium hydroxide, calcium chloride, sodium carbonate, and sodium hydroxide, are skin irritants. Organic alkalis, particularly amines, also are active irritants. Metallic salts, especially arsenicals, chromates, mercurials, nickel sulphate, and zinc chloride, severely irritate the skin. Organic solvents include many substances, such as chlorinated hydrocarbons, petroleum-based compounds, ketones, alcohols, and terpenes, that irritate the skin because of their solvent qualities (Figure 3–2).

Keratin solvents. All of the alkalis, organic and inorganic, injure the keratin layer with sufficient concentration and exposure time. These agents soften, dehydrate, and destroy the keratin cells, resulting in dry, cracked skin. This prepares the way for secondary infection and, at times, for the development of allergic contact dermatitis.

Keratin stimulants. Several chemicals stimulate the skin so that it undertakes growth patterns that can lead to tumor or cancer formation. Certain petroleum products, a number of coal tar-based materials, arsenic, and some polycyclic aromatic hydrocarbons can stimulate the epidermal cells to produce these effects (Figure 3–3).

Table 3–D. *Selected Chemical Causes of Skin Disorders*

Chemical	Primary Irritants	Sensitizers	Selected Skin Manifestations (some also have important systemic effects on other organs)	Selected Occupations, Trades, or Processes Where Exposure Can Occur
ACIDS				
Acetic	X	?	Dermatitis and ulceration	Manufacturing acetate rayon, textile printing and dyeing, vinyl plastic makers
Carbolic (phenol)	X		Corrosive action on skin, local anesthetic effect	Carbolic acid makers, disinfectant manufacturing, dye makers, pharmaceutical workers, plastic manufacturing
Chromic	X	X	Ulcers ("chrome holes") on skin, inflammation and perforation of nasal septum	Platers, manufacturing organic chemicals and dyestuffs
Cresylic	X		Corrosive to skin, local anesthetic effect	Manufacturing disinfectants, coal tar pitch workers, foundry workers
Formic	X		Severe irritation with blisters and ulcerations	Rubber and laundry workers, mordanters, cellulose formate workers, airplane dope makers
Hydrochloric	X		Irritation and ulceration of skin	Bleachers, picklers (metals), refiners (metals), tinners, chemical manufacturing, masons (clean cement)
Hydrofluoric	X		Severe chemical burn with blisters, erosion, or ulceration	Enamel manufacturing, etchers, hydrofluoric acid makers, fluorochemical workers
Lactic	X		Ulceration (if strong solutions are used)	Adhesives, plastics, textiles
Nitric	X		Severe skin burns and ulcers	Nitric acid workers, electroplaters, old metal cleaners, acid dippers, nitrators, dye makers
Oxalic	X		Severe corrosive action on skin, cyanosis (bluish discoloration), and brittleness of nails	Tannery workers, blueprint paper makers, oxalic acid makers
Picric	X	X	Erythema, dermatitis, scaling, yellow discoloration of skin and hair	Explosives workers, picric acid makers, dyers and dye makers, tannery workers
Sulfuric	X		Corrosive action on skin, severe inflammation of mucous membranes	Nitrators, picklers (metals), dippers, chemical manufacturing
ALKALIS				
Ammonia	X		Irritation including airborne dermatitis of face from vapors	Ammonia production, fertilizers, photocopying (blueprint, diazo); gas and liquid forms
Calcium cyanamide	X		Irritation and ulceration	Fertilizer makers, agricultural workers, nitrogen compound makers
Calcium oxide	X		Dermatitis, burns, or ulceration	Lime workers, manufacturing of calcium, salts, glass, and fertilizer
Potassium hydroxide	X		Severe corrosion of skin, deep-seated persistent ulcers, loss of fingernails	Potassium hydroxide makers, electroplaters, paper, soap, and printing ink makers
Sodium hydroxide	X		Severe corrosion of skin, deep-seated persistent ulcers, loss of fingernails	Sodium hydroxide makers, bleachers, soap and dye makers, petroleum refiners, mercerizers, plastic manufacturing
Sodium or potassium cyanide	X		Blisters, ulcers	Electroplaters, case hardening, extraction of gold
Trisodium phosphate	X		Blisters, ulcers	Photographic developers, leather tanning, industrial cleaning detergents
SALTS OR ELEMENTS				
Antimony and its compounds	X	?	Irritation and lichenoid eruptions of skin	Antimony extractors, glass and rubber mixers, manufacturing of various alloys, fireworks, and aniline colors

(Continues)

Table 3–D. *Selected Chemical Causes of Skin Disorders (Continued)*

Chemical	Primary Irritants	Sensitizers	Selected Skin Manifestations (some also have important systemic effects on other organs)	Selected Occupations, Trades, or Processes Where Exposure Can Occur
SALTS OR ELEMENTS (continued)				
Arsenic and its compounds	X	X	Spotty pigmentation of skin, perforation of nasal septum, skin cancer, keratoses especially on palms and soles, dermatitis, pustules	Leather workers, manufacturing insecticides, glass industry, agriculture, pesticides, tanning, taxidermy, alloy, lubricating oils
Barium and its compounds	X		Irritation of skin	Barium carbonate, fireworks, textile dyes, and paint makers
Bromine and its compounds	X		Irritation, vesicles, and ulceration; acne	Bromine extractors, bromine salts makers, dye and drug makers, photographic trades
Chromium and its compounds	X	X	Pitlike ulcers (chrome holes) on skin, perforation of nasal septum, dermatitis	Chromium platers, dye industry workers, chrome manufacturing, leather tanners
Mercury and its compounds	X	X	Corrosion and irritation of skin, dermatitis	Explosives manufacturing, silver and gold extractors, manufacturing electrical appliances and scientific equipment
Nickel salts	X	X	Folliculitis, dermatitis	Nickel platers, alloy makers
Sodium and certain of its compounds	X		Burns and ulceration	Bleaching: detergent, paper, glass, tetraethyl lead manufacturing
Zinc chloride	X	?	Ulcers of skin and nasal septum	Manufacturing chemicals, dyestuffs, paper, disinfectants
SOLVENTS				
Acetone	X		Dry (defatted) skin	Spray painters, celluloid industry, artificial silk and leather workers, acetylene workers, lacquer and varnish makers, garage mechanics
Benzene and its homologues (toluene and xylene)	X		Dry (defatted) skin	Chemical and rubber manufacturing
Carbon disulfide	X	X	Dry (defatted) irritated skin	Extraction of oils, fats, and a wide range of other materials, manufacture of rayon, rubber, rubber cements, germicides, and other chemicals
Trichloroethylene	X	?	Dermatitis	Degreasers, chemical intermediates
Turpentine	X	X	Dermatitis	Painters, furniture polishers, lacquerers, artists
Alcohols (such as ethanol)	X	X	Dermatitis	Chemical manufacture; painters
SOME DYE INTERMEDIATES				
Dinitrobenzene	X		Yellow discoloration of skin, hair, and eyes	Dye manufacturing
Nitro and nitroso compounds	X	X	Dermatitis	Dye manufacturing
Phenylhydrazine	X	X	Severe chemical burns, dermatitis	Dye and pharmaceutical manufacturing
PETROLEUM AND COAL-TAR DERIVATIVES				
Petroleum oils	X		Dermatitis, folliculitis	Petroleum workers, machinists, mechanics
Pitch and asphalt	X		Dermatitis, folliculitis, keratoses, skin cancer	Manufacturing pitch and asphalt, roofers
Tar (coal)	X	X	Dermatitis, folliculitis, skin cancer, eye inflammation (keratitis)	Tar manufacturing, manufacturing roofing paper and pitch, road building and repairing
DYES (such as paraphenylenediamine)	X		Contact dermatitis (erythema, blisters, edema)	Dye workers, cosmetologists

(Continues)

Table 3–D. *Selected Chemical Causes of Skin Disorders (Continued)*

Chemical	Primary Irritants	Sensitizers	Selected Skin Manifestations (some also have important systemic effects on other organs)	Selected Occupations, Trades, or Processes Where Exposure Can Occur
RUBBER ACCELERATORS AND ANTIOXIDANTS	X		Contact dermatitis (erythema, blisters, edema)	Rubber workers, such as compound mixers and calendar and mill operators; fabricators of rubber products
Mercaptobenzothiazole, tetramethylthiuram disulfide, diethylthiourea, and paraphenylenediamine				
SOAPS AND SOAP POWDERS	X	X	Dermatitis, dry skin, paronychia (inflammation around fingernails); allergy from fragrance, germicides, or dyes	Soap manufacturing, dishwashers, soda fountain clerks, maintenance workers—all associated with wet work
INSECTICIDES				
Arsenic	X		See above under salts or elements	Manufacturing and applying insecticides
Pentachlorophenols	X	?	Dermatitis, chloracne	Pesticides and wood preservatives
Creosote	X	X	Dermatitis, folliculitis, keratoses, hyperpigmentation, skin cancer	Manufacturing wood preservatives, railroad ties, coal tar lamp black and pitch workers
Fluorides	X		Severe burns, dermatitis	Manufacturing insecticides, enamel manufacturing
Phenylmercury compounds	X	X	Dermatitis	Manufacturing and applying fungicides and disinfectants
Pyrethrum		X	Dermatitis	Manufacturing and applying insecticides
Rotenone	X		Dermatitis	Manufacturing and applying insecticides
RESINS (Natural)*				
Cashew nut oils		X	Severe poison ivylike dermatitis	Handlers of unprocessed cashew nuts, varnish
Rosin		X	Dermatitis	Adhesive and paper mill workers, dentists, rubber industry
Shellac		X	Dermatitis	Coatings, cosmetics
Synthetic resins such as phenolformaldehyde, urea-formaldehyde, epoxy, vinyl, polyurethane, polyester, acrylate, cellulose esters	X	X	Dermatitis	Plastic workers, varnish makers, adhesives, coatings, rubber, cosmetology
* The skin reactions from this group of chemicals in some instances are due to the essential composition of the synthetic resin, but in other cases are due to the presence of added compounds such as plasticizers and other modifying agents.				
EXPLOSIVES				
Nitrates, mercury fulminate, tetryl, lead azide, TNT, nitroglycerin	X	X	Severe irritation, dermatitis, skin discoloration	Explosives manufacturing, shell loading
METAL WORKING FLUIDS				
Cutting oils	X		Oil acne (folliculitis), rare dermatitis	Machinists
Coolants—synthetic and semisynthetic	X	X	Dermatitis	Machinists
OXIDIZING AGENTS				
Hydrogen peroxide	X	?	Dermatitis	Chemical industry; medical disinfectant; cosmetology
Benzoyl peroxide	X	X	Dermatitis	Chemical industry; polyester manufacture
OTHER				
Isocyanates such as TDI, MDI, HDI	X	X	Dermatitis	Polyurethane makers, adhesive workers, organic chemical synthesizers
Vinyl chloride	X		Dermatitis, acro-osteolysis	Polyvinyl resin, rubber and organic chemical makers
Formaldehyde	X	X	Dermatitis	Undertakers, biologists, textile workers
Plants, weeds (such as poison oak, ivy, sumac)	X	X	Dermatitis	Outdoor workers (such as fire fighters, utility workers)

Figure 3–2. Eczematous dermatitis is a form of contact dermatitis caused by contact with organic solvents. It is one of the most prevalent types of dermatitis.

Fats and oil solvents. Just as organic solvents dissolve oily and greasy industrial soils, they remove the skin's surface lipids and disturb the keratin layer of cells so that they lose their water-holding capacity. Workers exposed each day to organic solvents develop exceedingly dry and cracked skin.

Protein precipitants. Several of the heavy metal salts precipitate protein and denature it. The salts of arsenic, chromium, mercury, and zinc are best known for this action.

Figure 3–3. Nodules in the keratin layer of the skin may result from repeated exposure to certain tars or coal tar derivatives.

Reducers. In sufficient concentration, salicylic acid, oxalic acid, urea, and other substances can actually reduce the keratin layer so that it is no longer protective, and an occupational dermatosis results.

SENSITIZERS

Some primary skin irritants also sensitize. Certain irritants sensitize a person so that a dermatitis develops from a very low, nonirritating concentration of a compound that previously could have been handled without any problem.

Some chemical and many plant substances and biological agents are classified as sensitizers. Initial skin contact with them may not produce dermatitis, but after repeated or extended exposure some people develop an allergic reaction called allergic contact dermatitis. Clinically, allergic contact dermatitis is often indistinguishable from irritant contact dermatitis (see sections on contact dermatitis for further discussion of allergic contact dermatitis and patch testing).

Substances that are both irritants and allergens include turpentine, formaldehyde, chromic acid, and epoxy resin components. Common sensitizers are plant oleoresins such as poison ivy, epoxy resins, azo dyes, certain spices, certain metals such as nickel and chromium, and topical medicaments such as neomycin.

Other chemicals can sensitize the skin to light. Known as photosensitizers, these chemicals include coal tar and pitch derivatives, fluorescent dyes, salicylanilides, musk ambrette, sunscreens containing p-aminobenzoic acid (PABA) and benzophenone, some plants, pesticides, and insecticides.

Mechanical

Trauma at work can be mild, moderate, or severe and occur as a single or repeated event. Friction results in the formation of a blister or callus, pressure in thickening and color change, sharp objects in laceration, and external force in bruising, punctures, or tears. A commonly cited example is fibrous glass, which can cause irritation, itching, and scratching. Secondary infection may complicate blisters, calluses, or breaks in the skin.

Physical

Physical agents such as heat, cold, and radiation can cause occupational dermatoses. For example, high temperatures cause perspiration and softening of the outer horny layer of the skin. This can lead to miliaria, or heat rash, common among workers exposed to hot humid weather, electric furnaces, hot metals, and other sources of heat.

High temperatures can also cause systemic symptoms and signs such as heat cramps, heat exhaustion, and even heat stroke. Burns can result from electric shock, sources of ionizing radiation, molten metals and glass, and solvents or detergents used at elevated temperatures.

Exposure to low temperatures can cause frostbite and result in permanent damage to blood vessels. The ears, nose, fingers, and toes are the most often frostbitten. Electric utility and

telephone line workers, highway maintenance workers, agricultural workers, fishermen, police officers, letter carriers, and other outdoor workers are most often affected.

Sunlight is the greatest source of skin-damaging radiation and is a source of danger to construction workers, fishermen, agricultural workers, foresters, and all others who work outdoors for extended periods of time. The most serious effect on the skin is skin cancer.

Increasing numbers of people come into casual or prolonged contact with artificial UV light sources such as molten metals and glass, welding operations, and plasma torches. A wide variety of newer lasers are being used in medicine and other scientific disciplines. Because lasers can injure the skin, eye, and other biological tissue, it is important to use appropriate protective devices.

Ionizing radiation sources include the following:

- Alpha-radiation is completely stopped by the skin and thus does not injure skin. However, alpha-radiation-emitting radioactive substances, such as plutonium, are harmful when ingested or inhaled.
- Beta-radiation can injure the skin by contact and substances such as phosphorus-32 are dangerous when inhaled or ingested. Beta-particles are usually localized at the surface or within the outer layers of skin, with the depth of penetration depending on the energy of the beta particle.
- Gamma-radiation and x-rays are well-known skin (radiodermatitis and skin cancer) and systemic (internal) hazards when sufficient exposure occurs. Radiodermatitis is characterized by dry skin, hair loss, telangiectasia, spider-like angiomas, and hyperkeratosis. Skin cancer may ultimately develop. (See Chapter 10, Ionizing Radiation, for more information.)

Biological

Bacteria, viruses, fungi, and parasites can produce cutaneous or systemic disease of occupational origin. Animal breeders, agricultural workers, bakers, culinary employees, florists, horticulturists, laboratory technicians, and tannery workers are among those at greater risk of developing infections. Examples include anthrax in hide processors; yeast infections of the nail in dishwashers, bartenders, and others engaged in wet work; and animal ringworm in agricultural workers and veterinarians. Parasitic mites are common inhabitants of grain and other foodstuffs and attack those handling such materials, such as grocers, truckers, longshoremen, and agricultural workers. Outdoor workers such as bricklayers and plumbers in southeastern states risk contracting animal hookworm via larvae deposited by infected animals in sandy soil. Health care workers, medical laboratory workers, and emergency medical technicians are exposed to a number of microorganisms, especially hepatitis B, HIV, herpes simplex (herpetic whitlow of the fingers from direct viral exposure and inoculation), fungi (*Candida* and superficial and deep fungi), and bacteria (staphylococci and tuberculosis), which may be acquired from patients or from biological specimens.

Botanical

Many plants and woods, of which poison ivy and poison oak are the most common, can cause contact dermatitis. Irritant contact dermatitis can also be caused by some plants, and although the chemical identity of many of the toxins is not known, the allergen or irritant occurs in the leaves, stems, flowers, bark, or other part of the plant. Other plants, such as wild parsnip and fresh or diseased celery (pink-rot) are photosensitizers. Several outbreaks of photodermatitis have been reported in grocery produce workers, especially those visiting tanning parlors. With woods, dermatitis occurs especially when they are being sandpapered, polished, and cut. Fomites can carry and transmit these allergens, which can also be dispersed by the smoke from burning.

PREDISPOSING FACTORS

In classifying and determining the severity of occupational dermatoses, a number of factors should be considered: the nature, duration, and extent of exposure to an environmental agent, the potential toxic effects of the agent, its chemical stability, and its potential for being absorbed through the skin. Other variables include preexisting skin disease or exposure to more than one agent. Indirect or predisposing factors leading to the development of occupational dermatoses are generally associated with age, sex, skin type, perspiration, season of the year, personal hygiene, and allergy.

Age and Experience

Younger, inexperienced, and inadequately trained workers have a higher prevalence of occupational dermatoses than older workers. However, older workers may be prone to chronic skin irritation because their skin is generally drier.

Skin Type

Workers with naturally dry skin cannot tolerate the action of solvents and detergents as well as persons with oily skin (Figure 3–4). Hairy arms and legs are common sites of folliculitis and acne induced by cutting oils (Figure 3–5).

Sweating

Hyperhidrosis, or increased sweating, can produce maceration with softening and resultant separation of skin already irritated by rubbing in adjacent body areas, as occurs in the armpit and the groin. This predisposes the skin to secondary fungal and bacterial infection. Some materials, such as caustics, soda ash, and slaked lime, become irritants in solution. However, sweating can also serve a protective function by diluting the toxic substances.

Gender

Because the incidence of nickel allergy is much greater in women (due to ear-piercing), they are more susceptible to developing dermatitis when handling coins or when in contact with nickel salts and metal alloys. The incidence of

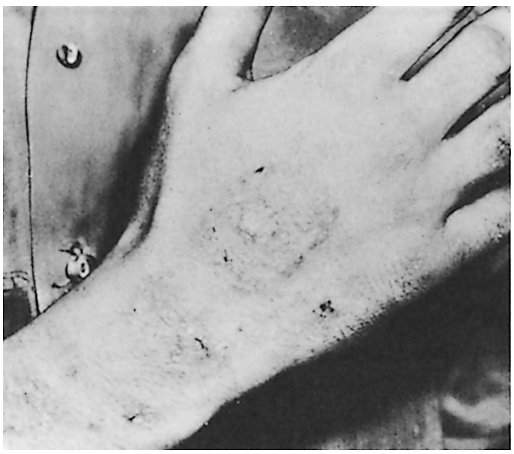

Figure 3–4. Cleaning hands with a strong petroleum solvent instead of a good industrial cleanser caused this case of dermatitis.

Figure 3–5. Acneiform disorder, shown on this worker's forearm, is often caused by exposure to cutting oils. Lack of splash guards and poor personal hygiene can be factors.

nickel allergy in men, even those with earrings, is lower, for reasons that are not known. A recent study suggested that women are more easily sensitized than men.

Seasons and Humidity

Occupational dermatoses are more common in warm weather, when workers wear less clothing and are more likely to come in contact with external irritants. Excessive perspiration, with resulting skin damage, is also more common in warm weather. When a work area is hot, workers may not use protective clothing. Warm weather also means that many workers have greater exposure to sunlight, poisonous plants, and insects, the effects of which may or may not be related to the job.

Winter brings chapping from exposure to cold and wind. Heated rooms usually are low in relative humidity, so skin loses moisture. Large-scale outbreaks of dermatitis in some factories has been traced to nothing more than low humidity. Clothing can keep dust particles and mechanical irritants in close contact with the skin. Infrequent bathing and changing of clothing can increase the incidence of skin irritation. (See Chapter 12, Thermal Stress, for more information.)

Hereditary Allergy (Atopy)

Atopy (the name means *uncommon* or *out of place*) is a relatively common genetic tendency toward the development of atopic dermatitis, asthma, and hay fever. Atopic people are predisposed to developing dermatitis because of their reduced skin resistance to chemical irritants, inherent dry skin, dysfunctional sweating, and a high skin colonization rate of the bacterium *Staphylococcus aureus.* In an atopic adult, the hands are the main location for dermatitis. Atopic people, especially those with eczema, are more prone to irritant dermatitis than those who are not atopic. Atopy is common among hairdressers, health care workers, and others performing wet work. Contact allergy and contact urticaria—especially to latex—also occur in atopic workers.

Personal Hygiene

Poor personal hygiene is believed to be a major factor causing occupational skin disorders. Unwashed skin covered with unwashed and unchanged clothes may be in prolonged contact with chemicals. Responsibility for maintaining clean skin is shared by employer and employee. Thus, adequate facilities for maintaining personal cleanliness should be provided in every place of employment. Educating workers in the preventive aspects of personal hygiene is imperative. On the other hand, excessive skin cleansing with harsh agents can produce an irritant contact dermatitis or aggravate preexisting dermatitis.

Preexisting Skin Disease

Other forms of skin irritation (eczema), such as atopic eczema, nonoccupational contact dermatitis, palmar psoriasis, and lichen planus, can be aggravated by chemicals in the work environment. Ultraviolet light-sensitive disease, such as lupus erythematosus, and cold-induced disease, such as Raynaud's phenomenon, can be aggravated and precipitated by sunlight and cold exposure, respectively.

CLASSIFICATION OF OCCUPATIONAL SKIN DISEASE

Skin disorders are relatively easy to recognize because they are visible. However, accurate diagnosis and classification of disease type and its relationship to employment usually requires a high level of clinical skill and expertise. The varied nature of skin responses causing occupational skin disorders takes several forms. The appearance and pattern of the dermatosis seldom indicates the provoking substance definitively, but can provide clues to the class of materials involved. Diagnosis depends on appearance, location, and (most importantly) on the history. Preexisting skin disorders, adverse effects of treatment, and secondary infections add to the difficulty in diagnosis. The following grouping includes most occupational dermatoses.

Contact Dermatitis

Contact dermatitis is the most frequent cause of occupational skin disease, accounting for most reported cases. Two types are generally recognized: irritant and allergic. Approximately 80 percent of all cases of occupational contact dermatitis result from irritation and 20 percent from allergy. Both are difficult to differentiate clinically because each can appear as an acute or chronic eczematous dermatitis. The acute form is erythematous (increased redness), vesicular (small blisters) to bullous (large vesicles), edematous (swollen), and oozing, and of short duration, lasting days or weeks. The chronic form is lichenified (thickened skin), scaly, and fissured, and may last for weeks, months, or years. Itching is usually a major symptom.

Contact dermatitis most often occurs on the hands, wrists, and forearms, although any area can be affected. Dusts, vapors, and mists can affect the exposed areas, including forehead, eyelids, face, ears, and neck, and often collect in areas where the body bends, such as under the collar and at the tops of shoes. The palms and soles are partially protected by a thick stratum corneum. The scalp tends to be protected by the hair, but the male genitalia are commonly affected, as irritants are often transferred by the hands. Contact dermatitis also localizes under rings and between fingers, toes, and other cutaneous areas that rub together.

IRRITANT CONTACT DERMATITIS

A primary skin irritant is a substance that causes damage at the site of contact because of its direct chemical or physical action on the skin. Irritants are generally divided into strong (absolute) and weak (marginal) types. Strong (absolute) irritants include strong acids, alkalis, aromatic amines, phosphorus, ethylene oxide, riot-control agents, and metallic salts, and produce an observable effect within minutes. In contrast, marginal irritants such as soap and water, detergents, solvents, and oils can require days before clinical changes appear. Cumulative exposure to marginal irritants causes most cases of occupational irritant dermatitis and is a major skin problem in the workplace. (See the following pages for further discussion and lists of irritants and sensitizers.)

Important factors to consider in irritant dermatitis are the nature of the substance (pH, solubility, physical state, concentration, duration of contact, and host and environmental factors). Despite the prevalence of irritant dermatitis, much is unknown about the precise mechanisms of how irritants disturb the skin. Several points merit emphasis:

- ➢ Contact dermatitis can occur from contact with several marginal irritants, the effects of which are cumulative.
- ➢ Cumulative irritant contact dermatitis can lead to skin fatigue, a condition in which even mild substances can irritate the skin, or to "hardening," in which the skin eventually accommodates repeated exposure to an offending agent.
- ➢ The clinical and histological differentiation of irritant and allergic contact dermatitis is often difficult or impossible.
- ➢ Constant exposure to irritants impairs the barrier function of the skin and allows penetration of potential allergens.
- ➢ Irritant and allergic contact dermatitis often coexist in the same patient.

ALLERGIC CONTACT DERMATITIS

A variety of industrial chemicals are potential contact allergens. The incidence of allergic contact dermatitis varies depending on the nature of the materials handled, predisposing factors, and the ability of the physician to accurately use and interpret patch tests. Allergic contact dermatitis, in contrast with primary irritation, is a form of cell-mediated, antigen–antibody immune reaction. Sensitizing agents differ from primary irritants in their mechanism of action and their effect on the skin. Unless they are concomitant irritants, most sensitizers do not produce a skin reaction on first contact. Following this sensitization phase of one week or longer, further contact with the same or a cross-reacting substance on the same or other parts of the body results in an acute dermatitis (elicitation phase).

Other essential points about allergic contact dermatitis include the following:

- ➢ As a general rule, a key difference between irritation and allergic contact dermatitis is that an irritant usually affects many workers, whereas a sensitizer generally affects few. Exceptions exist with potent sensitizers, such as poison oak oleoresin, or epoxy resin and components.
- ➢ Differentiation of marginal irritants from skin allergens also can be difficult. Marginal irritants may require repeated or prolonged exposure before a dermatitis appears; allergic contact dermatitis also may not develop for months or years after exposure to an agent.
- ➢ Many skin sensitizers, such as chromates, nickel salts, and epoxy resin hardeners, are also primary irritants.
- ➢ However, sensitization (allergy) can be produced or maintained by allergens such as nickel, chromates, formaldehyde, and turpentine in minute amounts and in concentrations insufficient to irritate the nonallergic skin.
- ➢ Cross-sensitivity is an important phenomenon in which a worker sensitized to one chemical also reacts to one or more closely related chemicals. A number of examples exist: rhus antigens such as poison oak, ivy, sumac, Japanese lacquer, mango, and cashew nutshell oil; aromatic amines such as p-phenylenediamine, procaine, benzocaine, and p-aminobenzoic acid (sunscreens); and perfume or flavoring agents such as balsam of Peru, benzoin, cinnamates, and vanilla.
- ➢ Systemic contact dermatitis is a widespread, eczematous contact-like dermatitis that can result from oral or parenteral (intravenous or intramuscular) administration of an allergen to which a worker is sensitized topically (such as oral administration of sulfonamides and thiazide diuretics in patients with contact allergy to p-phenylenediamine and benzocaine-containing topical anesthetics).

➢ Patch testing is used to differentiate allergic contact dermatitis from irritant dermatitis. The sine qua non for the diagnosis of allergic contact dermatitis is a properly performed and interpreted positive patch test.

The most common contact sensitizers in the general population have been determined from clinical experience and from published studies on the prevalence of positive patch test reactions in dermatology departments. Major sensitizers include the following:

➢ Rhus (poison oak, ivy, and sumac)
➢ P-phenylenediamine
➢ Nickel
➢ Rubber chemicals
➢ Quaternium-15 (a formaldehyde-releasing preservative)
➢ Topical medicaments containing benzocaine, antihistamines such as diphenhydramine, and antibiotics such as neomycin and bacitracin

Additional industrial allergens include the following:

➢ Chromates
➢ Plastics and adhesives (especially epoxy and acrylic resins)
➢ Formaldehyde and other preservatives
➢ Mercury
➢ Cobalt

Contact Urticaria/Latex Allergy

Contact urticaria is characterized by the appearance of urticaria, or hives, usually within several minutes at the site of contact with a wide variety of substances. There are three types: immunologic, nonimmunologic, and contact urticaria of uncertain mechanism. The nonimmunologic type is most common; causes include substances that release histamine or other vasoactive substances, such as plants (nettles), insects (caterpillars and moths), cobalt chloride, cinnamic aldehyde, nicotinic acid esters (trafuril), and dimethyl sulfoxide. Causes of contact urticaria of uncertain type include ammonium persulfate, certain types of solar urticaria (caused by sun exposure) and aquagenic urticaria (caused by water exposure). Examples of agents that may produce immunologic contact urticaria include penicillin, nitrogen mustard, neomycin, and the insect repellant diethyl toluamide (DEET).

The paradigm for the immunologic type of contact urticaria is natural rubber latex (NRL) allergy, which has become a significant medical and occupational health problem. Most affected patients have contact urticaria, but others have experienced generalized urticaria, angioedema, asthma, and anaphylaxis including vascular collapse and death. Terminology established by the Latex Task Force of the Health Industry Manufacturers Association identified natural latex as the milky fluid of agriculture origin produced by the *Hevea brasiliensis* tree. NRL refers to products made directly from water-based, natural latex emulsions. Gloves, balloons, tourniquets, and condoms are examples of products produced by means of dipping porcelain forms into liquid latex. Dry rubber latex refers to products made from processed, dried, or milled sheets of latex rubber. Syringe plungers, vial stoppers, and baby-bottle nipples are examples of extruded or compression-molded dry products. Most immediate-type reactions result from exposure to NRL products that are dipped. Dry-molded rubber products contain lower residual latex protein levels or have less easily extracted proteins than do dipped products produced from NRL. This may explain the relative lack of reports of NRL allergy in the tire industry.

Latex allergy is an immunoglobulin (Ig) E-mediated hypersensitivity to one or more of a number of proteins present in raw or cured NRL. Individuals at highest risk are patients with spina bifida (30–65 percent prevalence), health care workers, and other workers with significant NRL exposure. Most reported series of occupational cases involve health care workers, affecting 5–11 percent of those studied. Studies of populations of nonhealth care workers are infrequent and include kitchen workers, cleaners, rubber band, surgical glove, latex doll-manufacturing workers, and miscellaneous other occupations. Predisposing risk factors are hand eczema, allergic rhinitis, allergic conjunctivitis, or asthma in individuals who frequently wear NRL gloves; mucosal exposure to NRL; and multiple surgical procedures.

The spectrum of clinical signs ranges from contact urticaria, generalized urticaria, allergic rhinitis, allergic conjunctivitis, angioedema, and asthma to anaphylaxis. The majority of cases involve reactions to NRL gloves, i.e., donning NRL gloves or being examined by individuals wearing NRL gloves. Reactions from other medical and nonmedical NRL devices have occurred; these include balloons, rubber bands, condoms, vibrators, dental dams, anesthesia equipment, and toys for animals and children. The route of exposure to NRL proteins is important, and it includes direct contact with intact or inflamed skin and mucosal exposure, such as inhalation of powder from NRL gloves, especially in medical facilities and in operating rooms.

NRL allergy is sometimes associated with allergic reactions to fruit, especially bananas, kiwi, chestnuts, and avocados. This results from cross-reactivity between proteins in NRL and those found in the fruits. Symptoms range from oral itching and angioedema to asthma, gastrointestinal upset, and anaphylaxis.

Diagnosis of NRL allergy is strongly suggested by obtaining a history of angioedema of the lips when inflating balloons, and/or itching, burning, urticaria, or anaphylaxis when donning gloves, when undergoing surgical, medical, and dental procedures, or following exposure to condoms or other NRL devices. Diagnosis is confirmed by either a positive wear-or-use test with NRL gloves, a valid positive intracutaneous prick test to NRL, or a positive serum RAST to NRL. Severe allergic reactions have occurred from prick-and-wear tests; epinephrine and resuscitation equipment free of NRL should be available during these procedures.

Hyposensitization to NRL is not yet possible, and NRL avoidance and substitution are imperative. Because many patients with NRL allergy are atopic with hand eczema, immediate allergic symptoms, or both, the most important

issues for physicians are accurate diagnosis, appropriate treatment, and counseling. Dermatologic evaluation to exclude other causes of hand eruptions and allergy or pulmonary evaluation of associated rhinitis, conjunctivitis, asthma, angioedema or anaphylaxis is important.

Prevention and control of NRL allergy includes latex avoidance in health-care settings for affected workers and patients. Substitute synthetic non-NRL gloves and other personal protective equipment such as surgical masks and disposable respirators should be available; and in many cases, low-allergen NRL gloves should be worn by coworkers to accommodate those with NRL allergy, in order to minimize symptoms and to decrease induction of NRL allergy. Synthetic non-NRL gloves include those made of poly(vinyl chloride) (vinyl), block polymers (styrene-butadiene-styrene and styrene-ethylene-butylene-styrene), chloroprene (Neoprene®), polyurethane, synthetic polyisoprene, and nitrile.

Allergen content of gloves should be requested from manufacturers and suppliers; lists of glove allergen levels have also been published (see Bibliography, Palosuo et al, 1998). Patients with NRL allergy should obtain MedicAlert bracelets and inform health care providers of their diagnosis, and be given lists of substitute gloves, other non-NRL devices, potentially allergenic fruits, a latex-safe anesthesia protocol, and occult sources of NRL exposure such as dog and child toys, and dental prophylaxis cups. Some of this information is available in published sources and from latex allergy support groups. One group is ELASTIC (Education for Latex Allergy Support Team and Information Coalition), which provides Latex Allergy News (800/482-6869). Another is ALERT (Allergy to Latex Education and Support Service) (414/677-9707). The National Institute for Occupational Safety and Health (NIOSH) has issued a review on preventing allergic reactions to NRL in the workplace (NIOSH Alert, 1997).

Other information on latex allergy is available from the Spina Bifida Association of America (202/944-3285). The FDA recently issued a rule requiring labeling of NRL devices and outlining substitute language to replace the "hypoallergenic" label. The old "hypoallergenic" label was designed to prevent Type IV allergic contact dermatitis rather than Type I NRL allergy. Since these "hypoallergenic" gloves were still made of NRL, they caused adverse reactions in some patients with NRL allergy. (See the section on Gloves, later in this chapter.)

Photosensitivity

Photosensitivity is the capacity of an organ or organism or certain chemicals and plants to be stimulated to activity by light or to react to light. Two types are generally recognized: phototoxicity and photoallergy. Phototoxicity, like primary irritation, can affect anyone, although darkly pigmented people are more resistant. Photoallergens, like contact allergens, involve immune mechanisms and affect fewer people.

Industrial sources of photosensitivity can be obscure, requiring careful epidemiological and clinical investigation including photopatch testing. An example is phototoxicity from p-aminobenzoic acid used in the manufacture of ultraviolet-cured inks. Medical personnel may be occupationally exposed to photosensitizing drugs. Other workers who can have contact with topical photosensitizers include outdoor and field workers (photosensitizers in plants and chemicals), machinists (antimicrobials in metalworking fluids), pharmaceutical workers (drugs, dyes, and fragrances), and oil field, road construction, and coal tar workers (tars, pitch, and other hydrocarbons).

Occupational Acne

Occupational acne results from contact with petroleum and its derivatives, coal tar products, or certain halogenated aromatic hydrocarbons (Table 3–E). The eruption can be mild, involving localized, exposed, or covered areas of the body, or severe and generalized, with acne involving almost every follicular orifice. Chloracne, in addition to being a difficult cosmetic and therapeutic problem, is of considerable concern because it is caused by highly toxic chemicals.

Occupational acne is seen most commonly in workers exposed to cutting oils in the machine tool trades. The insoluble (straight) oils are the most common cause (see Figure 3–5). Oil acne typically starts as comedones and an inflammatory folliculitis affecting the tops of the hands and extensor surfaces of the forearms. However, covered areas of the body (thighs, lower abdomen, and buttocks) can be affected by contact with oil-saturated clothing. Although the lesions are commonly called oil boils, they almost never develop from bacteria present in the oils.

Any form of occupational acne or preexisting or coexisting acne vulgaris (nonoccupational) can be aggravated by heat (acne tropicalis and aestivalis); constant friction (acne mechanica), with acne localized to the forehead (hard hat), waist (belt), or other area; excessive scrubbing with harsh soaps (acne detergicans); cosmetics (acne cosmetica); pomade and vaseline (pomade acne); and topical corticosteroids (steroid rosacea). Acneiform eruptions from systemic med-

Table 3–E. ***Some Causes of Occupational Acne***

Petroleum and its derivatives (crude oil and fractious cutting oils)
Coal tar products (coal tar oils, pitch, creosote)
Halogenated Aromatic Compounds (chloracnegens)
Polyhalogenated naphthalenes
Polyhalogenated biphenyls (PCBs, PBBs)
Polyhalogenated dibenzofurans
Contaminants of polychlorophenol compounds especially herbicides (2,4,5-T and pentachlorophenol) and herbicide intermediates (trichlorophenols), e.g., dioxin
Contaminants of 3,4-dichloroaniline and related herbicides (Propanil and Methazole), azo- and azoxybenzenes

ication containing bromides, iodides, and corticosteroids and the syndrome of senile or solar comedones on the face are also to be considered in the differential diagnoses.

Coal tar oils, creosote, and pitch can produce extensive acne in coal tar facility workers, roofers, and road maintenance and construction workers. Comedones are typical of this form of acne. Phototoxic reactions involving both the skin and eye (keratoconjunctivitis) can complicate the picture and produce coal tar melanosis and exacerbations of the acne. Pitch keratoses and acanthomas (precancerous and cancerous skin lesions) can develop later.

Certain halogenated aromatic chemicals (some chloronaphthalenes, PCBs and dibenzofurans, dibenzo-p-dioxins, and chlorobenzenes) are the most potent acnegens and are among the most toxic environmental chemicals. These chemicals can produce chloracne, a type of acne that is often resistant to therapy, and can be accompanied by systemic toxicity. Chloracne is one of the most sensitive indicators of biological response to these chemicals, and acts as a marker of the medical and environmental impact of contamination of technical-grade chemicals with potentially highly toxic intermediates.

Pigmentary Abnormalities

Pigmentary abnormalities can result from exposure to certain chemical, physical, and biological agents. They not only represent difficult cosmetic problems, but can indicate exposure to potential systemic toxins. Differentiation from various nonoccupational, genetic, metabolic, endocrine, inflammatory, and neoplastic pigmentary conditions is necessary.

HYPERPIGMENTATION

Hyperpigmentation (skin darkening) can follow almost any dermatitis as a postinflammatory event. Chemical photosensitizers (tar, pitch, plant, and drug photosensitizers), physical agents (ultraviolet light and thermal and ionizing radiation), and trauma (chronic itching) are common causes. Exposure to certain chemicals (arsenic and acnegenic aromatic hydrocarbons) can also cause hyperpigmentation.

Figure 3–6. Pigment loss in the skin (hypopigmentation) was caused by exposure to a known depigmenting chemical.

HYPOPIGMENTATION

Pigment loss can also follow inflammation (Figure 3–6). Physical or chemical damage to the skin from thermal, ultraviolet, radiation, or chemical burns may cause not only loss of pigment, but also scarring. These changes usually pose no diagnostic problem.

However, pigment loss from certain chemical exposures can be difficult to differentiate from idiopathic vitiligo (a patchy loss of pigment from otherwise healthy skin). Occupational leukoderma (white skin) of this type was first reported from exposure to monobenzyl ether of hydroquinone (agerite alba), once used as an antioxidant in industrial gloves. During the past 20 years, a number of phenolic compounds have caused leukoderma among exposed workers. Sources include hospital and industrial germicidal cleaners, metalworking fluids, oils, latex glues, inks, paints, and plastic resins. Table 3–F lists some of these compounds. These chemicals interfere with melanin pigment biosynthesis, destruction, or both. Hands and forearms are usually affected, although covered parts can also be affected, possibly from ingestion or inhalation of the chemicals.

Sweat-Induced Reactions, Including Miliaria and Intertrigo

Miliaria (prickly heat or heat rash) results from obstruction of sweat ducts and is an inflammatory reaction to retained extravasated sweat. It is a common reaction of people who sweat profusely while exposed to heat. The lesions consist of pinpoint to pinhead-sized papules and vesicles (blisters) on the chest, back, and submammary, inguinal, and axillary folds.

Intertrigo represents maceration that occurs on apposing skin surfaces and is a scaling, erythematous eruption. Superimposed yeast or superficial fungal infection can also be present. Obesity and heat exposure are aggravating factors.

Cutaneous Tumors

Neoplastic growths of the skin are classified as benign lesions, precancers, or cancers. Benign viral warts (*verrucae*

Table 3–F. ***Some Chemicals Producing Occupational Leukoderma***

Monobenzyl ether of hydroquinone
Monomethyl ether of hydroquinone
Hydroquinone
P-Tertiary amyl phenol

P-Tertiary butyl catchol
Alkyl phenols
Selected other phenolic compounds

vulgaris) are more common among workers in certain occupations associated with wet work (such as butchers). Keratoacanthomas can be occupationally associated with exposure to sunlight or contact with various tars, pitch, and oils (pitch warts and acanthomas). Although classed as benign lesions, keratoacanthomas can be extremely difficult to differentiate clinically and pathologically from squamous cell carcinoma. Pitch and tar warts (keratoses) and acanthomas can be premalignant lesions.

Excessive exposure to sunlight is the most common cause of precancers and cancers in human skin. Additionally, inorganic arsenic compounds, polycyclic aromatic hydrocarbon compounds associated with asphalt, paraffins, coal tars, oils (creosote, shale, hydrogenated, petroleum, insoluble cutting, and mineral), and ionizing radiation can cause cancer of the skin and other organs. Precancerous actinic keratoses (caused by rays of light that produce chemical effects) appear in sun-exposed areas, can be extensive in workers with outdoor jobs (such as utility line workers, agricultural workers, construction workers, ranchers, fishermen, and sailors), and can progress to squamous cell and basal cell carcinomas. Such workers often have other signs of sun exposure from solar degeneration of collagen, including hyperpigmentation, thin and wrinkled skin, and telangiectasia (a spider-like growth composed of blood or lymph vessels). Epidemiological studies show that sunlight can also be a factor in the increased incidence of malignant melanoma. Skin biopsy is absolutely essential for the diagnosis of all types of skin cancer.

Ulcerations

Tissue injury on a skin or mucous membrane surface can result in erythema, blisters, or pustules, which may result in necrosis and ulceration. This can be caused by trauma, thermal or chemical burns, cutaneous infection, and a number of chemicals, including certain chromium, beryllium, nickel, and platinum salts, calcium oxide, calcium arsenate, calcium nitrate, and strong acids. Cutaneous tumors can also ulcerate. Self-inflicted or unintentionally produced skin disorders commonly appear as ulcerations.

Granulomas

These represent chronic, indolent areas of inflammation and can be localized or generalized. Scar formation often results. Causes include a variety of bacterial (anthrax), mycologic (sporotrichosis), viral (herpes simplex), parasitic (prototheocosis), and botanical (thorns) sources. Other causes include minerals (silica, beryllium, zirconium), bone, chitin, and grease.

Alopecia

Alopecia (absence of hair from the skin areas where it is normally present) has many causes: trauma, cutaneous and systemic disease, drugs, chemicals, and other physical factors, including ionizing radiation. Industrially caused hair loss is rare and the differential diagnosis is long. Chemicals or medications can cause extensive hair shedding by precipitating telogen (resting hair) development, directly poisoning the anagen (growing) hair, or acting in other unknown ways. Other alopecia-producing chemicals include thallium (rodent poison) and boric acid. Medications, primarily cancer chemotherapeutic agents, can precipitate anagen hair loss (immediate loss). Drugs capable of causing telogen hair loss (delayed loss) include oral contraceptives, anticoagulants, propranolol, and thallium.

Nail Disease

Chronic inflammation of the folds of tissue surrounding the fingernail (paronychia), with associated nail dystrophy, is a common occupational disorder associated with wet work (bartenders, maintenance workers, and kitchen workers). This disorder is commonly associated with *Candida* species, *Pseudomonas* species, other bacteria, or dermatophyte fungi.

Nail discoloration can result from exposure to chemicals such as bichromates (accompanied by nail dystrophy), formaldehyde, certain amines, picric acid, nicotine, mercury, resorcinol, or iodochlorhydroxyquin (Vioform).

Nail dystrophy can also accompany exposure to a number of chemicals, especially solvents; it is also caused by trauma or occupational marks in certain occupations such as weaving and the fur industry. Nail dystrophy can also be secondary to Raynaud's phenomenon, vibratory trauma, and acro-osteolysis.

Systemic Intoxication

A number of chemicals with or without direct toxic effect on the skin itself can be absorbed through it and cause (or contribute to, when a substance is also inhaled) systemic intoxication; the severity depends on the amount absorbed. A partial list of substances and their systemic effects includes the following:

- ➢ Aniline (red blood cells and methemoglobinemia)
- ➢ Benzidine (carcinoma of urinary bladder)
- ➢ Carbon disulfide (nervous system and psychological disturbances)
- ➢ Carbon tetrachloride (central nervous system, or CNS, depression, hepatotoxicity, and nephrotoxicity)
- ➢ Dioxane (CNS depression)
- ➢ Ethylene glycol ethers (CNS depression, pulmonary edema, hepatotoxicity, and nephrotoxicity)
- ➢ Halogenated naphthalenes, diphenyls, and dioxins (neurotoxicity and hepatotoxicity, altered metabolism)
- ➢ Methyl butyl ketone (CNS depression and peripheral neuritis)
- ➢ Organophosphate pesticides (inhibition of enzyme cholinesterase with cardiovascular, gastrointestinal, neuromuscular, and pulmonary toxicity)
- ➢ Tetrachloroethylene (CNS depression, suspected carcinogen)
- ➢ Toluene (CNS depression).

Chemicals whose absorption may contribute to the total exposure are designated with a "Skin" notation in the American Conference of Governmental Industrial Hygienists (ACGIH) book, *Threshold Limit Values for Chemical Substances and Physical Agents* (*TLVs®*) *and Biological Exposure Indices* (*BEIs®*). (Also see Appendix B.) More information can also be found in the ACGIH publication *Documentation of the Threshold Limit Values and Biological Exposure Indices,* 7th ed. Contact the ACGIH for details. Cutaneous absorption here refers to absorption by skin, mucous membranes, and eyes through either airborne or direct contact.

BURNS

Because all burns have essentially the same features, they are usually classified by degree according to depth of injury as first-, second-, or third-degree.

The main types of burns are as follows:

- ➢ Explosion burns, usually affecting exposed areas (hands, face)
- ➢ Steam burns, often superficial on exposed areas (more serious if with eye or respiratory contact)
- ➢ Hot-water burns, often leading to blistering depending on water temperature, more severe if victim is wearing heavy, permeable clothing
- ➢ Molten-metal burns, often affecting lower limbs, often extremely deep with metal encrusted in skin
- ➢ Hot-solid burns, normally not extensive, can be very deep
- ➢ Flame burns, almost always deep, often extensive, with the type of clothing being a major factor in severity
- ➢ Electricity and radiant energy burns, almost always severe, often with complications; ordinary clothing offers little protection

Nature of Chemical Burns

Burns caused by chemicals are similar to those caused by heat. In fact, some chemicals, such as sodium hydroxide, cause not only chemical burns because of their caustic action, but also thermal burns because of the heat they can generate when they react with moisture in the skin. After patients with chemical burns have been given emergency first aid, their treatment is the same as for patients with thermal burns.

Both thermal burns and chemical burns destroy body tissue. Some chemicals continue to cause damage until reaction with body tissue is complete or until the chemical is washed away by prolonged flushing with water. Strong alkalis penetrate tissue deeply, and strong acids corrode tissue with a characteristic stain.

Many concentrated chemical solutions have an affinity for water. When they come in contact with body tissue, they withdraw water from it so rapidly that the original chemical composition of the tissue (and hence the tissue itself) is destroyed. In fact, a strong caustic may dissolve even dehydrated animal tissue. The more concentrated the solution, the more rapid is the destruction.

Sulfuric, nitric, and hydrofluoric acids are the most corrosive of the inorganic acids, even more corrosive than hydrochloric acid. Some chemicals, such as phenol, are doubly hazardous. In addition to being highly corrosive, they are poisonous when absorbed through the skin. The severity of chemical burns depends on the following factors:

- ➢ Corrosiveness of the chemical
- ➢ Concentration of the chemical
- ➢ Temperature of the chemical or its solution
- ➢ Duration of the contact

The first three factors are determined by the very nature of the chemical and the requirements of the process in which it is used. The fourth factor, duration of the contact, can be controlled by the proper first-aid treatment administered without delay.

Classification of Burns

Burns are commonly classified as first-, second-, or third-degree. Second-degree burns may be further classified as superficial or deep dermal. However, for purposes of this chapter, the common classifications of first-, second-, and third-degree are adequate and are described here.

FIRST-DEGREE BURNS

These are characterized by redness and heat accompanied by itching, burning, and considerable pain. Only the outer layer of the epidermis is involved.

SECOND-DEGREE BURNS

These are highly painful and involve deeper portions of the epidermis and the upper layer of dermis. Generally, the skin is mottled red with a moist surface and blisters form. Such burns are easily infected.

THIRD-DEGREE BURNS

These are very severe forms of injury, involving loss of skin and deeper subcutaneous tissue. They are pearly-white or charred in appearance and the surface is dry. They are not exceedingly painful at first because nerve endings are usually impaired or destroyed.

SPECIAL TYPES OF BURNS

Cement and hydrofluoric acid deserve special mention. Recently, there have been many reports of severe burns from kneeling in wet cement or from wet cement becoming trapped inside boots. Pressure and occlusion are important factors, as well as the need to work fast with premixed cement, which can encourage prolonged contact. Symptoms may be delayed, so workers must be alert to the danger. Adherent cement should be removed by copious and gentle irrigation with water.

Hydrofluoric acid is one of the strongest acids known and is widely used in industry. Hydrofluoric acid burns are characterized by intense pain, often delayed, and progressive deep tissue destruction (necrosis). Immediate treatment

with topical magnesium sulfate or benzalkonium chloride and calcium gluconate gels and injections is recommended.

Complications of Burns

The dangers to life that result from extensive burns are infection (which causes most burn complications), loss of body fluid (plasma or lymph from the blood), and subsequent shock. Finally, the functional, cosmetic, and psychological sequelae may require the full attention of a rehabilitation team.

DIAGNOSIS

Anyone who works can develop a skin disorder, but not all skin disorders occurring in the workplace are occupational. Arriving at the correct diagnosis is not generally difficult, but it is more than a routine exercise. The following criteria are generally used.

Appearance of the Lesion

The dermatosis should fall into one of the accepted clinical types with respect to its morphological appearance.

Sites of Involvement

Common sites are the hands, wrists, and forearms, but other areas can be affected. Widespread dermatitis can indicate heavy exposure to dust because of inadequate protective clothing or poor hygiene habits.

History and Course of the Disease

A thorough and pertinent clinical history is the most important aspect in diagnosis of occupational dermatoses. This includes a description of the eruption, response to therapy, medical history and review of systems, a detailed work history (description of present and past jobs, moonlighting, preventive measures, cleansers, and barrier creams), and a detailed description of nonoccupational exposures. The behavior of the eruption on weekends, vacation, and sick leave can be very helpful in assessing the occupational component.

Ancillary Diagnostic Tests

When indicated, selected laboratory tests and office procedures are used for detecting skin disorders. These may include direct microscopic examination and bacterial and fungal cultures of the skin, skin biopsy for histopathological diagnosis, and patch tests and photopatch tests to detect any occupational or nonoccupational allergens and photosensitizers. Patch tests should be performed by physicians experienced with the procedure.

Treatment

Therapy of occupational skin disorders is essentially no different from that of the same nonoccupational disorder. However, two key factors are often overlooked when a worker's skin clears and he or she returns to work: identifying the cause of the disease and preventing a recurrence. Patients with skin disorders not responding to initial treatment should be referred for specialty evaluation.

WORKERS' COMPENSATION

State workers' compensation laws are no-fault statutes that hold employers responsible for the cost of occupational injury and disease claims while guaranteeing benefits to covered workers who meet the laws' requirements. All states now recognize responsibility for occupational diseases, and health professionals should become familiar with their own state workers' compensation laws and regulations. The American Medical Association's *Guides to the Evaluation of Permanent Impairment* is mandated, recommended, or often used by authorities in 40 of 53 jurisdictions (38 states and 2 territories). In general, three types of payment may be made when a claim is approved: temporary total disability payments to compensate for lost wages, payment of medical bills, and payment for permanent partial or permanent total disability.

Most claims based on occupational skin disease involve temporary total or permanent partial disability. Temporary total disability usually ceases when the patient has reached maximum medical improvement, has a valid job offer within his or her physical capabilities, or actually returns to work. Some states allow third-party liability suits arising out of workers' compensation cases.

EVALUATION OF OCCUPATIONAL DERMATOSES FOR WORKERS' COMPENSATION

In the evaluation of workers' compensation cases, the key elements are diagnosis, causation, impairment, and conclusions and recommendations.

Diagnosis

An accurate diagnosis of the claimant's condition is imperative. This often involves obtaining a detailed history of the present illness, reviewing of work exposures including material safety data sheets, and, whenever possible, visiting the workplace. Evaluation of the cutaneous findings should include an examination of the skin and skin biopsies, cultures, patch testing, or other ancillary tests if warranted. If diagnosis is in doubt, specialized consultation is warranted.

Causation

Determination of the cause-and-effect relationship between a skin disorder and an occupation is not always clear-cut. Questions to be considered include the following:

- ➢ Is the clinical appearance compatible with an occupational dermatosis?
- ➢ Are there workplace exposures to chemical, physical, mechanical, or biologic agents that may affect the skin?

- ➢ Is the anatomic distribution of the eruption compatible with job exposure? Many occupational dermatoses involve the hands.
- ➢ Is the temporal relationship between exposure and onset consistent with an occupational skin disease?
- ➢ Have nonoccupational exposures been excluded as causes?
- ➢ Does the dermatitis improve away from work exposure to the suspected agent(s)?
- ➢ Do patch or provocation tests identify a probable cause?

A "yes" answer to at least four of these questions is probably adequate to establish probable cause.

Impairment Evaluation

As a prelude to impairment evaluation, the physician must determine the impact of the medical condition on life activities and the stability of the condition. If the worker has a new or recent onset condition that significantly precludes working on the current job, then temporary total impairment may exist and an appropriate amount of time away from work may be warranted under most workers' compensation laws. Unduly restrictive limitations, such as avoiding all contact with a particular substance, may jeopardize a worker's job; before writing such recommendations, the physician should generally discuss them with the worker and employer.

The AMA's *Guides to the Evaluation of Permanent Impairment* are used to evaluate *permanent* impairment of any body system(s), from both occupational and nonoccupational causes; they are not designed for use in evaluating *temporary* impairment. They are guidelines, are not absolute recommendations, and are designed to bring objectivity to an area of great subjectivity. The *Guides* include clinically sound and reproducible criteria useful to physicians, attorneys, and adjudicators. They espouse the philosophy that all physical and mental impairments affect the whole person. A 95–100 percent whole person impairment is considered to represent almost total impairment, a state that is approaching death. Before using the *Guides* for evaluating cutaneous impairment, the health professional should read the two introductory chapters, the glossary and then Chapter 8, The Skin. Chapter 2, Practical Applications of the *Guides,* lists a suggested outline for a medical evaluation report.

Permanent impairment of the skin is "any dermatologic abnormality or loss that persists after medical treatment and rehabilitation and that is unlikely to change significantly in the next year, with or without medical treatment" (p. 173, *AMA Guides to the Evaluation of Permanent Impairment,* 5th ed., 2000). The *Guides* popularized the concept that impairment is a medical issue assessed by medical means, in contrast to disability, which is a nonmedical assessment generally determined by adjudicating authorities.

Disability is defined as an "alteration of an individual's capacity to meet personal, social, or occupational demands or to meet statutory or regulatory requirements because of an impairment," (p. 8, *AMA Guides to the Evaluation of Permanent Impairment,* 5th ed., 2000). It is important to remember that an impaired person is not necessarily disabled. The classic example often cited is that of two people who lose the distal portion of the phalanx of the same finger. Although impairment for both people is the same, disability is likely to be greater for a concert pianist than for a bank president.

The AMA chapter on the skin lists five classes of impairment, ranging from 0 percent to 95 percent (Table 3-G.)

The impact of the disorder on the activities of daily living should be the major consideration in determining the class of

Table 3–G. ***Criteria for Rating Permanent Impairment Due to Skin Disorders****

Class 1: 0%–9% Impairment of the Whole Person	Class 2: 10%–24% Impairment of the Whole Person	Class 3: 25%–54% Impairment of the Whole Person	Class 4: 55%–84% Impairment of the Whole Person	Class 5: 85%–95% Impairment of the Whole Person
Skin disorder signs and symptoms present or intermittently present	Skin disorder signs and symptoms present or intermittently present	Skin disorder signs and symptoms present or intermittently present	Skin disorder signs and symptoms constantly present	Skin disorder signs and symptoms constantly present
and	**and**	**and**	**and**	**and**
no or few limitations in performance of activities of daily living; exposure to certain chemical or physical agents may temporarily increase limitation	limited performance of some activities of daily living	limited performance of some activities of daily living	limited performance of many activities of daily living, including intermittent confinement at home or other domicile	limited performance of most activities of daily living, including occasional to constant confinement at home or other domicile
and	**and**	**and**	**and**	**and**
requires no or intermittent treatment	may require intermittent to constant treatment	may require intermittent to constant treatment	may require intermittent to constant treatment	may require intermittent to constant treatment

* The signs and symptoms of disorders in classes 1, 2 and 3 may be intermittent and not present at the time of examination. Consider the impact of the skin disorder on the ability to perform activities of daily living in determining the class of impairment. Consider the frequency and intensity of signs and symptoms (i.e., severity) and the frequency and complexity of medical treatment when selecting an appropriate impairment percentage and estimate within any class. (Source: *Evaluation of Permanent Impairment,* 5th Edition. American Medical Association, copyright 2000.)

impairment. The frequency and intensity of signs and symptoms and the frequency and complexity of medical treatment should guide the selection of an appropriate impairment percentage and estimate within any class.

The activities of daily living (ADLs) include self-care and personal hygiene, communication, physical activity, sensory function, hand functions (grasping, holding, pinching, percussive movements, and sensory discrimination), travel, sexual function, and sleep. Other examples of specific ADLs are listed in the glossary of the *Guides*.

The examples within each class are very important guides for the first time user. It is critically important to remember that impairment is not determined by diagnosis alone, but also by the effect of the disease on ADLs along with the frequency and intensity of disease and the frequency and complexity of therapy. Most cutaneous impairment falls within the first three classes ranging from 0 percent to 54 percent.

Unique to the *Guides'* skin chapter are the discussions of pruritus (itching), disfigurement, scars and skin grafts, and patch testing. Itching is evaluated by determining its interference with the ADLs and the extent to which the description of pruritus is supported by objective findings such as lichenification, excoriation, or hyperpigmentation. Disfigurement usually involves no loss of body function and little or no effect on the ADLs. Disfigurement may well impair self-image, cause life-style alteration, and result in social rejection. These changes are best evaluated in accordance with the criteria in the chapter on mental and behavioral conditions. Evaluation of scars and skin grafts is made according to the impact on ADLs. When impairment is based on peripheral nerve dysfunction or loss of range of motion, it may be evaluated according to the criteria in the chapters on the nervous system and musculoskeletal system. When properly performed and interpreted, patch tests can make a significant contribution to the diagnosis of allergic contact dermatitis

Conclusions and Recommendations

All diagnoses should be listed and summarized. A summary statement regarding causation is then made that states whether, within a reasonable degree of medical certainty, the disease is related to work. The diagnosis should include a description of specific clinical findings related to the impairment and how they relate to and compare with the criteria in the *Guides*. The impairment value also should be explained. Specific recommendations for therapy should be included along with a brief explanation of the treatment. Recommendations for prevention, including work restrictions, are next; possible suggestions are environmental modification (exhaust ventilation, splash guards) and personal protective equipment. The effect of future exposures to chemical, physical, and biological agents should be addressed, along with any need for rehabilitation. In conclusion, impairment evaluation is an important and sometimes daunting task for physicians evaluating workers with putative occupational diseases.

Physical Examinations

Preplacement examinations will help identify those who may be especially susceptible to skin irritations. The physician in charge of the examination should be provided with detailed information regarding the type of work for which a person is being considered.

Routine use of preplacement patch tests to determine sensitivity to various materials is not recommended. Patch tests cannot predict whether new workers will become sensitized to certain materials and develop dermatitis, but only tell whether people who have previously worked on similar jobs are sensitized to the chemicals with which they have worked.

The industrial physician has the primary responsibility for determining whether an applicant may be predisposed to skin irritations and for recommending suitable placement on the basis of these findings. Nevertheless, considerable responsibility also may fall to the safety and personnel departments, supervisors, industrial hygienists, and other people functionally responsible for accident prevention work and control of industrial diseases.

Care should be taken in restricting people who are not specifically sensitive to the agents involved in the job just because of a history of skin trouble unless there is active skin disease at the time of placement. In many cases, the physician is limited to simply counseling the person about risk.

PREVENTION AND CONTROL

Dermatoses caused by substances or conditions present in the work environment are largely preventable, but only through the combined effort of management and workers. This type of combined effort is best demonstrated in large industrial firms.

There are two major approaches to the prevention and control of occupational diseases in general and dermatoses in particular: environmental control measures and personal hygiene methods. In both cases, the key is cleanliness, both environmental and personal.

Environment

Environmental cleanliness includes good housekeeping (discussed later in this section). Its primary function in preventing industrial dermatitis (and other industrial diseases) is to reduce the possibility of contact with the offending agent.

PLANNING

Proper design of equipment during construction is of great importance in the reduction of dermatitis and other industrial health problems. Ventilation must meet the industry requirements.

Provisions must be made for the safe handling of irritant chemicals. Pumps, valves, pipes, fittings, and the like must be maintained to eliminate (as much as possible) the contact of workers with irritants. Empty drums or bags used to

transport incoming materials of a hazardous nature should be properly disposed of to prevent accidental exposure. Containers being readied for shipment should be filled in a manner that prevents contact with workers and left clean so that truckers, warehouse workers, and others cannot accidentally contact a harmful material on contaminated surfaces. Containers with harmful materials should be labeled with proper precautions.

PROCESS CONTROL

Before any new process or work procedure is introduced and before new substances are adopted in an established process, an industrial hygienist or chemist should carefully consider every aspect of the operation for possible or known dermatitis hazards, including those that can be caused by trace impurities. Analyzing work procedures and processes often requires specialized equipment and techniques.

Once the potential dermatitis-causing factors have been determined, suitable engineering controls can be instituted and built into the work processes or operations.

The best way of controlling dermatitis is to prevent skin contact with offending substances; if there is no exposure, there will be no dermatitis. Unfortunately, this is more easily said than done.

Operations should be planned and engineered to ensure minimal worker contact with irritants and sensitizing chemicals. When possible, chemicals of low toxicity and low irritant potential should be substituted. Enclosure guards and mechanical handling facilities may be necessary when an operation involves highly corrosive materials. Operations that give off dust, fumes, or vapors need suitable exhaust ventilation to minimize exposure. Low ambient relative humidity in the workplace may cause or contribute to some occupational skin diseases.

SELECTION OF MATERIALS

Much can be done to minimize hazardous conditions through careful selection of materials. Dry sodium and potassium hydroxide, for example, are now available in virtually dust-free forms; for many uses, they can be purchased in solution and handled with pumps. Other products are available as prills (beads), pellets, granules, or solutions that do an adequate job and reduce the dust hazard. Concentrated solutions are also finding favor not only for safety, but for economy in handling.

Some compounds can be successfully used when the percentage of the irritant in the compound is reduced. In other cases, a less irritating or nonirritating material, or a less sensitizing material, can be substituted. The supplier should be asked to provide a closely related and generally satisfactory substitute for the irritating or sensitizing material. Examples include substituting one germicide for another in metalworking fluids when an allergy to the first germicide is found and using vinyl gloves in place of rubber gloves if a rubber allergy is found.

Monitoring and Control Technology

In order to correctly measure and sample skin exposure to chemicals, it is important to understand the methods of such exposure. These include contact with chemicals in a container (spill), contact with contaminated surfaces (tools or rags), exposure to aerosols (fallout of mist or soluble powder), exposure to sprays (ballistic droplets versus mist), and permeation through clothing (protective and personal). Other factors to be considered in the evaluation of skin exposure to chemicals include variable deposition rates onto the body, the effect of clothing, duration of skin contact with the chemical, and time of skin retention and permeation through the skin.

SAMPLING PROCEDURES

Current sampling procedures are often difficult to apply to prevention of occupational skin disease. Some exceptions include use of wipe samples for chemical analysis, hand or skin rinses, dermal dosimeters or patches, sampling cotton socks when shoe contamination is suspected, and sampling air inside a suit when the air is contaminated. Air levels of dusts and chemicals may have some limited application. The use of fluorescent tracers, fiber-optic luminescence skin monitoring, and charcoal cloth absorptive padosimeters are currently being evaluated. Color-indicator soaps have been used to detect exposure to tetryl (used in munitions facilities) and mercury. A scientific study established methods to determine relative benefits of equipment such as gloves and clothing to protect skin against styrene in a reinforced plastics facility. Another study dealt with the biological surveillance of workers exposed to dimethylformamide and the influence of skin protection on its percutaneous absorption. Standardized techniques have improved measurement of the effectiveness of protective material such as gloves and clothing against carcinogens and polychlorinated biphenyls.

GOOD HOUSEKEEPING

Environmental cleanliness is nothing more than good housekeeping and it is maintained by frequently cleaning floors, walls, ceilings, windows, and machinery. Good housekeeping work is usually performed by a special maintenance group that is given direct responsibility for maintenance cleaning. In order to be effective, cleaning should be part of a plan and should be performed on schedule. The necessary equipment and materials to do the most effective job possible in a reasonable amount of time should be assigned, and housekeeping workers should be trained so that they perform their operations efficiently and safely.

Environmental cleanliness is important to maintain good morale, reduce contact dermatitis, and set an example for workers. Floors, walls, ceilings, and light fixtures should be cleaned regularly in order to maintain the best possible conditions in the facility. (The requirements of Part 1910 of the Occupational Safety and Health Standards, Section 1910.14, "Sanitation," contain details on housekeeping, waste disposal,

vermin control, water supply, toilet facilities, washing facilities, change rooms, consumption of food and beverages on premises, and food handling.) As pointed out in the OSHA standards, washrooms, showers, toilets, and locker rooms should be kept clean and sanitary.

Many types of cleaners are available, from simple cleaning agents to complex formulations. These come in solid, liquid, or paste, and contain cleaners and sanitizing agents using synthetic detergents, soaps, and alkaline salts in combinations. Some mixtures include sanitizing agents to help prevent the spread of bacteria, fungi, and other biological agents. Environmental cleanliness and good housekeeping are also beneficial because they set an example for the workers and encourage personal cleanliness.

Personal Cleanliness

The importance of personal cleanliness in the prevention and control of occupational dermatoses cannot be overemphasized. When investigating contact dermatitis, one should also consider the possibility of irritants contacted at home or with a hobby.

PREVENTION OF CONTACT

When facility and process design cannot eliminate all contact with irritants, personal protective equipment must be used. Included are gloves, gauntlets, aprons, and boots made of a material that is impervious to the particular substance. These, along with goggles, afford sufficient protection in most cases. Disposable gauntlets, aprons, boots, and gloves are available, but they are more subject to tears than heavier safety gear. Other gear may provide insulation against heat or light. All personal protective equipment required for a job should be carefully maintained and replaced when it becomes worn.

In order to minimize contact with harmful agents, workers must have access to facilities for washing hands and be furnished with other means of keeping clean. It is up to the employer to provide adequate washing facilities, good cleansing materials, and education on the need for good hygiene practices. Washbasins must be well-designed, conveniently located, and kept clean; otherwise they will be used infrequently, if at all. The farther workers must walk to clean up, the less likely they are to do so. Inconveniently located washbasins invite such undesirable practices as washing with more easily available solvents, mineral oils, or industrial detergents, none of which is intended for skin cleansing. For workers to keep their skin reasonably free of injurious agents, they must use washing facilities at least four times a day: during work (before eating, drinking, smoking, or using the restroom), before lunch, after lunch, and before leaving the facility (see Figure 3–7).

Those who work with toxic chemicals and radioactive substances must receive specific safe handling instructions and should take a shower after their work shift and change their clothing. Workers should be instructed in specific procedures for cleanliness. They should be told where, how, and when to wash and should be given sufficient time to wash, advised that they will be rated on this part of their job performance, and informed of the possible health hazards involved.

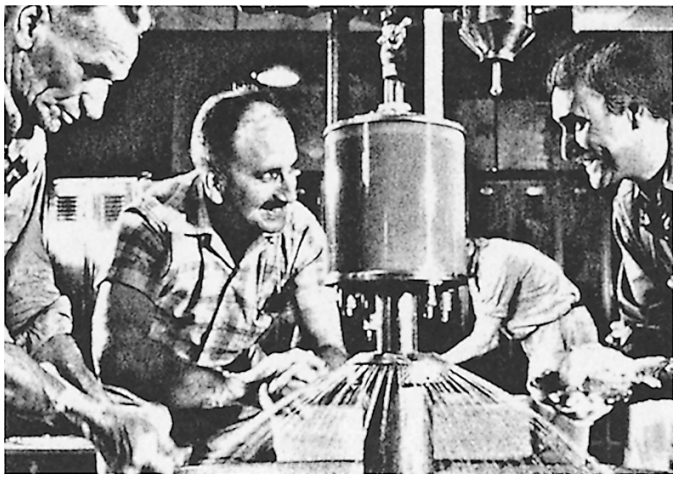

Figure 3–7. Wash facilities should be conveniently located and should be adequate for all needs.

For many exposures, frequent washing alone is a successful preventive, particularly when the dermatitis is caused by plugging of the pores, as from dust. In all cases, however, the use of large quantities of water on the skin following exposure to irritants is necessary. Safety showers and eyewash fountains should be available, and flushing should continue for at least 15 minutes.

It may be advisable in some instances to use neutralizing solutions after a thorough flushing with water. However, because some neutralizing solutions are themselves irritants, they should be used only on the advice of a physician.

The type of soap used is important. Even a generally good soap can cause irritation on certain types of skin. Harsh mineral abrasives can cause dermatitis in many people.

The choice of a good soap may in some cases involve technical considerations, which are better left to the medical department or other qualified department than to laypeople. The basic requirements of industrial skin cleansers are as follows:

- ➢ They should remove industrial soil quickly and efficiently.
- ➢ They should not harmfully dehydrate, abrade, or irritate the skin by normal application.
- ➢ They should flow easily through dispensers.
- ➢ They should be adequately preserved against microbial contamination.

Additional desirable qualities include the following:

- ➢ They should have aesthetic appeal (color and odor).
- ➢ They should have good foaming qualities.

A number of cases of industrial dermatitis are reported to be caused not by substances used in the workplace, but by cleansing materials used to remove those substances. A worker may be inclined to wash the hands with the cleaning agents that are most available and work the fastest, but these

are often dermatitis-producing solvents. Overuse of waterless cleansers can irritate and dry the skin. Generally, workers should apply a good hand lotion after applying waterless cleansers.

The installation in work-area washing places of soap-dispensing units containing properly selected cleansing agents has proved to be a valuable measure. Such units should be placed in convenient locations, and enough of them should be provided to accommodate all employees who are exposed to skin irritants. Where soap-dispensing units are furnished, workers should be required to use them.

BARRIER CREAMS

A barrier cream is the least effective way of protecting skin (Figure 3–8). However, there are instances when a protective cream may be used for preventing contact with harmful agents when the face cannot be covered by a shield or gloves cannot be worn (Figure 3–9). Several manufacturers compound a variety of products, each designed for a certain type of protective purpose. Thus, there are barrier creams that protect against dry substances and those that protect against wet materials. Using a barrier cream to protect against a solvent is not as effective as using an impervious glove; however, there are compounds that offer some protection against solvents when applied with sufficient frequency.

Barrier creams and lotions should be used to supplement, but not to replace, personal protective equipment. Protective barrier agents should be applied to clean skin. When skin becomes soiled, both the barrier and any soil should be washed off and the cream reapplied.

Three main types of barrier creams and lotions are available.

Vanishing cream usually contains soap and emollients that coat the skin and cover the pores to make subsequent cleanup easier.

Water-repellent cream leaves a thin film of water-repellent substance such as lanolin, beeswax, petrolatum, or silicone on the skin, and helps to prevent ready contact with water-soluble irritants such as acids, alkalis, and certain metallic acids. Remember, however, that the protection may not be complete, especially when the barrier has been on the skin for some time. Alkaline cleaning solutions tend to emulsify and remove the barrier rapidly, thus leaving the skin unprotected.

Solvent-repellent creams contain ingredients that repel oil and solvent. Lanolin has some oil-repellent and water-repellent properties and can be used as an ingredient. There are two types of solvent-repellent barrier preparations; one leaves ointment film and the other leaves a dry, oil-repellent film. Sodium alginates, methyl cellulose, sodium silicate, and tragacanth are commonly used. Lanolin offers some protection against oils as well as water.

Special types. In addition to these three main types, a number of specialized barriers have been developed. Creams and lotions containing ultraviolet screening and blocking agents are used to help prevent overexposure to sun or other ultraviolet sources. Others have been developed to afford protection

Figure 3–8. Barrier cream is applied by an employee before starting work and is washed off before lunch; it is reapplied after lunch and washed off before the worker leaves. Barrier cream is the least effective way of protecting the skin.

Figure 3–9. Most glove manufacturers provide a hand protection counseling service. They assess hazards and match them with gloves or other devices. It is up to the employer to educate employees to use the proper protection for the job performed.

from such diverse irritants as insects, gunfire backflash, and poison oak dermatitis.

Personal Protective Equipment

CLOTHING

Whenever irritating chemicals are likely to contaminate clothing, care must be taken to provide clean clothing at least daily. Because workers' families have developed contact dermatitis or chloracne from contact with clothing worn home from the job, clothing worn on the job should not be worn at home. Clothing contaminated with chemicals should always be thoroughly laundered before it is worn again. Clothing contaminated on the job should be changed at once.

PROTECTIVE CLOTHING

Sometimes handling irritant, allergenic, or toxic materials cannot be avoided; in this situation, protective clothing may provide a good barrier against exposure. OSHA requirements for "Personal Protective Equipment" (PPE) are described in 29 *CFR* Part 1910, Subpart 1, which includes general requirements on indications for use, ensuring adequacy of employee owned equipment and safe design of PPE for the work to be performed. This section was amended in 1994 to include requirements for hazard assessment and equipment selection, a ban on defective equipment, detailed training requirements and revised sections on protection of the eyes and face (1910.133), head (1910.135), feet (1910.136), and hands (1910.138). The American National Standards Institute has also issued a new standard (ANSI/ISEA 105) for hand protection (see also the section on "Gloves" in this chapter. Other protective clothing requirements appear in standards covering specific hazards (bloodborne pathogens) and specific occupations (shipyard workers).

High-quality clothing should be obtained. Manufacturers provide a large selection of protective garments made of rubber, plastic film, leather, cotton, or synthetic fiber that are designed for specific purposes. For example, there is clothing that protects against acids, alkalis, extreme exposures of heat, cold, moisture, and oils. When such garments must be worn, management should purchase them and enforce their use. Management should make sure that the clothing is mended and laundered often enough to keep it protective. If work clothes are laundered at home, the worker's other clothes may be contaminated with chemicals, glass fiber, or other dusts.

Closely woven fabrics also protect against irritating dust. Gloves and aprons of impervious materials (such as rubber or plastic) protect against liquids, vapors, and fumes (Table 3–H). Natural rubber gloves, aprons, boots, and sleeves are impervious to water-soluble irritants, but soon deteriorate if exposed to strong alkali and certain solvents.

Synthetic rubbers, such as neoprene and many of the newer plastics, are more resistant to alkalis and solvents than natural rubber; however, some materials are adversely affected by chlorinated hydrocarbon solvents. The protection used should be based on the particular solvents that are used. For workers who wear rubber or plastic, the irritant will eventually penetrate and

Table 3–H. ***Physical Performance Chart of Selected Glove Materials***

Coating	*Abrasion Resistance*	*Cut Resistance*	*Puncture Resistance*	*Heat Resistance*	*Flexibility*	*Ozone Resistance*	*Tear Resistance*	*Relative Cost*
Natural rubber	E	E	E	F	E	P	E	Medium

Grip/slip is related to glove surface and is enhanced when the glove is rough.

Dexterity is related to glove thickness and decreases as the glove thickness increases.

KEY TO CHART: E=excellent; G=good; F=fair; P=poor (Ratings are subject to variation, depending on formulation, thickness, and whether the material is supported by fabric).

The listings were taken from various glove manufacturers and NIOSH, and are ONLY A GENERAL GUIDE. When selecting gloves for any application, contact the manufacturer, giving as much information as possible.

This table shows the *physical* properties of selected glove materials. For chemical resistance properties of glove materials see section *Gloves* and published reference guides in that section.

be trapped next to the skin, causing repeated exposure every time the garment is worn. So gloves should be used to protect against splashes and wet items, but will not protect against immersions. Instruments or containers should be used for items that must be immersed. Reusable gloves should be washed according to the manufacturer's instructions.

Disposable paper and plastic garments can also be used for some tasks. Garments are also necessary in sterile areas to keep products from being contaminated (Figure 3–10).

FABRICS

Fabrics without coatings are generally unsuitable as protective clothing for toxic chemical exposures because they are all permeable and have other weaknesses. Cotton and rayon, for instance, are degraded by acids; wool is degraded by alkalis.

GLOVES

Because a high percentage of occupational contact dermatitis cases involve the hands, it is imperative for health and safety professionals to be knowledgeable about the types of glove materials available, their selection and use, and the types of adverse dermatological reactions to gloves.

Glove materials include the following:

- ➢ Natural rubber latex
- ➢ Synthetic rubber latex and synthetic rubber: butyl, chloroprene (Neoprene®), fluon (Viton®), nitrile, styrene-butadiene-styrene, styrene-ethylene-butylene-styrene, polyethylene, and synthetic polyisoprene
- ➢ Plastic polymers: ethylene-methyl methacrylate, polyethylene, polyvinyl alcohol, and polyvinyl chloride
- ➢ Laminated plastic polymers: a laminate of polyethylene-ethylenevinylalcohol copolymer-polyethylene (Silver Shield® and 4 H® gloves)
- ➢ Leather (chrome or vegetable tanned)
- ➢ Textiles: natural or synthetic; woven from fabrics, knit or terry cloth; also may be coated with rubber or plastic; fabric such as cotton or nylon may also be used as glove liners
- ➢ Other materials: wire cloth made of stainless steel or nickel as used by autopsy prosectors

A number of standards, guides, and rules have been published for gloves in both the United States and Europe. Categories of glove standards depend on the type of glove material used, type of work being done, and type of hazard encountered. Parameters of glove performance evaluated include physical strength, dexterity, abrasion, and heat and cold resistance. Other physical resistance factors include cut and puncture resistance, tear and tensile strength, and flammability (see Table 3-H). Resistance to swelling, degradation, permeation, and penetration are some of the more important chemical parameters evaluated; biological resistance to liquids and microorganisms also has been evaluated. Consult the references by Henry (1994) and Mellstrom & Carlsson (1994) for a list of current standards.

Figure 3–10. Protective clothing is worn over work clothes to prevent contamination of both the worker and, in sterile rooms, the product.

The new ANSI/ISEA 105-2000, *American National Sandard for Hand Protection Selection Criteria,* published by the International Safety Equipment Association (ISEA), provides a numeric scale method for manufacturers to rate their products against certain contaminants and exposures. With classification based on this scale, users can make decisions on which gloves are suitable for which tasks. Glove performance

and pass/fail criteria are included for the following hazardous exposures: cut, puncture and abrasion resistance; protection from cold; chemical permeation and degradation; detection of holes; and heat and flame resistance. The standard also includes reference information on special considerations such as biological protection, electrical protection, and radiation hazards. Every end use is different and no single test method can fully replicate the variety of hazards that a worker may encounter. The ISEA suggests that users should contact glove manufacturers for information on the new glove ratings and labeling of their products that meet the standard.

Forsberg & Mansdorf (1997) outline a number of factors to consider in the selection of gloves and other protective clothing:

- ➢ Chemicals ultimately penetrate protective barriers and can do so without evidence of damage to the barrier.
- ➢ Protective equipment cannot be used if torn or damaged.
- ➢ A barrier may protect against a single chemical but not necessarily against a mixture of chemicals.
- ➢ Temperatures higher than room temperature decrease breakthrough time of chemicals. The authors' *Quick Selection Guide* (1997) is based on room temperature data.
- ➢ Generally, thicker materials or layers of material are better for chemical resistance.
- ➢ Beware of lookalikes with chemical protective clothing.
- ➢ If a chemical has penetrated a material, the garment must be decontaminated before reuse. Gloves used in health care must be disposed of properly after each patient contact and cannot be decontaminated.
- ➢ Users of chemical protective clothing should check with their suppliers to confirm the performance standards of their products, to verify information on proper storage and care, and to select materials.

Another critically important factor is safety. Gloves should not be used where they may be caught in machinery, with potential for serious injury or loss of fingers or hands. Safety and health professionals should review any recommendation for glove use by health care providers who may not be familiar with a specific job.

Reference guidelines for the selection of gloves include the following:

- ➢ Schwope AD, et al. *Guidelines for the Selection of Chemical Protective Clothing,* 3rd ed., Vols. I and II. Cincinnati: American Conference of Governmental Industrial Hygienists, 1987. (Prepared by A.D. Little, Inc., for the EPA.)

- ➢ *Chemical Protective Clothing: Theory and Information* (volume 1): *Product and Performance Data* (volume 2). Fairfax, VA: American Industrial Hygiene Association, 1990.
- ➢ *American National Standard for Hand Protection Selection Criteria ANSI/ISEA 105-2000.* Arlington, VA: International Safety Equipment Association (ISEA), 2000.
- ➢ Computer data bases: Consult Mellstrom & Carlsson (1994) for a list of data bases.
- ➢ *NIOSH Pocket Guide to Chemical Hazards and Other Data Bases,* CD ROM, NIOSH Publication # 99-115. Cincinnati: NIOSH, April 1999 (available from the National Safety Council, [800] 621-7619).
- ➢ *Instant Gloves + CPC Data Base: Version 2.0.* Blacksburg, VA: Instant Reference Sources, Inc., 1999.
- ➢ Other sources: Consult Mellstrom et al (1994) for lists of other general texts on chemical protective clothing and the reference by Hamann & Kick (1994) for the selection of gloves for health care workers. Also see the discussion of contact urticaria/latex allergy above and of dermatologic reactions to gloves below.

Dermatologic reactions to gloves are classified as irritation from occlusion, friction, and maceration; allergy to glove materials and their chemical additives causing allergic contact dermatitis or allergy to certain natural rubber latex proteins causing contact urticaria; aggravation of preexisting skin diseases; and penetration of chemicals through gloves. Infrequent reactions to endotoxins and ethylene oxide, and to potentially depigmenting chemical constituents of gloves have been reported. Accurate diagnosis of any suspected adverse reactions to gloves is imperative before recommending alternatives to gloves. This is especially true of workers with contact urticaria to latex (latex allergy) who may still develop a severe reaction from gloves labeled as hypoallergenic. Because so-called hypoallergenic gloves may still contain allergenic latex proteins, synthetic gloves are necessary for these workers. See Table 4 in the Hamann & Kick (1994) and other chapters in the book *Protective Gloves of Occupational Use* (Mellstrom et al, 1994) for help in the selection of medical examination and sterile surgical gloves. *As this information may change, it is important to consult the glove manufacturer for the latest data.*

SAFETY

It is imperative that all safety gear be worn only when safely possible. Protective clothing, especially gloves, can be caught in moving machinery, resulting in serious injury.

Responsibility for Control

Top management, the safety department, the purchasing department, the medical department or company physician, the supervisors, and the workers all have specific responsibilities for the prevention of industrial skin diseases and the control of exposure to skin irritants.

To control or eliminate dermatitis in the workplace, management should first recognize the scope of the problem and then delegate authority for action to the proper employees. When it is necessary to have more than one department work on phases of dermatitis control or elimination, the activities of those departments should be coordinated. Periodic reports on the status of the dermatitis problem within the organization should be made to management by its delegated representatives.

The industrial hygienist (or people doing this type of work, such as the safety professional, safety committee members, the nurse, or the industrial hygienist) should gather information on dermatitis hazards of materials used in the plant and should disseminate this information among supervisors and other operating personnel. The industrial hygienist should make periodic surveys to check for exposure to skin irritants and should suggest means to correct any hazards found.

Case Examples of Control

The following examples of the use of controls to reduce or eliminate occupational dermatoses were taken from the 1978 *Report of the OSHA Advisory Committee on Cutaneous Hazards* and are still applicable today.

POWDERED EPOXY SPRAYING OPERATION

A manufacturer of household washing machines began using an epoxy material as a finished surface on its products. The epoxy material came in powdered form and was sprayed on the parts to be assembled, which were then baked in an oven to form an extremely hard surface. The spraying was done automatically, inside a booth. The parts passed through the booth hanging from an overhead conveyor. Overspray was exhausted out the bottom of the booth and into a barrel; some overspray remained on the inside walls of the booth. The only worker in the area during the spraying was an operator who sat inside an enclosed control booth and thus was not exposed to the epoxy powder.

On the midnight shift, however, when production was stopped, a cleanup crew entered the area to perform a number of duties:

- ➢ They used air hoses to blow out the overspray that had accumulated on the inside walls of the spray booth.
- ➢ They dumped barrels of exhausted overspray back into the supply system for reuse.
- ➢ They swept floors and other surfaces outside the booth to clean up some spray that had escaped the booth.

The powder was very fine and the slightest turbulence caused it to become airborne; consequently, a great concentration of epoxy dust was in the air. The cleanup crew was equipped with disposable respirators, hair covers, boots, and complete coveralls. Despite the personal protection, several members of the cleanup crew broke out in rashes after spraying had been performed for a few weeks.

The problem was solved, after an investigation, by changing the overspray exhaust system to return the overspray directly into the supply system, thus eliminating one major source of dust. Using a vacuum system rather than sweeping or air hoses eliminated the other sources of dust. No cases of dermatitis recurred.

MACHINING OPERATIONS

Exposure to cutting fluids in machining operations constitutes one of the major causes of industrial dermatitis. Controls that have virtually eliminated dermatitis have been instituted in many machining operations. For example, in one well-controlled plant that produces diesel engines, more than 2,000 workers on two shifts operating approximately 1,000 machines had not a single recordable case of occupational dermatitis in 1977, in contrast with some poorly controlled operations in which roughly 30 percent of the work force have skin problems. Control programs put into effect included the following:

- ➢ Careful identification, by generic name, of all ingredients in the cutting fluids used
- ➢ Programs to keep the coolant free of tramp oil, foreign particles, and dirt through the use of effective filters and redesign of the coolant flow system to eliminate eddies and backwash of coolant
- ➢ Daily programs to monitor coolant characteristics such as pH and bacteria count
- ➢ Daily programs such as hosing down to keep machinery clean
- ➢ Redesign of spray application to minimize coolant splash and spray
- ➢ Use of splash goggles and curtains
- ➢ Use of local exhaust systems and oil collectors to reduce airborne oil mist
- ➢ Use of abundant quantities of shop rags
- ➢ Provision of paid wash time to allow operators to keep clean

Experience shows that when the coolant is well-controlled and measures are taken to reduce the amount of coolant splashed on the worker, the rate of dermatitis is reduced.

For more information, see the NIOSH publication, *What You Need to Know About Occupational Exposure to Metalworking Fluids* (1998), which summarizes safety and health training, worksite analysis, hazard prevention and control and medical monitoring of exposed workers from the recently released NIOSH *Criteria for a Recommended Standard—Occupational Exposure to Metalworking Fluids.*

RUBBER MANUFACTURING

Improvements in rubber manufacturing operations have reduced problems with skin disease in the facilities where the improvements were made. These improvements have taken many forms:

- ➢ Methods of material handling have been improved to reduce the amount of skin contact with rubber and related chemicals.
- ➢ Known skin sensitizers have been replaced by less hazardous chemicals, such as the replacement of isopropylphenylparaphenyl-diamine (IPPD), used as an antioxidant in tires, with less toxic derivatives of paraphenylene diamine.
- ➢ Methods of mixing rubber chemicals have been improved to reduce exposure to a wide variety of known skin irritants and sensitizers; such improvements have included preblending chemicals, using exhaust-ventilated mixing booths, and automating the mixing process.

➢ In one plant, an air-conditioned isolation booth was installed for a worker who was strongly sensitized to an antiozonent.

For more information, see the NIOSH publication, *Rubber Products Manufacturing Industry* (1993), which summarizes health efects, exposures and research needs in the rubber industry.

CHEMICAL MANUFACTURING

A major producer of industrial chemicals has instituted a wide variety of controls that have resulted in a reduced rate of dermatitis. Their program includes the following controls:

➢ Extensive use of self-contained systems to handle chemicals to eliminate worker exposure to dermatitis-producing substances, designed with a goal of zero emissions
➢ Mechanization of material-handling systems to eliminate worker exposure to chemicals
➢ Emphasis on good housekeeping
➢ Use of wipe testing to check equipment surfaces for films of toxic materials
➢ Adoption of extensive employee education programs to inform employees of the risks of chemicals
➢ Implementation of programs of personal hygiene that, in the case of one particularly hazardous material, included three daily showers for the exposed employee
➢ For handling liquid chemicals, use of seal-less pumps and, where leaks cannot be permanently sealed, use of local exhaust systems; grouping of all pumps in one central area for better control; and scaling of floors around the pumps
➢ Preparation of educational materials to be supplied to purchasers of chemicals, including proper controls for the materials

SUMMARY

Occupational skin disorders are a significant cause of impairment and disability that in many cases are entirely preventable. Accurate diagnosis and a complete knowledge of the workplace are the keys to appropriate treatment and prevention. The industrial hygienist is a major player in this cooperative effort, along with the occupational physician, dermatologist, safety professional, and occupational health nurse.

Chapter 4

The Ears

by George S. Benjamin, MD, FACS
and Barry J. Benjamin, MD, FACS
revised by Marjorie De Groot, MA, CCC-A
and Sarah A. Jewell, MD, MPH

This chapter covers the components of the external, middle, and inner ear, and how they function to produce hearing; the basic types of pathology that can affect the ears; how hearing is measured; the effects of noise on hearing and general health; and the effects of hearing loss on quality of life, and how this impairment is rated. The auditory mechanism enables us to hear sound conveyed from a source to our ears via gases, fluids or solids. The physics of sound generation and transmission is covered in detail in Chapter 9, Industrial Noise. This chapter provides an overview of our auditory system: the anatomy, physiology, and pathology of the human ear, evaluation of hearing, types of hearing loss, effects of noise exposure on hearing, and effects of hearing loss on communication.

ANATOMY AND PHYSIOLOGY

The organ of hearing is divided into three parts—the external, the middle and the inner ear. The entire system is shown in Figure 4–1.

External Ear

The external ear is composed of the auricle, or pinna, and the external auditory canal.

Auricle

The *auricle* (*pinna*) is the most visible part of the ear. It is a delicately folded cartilaginous structure with a few small muscles, covered by subcutaneous tissue and skin. The auricle collects sound waves from the air and funnels them into the ear canal to the tympanic membrane (eardrum).

External Auditory Canal

The *external auditory canal* (*meatus*) is a skin-lined pouch about 1.5 in. (3.8 cm) long, supported in its outer third by the cartilage of the auricle and in its inner two-thirds by the

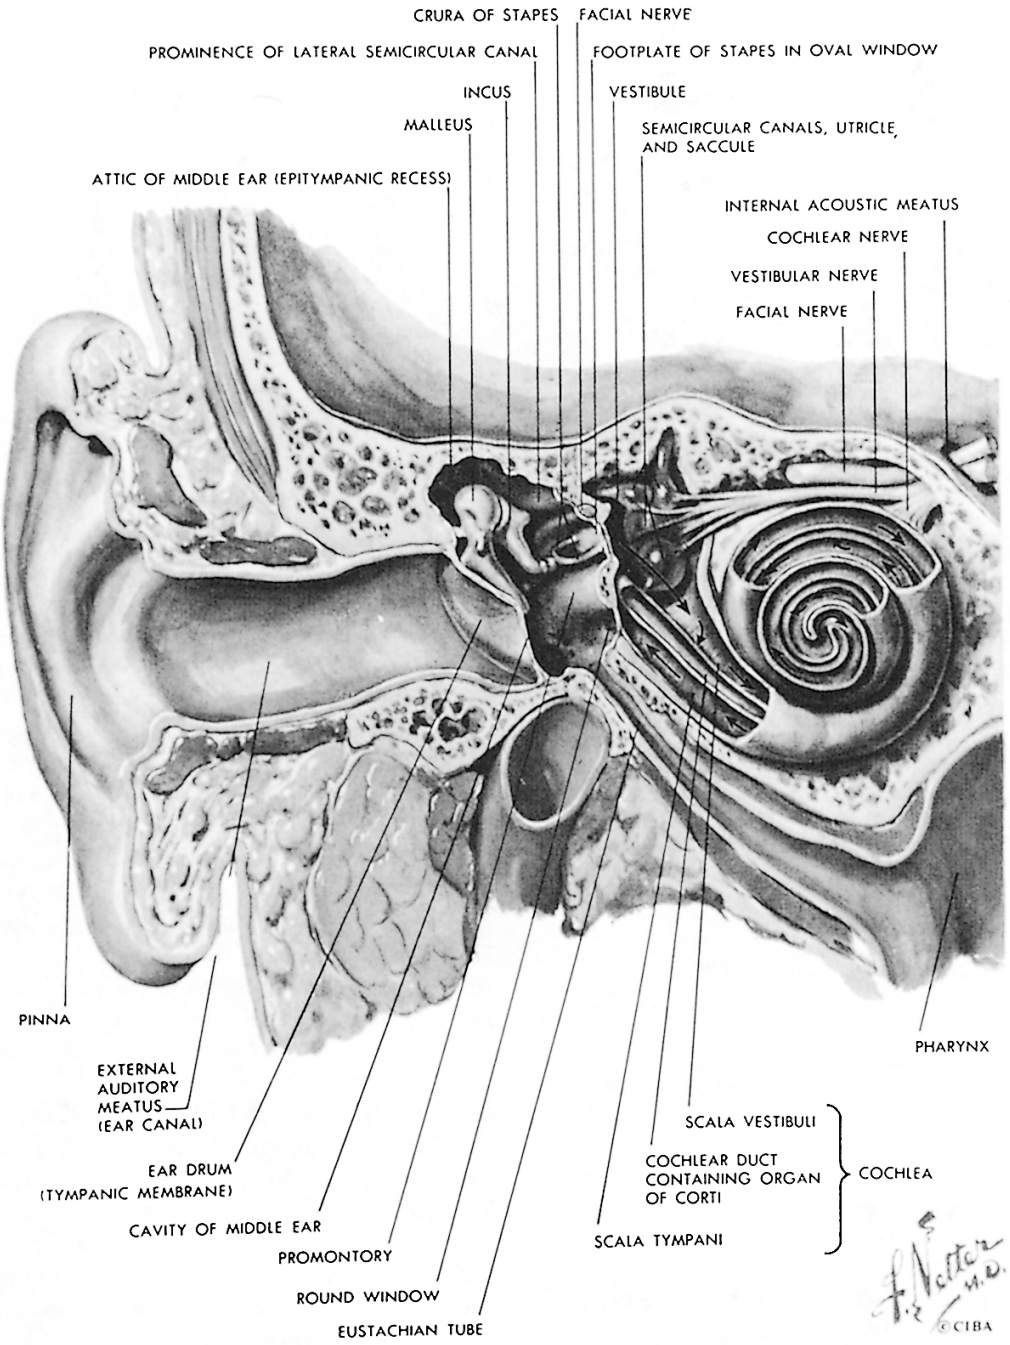

Figure 4–1. Illustration of the outer, middle, and inner ear. (Reprinted with permission from Netter FH, *Clinical Symposia.* CIBA Pharmaceuticals Co.)

bone of the skull. The cartilaginous meatus is curved and lies at an angle to the bony part, thus protecting the tympanic membrane and middle ear lying beyond it from direct trauma.

The small hairs, or *vibrissae,* and ceruminal glands, which secrete a waxy substance called cerumen, are located in the skin of the outer third of the ear canal. The hairs serve a protective function by filtering out particulate matter and other large pieces of debris. Cerumen, which is both sticky and bactericidal, prevents smaller particles from entering the ear canal and keeps the canal healthy and free of infection.

The function of the outer ear in the hearing process is relatively simple: The external portion of the ear collects sound waves from the air and funnels them into the ear canal, where they are transported to the eardrum. The collected sound waves cause the eardrum to move back and forth in a

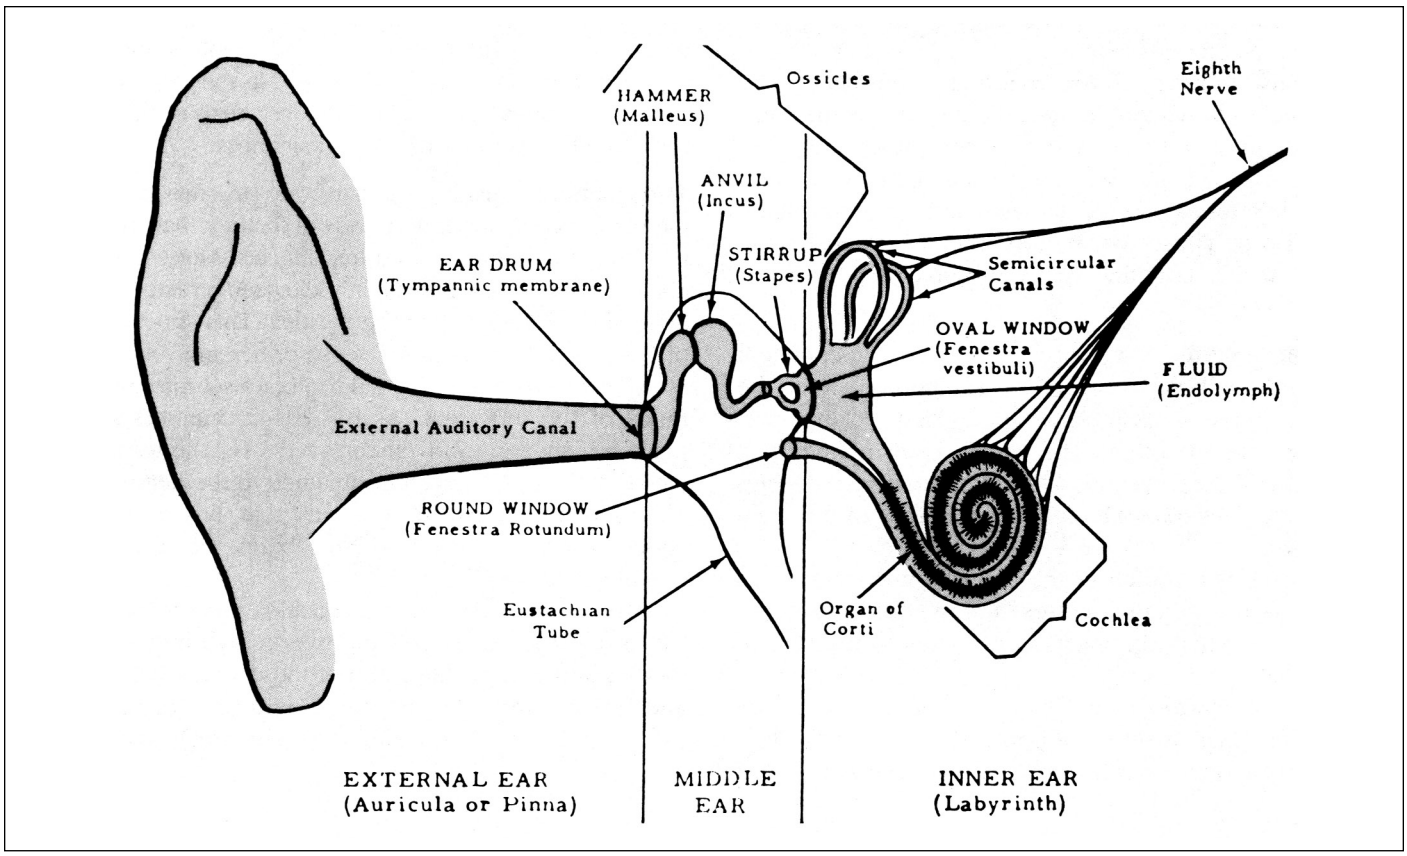

Figure 4–2. How the ear hears: Wave motions in the air set up sympathetic vibrations that are transmitted by the eardrum and the three bones in the middle ear to the fluid-filled chamber of the inner ear. In the process, the relatively large but feeble air-induced vibrations of the eardrum are converted to much smaller but more powerful mechanical vibrations by the three ossicles, and finally into fluid vibrations. The wave motion in the fluid is sensed by the nerves in the cochlea, which transmit neural messages to the brain. (Reprinted with permission from the American Foundrymen's Society.)

vibrating mechanical motion that is passed on to the bones of the middle ear (Figure 4–2).

Middle Ear

The middle ear is the space or cavity, about 1–2 mL in volume, between the eardrum and the bony wall of the inner ear (Figure 4–3). The middle ear is lined with mucous membrane essentially the same as that lining the mouth. The ossicles, which are the smallest bones in the body, are located within the middle ear cavity. The ossicles connect the eardrum to an opening in the wall of the inner ear called the oval window.

Picture the middle ear space as a cube:

- ➢ The eardrum forms the outer wall.
- ➢ The inner wall is the bony partition separating the inner ear from the middle ear. The round and oval windows fit into this wall and are the only two movable barriers between the middle and inner ear.
- ➢ The front wall opens into the eustachian tube.
- ➢ The back wall opens into the mastoid air cells.
- ➢ The roof separates the middle ear from the temporal lobe of the brain.
- ➢ The floor separates the middle ear from the jugular vein and the internal carotid artery, which lies high in the neck.

EUSTACHIAN TUBE

The *eustachian tube* serves to equalize pressure on either side of the tympanic membrane. An increase in pressure in the middle ear cavity, relative to atmospheric pressure, is usually compensated for passively by way of the eustachian tube. A decrease in pressure usually requires active ventilation by using muscles to open and close the eustachian tube (e.g., by yawning and swallowing).

EARDRUM

The eardrum is a membrane that separates the external ear canal from the middle ear. It consists of an inner layer of mucous membrane, a middle layer of fibrous tissue, and an outer layer of squamous epithelium. It is shaped like a spider web, with radial and circular fibers for structural support.

OSSICULAR CHAIN

The *ossicles,* which together are called the *ossicular chain,* are the *malleus, incus,* and *stapes.*

- ➢ The *malleus,* or hammer, is fastened to the eardrum by the handle. The head lies in the upper area of the middle ear cavity and is connected to the incus.
- ➢ The *incus,* also called the anvil, is the second ossicle and has a long projection that runs downward and joins the stapes.

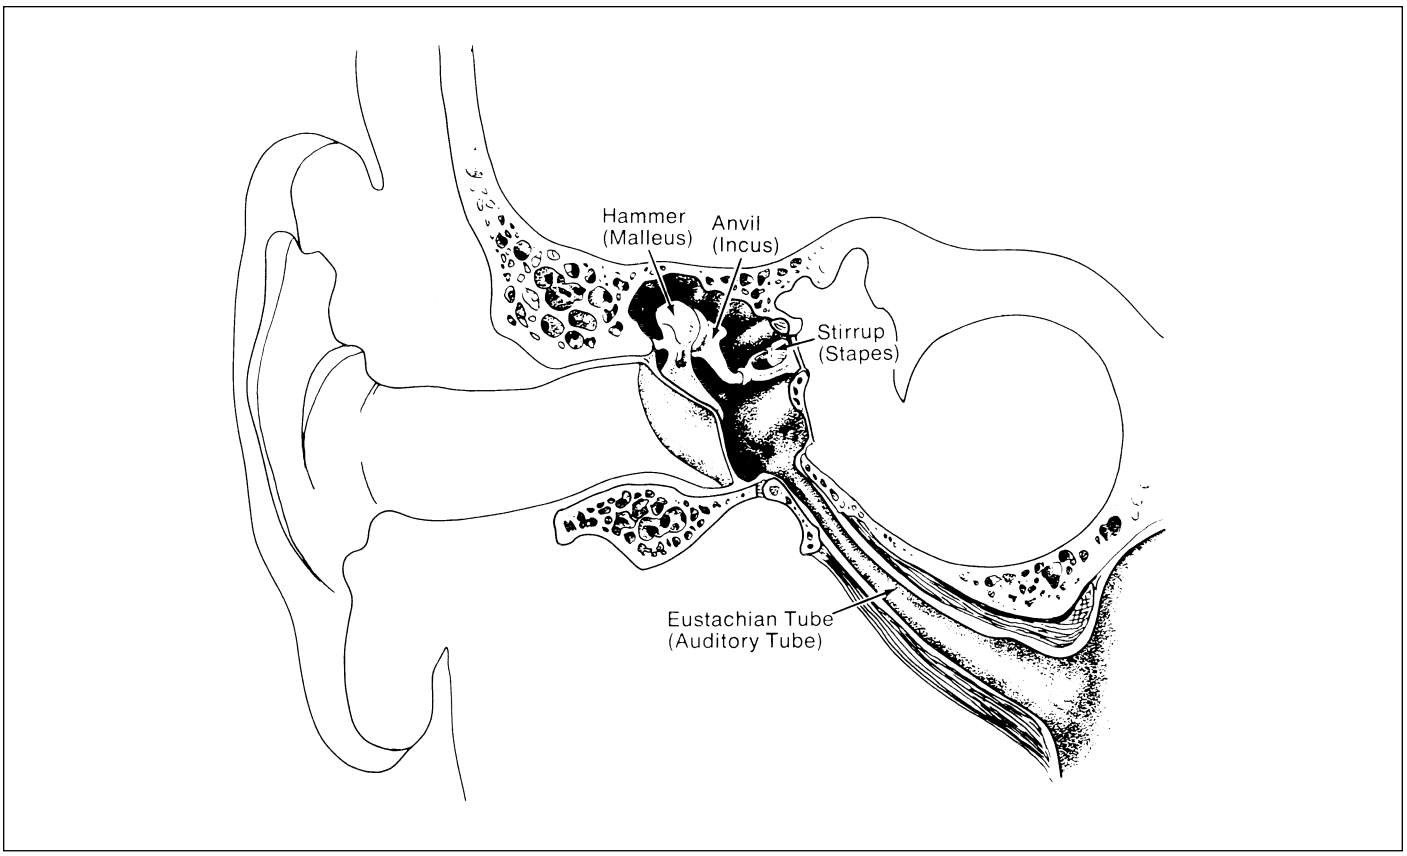

Figure 4–3. The middle ear is contained within the temporal bone and is made up of the eustachian tube, the middle ear space, and the mastoid air cell system. (Adapted from Figure 4–1.)

➢ The *stapes,* also called the stirrup, lies almost perpendicular to the long axis of the incus. The two branches of the stapes, anterior and posterior, end in the footplate that fits into the oval window.

The primary function of the middle ear in the hearing process is to transfer sound energy from the outer to the inner ear. As the eardrum vibrates, it transfers its motion to the attached malleus. Because the bones of the ossicular chain are connected to one another, the movements of the malleus are passed on to the incus, and finally to the stapes embedded in the oval window.

As the stapes moves back and forth in a rocking motion, it passes the vibrations on to the inner ear through the oval window (Figures 4–3 and 4–4). Covering the round window is a very thin membrane that moves out as the stapedal footplate in the oval window moves in. As the action is reversed and the footplate in the oval window is pulled out, the round window membrane moves inward. Thus, the mechanical motion of the eardrum is effectively transmitted through the middle ear and into the fluid of the inner ear.

AMPLIFICATION

The sound-conducting mechanism also amplifies sound by two main mechanisms. First, the large surface area of the base of the stapes (footplate) creates a hydraulic effect. The eardrum has about 25 times as much surface area as the oval window (Figure 4–5). All of the sound pressure collected on the eardrum is transmitted through the ossicular chain and is concentrated on the much smaller area of the oval window. This produces a significant increase in pressure. Second, the bones of the ossicular chain are arranged in such a way that they act as a series of amplifying levers. The long arms are nearest the eardrum and the shorter arms are near the oval window. The fulcrums are located where the individual bones meet. A small pressure on the long arm of the lever produces a much stronger pressure on the shorter arm. The magnification effect of the entire sound conducting mechanism is about 22 to 1.

Two tiny muscles attach to the ossicular chain: the stapedius to the neck of the stapes bone and the tensor tympani to the malleus. Loud sounds cause these muscles to contract, which stiffens and diminishes the movement of the ossicular chain, reducing the amount of sound energy transmitted to the inner ear.

MASTOID AIR CELL SYSTEM

On the back wall of the middle ear space is an opening that extends into the mastoid bone. This opening resembles a honeycomb of spaces filled with air.

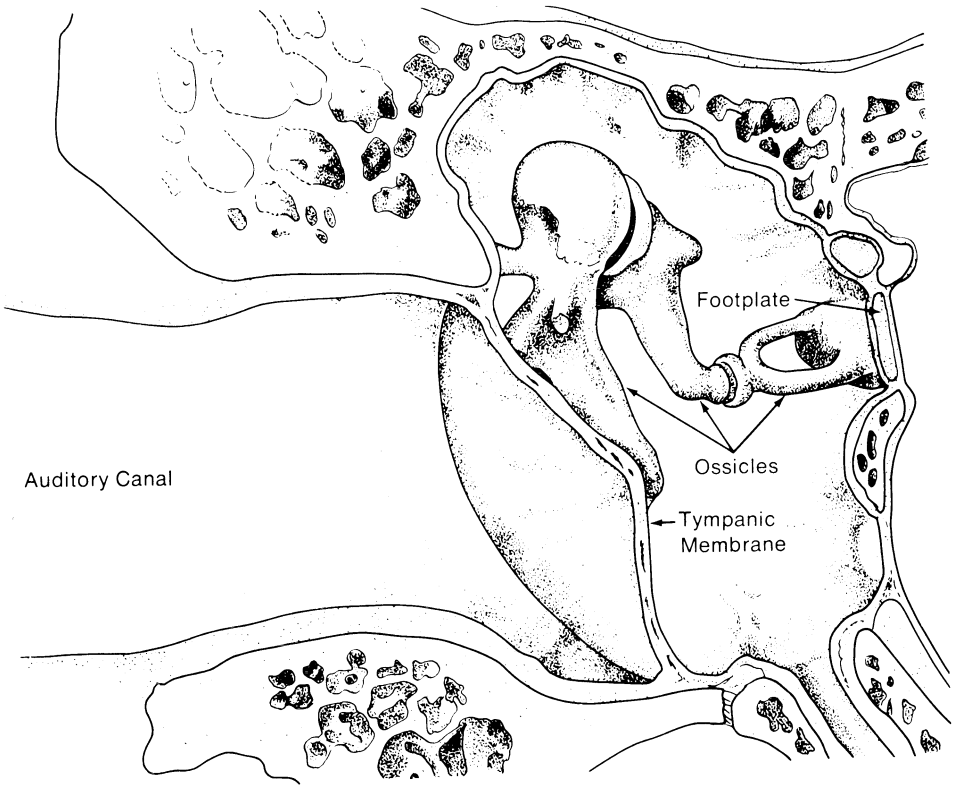

Figure 4–4. The ossicles, located in the middle ear cavity, link the eardrum to an opening in the wall of the inner ear (the oval window). (Adapted from Figure 4–1.)

Inner Ear

The inner ear contains the receptors for hearing and position sense. The major components of the inner ear include the vestibular receptive system and the cochlea, housed within the compact temporal bone (Figures 4–6 and 4–7). This bony labyrinth is filled with fluid called perilymph. The inner ear components are made up of a membranous labyrinth structure, which is suspended in the perilymph. Within the membranous labyrinth are the sensory organs for hearing (the cochlea) and position (the vestibular system), bathed in endolymph fluid.

COCHLEA

The *cochlea* is a tubular snail-shaped structure lined with the basilar membrane, which contains thousands of feathery *hair cells* tuned to vibrate to different sound frequencies. Nerve endings are contained in a complex, slightly elevated structure over the floor of the tube forming the cochlea. This structure, the *organ of Corti,* is the essential receptor end organ for hearing. It is a very complicated structure, consisting of a supporting framework on which the hair cells rest.

Vibrations of the stapedial footplate set into motion the fluids of the inner ear. As the basilar membrane is displaced, a shearing movement occurs on the tectorial surface that drags the hair cells attached to the nerve endings. This sets up electrical impulses that are appropriately coded and transmitted to the brain via the auditory (or cochlear) nerve (Figure 4–8). The frequency or pitch of the sound determines which part of the cochlea responds (high frequencies stimulate the base of the cochlea near the oval and round windows, whereas the nerve endings that respond to low frequencies are located at the small end of the cochlea).

VESTIBULAR SYSTEM

Our sense of balance is dependent not on hearing, but on organs of equilibrium. Near the cochlea are three semicircular canals lying in planes perpendicular to each other (Figure 4–9). The canals contain endolymph fluid that responds to movement of the head. Additional positional information is provided by receptors located in the vestibule. The vestibular branch of the auditory nerve (combined, called the eighth cranial nerve) transmits these impulses to the cerebral cortex and we recognize the position of our head in space as it relates to the pull of gravity.

PATHOLOGY

A number of disorders can affect the components of the auditory system. In this section, some of these conditions and their relevance to the occupational setting will be

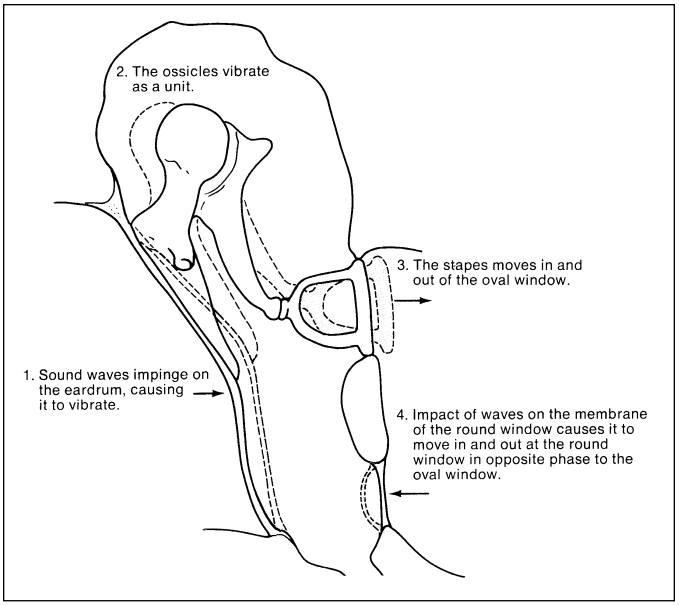

Figure 4–5. The eardrum has about 25 times as much surface area as the oval window. All of the sound energy collected on the eardrum is transmitted through the ossicular chain to the smaller area of the oval window.

presented, along with a review of hearing assessment and the effects of noise.

Pathology of the External Ear

This section begins with a look at the pathology of the external ear—specifically the pinna and auditory canal, the eardrum, and the eustachian tube.

PINNA AND AUDITORY CANAL

Because of its prominence and its thin, tight skin, the *pinna* is especially subject to sunburn and frostbite. Thus, it must be protected from the elements. Injured cartilage is replaced by fibrous tissue and repeated injuries result in the cauliflower-shaped ear seen on many boxers. Disorders of the auricle include congenital malformations (in which the cartilage is misshapen) and protruding or lop ears, both of which may be surgically corrected. Dermatitis and infection are common in this area, and can arise locally or spread from other body sites. Deformation or inflammation of the pinna can affect a worker's comfort in using headwear and muff-type hearing protection.

The *ear canal* is prone to infection (otitis externa) because of its high skin temperature and humidity. These bacterial or fungal infections occur more readily under circumstances of heavy perspiration or head immersion (hence the name, "swimmer's ear"). Skin disorders (dermatitis) are also common ear canal problems, and can either occur locally or spread from the scalp and other skin areas.

Foreign objects accidentally lodged in the ear canal can be dangerous and should be removed only by a physician. A live

insect in the ear canal can be especially annoying or painful. If this happens, drop light mineral oil into the canal to suffocate and quiet the insect until it can be removed. Normally, the ear canals are self-cleaning but occasionally this mechanism fails, resulting in wax impaction. The use of cotton-tipped swabs for cleaning tends to pack wax into the ear canal. Also, swabbing stimulates excess production of wax.

An abnormal narrowing of the ear canal is called stenosis and may be caused by congenital malformation, bony growth (exostosis) or infection. Tumors are rare in this area. Abnormalities in ear canal anatomy, or canal infection/inflammation, can cause difficulties in using earplugs or other insert hearing protective devices. It is not common for ear canal problems to affect hearing; the canal must be almost totally occluded (blocked) before attenuation of sound occurs.

EARDRUM

Infections localized to the eardrum are rare; when they do occur, they are caused by viruses such as the varicella zoster virus (shingles). However, the eardrum is often included in infections of the external auditory canal or the middle ear.

Perforation or rupture of the tympanic membrane can be caused by infection, direct injury (e.g., from penetrating object) or sudden pressure changes (barotrauma). Examples of the latter would be a blow to the side of the head, or large pressure changes associated with air flight, underwater diving, or explosions. Most perforations heal spontaneously and do not require surgical repair, except for those caused by hot substances such as welding splatter.

EUSTACHIAN TUBE

In the presence of swelling, adhesions, or masses the eustachian tubes can become obstructed. This is a common consequence of allergic and infectious conditions that affect the nose and throat. Failure of the eustachian tube to ventilate creates a vacuum in the middle ear space, which in turn causes one of two pathological events to occur: It pulls fluid into the middle ear, resulting in a condition called nonsuppurative (serous) otitis media, or it pulls the eardrum inward (retraction). Either one of these events can interfere with mobility of the tympanic membrane, causing hearing loss. Eventually any serous fluid present can thicken and create persistent hearing problems.

The opposite condition, which is uncommon, is a patent eustachian tube in which the tube constantly remains open. This condition results in the annoying symptom of hearing one's own voice and breath sounds (autophonia) in the involved ear.

Pathology of the Middle Ear

The middle ear space is prone to infectious diseases, especially in childhood. These are predominantly bacterial in origin and called suppurative otitis media. Because the middle ear space connects with the mastoid air cell system, infection can easily spread to this area (mastoiditis). Before the days of

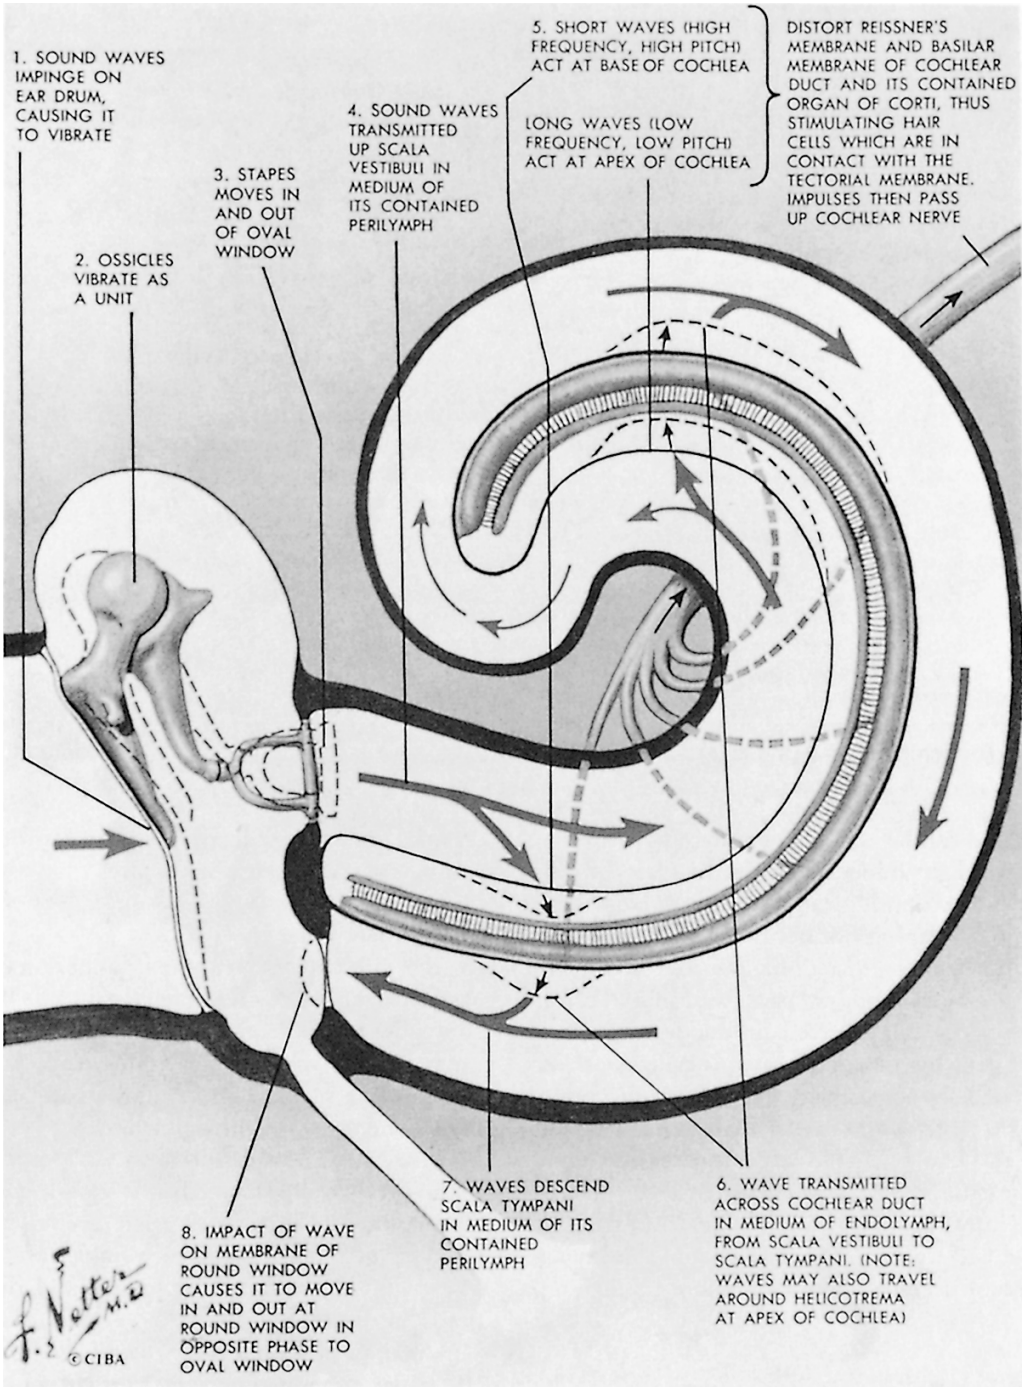

Figure 4–8. The mechanism for transmission of sound vibrations from the eardrum through the cochlea. (Reprinted with permission from Netter FH, *Clinical Symposia*. CIBA Pharmaceutical Co.)

antibiotics, these were serious, often life-threatening problems because the infection could spread to the brain or major vessels surrounding the ear. Though less likely to occur today, these dangers still exist.

Disease of the middle ear *ossicles* can impair hearing in two ways:

- ➢ fixation (the bony chain cannot vibrate or vibrates inefficiently) and
- ➢ interruption (a gap in the chain)

Fixation can result from developmental errors, adhesions, or scars from old middle ear infections or bone diseases that affect this area. Otosclerosis is a prime example of fixation. It usually

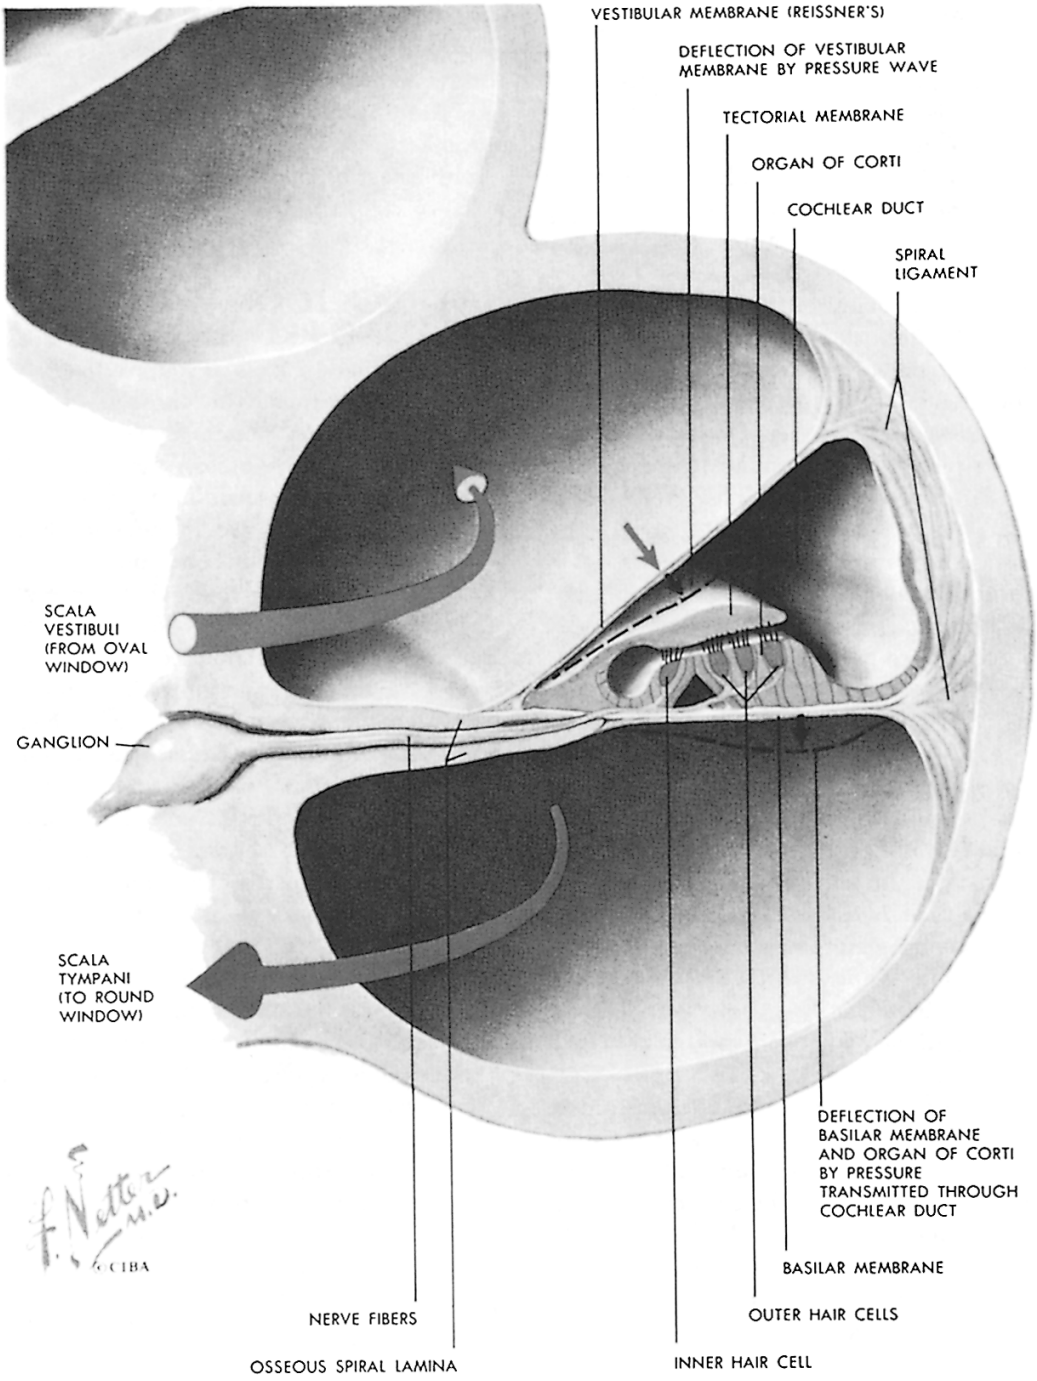

Figure 4–9. This schematic diagram depicts the transmission of sound across the cochlear duct, stimulating the hair cells. (Reprinted with permission from Netter FH, *Clinical Symposia*. CIBA Pharmaceutical Co.)

begins in early adult life. Interruptions are usually caused by middle ear infections, cholesteatomas, or head injuries.

Conductive hearing loss is hearing loss that arises from conditions affecting the outer or middle ear. This is because sound waves cannot be conducted effectively to the cochlear sensory organ via the normal pathways. Some amount of sound energy can still be transmitted to the inner ear by direct transmission through the cranial bone; although the loudness of sounds is diminished, clarity of sound is preserved because the cochlea retains its phenomenal sensitivity to a wide range of sound characteristics.

Pathology of the Inner Ear

A variety of ailments can affect the delicate cochlea, semicircular canals and eighth cranial nerve. For example, damage to these components can result from congenital/developmental

defects, systemic diseases (multiple sclerosis, diabetes), infection (mumps or chronic otitis media), exposure to noise or certain toxins (including medications, such as some antibiotics or diuretics), circulatory problems (stroke) and trauma (concussion or skull fracture). In the workplace, exposure to excessive vibration, heavy metals, organic solvents and carbon monoxide may contribute significantly to the hearing loss induced by chronic ambient noise or other medical problems.

A steady loss of hearing acuity often occurs as we grow older (presbycusis). The normal young ear can hear tones within a range of 20 Hz (the lowest bass note of a piano) up to high-pitched sounds of 20,000 Hz. People in their 60s are lucky to hear normal level sounds at 12,000 Hz. This hearing loss is greater for high-frequency sounds and is considered normal because it happens to practically everybody as the years roll on.

Disorders affecting the vestibular system can cause loss of balance, vertigo, and nausea or vomiting. Examples of these disorders include *viral labyrinthitis* and *Meniere's disease*. Meniere's disease affects both parts of the inner ear (hearing and balance) and its cause is unknown. It is characterized by episodic dizziness, often severe, and associated with nausea and vomiting, fluctuating hearing loss that is generally progressive, ringing or hissing noise (tinnitus), and a peculiar sensation of fullness in the involved ear.

Another important condition that can affect the eighth cranial nerve is acoustic neuroma. This tumor occurs most commonly in middle-aged persons. Although not malignant, it can cause disabling symptoms of both hearing loss and vestibular dysfunction. Workers with vertigo or equilibrium problems may not be medically fit for safety-sensitive tasks such as operating motor vehicles or working at heights (ladders, etc.).

Sensorineural hearing loss is the hearing difficulty caused by inner ear damage. (*Sensori-* refers to the sense organ in the inner ear, and *-neural* refers to the nerve fibers). Sensorineural can involve impairment of the cochlea, the auditory nerve, or both. Unlike conductive hearing loss, the hearing deficit cannot be overcome by sound transmission through the bone. Often both the perception of loudness and clarity of sound are impaired.

Tinnitus

Tinnitus is a symptom, not a disease. It is a perception of sound arising in the head. It may be heard only by the affected person (subjective tinnitus) or it may be audible to the examiner also (objective tinnitus). Objective tinnitus is usually a symptom not of disease of the ear but of a tumor or vascular malformation. All cases should be evaluated by a qualified physician.

Subjective tinnitus is usually perceived as a ringing or hiss. Occasionally, no explanation can be found, but most cases are secondary to high-frequency hearing loss. Some cases can be caused by wax, perforation of the drum, or fluid in the middle ear. Drugs or stimulants such as caffeine, aspirin, or alcohol can also cause the symptom by disturbing the inner ear.

Tinnitus can lead to psychological stress and be disabling. Maskers that match the frequency of the tinnitus, combined with a hearing aid, can be helpful. Patient education is essential to successful treatment.

A QUICK LOOK AT THE HEARING PROCESS

The external ear collects sound waves and funnels them to the tympanic membrane through the ear canal. The tympanic membrane vibrates in response to the sound waves that strike it. This vibratory movement, in turn, is transmitted to the ossicular chain in the middle ear. The vibration of the ossicles creates waves in the inner ear fluid that stimulate microscopic hair cells. The stimulation of these hair cells generates nerve impulses which pass along the auditory nerve to the brain for interpretation.

The outer and middle sections of the ear conduct sound energy to the deeper structures. Therefore, the outer and middle ear sections act together as the conductive hearing mechanism. In contrast, the deeper structures, including the inner ear and the auditory nerve, are referred to as the sensorineural mechanism. Although nature has surrounded the delicate ear mechanism with hard, protective bone, any portion of the ear can become impaired. The part of the hearing mechanism affected and the extent of damage has a direct bearing on the type of hearing loss that results. The words *conductive* and *sensorineural* describe two major types of hearing impairment.

As long as the hearing mechanism functions normally, the ear can detect sounds of minute intensity while tolerating sounds of great intensity. The loudest sound the normal ear can tolerate is more than 100 million (10^8) times more powerful than the faintest sound the ear can detect (see Figure 4–10). Furthermore, a young listener with normal hearing can detect sounds across a wide frequency range, from very low-pitched sounds of 20 Hz to very high-pitched sounds of 20,000 Hz.

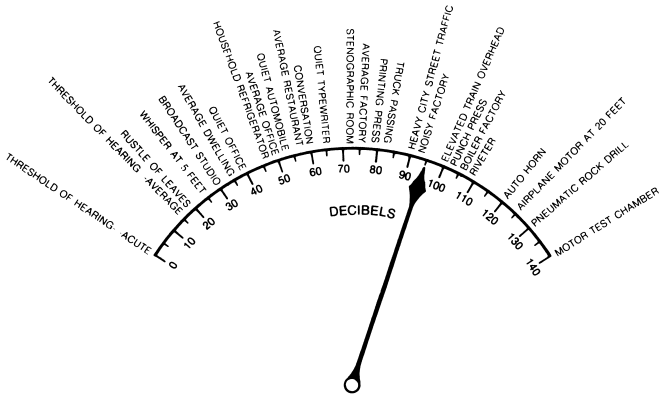

Figure 4–10. Typical sound levels associated with various activities.

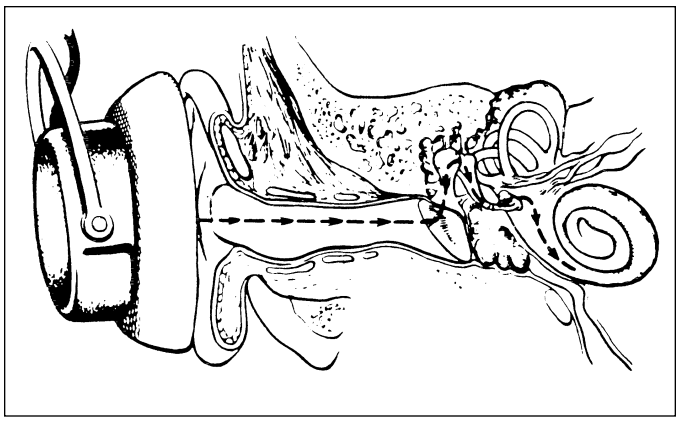

Figure 4–11. An air-conduction earphone is depicted; note that the earphone is placed directly over the external ear canal and the sound waves are conducted (by air) to the eardrum and through the middle ear to the inner ear.

HEARING MEASUREMENT

The measurement of hearing is done using an audiometer. This is described in the next section.

Audiometer

An audiometer is a frequency-controlled audio-signal generator. It produces a pure tone signal, the frequency and intensity of which are varied for use in hearing measurement. Audiometry is used to determine hearing thresholds for both pure tone and speech, by air conduction and bone conduction.

The audiometer was developed to provide an electronic pure-tone sound similar to that of the tuning fork. With the audiometer, however, intensities can be controlled much more accurately and, therefore, the results can be more carefully quantified. The equipment is calibrated according to American National Standard Institute (ANSI) standards *Specification for Audiometers* (ANSI S 3.6 1996) and *Reference Zero for the Calibration of Pure Tone Bone-Conduction Audiometers* (ANSI S3.43-1992).

AIR CONDUCTION TESTING

When testing hearing by air conduction, headphones are placed over the ears of the test subject. A pure tone signal from the audiometer is presented through the headphones and travels through the ear canal, the middle ear and into the inner ear, thus allowing evaluation of the entire hearing mechanism, both conductive and sensorineural (Figure 4–11).

BONE CONDUCTION TESTING

Bone conduction audiometry evaluates only the sensorineural hearing mechanism. A bone vibrator is placed on the mastoid bone behind the outer ear. This sends vibrations directly through the skull bones to the cochlea in the inner ear, bypassing the conductive pathway of the outer and middle ear (Figure 4–12). Bone conduction testing is considered a diagnostic test and is not performed as part of routine industrial hearing assessments.

Audiogram

Audiometric results are recorded on a standard chart called an audiogram (Figure 4–13). It is a frequency-by-intensity graph on which a person's hearing threshold for pure tones is plotted.

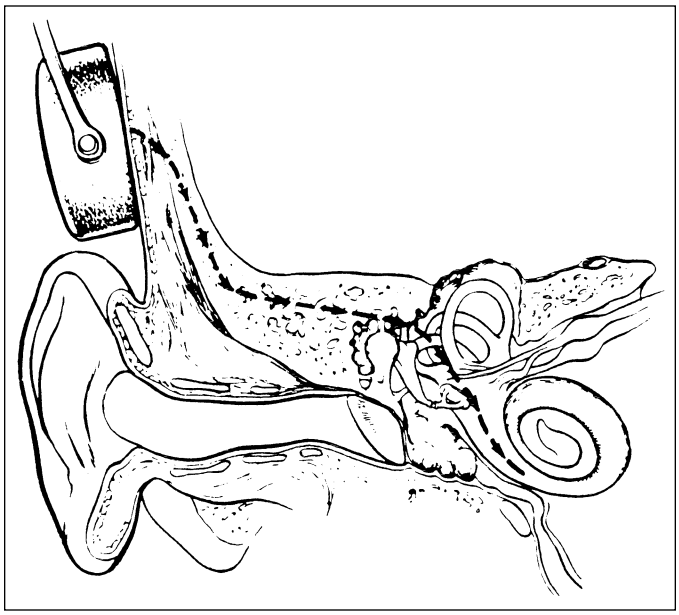

Figure 4–12. Sound can be transmitted directly to the inner ear through the bones of the skull using a bone-conduction vibrator placed on the mastoid bone behind the outer ear. The broken line (with arrows) shows the path taken by the sound waves through the bony areas of the head to the inner ear.

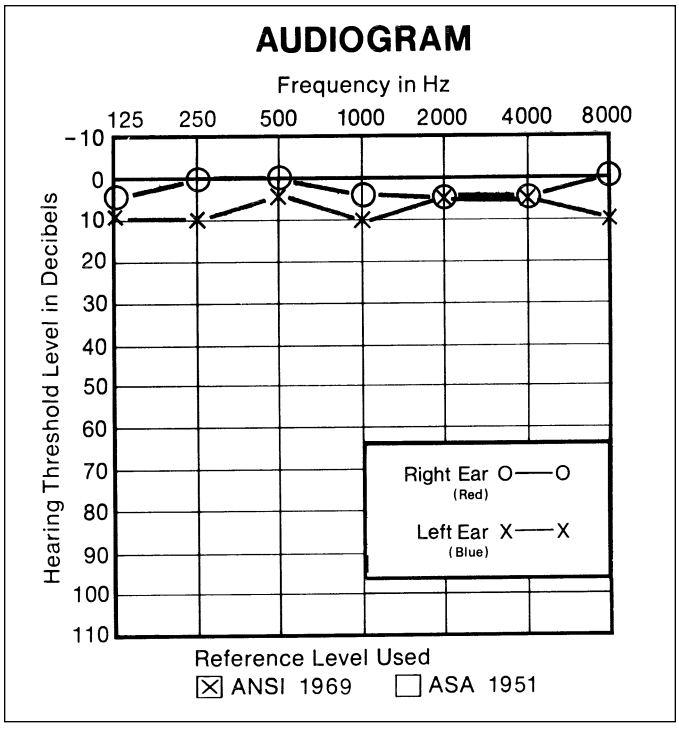

Figure 4–13. A typical manual audiogram showing hearing thresholds within the normal range.

The numbers across the top represent the frequency, or pitch, of the tones from the lowest frequency (125 Hz) to the highest frequency (8,000 Hz). For example, a 250-Hz tone corresponds to middle C on the piano while a 4,000-Hz tone sounds much like a piccolo hitting a high note. The vertical column of numbers on the left side of the graph represents intensity, or loudness, in decibels (dB). The smaller the number, the lower the dB level, the softer the sound (e.g., 10 dB) and conversely, the larger the number, the higher the dB level, the louder the sound (e.g., 100 dB).

Threshold of hearing is the very softest level at which a person is able to hear. When a threshold, measured in dB, is determined through audiometry at any given frequency, the result is plotted on the graph. Audiometric symbols used for recording results are specified by ANSI standards. Pure tone, air conduction thresholds are plotted with an "0" for the right ear and with an "X" for the left ear. A threshold of 0 dB indicates that there is no difference between the hearing sensitivity of a test subject compared with a normal standard.

The American Academy of Ophthalmology and Otolaryngology has recommended that audiograms be drawn to a scale like the illustration shown in Figure 4–13. For every 20-dB interval measured along one side and for one octave measured across the top (250–500 Hz, for example), there is a perfect square. The reason for a standardized scale is that the apparent hearing loss can be altered a good deal by changing the dimensions of an audiogram. If the proportions of the audiogram are different from standard dimensions, a person's hearing loss may look quite different than if it were plotted on the standard audiogram format. Customarily, audiograms are scaled in 10-dB steps. Of course, if a person has a threshold of 55 dB, it is plotted on the appropriate frequency line at the halfway point between 50 and 60 dB.

Hearing losses plotted on a standard chart produce a profile of a person's hearing. A trained person can review an audiogram to determine the type and degree of hearing loss and can estimate the difficulty in communication this loss will cause.

EFFECTS OF NOISE EXPOSURE

Exposure to noise can cause temporary or permanent damage to the auditory system. In addition, noise appears to be harmful to our general health, in ways that are not yet fully appreciated.

Noise-Induced Hearing Loss

Noise (defined as unwanted sound) is a pervasive, insidious cause of hearing loss. It causes no particular pain unless it is as loud as a rifle blast. The ears have considerable comeback power from brief exposure to *intense* noise and ordinarily recover within 14 hours or so (this is called a temporary threshold shift [TTS], typically most prominent at 4,000 Hz). However, prolonged exposure to intense noise gradually damages the cochlear hair cells of the inner ear (see Figure 4–14), resulting in a permanent threshold shift (PTS) across multiple frequencies (see Figure 4–15).

What are the factors that determine the duration and severity of noise-induced hearing loss?

- ➢ *Sound level*—Sound levels must exceed 60–80 dB before the typical person will experience a temporary decrease in hearing sensitivity. NIOSH estimates that eight percent of individuals exposed at the NIOSH Recommended Exposure Limit (85 dB, A-weighted, averaged over eight hours/day for 40 years) will develop noise-induced hearing loss.
- ➢ *Frequency distribution of sound*—Sounds having most of their energy in the speech frequencies (500 Hz–2,000

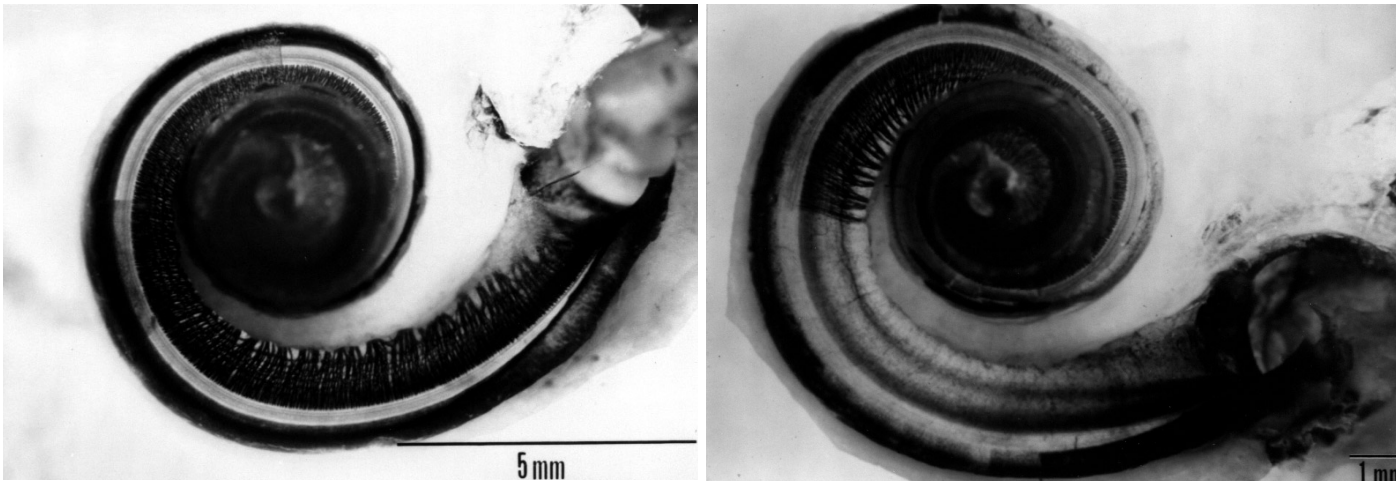

Figure 4–14. Enlarged views of human cochlear specimens. Compare the normal cochlea on the left with that of a 50–year-old patient exposed to noise during factory work and recreational hunting activities. Note the nearly complete loss of the organ of Corti and nerve fibers throughout the base of the cochlea, consistent with his irreversible high frequency hearing loss. (Courtesy of J. E. Hawkins, DSc and L.G. Johnsson, Kresge Hearing Research Institute.)

Hz) are more potent in causing a threshold shift than are lower frequency sounds.

- ➢ *Duration of sound*—For a given sound level, longer duration exposure increases the risk of hearing effects.
- ➢ *Temporal distribution of sound exposure*—The shorter and less frequent the quiet periods between periods of sound, the greater the hazard.
- ➢ *Type of sound energy* (continuous, intermittent, impulse, or impact)—The tolerance to peak sound pressure is greatly reduced by sudden changes in the sound energy level.
- ➢ *Individual differences in tolerance of sound*—Sensitivity to noise-related hearing loss varies widely among individuals, but there are no reliable predictors to identify those at increased risk.

Millions of workers in the United States are exposed to significant levels of noise on the job. For this reason OSHA has required formal hearing conservation programs for most employees exposed above the Action Level (currently 85 dBA averaged over an eight-hour workday) since the mid-1970s (see Chapter 9, Industrial Noise). Occupational health and safety professionals should also be aware that recreational (nonoccupational) noise exposure from music, firearms, and vehicles such as snowmobiles and motorcycles is fairly ubiquitous, and incorporate this information into worker risk assessment and education programs.

Nonauditory Effects of Noise

Research on other effects of noise indicates that it may cause interference with communication, altered performance, annoyance, and physiological responses such as elevated blood pressure and sleep disturbances. Definitive studies have yet to be done on most of these issues. Certainly, levels of background noise above 80 dBA reduce the intelligibility of speech to workers with normal hearing. Furthermore, repeated shouting to overcome noise has been observed to lead to chronic laryngitis and even traumatic vocal cord polyps. However, the stress effects of noise (decreased attention, accidents, hypertension, and sleep problems) are not consistently correlated with noise level.

Noise exposure does seem to have deleterious health effects during pregnancy. Women exposed to high levels of noise are at increased risk of shortened gestation and delivery of preterm or low birthweight infants. Fetal exposure to noise may result in birth defects and permanent hearing deficits, although human and animal studies have not demonstrated this conclusively.

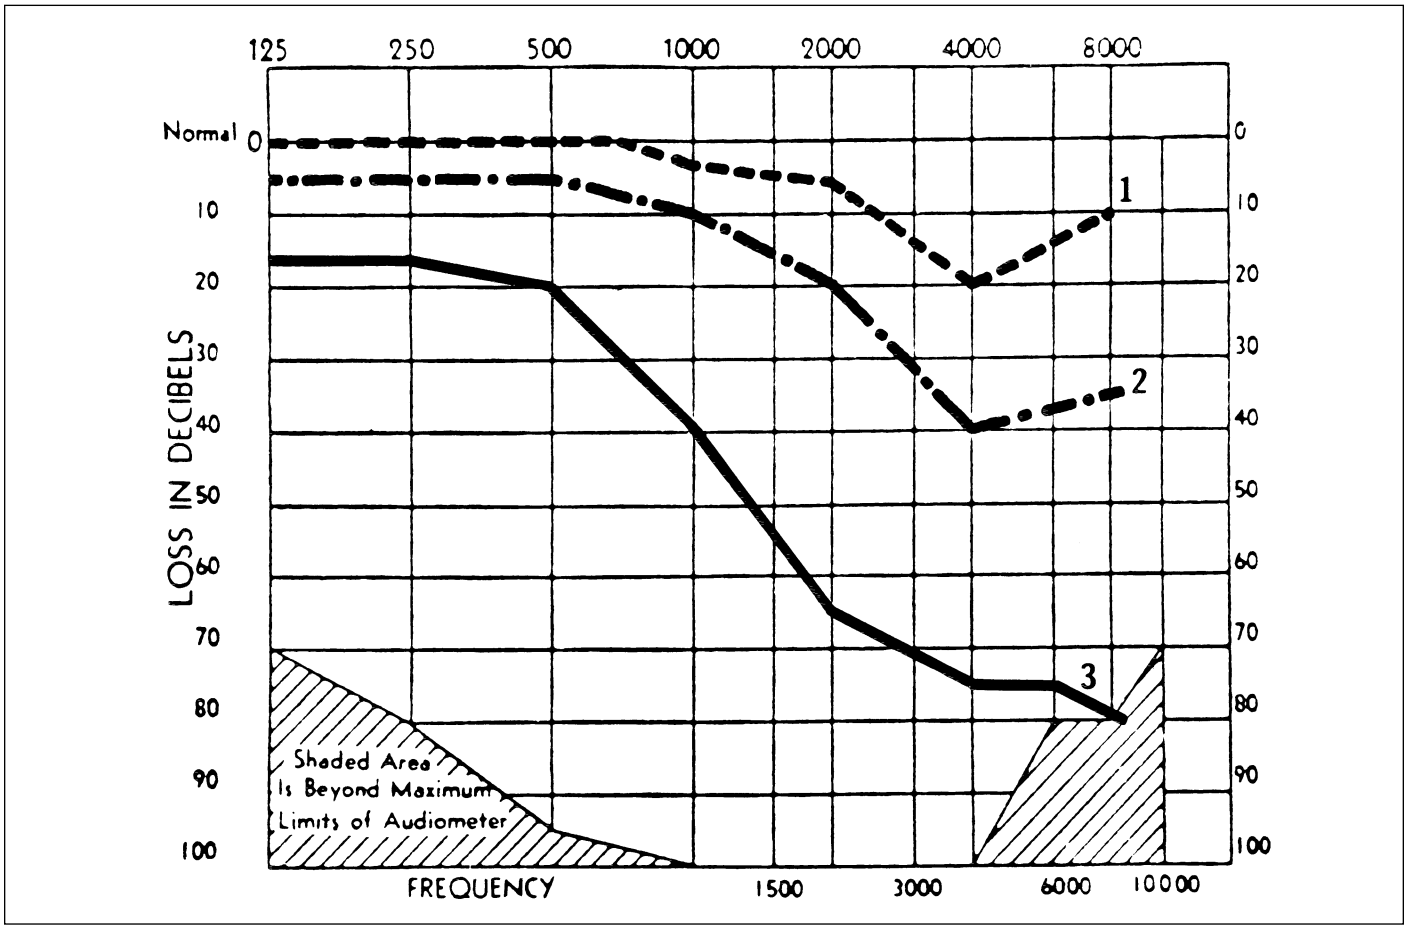

Figure 4–15. Sensorineural hearing losses of the kind produced by noise or other causes. Curve 1 = early; curve 2 = intermediate; curve 3 = advanced. (As shown, curve 3 might include some involvement of presbycusis.)

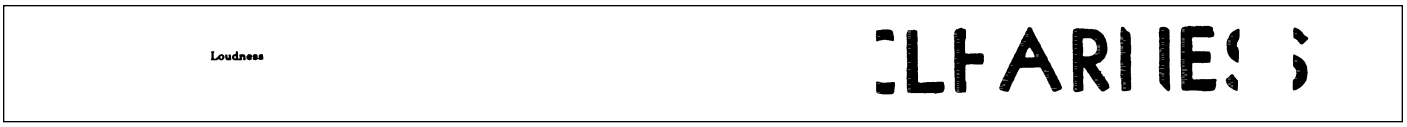

Figure 4–16. Both sides of this illustration visually represent two important dimensions of normal hearing: the ability to hear sounds as loudly as they really are and the ability to hear sounds with complete clarity. Leff: It is almost impossible to read the word Loudness; this is comparable to not being able to hear faint sounds. Moving the figure closer makes it easier to read, just as increasing volume makes sounds easier to hear. Right: No matter how closely the illustration is held, it is difficult to interpret. The word is not clear because some important parts of the letters are missing. This shows, by analogy, hearing difficulty caused by a loss in the ability to distinguish between various sounds (the word is CLEARNESS).

COMMUNICATION

Quality of life can be drastically affected for individuals whose hearing has been impaired by exposure to noise. Verbal communication, our primary connection to other human beings, often becomes a source of frustration for the person with the hearing loss as well as for family and friends. Typically, this type of hearing loss produces inconsistent auditory behavior. That is, in certain situations there may be no problem hearing whereas in others there can be considerable difficulty.

To better understand why this occurs, we will discuss two important characteristics of hearing: loudness, the ability to hear sounds as loud as they actually are, and clarity, the ability to hear sounds clearly and distinctly.

Loudness

If Figure 4–16 is held at arm's length, the printing on the left side is obvious but almost impossible to read. A close look confirms that it is indeed a word; an even closer look reveals that the word is *Loudness*. This example is analogous to the concept of loudness as it relates to hearing and hearing loss. For some types of hearing loss, sounds only need to be made louder to hear, just as the word *Loudness* needed to be made bigger to see.

Clarity

If Figure 4–16 is held at arm's length, there is no difficulty in seeing everything on the right side. But can the word be read? If not, the reason is that too much of the word is missing, even though it is large enough. Regardless of how closely you look, it is difficult to read because some of the important parts are missing. This illustrates the problem of loss of clarity, or an inability to distinguish between the various sounds in spoken language. (The word is *CLEARNESS.*)

Conductive hearing loss associated with pathology in the external or middle ear generally affects a person's ability to hear at normal loudness levels. It does not usually impair the clarity with which that person hears once the sound is made loud enough to compensate for the hearing loss. The key to clarity in hearing is held by the inner ear mechanism and the nerve fibers that carry the message to the brain.

When damage occurs to the inner ear or auditory nerve, the resulting sensorineural hearing loss can affect not only the perceived loudness of incoming sounds, but also their clarity. Speech in particular can seem unclear or distorted regardless of how loud it is. The main complaint associated with this type of hearing loss is that patients can "hear" but cannot understand, especially in the presence of background noise. This occurs because the tiny hair cells that respond to specific speech sounds are so severely damaged that they cannot react when the vibrations from sound waves strike them while hair cells for other speech sounds may be functioning normally.

Speech Sounds

Speech sounds can be classified as vowels or consonants. The vowel sounds—located in the lower frequencies—are the more powerful speech sounds. Therefore, vowels carry the energy for speech. In contrast, consonants—located in the higher frequencies—are important in distinguishing one word from another. This is the heart of the communicative problem for people with noise-induced (high-frequency) hearing loss. They are often unable to distinguish between similar words such as *stop* and *shop*. If one word in a sentence is mistaken for another, the entire meaning of the sentence may be misunderstood, leading to embarrassing situations.

Background Noise

People with high-frequency hearing loss often manage fairly well in quiet listening situations. However, in a noisy environment, such as in traffic, in a restaurant, or on the job, it can become extremely difficult to communicate through hearing alone.

A listener with normal hearing can hear a speaker in the presence of typical background noise with little or no difficulty. However, if the listener developed a hearing loss for all speech sounds above 1,000 Hz, there would be a marked decrease in that person's ability to hear the speaker clearly. Most ambient (background) noise is low frequency. Since there is more energy in the low frequencies, the noise masks the weaker, high frequency speech sounds, so crucial for clarity, making it even more challenging to understand what is being said.

Quality of Life

Most often noise-induced hearing loss occurs gradually, over time. In the initial stages the person may experience little

difficulty in most situations. However, as the hearing loss increases in severity and affects more frequencies, the hearing-impaired individual often begins to avoid certain situations (such as parties) and may have a tendency to withdraw socially. Everyday situations, such as listening to the grandchildren or talking to a spouse while the television is on, become sources of frustration.

Rehabilitation

There is no medical or surgical cure for sensorineural hearing loss. However, much can be accomplished with amplification (hearing aids) and counseling to minimize the effects of the hearing impairment on the quality of life.

The hearing aids of today are a vast improvement over the hearing aids of the past, although they are still unable to compensate completely for the lost hearing. New technology and fitting techniques make it possible to finely tune a hearing aid by adjusting a series of parameters to compensate for the uniqueness of each person's hearing loss. This allows a hearing-impaired user to hear more naturally and with less interference from background noise.

Counseling is a crucial component of aural rehabilitation. An explanation of the hearing test results, options regarding amplification, a discussion of realistic expectations, and tips for easier communication are all beneficial in helping the individual to live comfortably with the hearing impairment.

Further Medical Evaluation

When should an individual be referred to a physician for further medical evaluation? The American Academy of Otolaryngology-Head and Neck Surgery recommends referral for evaluation of significant hearing loss (or other ear problems) as follows:

HEARING LOSS

- Baseline audiogram
  - Average hearing level at 500, 1,000, 2,000, and 3,000 Hz is greater than 25 dB in either ear; or,
  - Difference in hearing level between the ears of more than 15 dB at 500, 1,000, and 2,000 Hz or more than 30 dB at 3,000, 4,000, and 6,000 Hz
- Periodic audiogram
  - Change of average hearing (for the worse) in either ear compared to the baseline of more than 15 dB at 500, 1,000, and 2,000 Hz, or more than 20 dB at 3,000, 4,000, and 6,000 Hz

OTHER

- Ear pain; drainage; dizziness; severe persistent tinnitus; sudden, rapidly progressive or fluctuating hearing loss; a feeling of fullness or discomfort in the ear within the preceeding 12 months
- Excessive cerumen accumulation or foreign body in the ear canal

EVALUATING IMPAIRMENT: *THE AMA GUIDES*

Chapter 11.2 of the American Medical Association's *Guides to the Evaluation of Permanent Impairment* includes criteria for evaluating permanent impairment resulting from damage to the ear's hearing and/or vestibular functions. This determination is important in assessing employability and compensation for loss of function due to injury (e.g., workers' compensation). Because many state agencies have adopted the use of the AMA formula for determining hearing impairment, it is important that the industrial hygienist or occupational clinician understand it.

In these *Guides,* permanent impairment of any particular body part or system is expressed in terms of the capacity of the whole person to perform activities of daily living. The actual level of function should be determined without the aid of a prosthetic device (in this case, a hearing aid). Equilibrium and hearing are considered separately. Only general criteria are provided for disturbances of equilibrium, but the criteria for evaluating hearing impairment are relatively specific.

Hearing loss for each ear is calculated at thresholds of 500, 1,000, 2,000, and 3,000 Hz. No allowance is made for impairment of speech discrimination due to deficits at higher frequencies. The *Guides to the Evaluation of Permanent Impairment* include a formula for calculating the binaural hearing loss based on the percentage impairment of each ear, tested separately. Each ear must have an average hearing shift of more than 25 dB for the frequencies measured to be ranked as impaired. The percentage of impairment of the poorer ear is added to five times the percentage of impairment of the better ear and the total divided by six. Thus, a person with normal hearing in one ear (0 % impairment) but totally deaf in the other (100 % impairment) would have a binaural hearing impairment of 17 percent ([(5 x 0 %) + 100 %]) ÷ 6 = 17 %). In our example, the 17-percent binaural impairment translates into a 6-percent whole-person impairment.

OSHA HEARING CONSERVATION PROGRAM (29 *CFR* 1910.95)

On April 7, 1983, the Hearing Conservation Amendment (HCA), included in the *Federal Register 29 CFR* 1910.95, became effective. The Occupational Health and Safety Administration (OSHA) Noise Regulation provides specifics on the content of required hearing conservation programs. The regulation covers the following:

- Noise monitoring
- Audiometric testing program
- Definition of standard (permanent) threshold shift
- Employee follow-up and referral
- Hearing protection
- Employee training
- Recordkeeping

This amendment requires that all OSHA-covered workers be included in hearing conservation programs if they are exposed at or above an eight-hour time-weighted average (TWA) of 85 dBA or more. Chapter 9 contains a complete discussion of the requirements of the HCA. Unfortunately, a number of people develop threshold shifts on prolonged exposure to levels as low as 80 dBA. For a discussion of compensation laws as they relate to hearing, see Chapter 9, Industrial Noise.

SUMMARY

The sophisticated hearing and vestibular functions of the ear are linked to the anatomy and physiology of the external, middle, and inner ear. Damage to the external and middle ear can cause conductive hearing loss. Sensorineural hearing loss and/or equilibrium problems are consequences of dysfunction of the inner ear components. Hearing problems can be diagnosed and monitored through the use of precise, standardized audiometric testing. Occupational hazards, particularly noise, are capable of inducing temporary and permanent hearing loss. Hearing loss of any cause can have devastating effects on an individual's general well-being.

Chapter 5

The Eyes

by George S. Benjamin, MD, FACS
revised by Allison S. Zaum, OD, MPH, CIH (retired)

The eye may be the organ most vulnerable to occupational injuries. Although the eye has some natural defenses, they do not compare with the healing properties of the skin, the automatic cleansing abilities of the lungs, or the recuperative powers of the ear. Consequently, the eye is at greater risk and eye and face protection is a major occupational health issue.

The demands placed on the eye in modern workplaces and practices, such as prolonged viewing at close distances or at distances neither near nor far, are great. Both of these conditions can cause acute and chronic eye fatigue and visual discomfort. Hazardous substances can be absorbed into the eye system. Machinery, if guarding mechanisms fail, can propel objects capable of causing traumatic injury to the eye. In 1998, the Bureau of Labor Statistics reported 58,526 total cases of lost-time injuries or illnesses related to the eyes. The incidence rate was 6.6 per 10,000. These statistics represent only the OSHA-reportable injuries and illnesses.

The eye, with its remarkable ability to translate radiant light energy into neural impulses, which are transmitted to the visual cortex of the brain, is certainly one of the most valued organs. Protection of the sensory organs of this complex system should be a high priority in every occupational health and safety program.

ANATOMY

A look at the structure of the human eye and how it can be affected by industrial hazards clarifies the need for eye protection programs. The eyeball is housed in a cone of cushioning fatty tissue that insulates it from the skull's bony eye socket. The skull has brow and cheek ridges projecting in front of the eyeball, which is composed of specialized tissue that does not react to injury like other body tissue (Figure 5–1).

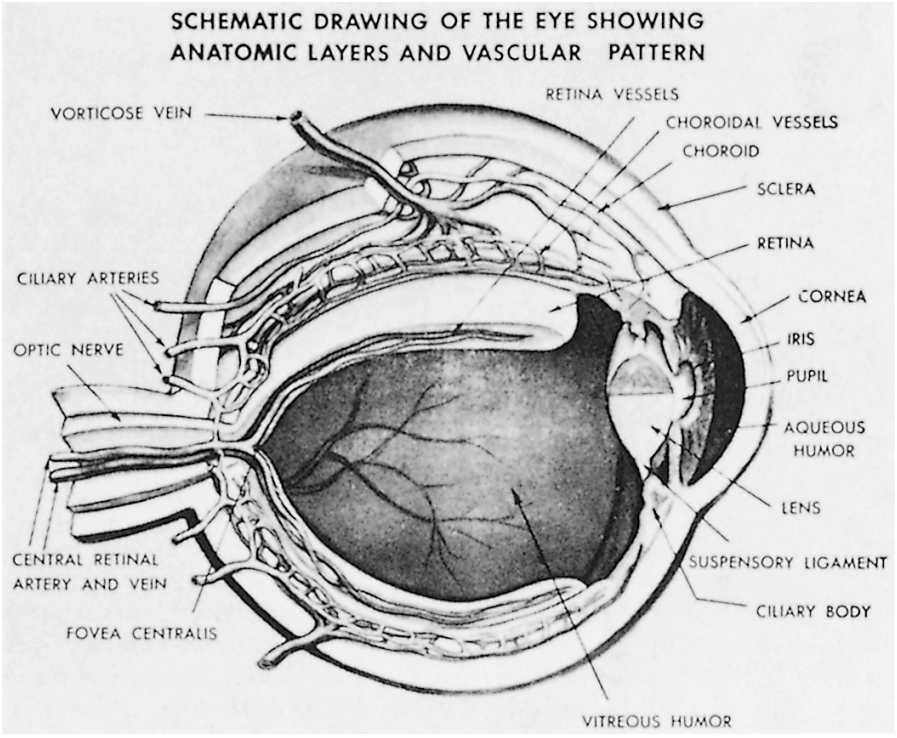

Figure 5–1. Schematic drawing of the eye showing anatomic layers and vascular pattern. (Reprinted with permission from the American Medical Association, *The Wonderful Human Machine.* Chicago: AMA, 1971.)

Eyeball

The eyeball consists of three coats, or layers, of tissue surrounding the transparent internal structures. There is an external fibrous layer, a middle vascular layer, and an inner layer of nerve tissue.

The outermost fibrous layer of the eyeball consists of the sclera and the cornea. The sclera, also called the white of the eye, is composed of dense fibrous tissue and is the protective and supporting outer layer of the eyeball. In front of the lens this layer is modified from a white, opaque structure to the transparent cornea. The cornea is composed of dense fibrous connective tissue and has no blood vessels. The cornea must be transparent to let light through to the receptors in the eyeball.

The middle vascular layer of the eyeball is heavily pigmented and contains many blood vessels that help nourish other tissues.

The nerve layer, or retina, is the third and innermost layer of the eyeball. Toward the rear, the retina is continuous with the optic nerve; toward the front, it ends a short distance behind the ciliary body in a wavy border called the ora serrata. The retina is composed of two parts: the outer part is pigmented and attached to the choroid layer and the inner part consists of nerve tissue.

The front of the eyeball is protected by a smooth, transparent layer of tissue called the conjunctiva. A similar membrane covers the inner surfaces of the eyelids. The eyelids also contain dozens of tiny tarsal glands that secrete an oil to lubricate the surfaces of the eyeball and eyelids. Still further protection is provided by the lacrimal gland, located at the outer edge of the eye socket. It secretes tears to clean the protective membrane and keep it moist (Figure 5–2).

The region between the cornea and the lens is filled with a salty, clear fluid known as the aqueous humor. The eyeball behind the lens is filled with a jelly-like substance called the vitreous humor.

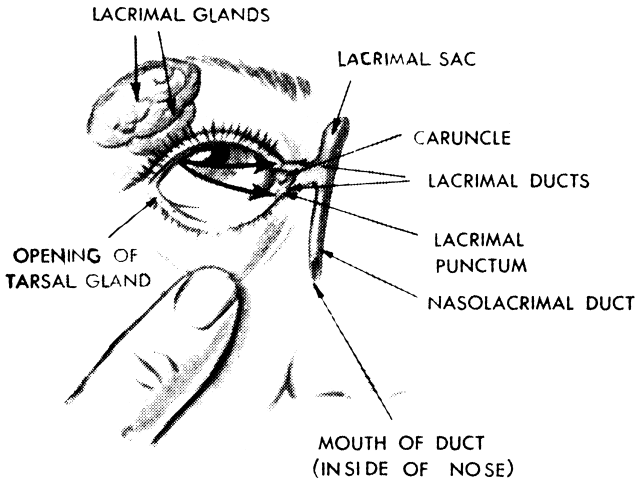

Figure 5–2. Illustration of the eye and tear ducts. (Reprinted with permission from the AMA, *The Wonderful Human Machine.* Chicago: AMA, 1971.)

Light rays enter the transparent cornea and are refracted at the curved interface between air and the fluid bathing the cornea. After passing through the cornea and the clear liquid, (the aqueous humor, contained in the anterior chamber), the bundle of rays is restricted by a circular variable aperture, the pupil. Its size is changed by action of the iris muscles.

The light rays are further refracted by passage through the lens, traversing the clear, jelly-like vitreous humor, so that, in a properly focused eye, a sharp image is formed on the retina. Scattering of light within the eye is minimized by a darkly pigmented layer of tissue underlying the retina, called the choroid. The choroid contains an extremely rich blood supply that is believed to dissipate the heat resulting from absorbed light energy. The shape of the eyeball is maintained by its enclosure in an elastic capsule, the sclera, and by the fluids within that are maintained at positive pressure.

The lens is attached by suspensory ligaments to the ciliary body, a muscular organ attached to the sclera. The ciliary body muscles alter the lens shape to fine-focus the incoming light beam. Ordinarily, these muscles are active only when looking at objects closer than 20 ft (6.1 m). Consequently, when doing close work, it is restful to pause occasionally and look out a window into the distance. Many complaints of eye fatigue are really complaints about tired ciliary muscles. The pigmented iris, overlying the lens, is a muscular structure designed to expand or contract and thus regulate the amount of light entering the eye. The circular aperture formed by the iris is called the pupil.

The aqueous and vitreous humor and other eye tissues are composed primarily of water, so their absorption characteristics are similar to those of water.

Retina

The retina, a thin membrane lining the rear of the eye, contains the light-sensitive cells. These cells are of two functionally discrete types: rods and cones. They get their names from the rod and cone shapes seen when the layer is viewed under a microscope. The rods are more sensitive to light than the cones; the cones are sensitive to colors.

There are more rod cells than cones; each eye has about 120 million rods and only 6 million cones. The rods are incapable of color discrimination because they contain a single photosensitive pigment. There are fewer cone cells, and they are less sensitive to low levels of luminance. There are three types of cones in the human eye; each contains a different photopigment, with peak response to a particular part of the visible spectrum. Thus, by differential transmission of nerve impulses on stimulation, the cones encode information about the spectral content of the image so that the observer experiences the sensation of color. About four percent of the population (95 percent of whom are male) inherits a defect in one of the cone pigments, so that the wavelength of maximum absorption is somewhat shifted. People with these color defects are not color "blind," as they do see colors, but rather are color defective, in that they perceive certain colors differently from people with "normal" cone pigments.

Binocular Vision

Binocular vision refers to vision with two eyes. The advantages of binocular vision are a larger visual field and a perception of depth, or stereoscopic vision. There is a slight difference in the images on the two retinas; there is a right-eyed picture on the right retina and a left-eyed picture on the left retina. It is as if the same landscape were photographed twice, with the camera in two positions a slight distance apart. The two images blend in consciousness and give us an impression of depth or solidity. Binocular vision is not identical to depth perception but is an important clue to that visual function. Depth perception is further discussed in the section on visual performance of this chapter.

EYE PROBLEMS

Specialists in the field of vision include *ophthalmalogists, optometrists,* and *opticians*. They use a variety of tests and instruments to examine a person's visual status, including the Snellen chart to test for distance acuity, ophthalmoscope, slit-lamp microscope, tonometer, perimeter, gonioscopic lens, and phoropter.

Specialists

OPHTHALMOLOGIST

The American Academy of Ophthalmology defines an *ophthalmologist* as a doctor of medicine (MD) who specializes in the comprehensive care of the eye and visual system. Each is licensed by a state to practice medicine and surgery.

OPTOMETRIST

The American Optometric Association defines an *optometrist* (Doctor of Optometry, or OD) as a primary healthcare provider who diagnoses, manages, and treats conditions and diseases of the human eye and visual system. All states now permit optometrists to prescribe certain therapeutic pharmaceuticals and provide treatment for ocular diseases; the specifics vary with each state. Both ophthalmologists and optometrists prescribe eyeglasses and contact lenses.

OPTICIAN

The Opticians Association of America defines an *optician* as an individual who manufactures, verifies, and delivers lenses, frames, and other specially fabricated optical devices.

Examining Instruments

The vision tests used in industrial preplacement examinations are screening tests. They detect possible problems in visual performance and are not by themselves diagnostic. They should not be the basis of any job restrictions without further evaluation by a qualified ophthalmologist or optometrist and consideration of reasonable accommodations.

Snellen Chart

The most common industrial test for distance acuity is the

Snellen wall chart in its several variations. The Snellen chart consists of block letters in diminishing sizes so that at various distances, the appropriate letter subtends a visual angle of five minutes at the nodal point of the eye. Thus, the top large letter appears to be the same size when it is 200 ft (61 m) away as the standard appears at 20 ft (6.1 m).

The distance of 20 ft (6.1 m) is considered to be infinity. This means that the rays of light coming from an illuminated object are parallel; they neither diverge nor converge. If the object is closer than 20 ft (6.1 m), the light rays diverge and must be made parallel by action of the lens within the eye or by the addition of a supplementary lens held in front of the eye; otherwise, they do not come to a sharp focus on the area of central visual acuity of the retina.

The cornea and lens of the eye bend the parallel rays to converge to a focus on the retina. Looking at an object at 20 ft (6.1 m) or more, the normal lens is relaxed into its usual biconvex shape. The parallel rays of light that are bent (refracted) by the cornea and lens cross at the nodal point of the eye (about 7 mm behind the cornea) and, continuing their straight course, fall on the retina, forming an inverted image.

It is important to check several factors. The distance from the chart to the person being tested must be 20 ft (6.1 m), or 10 ft (3 m) if a mirror and reversed chart are used. The lighting should be uniform, its source not visible to the person being tested. The chart should be clean. Finally, the tester must be trained to hold the cover correctly over the eye not being tested, to vary the order of lines and letters, and to be alert for any unusual factors. It is important to separately test and record the vision of each eye and the vision when reading the chart with both eyes.

Satisfactory vision at a distance does not ensure adequate near-point vision, so it is important to recognize near-point abnormalities. Many industrial work situations involve near-point seeing even though they are not confined to near-point work.

Industrial vision testing should be done with standardized tests to detect and identify substandard visual functions. Accuracy is vital, since workers with visual defects can put themselves and others at risk. A competent examination of the eyes requires the use of a number of special examining instruments.

- An *ophthalmoscope* permits study of the interior structures of the eye, such as the retina, optic nerve, and vitreous.
- A *slit-lamp microscope* allows study of the anterior segment of the eye, and with the use of additional lenses, the posterior (interior) structures of the eye as well.
- A *tonometer* is used to measure the pressure in the eyeball (one of the tests for glaucoma).
- A *perimeter* is used to map the limits of the fields of vision.
- A *gonioscopic lens* views the angle of the anterior chamber where the outflow drainage apparatus of the eye is found.
- A *phoropter* is used to determine refractive correction (eyeglass prescription) and binocular vision abnormalities. It consists of test lenses and prisms that are added and removed using both objective criteria and subjective responses (Figure 5–3).

Eye Defects

A 1995 study by Lighthouse International compiled statistics on visual impairments in the United States. Approximately 1.1 million Americans (0.5 percent) are considered legally blind, as defined by clinical measurement (a visual acuity with corrective devices of 20/200 or less, or a visual field in the better eye of 20 degrees or less). In addition, more than 10 million people (about one in every 20) in the United States suffer from significant impairment of vision which cannot be improved by corrective lenses. This condition is designated as "low vision." The leading causes of existing cases of blindness are glaucoma, macular degeneration, cataracts, atrophy of the optic nerve, diabetic retinopathy, and retinitis pigmentosa. These causes account for 51 percent of all cases of blindness, according to the National Society to Prevent Blindness. The leading causes of new cases of blindness are macular degeneration, glaucoma, diabetic retinopathy, and cataract; combined, these account for 52.5 percent of all new cases. A large percentage of all cases of blindness could be prevented by taking advantage of current medical technology and proper safety measures.

It has been estimated that 40 percent of the population wear glasses, indicating that nearly one in two people have some visual defect. Three common eye defects—farsightedness, nearsightedness, and astigmatism—are the results of simple optical aberrations in the eye. Additionally, with the aging of America, *presbyopia,* the age-related decrease in near vision, will affect an increasingly larger segment of the population.

FARSIGHTEDNESS

When the eyeball is too short from front to back, the light rays come to a focus behind the retina. Light rays coming from a distant object may reach their focus at the retina, so that distant vision is good, but near vision is blurred. This condition is called farsightedness or *hyperopia*. The treatment is to wear a convex lens that converges the light rays from near objects so that they are brought to a focus on the retina (Figure 5–4).

NEARSIGHTEDNESS

If the eyeball is too long from front to back, as it is in nearsightedness, or *myopia,* the image of an object 20 ft (6.1 m) or more away falls somewhere in front of the retina. The eye can focus on it sharply only by looking through a concave lens, which diverges the rays coming from the object. By bringing the object near enough to the eyes, a myopic person can get a good focus (Figure 5–5).

Figure 5–3. A phoropter is used with a set of test lenses to find which ones aid vision. (Photograph reprinted with permission of Reichert Ophthalmic Instruments.)

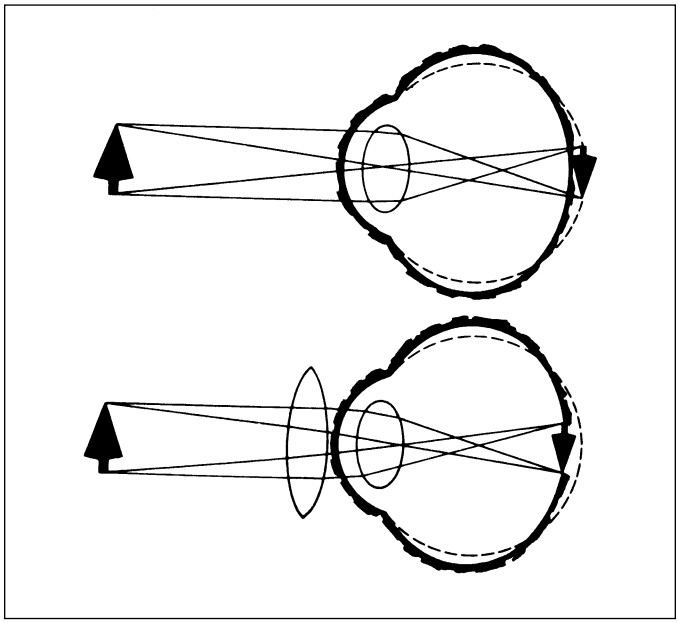

Figure 5–4. In farsightedness, or hyperopia, the eyeball is too short, so the image of an object is focused behind the retina. A convex lens brings the light rays into focus on the retina. Although hyperopic people may be able to see things sharply by thickening the lens of the eye (accommodation), this involves effort of inner muscles of the eye and may cause eye fatigue. (Reprinted with permission from Cooley DG, ed. Family Medical Guide. New York: Better Homes and Gardens Books, 1973.)

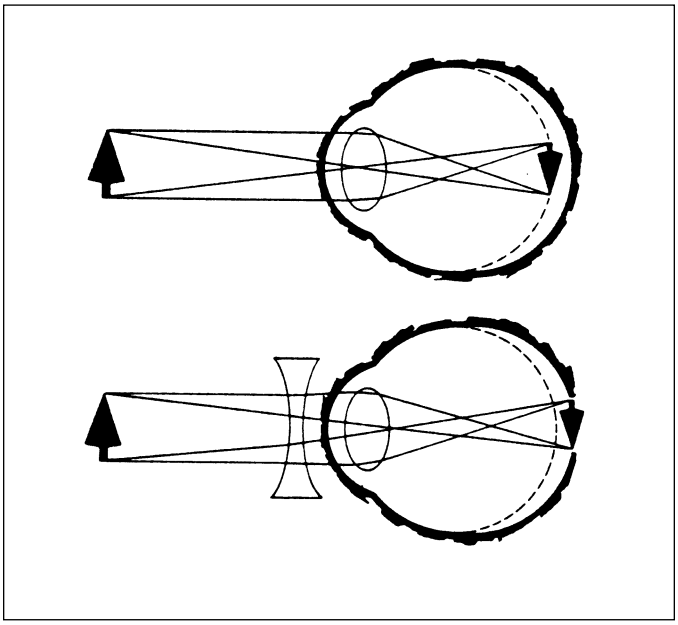

Figure 5–5. In nearsightedness, or myopia, the image of an object (unless it is held close to the eyes) falls in front of the retina instead of on it, and the object is seen indistinctly. The condition is corrected by using a concave lens of proper curvature to bring the image into focus on the retina. (Reprinted with permission from Cooley DG, ed. Family Medical Guide. New York: Better Homes and Gardens Books, 1973.)

ASTIGMATISM

If the curvature of the cornea is irregular so that some rays of light are bent more in one direction than in another, the resulting image is blurred because if one part of the ray is focused, the other part is not. This is something like the distortion produced by a wavy pane of glass, and is called *astigmatism.* It is corrected by using a lens that bends the rays of light in only one diameter (axis). This lens is called a cylindrical lens and it can be turned in the trial frame to its proper axis to even up the focusing of the light rays in all parts. (Figure 5–6)

A person can have astigmatism in addition to either nearsightedness or farsightedness. Small amounts of astigmatism that do not severely affect distance vision may cause eyestrain for people who spend prolonged time working at a computer. "Computer glasses" may be indicated for such individuals.

PRESBYOPIA

The closer an object is brought to the eye, the more convex the human eye lens must become in order to focus on it. Through aging, the human lens loses its accommodative power, that is, its elasticity and its power of thickening. This condition is known as *presbyopia,* and usually develops after age 40 years. A common symptom is finding that our arms are too short to read a book. Nearsighted individuals may find they need to remove their spectacles for reading or other close work. Farsighted people, many of whom who never needed glasses before, will start to experience near blur or eyestrain while working at the computer.

Presbyopia is corrected by wearing convex lenses, often in a bifocal or other multifocal lens. The reading prescription (or "add") gets progressively higher until around the age of 55 years, when it generally stabilizes.

Eyeglasses

The purpose of wearing eyeglasses is to help focus the rays of light on the retina. Glasses cannot change the eye or produce any disease even if they are badly fitted.

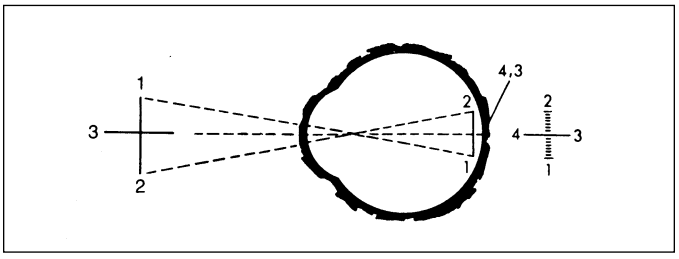

Figure 5–6. Astigmatism resulting from irregular curvature of the cornea is something like distortion produced by a wavy pane of glass. Drawing shows light rays (3,4) in sharp focus on retina, with light rays (1,2) focused in front of the retina, resulting in a blurred image. The small diagram on the right shows horizontal image in focus, vertical image out of focus. A cylindrical lens placed in the proper axis to bring light rays to even focus corrects astigmatism.

A prescription for glasses may look something like this:

+ 2.50 – 0.50 x 180

The + sign indicates a convex lens suitable for a farsighted person. A – sign would indicate a concave lens for a myopic person. The *2.50* indicates the *diopters,* which indicate the strength or power of the lens. A diopter (D) is a unit of measurement of the refractive or light-bending power of a lens. The normal human lens in its relaxed biconvex shape has a power of about 10 D.

Thus, the prescription in the example means that the optician grinds a convex spherical lens of 2.50 diopters combined with a concave cylindrical lens of half a diopter (0.50) situated horizontally (axis 180 degrees). Lens prescriptions look strange, but opticians everywhere know what they mean.

Bifocal or other multifocal lenses (such as progressive or "no line bifocal" lenses) also include a prescription for reading, called an addition or "add." If the person with the above hyperopic (farsighted) correction also needed 2.00 diopters additional to read, the prescription would read as follows:

+ 2.50 – 0.50 x 180 with + 2.00 add

VISUAL PERFORMANCE

Normal visual performance involves a number of interdependent discriminations made in response to the visual environment and mediated by the visual system.

Visual Acuity

There are many definitions of the term *visual acuity;* all, however, incorporate the concept of detail resolution. Many test patterns have been used to measure acuity, from single dots to twin stars, gratings, broken rings, checkerboards, and letters. The Snellen Letter Test is probably the most familiar and is widely used. The most satisfactory expression for visual acuity is the amount of critical detail that can just be discriminated.

Some important variables affecting visual acuity are as follows:

LUMINANCE

The level of adaptation of the eye has a profound effect on visual acuity.

POSITION IN THE FIELD

At photopic levels, acuity is best at the fovea and drops off as the retinal periphery is approached because there are fewer cones at the periphery. Nocturnal acuity is quite poor, with essential blindness at the fovea and best resolution in the periphery, where rods are more plentiful. This can be appreciated when looking at stars, as a star can often be detected more clearly when viewed peripherally than straight on.

DURATION

When the pattern is viewed for only a short time, measured acuity diminishes.

CONTRAST

Visual acuity decreases as the contrast between pattern and background diminishes. The strength of this correlation depends on the adapting luminance. People with visual disorders often have reduced contrast sensitivity but reasonable Snellen acuities; some states are requiring contrast sensitivity testing for driver's licenses, in addition to acuity.

Dark Adaptation

Optimal visual discrimination under conditions of very low light can be made only if the eyes are adapted to the level of the prevailing light or lower. If a fully light-adapted eye is suddenly plunged into darkness, its initial sensitivity is poor. With time, however, sensitivity increases as a result of photochemical regeneration, certain functional neural changes, and, to a much smaller degree, enlargement of the pupil. After the eye remains in total darkness for 30–60 minutes, the adaptation process is nearly complete; the sensitivity of the eye in parts of the retina where both rods and cones are present is increased by a factor of 10,000 for white light.

There are several important operational consequences of the dark adaptation process:

- ➢ Best performance on a task in low light requires that the eye be preadapted to an appropriately low level long enough to attain maximum sensitivity.
- ➢ Because the rods are more sensitive than the cones at low light levels, detection capability is highest on the parts of the retina where rods abound (10–30 degrees from the fovea) and averted vision is required for optimal performance.
- ➢ Because the rods are relatively insensitive to extreme red wavelengths, dark adaptation is facilitated if the observer wears red goggles or if the illumination provided is a very deep red, as in a spacecraft or photographic darkroom. By this means, the observer can continue to use the high-acuity capability of the central fovea at elevated luminance levels for reading instruments and such while the adaptation process goes on, although vision naturally is monochromatic in this case.
- ➢ Because the two eyes are essentially independent in adaptation, it is possible to maintain dark adaptation in one (using an eye patch, for example) while the other is used at high light levels.

Depth Perception

Depth can be estimated by an experienced observer through use of various cues. Some of these cues are provided by the nature of the scene of interest; others are inherent in the observer.

In cases where only internal cues to distance are available—that is, when objects of interest are of unknown size and shape—the observer must depend on his or her stereoscopic acuity, accommodation, and convergence, and, where possible, movement parallax. Accommodation is the only effective cue to distances at ranges of a meter or less, and even here it is inaccurate. Convergence (bringing the eyes toward the nose) alone is a somewhat more useful cue, but only within about 20 m of the observer. Stereoscopic acuity provides a powerful clue to distance, but it should not be assumed that people with monocular vision cannot do tasks normally assumed to require stereoscopic vision; actual performance should be tested. Certain jobs (e.g., pilots), however, do require a minimum amount of depth perception.

Commercially available stereopsis tests include the Titmus "Fly"and the Randot stereo test (available from Bernell and other suppliers).

Color Vision

Color deficiencies can impose restrictions in certain occupations. These include electricians, pilots, commercial drivers, firefighters, dye workers, and many other professions. A commonly administered test is the Ishihara color plate test. These plates are extremely sensitive at identifying red-green defects, the most common inherited color defects. Another color test is the Farnsworth D-15 Panel Test. In this test, the subject arranges a series of colored caps. Some employers accept individuals with a color deficiency if they can pass certain "trade tests," such as the FALANT (Farnsworth Lantern Test), used to evaluate recognition of aviation and maritime colored signal and marker lights. People with mild or borderline color deficiencies may be able to demonstrate sufficient color vision for a particular job by passing the D-15 Panel.

Even when color discrimination is not a job criterion, baseline color vision testing for all employees is useful, in that it can help distinguish between inherited color defects from those that are acquired (caused by disease).

A very small percentage of the population is truly "color blind," in that they have no cones in their retinas, only rods. This condition is called *rod monochromatism*. These people are extremely photophobic and have very decreased visual acuity. They usually need to wear tinted glasses for comfort, and may require additional occupational modifications and low vision aids.

EYE DISORDERS

There are numerous eye disorders. Conjunctivitis, infections, uveitis, glaucoma, cataracts, sensitivity to excessive brightness, night blindness, eyestrain and nystagmus are among the disorders most commonly encountered. They are briefly described.

Conjunctivitis, Infections, and Uveitis

Various types of conjunctivitis, or inflammation of the mucous membrane, can develop beneath the eyelids. The eye becomes scratchy and red and has a discharge. Most often the cause is viral, bacterial, or allergic. All causes produce varying degrees of redness, which is often referred to as "pink eye." Viral infections usually produce tearing, bacterial infections

cause pus or mucous discharge, and allergic reactions cause itching and occasionally a "stringy" discharge.

Bacterial, viral, or fungal infections can affect the cornea. They can cause pain, decreased vision, and photophobia (light sensitivity). Contact lens wearers are particular susceptible to bacterial infections. Employees presenting with red eyes should be immediately evaluated by an eye care practitioner, as there are bacterial strains that can penetrate an intact cornea within 24 hours.

A fairly common type of infection, especially in adults, is caused by the herpes simplex virus on the anterior surface of the eyeball. This can lead to blurred vision, scarring, and permanent damage to vision. It may affect one or both eyes and quite often recurs. Topical steroids often used for other types of conjunctivitis greatly aggravate herpes infections. Therefore, any signs suggesting inflammation near the cornea should be immediately referred to an eye care practitioner experienced in treating eye disorders.

Inflammation of the interior eye is common in adults. One of the most common areas of infection is the uveal tract, which is the middle coat of the eye. Inflammation of this type damages the retina, the lens, and the cornea. The cause of a uveal inflammation (or *uveitis*) is often idiopathic, but can also be associated with diseases of the joint, lung, or intestinal tract. A search must be made for disease elsewhere in the body that might be the cause of the eye problem. When found, the primary cause should be treated. The eye should also be treated to prevent damage to vision. Once again, an employee presenting with a red, painful, and photophobic eye should be immediately evaluated by an eye care practitioner.

Glaucoma

Glaucoma is a leading cause of blindness in America. The most common form, *primary open-angle glaucoma* (POAG), was originally thought to develop when the fluid that normally fills the eyeball, the aqueous humor, fails to drain properly. Ordinarily, the fluid is continuously produced in the eye and excess drains off through a small duct near the iris. Aging, infection, injuries, congenital defects, and other causes can constrict or block the duct. Fluid pressure then builds up and the pressure, if great and of long duration, can damage the optic nerve. Recent research has hypothesized that reduced blood perfusion to the optic nerve may be a potential cause of POAG.

In another form of the disease, *acute-angle closure glaucoma,* vision dims suddenly, the eyeball becomes painful and very light-sensitive, and the patient feels quite ill. An angle closure attack should be considered an ocular emergency. However POAG causes no pain, injuring vision very slowly. Sometimes symptoms include the perception of colored rings and halos about bright objects or dimming of side vision.

Much can be done to preserve vision in most cases when glaucoma is diagnosed early. Medication is often effective in controlling the pressure. In recalcitrant cases, laser treatment or filtering surgery may be indicated.

Cigarette smoking has been shown to increase the risk of developing glaucoma, providing yet another reason to counsel employees about the hazards of smoking.

Cataracts

Cataracts are opacities that form on the lens and impair the vision of many elderly and some younger people. Many cases are associated with metabolic disease or aging, but there are also traumatic cases associated with industrial exposures to ionizing radiation, ultraviolet radiation, infrared radiation, foreign bodies, and certain chemicals. Cataracts can also be caused by certain medications, particulary prolonged treatment with corticosteroids. There is also evidence that cigarette smoking increases cataract development. If the vision impairment is severe, the diseased lens can be removed, and is generally replaced with a plastic implant.

Excessive Brightness

Good sunglasses can protect the eyes in bright sunlight. Poor ones compound or create problems. Glasses with scratches and irregularities should not be used. Some glasses are too lightly tinted to do much good; good glasses reduce the invisible as well as the visible light. (Injury from light will be discussed later in this chapter under irradiation burns.) In addition to helping relieve discomfort caused by glare, sunglasses provide important protection to the anterior and posterior structures of the eyes.

Night Blindness

Inability to see well or at all in dim light can mean something is wrong not only with the eye but with the entire visual system. Night blindness, as it is called, is a threat to safety, particularly on the highway, because a driver may have 20/20 vision and not realize that his or her vision is somewhat impaired at night. The condition produces no discernible change in eye tissues, so it cannot be diagnosed unless a patient tells the physician of difficulty in reading road signs or picking out objects at night. It is not normal to have trouble seeing in dim light because sufficient accommodation occurs in two or three minutes.

Eyestrain

Eyestrain can lead to severe signs of local irritation, headaches, fatigue, vertigo, and digestive and psychological reactions. This condition can result from a need for eyeglasses or from using glasses with the wrong correction. Eye muscle strain may also result from unfavorable conditions such as improper lighting while reading or doing close work. To avoid strain when reading, do not face the light; it should come from behind and to the side. Be sure light bulbs are strong enough (75–100 watts). Hold the book or paper about 16–18 in. (0.4 m) away and slightly below eye level. Avoid glare and occasionally rest the eyes by shifting focus and looking off into the distance. ANSI/ IES-RP-7 provides detailed recommendations for the design of industrial lighting.

Nystagmus

Nystagmus, involuntary movement of the eyeballs, may occur among workers who, for extended periods, subject their eyes to abnormal and unaccustomed movements. Complaints of objects dancing before the eyes, headaches, dizziness, and general fatigue are associated symptoms; all can clear up quickly if a change of work is made. The involuntary movements of the eyeball characteristic of nystagmus can sometimes be induced by occupational causes affecting the eyes through the central nervous system or by some extraneous cause. The most prevalent form of occupational nystagmus is seen in miners.

PHYSICAL HAZARDS

The eye is subject to many kinds of physical injury—blows from blunt objects, cuts from sharp objects, and damage from foreign bodies.

Blows from Objects

A blow from a blunt object can produce direct pressure on the eyeball or, if the object delivering the blow seals the rim of the bony orbit on impact, it can exert hydraulic pressure. Such blows may cause contusion of the iris, lens, retina, or even the optic nerve. Violent blows might rupture the entire globe or fracture the thin lower plate of the bony orbit, entrapping the eye muscles.

Contusions may result in serious, irreversible injury if not treated promptly and adequately. Hemorrhaging releases blood, which can be toxic to eye tissues, and physical dislocations of lens, retina, and other parts are unlikely to repair themselves. Lacerations of the cornea, lid, or conjunctiva can be caused by any sharp object, from a knife to the corner of a piece of typing paper.

Corneal Lacerations and Abrasions

Corneal lacerations, if full-thickness, may allow the aqueous solution behind the cornea to gush out until the iris, which has the consistency of wet tissue paper, is pulled toward the laceration and plugs the wound. The iris can be put back in place, the laceration sutured, and the eye made nearly as good as new. More common corneal injuries are scrapes or abrasions that do not penetrate to the chamber behind the cornea. Such abrasions are very painful, but heal within several days if treated properly. If they are too deep or allowed to become infected, scars that interfere with vision result.

Lacerations of the lid heal, but the scar tissue can pull the lid into an unnatural position. In addition to cosmetic deformity, the lids might not close completely or lashes might turn in against the eyeball. Vertical lacerations are more serious in this respect.

Because it is composed of highly differentiated tissues, the eye is more likely than a finger to suffer permanent damage from injury. This does not mean the eye has no natural defenses. The bony ridges of the skull protect the eyeball from traumatic injury caused by massive impact. A baseball, for instance, is too big to crush the eyeball—it is stopped by the bony orbit. The cushioning layers of conjunctiva and muscle around the eyeball absorb impact. The fact that the eyeball can be displaced in its socket is also a defense against injury. In addition, the optic nerve is long enough to allow some displacement of the eyeball without rupture of the nerve.

Blink Reflex

The eye is most vulnerable to attack at the corneal surface. Here, the eye is equipped with an automatic wiper and washer combination. The washers are the lacrimal glands; the wiper is the blinking action.

The teary blink washes foreign bodies from the corneal or conjunctival surfaces before they can become embedded. The triggering mechanism is irritation.

The reflex blink can also act like a door to shut out a foreign object heading for the eye if the eye can see it coming and it isn't coming too fast. Protective equipment for the eye is used in industry to improve or extend these natural defenses. These defenses might be adequate protection against light and small foreign objects and small quantities of mildly toxic liquids, but they are no match for industrial eye hazards such as small high-speed particles or caustic powders and liquids.

Foreign Bodies

Invasion by a foreign body is the most common type of physical injury to the eye. Not all foreign bodies, however, affect the eye in the same way.

Foreign bodies affecting the conjunctiva are not usually very serious. They may result in redness and discomfort, but not vision damage. Bodies on the conjunctiva, however, can be transferred to the cornea and become embedded if a person rubs the eye. Even with minor irritations of the conjunctiva, a trip to the nurse is advisable. If there is obvious irritation and no object can be found, it is advisable to see a physician immediately.

Some industrial eye injuries may appear trivial, but can become serious due to complications. The most common complication is infection, which can cause delayed healing and corneal scarring. The infection can be carried into the intraocular tissues by a foreign substance and the bacteria can originate either from sources outside of the eye or from pathogenic organisms already present on the lids, conjunctiva, or in the lacrimal apparatus.

Foreign bodies in the cornea can cause the following problems:

- ➢ *Pain.* Because the cornea is heavily endowed with nerves, an object sitting on the surface of the cornea constantly stimulates the nerves.
- ➢ *Infection.* Bacteria or fungi can be carried by the foreign particle or by fingers used to rub the eye. Such infections

used to be much more common, but antibiotics (and antifungals) have greatly reduced the problem.

➢ *Scarring.* Corneal tissue will heal, but the scars are optically imperfect and may obscure vision.

Intraocular foreign bodies can cause the following problems:

➢ *Infection.* Infection is much less of a problem with low-speed, low-mass particles, but in some cases, the speed of small metallic particles often creates enough heat to sterilize them. Wood particles, however, do not heat up; if they penetrate the eye, they can cause dangerous infection, which usually causes a marked reduction in vision.

➢ *Damage.* Depending on its angle, point of entry, and speed, an intraocular particle may cause traumatic damage to the cornea, iris, lens, or retina. Damage to the lens is especially serious because it is not supplied with blood and is slow to heal. Also, any damage to the lens can act as a catalyst for protein coagulation, resulting in opacity and loss of vision.

Pure copper particles can cause serious damage to the eye because the toxic copper molecules become deposited in the lens, cornea, and iris (chalcosis). Copper alloys do not seem to have any toxic effects.

Pain cannot be relied on to alert the worker that there is a foreign body in his or her eye. The cornea is very sensitive, but if the object has penetrated into the eyeball, there may be no acute pain.

Thermal Burns

Heat can destroy eye and eyelid tissue just as it does any other body tissue, but eye tissues do not recover as well as skin and muscle from such trauma. The lids are more likely to be involved in burns than the eye itself because involuntary closing of the eye is an automatic response to excessive heat.

Irradiation Burns

Nonionizing radiation can be an ocular hazard. Infrared, visible, and ultraviolet light and lasers can present the most significant exposures. Workplace assessments of nonionizing radiation hazards should always include the potential for damage to the eyes, and appropriate engineering controls and protective equipment specified where needed to prevent such injuries. (See Chapter 11, Nonionizing Radiation for more details.)

DAMAGE MECHANISMS

Light in sufficient amounts may damage eye tissue, ranging from barely detectable impairment to gross lesions. The degree of damage depends on the tissue involved and the energy of the incident light photon. Far-infrared light usually effects damage through a general increase in tissue temperature, whereas far-ultraviolet light generally causes specific photochemical reactions.

Damage to lens cells may not be apparent for some time after insult because of the low level of metabolic activity. Low-degree damage is evidenced by vision clouding or cataract and usually is not reversible. When recovery does occur, it is a slow process. Lens damage may be cumulative because dead cells cannot be eliminated from the lens capsule, causing a progressive loss of visual acuity.

Retinal damage can take a number of forms. Generally, the neural components of the retina, such as the photoreceptors, may regenerate when slightly injured, but usually degenerate when extensively injured.

ULTRAVIOLET RADIATION

Harmful exposures to ultraviolet (UV) light usually occur in welding operations, particularly in electric arc welding. The effects include acute keratoconjunctivitis (welder's flash), an acute inflammation of the cornea and conjunctiva which develops in about six hours after even a momentary exposure to the arc light. The welder rarely is involved, being too close to the arc to look at it without an eyeshield, but welders' helpers and other bystanders often suffer from exposure.

INFRARED RADIATION

Unlike UV, infrared (IR) radiation passes easily through the cornea and its energy is absorbed by the lens and retina. With automation of metals operations, eye damage from IR radiation is not as common as it once was.

VISIBLE LIGHT

Various combinations of light sources, exposure duration, and experimental animals have been used to determine the threshold level of light capable of producing a visible retinal lesion. Unfortunately, the experiments recorded were not systematically designed or standardized, leaving numerous gaps and inconsistencies in the reports. Such parameters as pulse duration and irradiated spot area or diameter on the retina are notably lacking. Methods of measurement are often unstated, making comparisons and appraisals of accuracy difficult.

Many models have been proposed to explain the production of visible lesions on the retina from exposure to laser light. Most of the models consider thermal injury to be the only cause of damage. (See Chapter 11, Nonionizing Radiation, for more details.)

Chemical Hazards

The effects of accidental contamination of the eye with chemicals vary from minor irritation to complete loss of vision. In addition to accidental splashing, some mists, vapors, and gases produce eye irritation, either acute or chronic. In some instances, a chemical that does no damage to the eye can be sufficiently absorbed to cause systemic poisoning.

Exposure to irritant chemicals provokes acute inflammation of the cornea (acute keratitis), with pinpoint vacuoles (holes) of the cornea, which rapidly break down into erosions. Some industrial chemicals irritate the mucous mem-

brane, stimulating lacrimation (excessive watering of the eyes). Other results can include discoloration of the conjunctiva, disturbances of vision, double vision from paralysis of the eye muscles, optic atrophy, and temporary or permanent blindness.

Chemical Burns

Because caustics are much more injurious to the eyes than acids, the medical prognosis of caustic burns is always guarded. An eye might not look too bad on the first day after exposure to a caustic, but later it may deteriorate markedly. This is in contrast to acid burns, in which the initial appearance is a good indication of the ultimate damage.

This is because strong acids tend to precipitate a protein barrier that prevents further penetration into the tissue. The alkalis do not do this; they continue to soak into the tissue as long as they are allowed to remain in the eye.

The ultimate result of a chemical burn may be a scar on the cornea. If this is not in front of the window in the iris, vision may not be greatly hampered. If the scar is superficial, a corneal transplant can alleviate burn damage. Densely scarred corneal tissue cannot be repaired by transplants, but plastic implants are now available.

When the chemical penetrates the anterior chamber of the eye, the condition is called iritis (irritation caused by bathing the iris with the chemical agent). Glaucoma may be a complication of chemical iritis.

Evaluating Eye Hazards

It does not take special training or engineering skills to identify most eye hazards. When people handle acids or caustics, when airborne particles of dust, wood, metal, or stone are present, or when blows from blunt objects are likely, eye protection is necessary. Biohazards to hospital and other health care workers also need to be considered.

Workers directly involved with operations producing these hazards are usually included in protective equipment programs, but often workers on the perimeter of eye-hazardous operations are left unprotected, with costly results. Who has not heard of pieces of broken metal tools propelled from the drill press into a worker's eye or flash burns from reflected radiation?

The danger from agents with delayed or cumulative effects is even less likely to be recognized. A host of new technologies carry risk of exposure to a portion of the ultraviolet spectrum: industrial photo processes, sterilization and disinfection, UV therapy and diagnosis in ambulatory medicine and dentistry, polymerization of dental and orthopedic resins, research labs, and insect traps. Nonoccupational exposures from outdoor activities or tanning parlors may enhance borderline exposures in the workplace.

Although work may only occasionally bring an employee near eye hazards, the safest policy is to encourage all-day eye protection. The outdated technique of hanging a pair of community goggles near the grinding wheel is an example of the *eye-hazard job* approach to eye protection, in which jobs that involved eye hazards were identified and eye protection was required only for the worker actually doing the job.

The *eye-hazard area concept* is a better approach. An eye-hazard area is an area where the continuous or intermittent work being performed can cause an eye injury to anyone in the area. The concept emphasizes the need for process and environmental controls such as enclosures and radiation-absorbing surfaces and provides eye protection equipment for workers, neighboring workers, supervisors, and visitors. With proper enforcement and designation of areas, this approach is the most effective way to prevent eye injuries.

First Aid

Propelled object injuries require immediate medical attention. Even for foreign bodies on the corneal surface, self-help should be discouraged; removal of such particles is a job for a trained medical staff member.

Chemical splash injuries require a different approach. Here the extent of permanent damage depends almost entirely on how the victim reacts. If the victim of a concentrated caustic splash gets quickly to an eyewash fountain, properly irrigates the eye for at least 15 minutes, and promptly receives expert medical attention, the chances are good for a clear cornea or, at most, minimal damage.

Such irrigation should be with plain water from standard eyewash fountains, emergency showers, hoses, or any other available sources. Water for eye irrigation should be clean and within certain temperature limits for comfort. Tests show that 112 F (33 C) is about the upper threshold limit for comfort, but colder water, even ice water, apparently causes no harm and is not uncomfortable enough to discourage irrigation.

ANSI Z358.1–1990

The American National Standard Institute (ANSI) standard Z358.1–1990 covers the design and function of eyewash fountains; the water should meet potable standards. It has been noted that acanthamoebae capable of infecting traumatized eyes can be present in potable water. No cases have been directly attributed to the presence of these organisms in eyewash stations, but it seems prudent to follow the ANSI recommendation of a weekly systemic flushing. At least three minutes of flushing significantly reduces the number of organisms.

Portable units are intended for brief irrigation of an injury. A full 15-minute flushing of the injured eye at a stationary station should follow. It has been suggested that water for a portable station be treated with calcium hypochlorite up to 25 ppm free chlorine to eliminate acanthamoebae.

Some industrial medical units use sterile water for irrigation. Use of water substitutes such as neutralizing solutions, boric acid solutions, and mineral oil is discouraged by nearly all industrial ophthalmologists because in many instances, such preparations can cause eye damage greater than if no irrigation were used at all.

PROTECTIVE EQUIPMENT

All eye-protection equipment is designed to enhance one or more of the eye's natural defenses. Chipper's cup goggles extend the bony ridge protecting the eye socket and provide an auxiliary, more penetration-resistant cornea. Chemical splash goggles are better than a blinking eyelid.

There is a tremendous variety of eye protection available, from throwaway visitor's eye shields to trifocal prescription safety spectacles and from welder's helmets to clip-on, antiglare lenses. But the classic safety glasses, with or without sideshields, are probably adequate for 90 percent of general industrial work.

The requirement for proper eye protection should be vigorously enforced to ensure maximum protection for the degree of hazard involved. On certain jobs, 100 percent eye protection must be insisted on.

Protection of the eyes and face from injury by physical and chemical agents or by radiation is vital in any occupational safety program. Eye-protective devices must be considered optical instruments and should be carefully selected, fitted, and used.

Unfortunately, the very term *safety glasses* can be confusing. A Food and Drug Administration (FDA) ruling, effective January 1, 1972, requires that all prescription eyeglass and sunglass lenses be impact-resistant. However, such lenses are not the equivalent of industrial-quality safety lenses and they should not be used in an industrial environment where protection is mandatory.

ANSI Z87.1–1989

Only safety eyewear that meets or exceeds the requirements of ANSI standard Z87.1–1989, *Practice for Occupational and Educational Eye and Face Protection* (referenced in OSHAct Regulations), is approved for full-time use by industrial workers.

The Z87 standard specifies that industrial safety lenses must be at least 3 mm thick and capable of withstanding impact from a 1-in. diameter steel ball dropped 50 in. (1.3 m). The FDA ruling does not mention lens thickness, and requires that a 5/8-in. (16-mm) diameter steel ball be used to verify impact resistance. To pass this test, the lens cannot become chipped or displaced from the frame. For more information, refer to OSHA regulations on eye protection in the general industry codes, in particular, 29 *CFR* 1910.133.

Impact Protection

Three types of equipment are used to protect eyes from flying particles: spectacles with impact-resistant lenses, flexible or cushion-fitting goggles, and chipping goggles.

SPECTACLES

For safety eyewear, polycarbonate lenses are the most impact resistant, and should be considered the lens of choice for industrial environments. In addition, frames must meet the requirements for safety eyewear; an employees personal spectacles (or "dress" frames) would not be considered appropriate eye protection by OSHA in certain occupational environments, even if the lenses were polycarbonate.

Spectacles without sideshields should be used for limited hazards requiring only frontal protection. Where side as well as frontal protection is required, the spectacles must have sideshields. Full-cup sideshields are designed to restrict side entry of flying particles. Semifold or flatfold sideshields can be used where only lateral protection is required. Snap-on and clip-on sideshield types are not acceptable unless they are secured (Figure 5–7). Whether side shields are needed should be determined by the health and safety professional who has evaluated the work environment.

FLEXIBLE-FITTING GOGGLES

These should have a wholly flexible frame forming the lens holder. Cushion-fitting goggles should have a rigid plastic frame with a separate, cushioned surface on the facial contact area (Figure 5–8). Both flexible and cushioned goggles usually have a single plastic lens. These goggles are designed to give the eyes frontal and side protection from flying particles. Most models fit over ordinary ophthalmic spectacles.

CHIPPING GOGGLES

These have contour-shaped rigid plastic eyecups and come in two styles: one for people who do not wear eyeglasses, and one to fit over corrective glasses. Chipping goggles should be used where maximum protection from flying particles is needed.

If lenses will be exposed to pitting from grinding wheel sparks, a transparent and durable coating can be applied to them.

Figure 5–7. Full-cup sideshields are designed to restrict the entry of flying objects from the side of the wearer.

Figure 5–8. Flexible-fitting goggles should have a flexible frame forming the lens holder.

Eye Protection for Welding

In addition to damage from physical and chemical agents, the eyes are subject to the effects of radiant energy. Ultraviolet (UV), visible, and infrared (IR) bands of the spectrum all produce harmful effects on the eyes, and therefore require special attention.

Welding processes emit radiation in three spectral bands. Depending on the flux used and the size and temperature of the pool of melted metal, welding processes emit UV, visible, and IR radiation; the proportion of the energy emitted in the visible range increases as the temperature rises.

All welding presents problems, mostly in the control of IR and visible radiation. Heavy gas welding and cutting operations as well as arc cutting and welding exceeding 30 amperes also emit UV radiation.

Welders can choose the shade of lenses they prefer within one or two shade numbers:

- Shades numbered 1.5–3.0 are intended to protect against glare from snow, ice, and reflecting surfaces and against stray flashes and reflected radiation from nearby cutting and welding operations. These shades also are recommended for use as goggles or spectacles with sideshields worn under helmets in arc-welding operations, particularly gas-shielded arc-welding operations.
- Shade number 4 is the same as shades 1.5–3.0, but for greater radiation intensity.

For welding, cutting, brazing, or soldering operations, the guide for the selection of proper shade numbers of filter lenses or windows is given in ANSI Z87.1–1979, *Eye and Face Protection*. (For more details, see Chapter 11, Nonionizing Radiation.)

Laser Beam Protection

No one type of glass offers protection from all laser wavelengths. Consequently, most laser-using firms do not depend on safety glasses to protect employees' eyes from laser burns. Some point out that laser goggles or glasses might give a false sense of security, tempting the wearer to expose himself or herself to unnecessary hazards (Figure 5–9).

Nevertheless, researchers and laser technicians often need eye protection. Both spectacles and goggles are available and glass for protection against nearly all known lasers can be ordered from eyewear manufacturers. Typically, the eyewear has maximum attenuation at a specific laser wavelength; protection falls off rapidly at other wavelengths. (For more details, see Chapter 11, Nonionizing Radiation.)

Visual Display Terminals (VDTs)

Much concern has focused on health problems associated with the use of VDTs. There is no doubt that use of these

Figure 5–9. One type of safety goggles suitable for protection against laser beams.

devices can cause increased eye fatigue and visual discomfort. Factors that lead to visual discomfort are poor contrast between the characters and background, high contrast between the screen and other surfaces (such as the documents), and glare from and flicker on the screen. Long periods of eye fixation and refractive errors are also significant contributors.

Often, the displays are at a distance of about 30 in. (76 cm) from the operator's eye. Special corrective lenses may be required because the distance is neither near nor far vision.

Regulations for the design and operation of VDT workstations have been issued by some countries, but most authorities oppose rigid rules. Because of the variety of visual problems and work practices of operators, proper design should allow for flexibility in the placement of the screen, keyboard, source documents, and work surfaces. Ambient lighting must be adjustable, bright backgrounds such as windows should be eliminated, and appropriate rest periods are indicated. ANSI/HSF 100–1988 gives detailed recommendations for the design of a visual display terminal workstation. (See Chapter 13, Ergonomics, for additional information.)

Sunglasses

Use of safety sunglasses is a common practice for people who work outdoors, but they are not appropriate for indoor work. Darkly tinted lenses should not be worn indoors unless specifically required because of excessive glare or eye-hazardous radiation. Some computer users feel more comfortable with a light tint on their spectacles; however, to address glare problems, the computer screen itself should be fitted with an anti-glare shield, and the computer situated properly relative to natural and artificial lighting.

PHOTOTROPIC LENSES

Phototropic or photochromic lenses automatically change tint from light to dark and back again, depending on their exposure to UV light. The convenience of sunglasses with variable-tint lenses is obvious, even though such lenses do not react indoors, in a car, or anywhere else that UV light cannot reach.

The ANSI Z87 standard recommends a variety of fixed-density tinted lenses for specific job situations involving radiation harmful to vision. Each tint is assigned an individual shade number, which is inscribed on the front surface of each such lens. The current Z87 standard makes no mention of phototropic lenses; this fact alone should give pause to health and safety specialists who might be pressured to shift a work force immediately into phototropic lenses.

Such lenses may have a future for outdoor use by telephone line and brush crews and gas-line transmission workers. However, until safety eyewear manufacturers are willing—or able—to certify phototropic lenses as being fully in compliance with the Z87 standard, industry would be well-advised to follow ANSI guidelines.

Contact Lenses

Contact lenses have had a history of being banned in industrial environments. However, there is little (to no) evidence that across-the-board prohibition of their use is warranted. In May 1998, the Contact Lens Section of the American Optometric Association issued revised "Guidelines For The Use of Contact Lenses in Industrial Environments." In this, they stated that "Contact lenses may be worn in some hazardous environments with appropriate covering safety eyewear. Contact lenses of themselves do not provide eye protection in the industrial sense." Contact lenses should not be considered eye protection and are not intended as such. However, if eye protection appropriate for the job being done is worn over the contact lenses, employees should be able to safely use them. There are certain eye conditions, such as keratoconus, where an individual's vision may be significantly decreased by wearing glasses instead of contact lenses; in this situation, a greater hazard may be produced by insisting on the wearing of glasses.

Health and safety practitioners often have banned the use of contact lenses with respiratory protection. Lawrence Livermore National Laboratory conducted a study of contact lens wearers who used self-contained breathing apparatus, and found no adverse effects to the eyes. Some state OSHA plans may still prohibit the use of contact lenses with respiratory protection; health and safety professionals are advised to consult the applicable regulations.

Because each workplace presents its own unique hazards, the health and safety professional should assess and make the ultimate decision as to the use of contact lenses.

Employees must not insert or remove contact lenses in hazardous environments. In the event of a chemical splash to

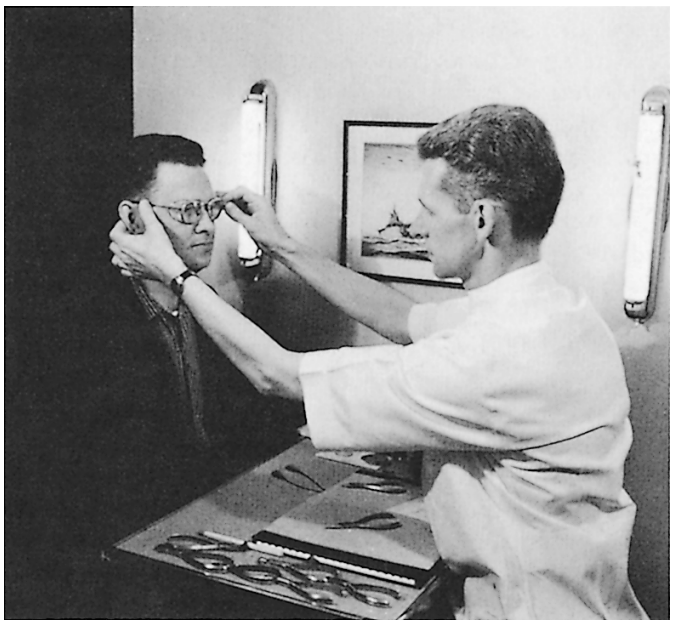

Figure 5–10. Safety glasses should be properly fitted and adjusted.

the eyes, the person should start irrigating the eyes while still wearing the contacts, and remove them while irrigating (often the pressure of the water will force them out of the eyes).

Comfort and Fit

To be comfortable, eye-protective equipment must be properly fitted. Corrective spectacles should be fitted only by a qualified, licensed practitioner. However, a technician can be trained to fit, adjust, and maintain eye-protective equipment. Of course, each worker should be taught the proper care of the device being used.

To give the widest possible field of vision, goggles should be close to the eyes but the eyelashes should not touch the lenses (Figure 5–10).

Various defogging materials are available. Before a selection is made, test to determine the most effective type for a specific application.

In areas where goggles or other types of eye protection are extensively used, goggle-cleaning stations should be conveniently located, along with defogging materials, wiping tissues, and a waste receptacle.

VISION CONSERVATION PROGRAM

There are four steps in a vision conservation program:

1. The environmental survey
2. Vision screening program
3. Remedial program
4. Professional fitting and follow-up procedures

Environmental Survey

The environment should be surveyed by people qualified in occupational health and safety. The survey should assess the likelihood of injury and potential severity of injury from the worker's job operation, the potential for injury from adjacent operations, and the optimum visual acuity requirements for fast, safe, efficient operations.

The environmental survey includes illumination measurements and recommendations for improvements to make the workplace safer. Often, simply cleaning existing lighting can increase illumination 100 percent.

Job working distances and viewing angles should be measured so eye doctors have the necessary information to prescribe lens strengths affording optimum comfort, efficiency, safety, and ergonomic advantage (Figure 5–11).

Each workstation should be free of toxic or corrosive materials and employees should be instructed in the correct use of eyewash facilities. Eyewash fountains should be examined to make certain they work properly and provide an even flow of water.

All environmental factors influencing an employee's visual performance and safety should be written in a visual job description, in terms understandable to the eye doctors who will care for employees with deficient vision.

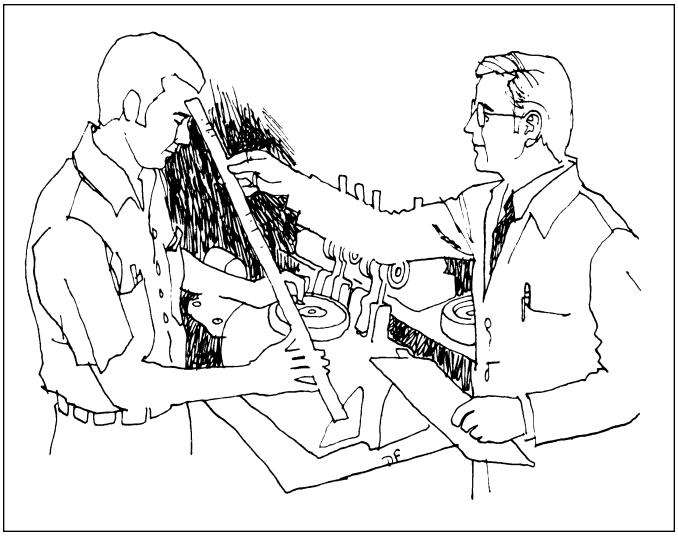

Figure 5–11. Measuring the distance from the eye to the work plane is essential for proper safety vision prescriptions.

Vision Screening Program

The next step, after working conditions and visual requirements are known, is to determine the visual status of the work force. Reliable vision screening instruments are available for use by nurses or trained technicians.

These instruments test the visual acuity in each eye separately, both eyes together, both at near point (usually working distance), both at far point (distant vision), and binocular coordination (the ability to make the two eyes work together). Additional specific tests—such as color vision, field of vision, glaucoma testing, and depth perception—can be added when a need is indicated.

Often, an employee actually performs many jobs. In these instances, recommendations are made after the job most frequently performed is compared with the one most visually demanding.

Remedial Program

Each employee is told the result of his or her vision screening; people showing deficiencies are referred to the eye doctor of their choice. The employee goes to the doctor with the prescription form for safety glasses and a written description of the visual aspect of the job or duties at work. The job description includes recommendations concerning the type of prescription that will make the worker more comfortable and more efficient.

Professional Fitting

The final step in a vision conservation program is professionally fitting the protective and corrective safety eyewear to the employee. Proper fitting and sizing are essential and cannot be correctly done by the tool crib attendant or purchasing agent. Workers come in various sizes and shapes, as do safety glasses. Proper measurement and fitting can be the difference between a successful and an unsuccessful program. A

perfect prescription is useless if the frame hurts so much that it cannot be worn.

This fitting procedure is equally important for employees required to wear nonprescription safety glasses. These employees usually are the most difficult to fit. They are not accustomed to having anything in front of their eyes or feeling weight on their nose or ears. Considerable care must be exercised in the fitting for such employees. Adjustment and alignment should be readily available.

Human vision is not static; it changes constantly. Employees, especially those over age 40, should be advised that gradual, sometimes unnoticed, changes in their vision may affect their safety and efficiency.

Continued testing must be instituted as a health and safety department policy. If no health specialist is employed at the facility, make arrangements for this service with your local health care community. The local academy of ophthalmology or optometry can usually provide trained personnel.

Guidelines

The following guidelines should be a part of every vision conservation program:

- ➢ Make it a 100-percent program; include everyone. Employees will accept it more readily and it will be easier to administer. Promote it well in advance; get union cooperation.
- ➢ Make certain that safety eyewear is properly fitted. A few jobs (welding, labs, lasers) require special types. Optical companies will assist in fitting eyewear and explaining maintenance.
- ➢ Include eye-care stations for first aid and for cleaning lenses.
- ➢ Control eye hazards at the source; install safety glass guards on machines to prevent flying chips or splashing liquids and install enclosures to control fine dusts, mists, or vapors.
- ➢ Make sure all areas have adequate lighting, are free from glare, and are painted in colors that emphasize depth perception and highlight potential hazards.
- ➢ Post signs such as ALL PERSONNEL AND VISITORS MUST WEAR PROTECTIVE EYEWEAR in all hazardous areas.
- ➢ All employees should be given preplacement eye examinations. Periodic follow-up examinations should be scheduled, especially for employees over 40 years of age.

AMA *GUIDES TO THE EVALUATION OF PERMANENT IMPAIRMENT*

This section is adapted from the AMA's *Guides to the Evaluation of Permanent Impairment,* 5th edition. It is included in this chapter to assist health and safety professionals in interpreting and understanding medical reports of workers' compensation cases.

This guide provides a method for determining permanent visual impairment and its effects on a person's ability to perform the activities of daily living. The guide focuses on functional impairment of the visual system as a whole. The fifth edition of the AMA guide, published in 2000, was revised substantially from the fourth edition. They used the consensus document, *Guide to the Evaluation of Visual Impairment,* developed by the International Society for Low Vision Research and Rehabilitation.

A *permanent visual impairment* is defined as a permanent loss of vision that remains after maximal improvement of the underlying conditions has been reached. Measurement of both visual acuity and visual field are obtained, and numerical assessments of these functions are used to derive an estimate of their effect on functional vision—the ability to perform generic activities of daily living.

The guide uses a *Functional Vision Score* (FVS), which is based on an assessment of visual acuity and visual field. *Visual acuity* is described as the ability of the eye to perceive details. *Visual field* refers to the ability to detect objects in the periphery of the visual environment. (See Table 5–A.)

Another important visual function is *contrast sensitivity,* which refers to the ability to detect larger objects of poor contrast. In addition, the guides allow for individual adjustments for other defects such as glare sensitivity, color vision, binocularity, stereopsis, suppression, and diplopia. If these deficits cause a significant loss that is not reflected in a visual acuity or visual field loss, they may be used to adjust the impairment rating.

Clinical Evaluation of Vision Loss

To accurately assess visual impairment, the clinician needs to perform a thorough visual exam, which includes the cause, severity, and prognosis of the underlying disorder and the expected or documented effects of the vision loss on the ability to perform activities of daily living. The assessment should include the following:

- ➢ Medical history with an emphasis on preexisting conditions, treatments, and the major cause of the current vision loss.
- ➢ Current condition of the eyes and visual system, with documentation of anatomic findings.
- ➢ Visual acuity measurements with best correction, binocularity, and for each eye separately.
- ➢ Visual field measurement for each eye.
- ➢ Other visual functions such as contrast sensitivity or color vision.
- ➢ Calculation of an initial impairment rating.
- ➢ Other factors that may affect the individual's ability to perform activities of daily living.
- ➢ Discussion of factors that may cause an adjustment of the initial ability estimate.

The required equipment to perform these tests includes a standardized letter chart, standardized reading tests, visual field equipment, and other tests such as contrast sensitivity tests and glare tests.

Calculating the Visual Impairment Rating

The recommended methods to calculate visual impairment is given in the following (also see Table 5–A):

1. Measure visual acuity and convert to a Visual Acuity Score (VAS). (Table 5–B)
2. Combine acuity scores and use table to determine a Functional Acuity Score (FAS). (Tables 5–C and 5–D)
3. Measure visual fields and convert each to a Visual Field Score (VFS). (Table 5–E)
4. Use table to combine both eyes to obtain a Functional Field Score (FFS). (Table 5–F)
5. Use rules to combine functional acuity score and functional field score to a Functional Vision Score (FVS) (Table 5–A).
6. Subtract the functional vision score from 100 to obtain the impairment rating for the visual system.

If additional visual impairments are not reflected in the reductions of visual acuity or visual field the examiner may make adjustments as described in the section 12.4—Impairment of the Visual System, pages 296–300 in the AMA *Guides to the Evaluation of Permanent Impairment,* 5th edition (see Bibliography). Table 5–D gives classifications of Visual Acuity Impairment (assuming normal visual fields) and Table 5–G gives classification of Visual Field Impairment (assuming normal visual acuity).

For more complete information of assessing visual impairment consult Chapter 12 in the AMA's *Guide to the Evaluation of Permanent Impairment,* 5th ed.

SUMMARY

Ocular anatomy, visual performance, disorders, and problems were discussed. Also covered were potential hazards and how to protect and conserve vision, as well as how to evaluate visual impairment using the fifth edition of the AMA *Guides to the Evaluation of Permanent Impairment.*

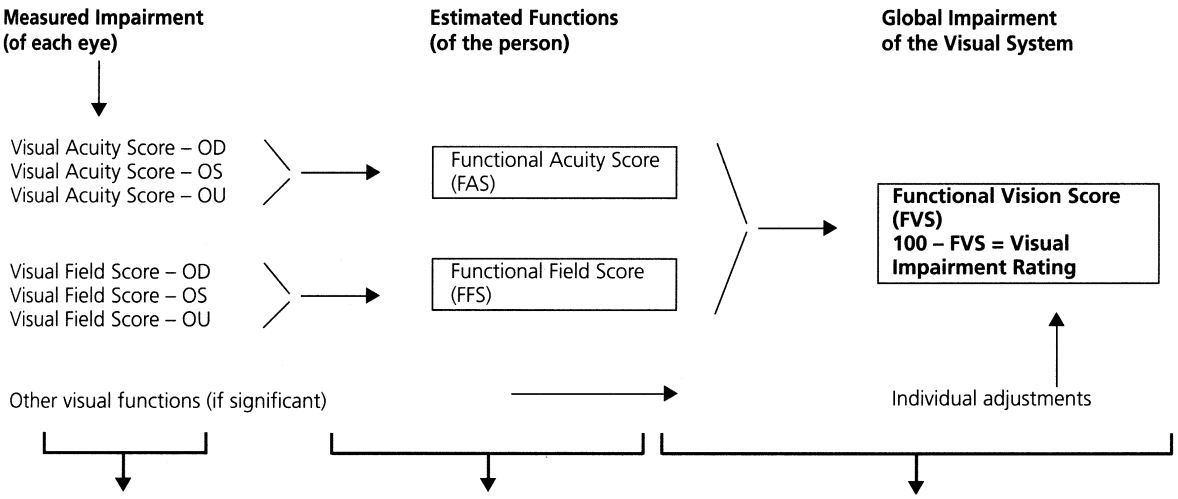
Table 5–A. *Calculation of the Impairment Rating for the Visual System*



1. Use Table 12-2 to convert each of the measured acuity values to a *Visual Acuity Score.*
3. Use Table 12-5 or the rules in Section 12.3c to convert each of the measured field values to determine a *Visual Field Score.*
2. Use Table 12-3 to combine the acuity scores from each eye to determine a single *Functional Acuity Score.*
4. Use Table 12-6 to combine the field scores from each eye to determine a single *Functional Field Score.*
5. Use the rules in Section 12.4 to combine the Functional Acuity Score and the Functional Field Score to determine the *Functional Vision Score.*
6. Make adjustments for other visual function deficits, if significant.
7. Use Table 12-10 to adjust to a whole person impairment.

Note that the prefix *visual* is used when the score refers to each eye. The prefix *functional* refers to the estimated performance of the individual. The term vision *score* combines visual acuity and visual field estimates (and individual adjustments, if significant). Source: *Evaluation of Permanent Impairment*, 5th ed. American Medical Association, copyright 2000.

Table 5–B. ***Impairment of Visual Acuity****

Impairment Classes (Based on *ICD-9-CM*)		Visual Acuity		Visual Acuity Score (ability)	Visual Acuity Impairment Rating (%) (ability loss)	Estimated Reading Ability
		US Notation	1 m Notation			
(Near-) Normal Vision	Range of Normal Vision	20/12.5 20/16 20/20 20/25	1/0.63 1/0.8 1/1 1/1.25	110 105 100 95	... ... 0 5	Normal reading speed Normal reading distance Reserve capacity for small print
	Near-Normal Vision	20/32 20/40 20/50 20/63	1/1.6 1/2 1/2.5 1/3.2	90 85 80 75	10 15 20 25	Normal reading speed Reduced reading distance No reserve for small print
Low Vision	Moderate Low Vision	20/80 20/100 20/125 20/160	1/4 1/5 1/6.3 1/8	70 65 60 55	30 35 40 45	Near-normal with reading aids Uses low-power magnifier or large-print books
	Severe Low Vision	20/200 20/250 20/320 20/400	1/10 1/12.5 1/16 1/20	50 45 40 35	50 55 60 65	Slower than normal with reading aids Uses high-power magnifiers

Add OU, OD, and OS		= ____
Divide by 5 to calculate the weighted average		= ____ = Functional Acuity Score (FAS)
Acuity-Related Impairment Rating = 100 – FAS		= ____

Optionally, calculate a Visual Acuity Score for reading (near) acuity. If the outcome is significantly different from the letter chart acuity score, document the differences and calculate the average:

$$\mathbf{FAS_{global} = (FAS_{letter\ chart} + FAS_{reading})/2}$$

* If visual fields are normal and no individual adjustments are made, the acuity-related impairment rating equals the whole person impairment rating. Source: *Evaluation of Permanent Impairment*, 5th ed. American Medical Association, copyright 2000.

Table 5–D. ***Classification of Visual Acuity Impairment****

Class 1 0%-9% Impairment of Visual Acuity	**Class 2 10%-29% Impairment of Visual Acuity**	**Class 3 30%-49% Impairment of Visual Acuity**	**Class 4 50%-69% Impairment of Visual Acuity**	**Class 5 70%-89% Impairment of Visual Acuity**	**Class 6 90%-100% Impairment of Visual Acuity**
FAS: ≥ 91	FAS: 90-71	FAS: 70-51	FAS: 50-31	FAS: 30–11	FAS: ≤ 10
Range of normal vision	Near-normal vision (mild vision loss)	Moderate vision loss	Severe vision loss	Profound vision loss	(Near-) Total vision loss
Both eyes have visual acuity of 20/25 or better	Both eyes have visual acuity of 20/60 or better	Both eyes have visual acuity of 20/160 or better	Both eyes have visual acuity of 20/400 or better	Both eyes have visual acuity of 20/1000 or better	Both eyes have visual acuity worse than 20/1000
	One eye has 20/200 or less; the other eye is normal	One eye has 20/200 or less; the other eye has 20/80	One eye has 20/200 or less; the other eye has 20/200		

*This table assumes that the visual fields are normal and provides general impairment ranges for the listed conditions. Use Tables 12-2 and 12-3 to calculate a more exact impairment rating and to handle cases of visual acuity loss that are not listed. Proceed to Tables 12-5 and 12-6 if visual field loss is present. Source: *Evaluation of Permanent Impairment,* 5th ed. American Medical Association, copyright 2000.

Table 5–E. ***Impairment of the Visual Field****

Impairment Classes (Based on *ICD-9-CM*)		**Special Conditions**	**Average Radius If Loss Is Concentric**	**Visual Field Score (ability)**	**Visual Field Impairment Rating (%) (ability loss)**	**Estimated Ability for Visual Orientation and Mobility (O + M) Tasks**
(Near-) Normal Vision	Range of Normal Vision		 60°	110 105 100 95	… … 0 5	Normal visual orientation Normal mobility skills
	Near-Normal Vision	 Loss of 1 eye	50° 40°	90 85 80 75	10 15 20 25	Normal O + M performance Needs more scanning Occasionally surprised by events on the side
Low Vision	Moderate Low Vision	 Lost upper field	30° 20°	70 65 60 55	30 35 40 45	Near-normal performance Requires scanning for obstacles
	Severe Low Vision	Hemianopia Lost lower field	10° 8°	50 45 40 35	50 55 60 65	Visual mobility is slower than normal Requires continous scanning May use cane as adjunct
	Profound Low Vision		6° 4°	30 25 20 15	70 75 80 85	Must use long cane for detection of obstacles May use vision as adjunct for identification
(Near-) Blindness	Near-Blindness		2° or less 0°	10 5	90 95	Visual orientation unreliable Must rely on long cane, sound, guide dog, and other blind mobility skills
	Total Blindness	No visual fields		0	100	

* This table follows the clinical usage of describing filed losses on the basis of the remaining radius. In the rehabilitation and disability literature, filed losses are often described on the basis of the remaining diameter (eg, a concentric field loss to a radius of 10° leaves a field with a diameter of 20°). Recognition of Hazards

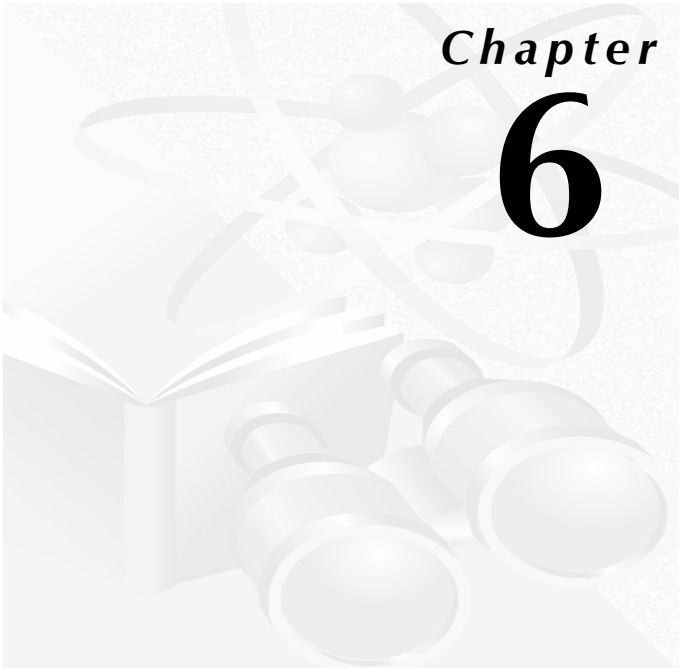
Part III



Chapter 6

Industrial Toxicology

by Richard Cohen, MD, MPH

Toxicology is the science that studies the harmful, or toxic, properties of substances. We are exposed daily to a variety of substances which are not hazardous under usual circumstances. However, any substance contacting or entering the body is injurious at some excessive level of exposure and theoretically can be tolerated without harmful effect at some lower exposure.

DEFINITION

A *toxic effect* is any reversible or irreversible harmful effect on the body as a result of contact with a substance via the respiratory tract, skin, eye, mouth, or other route. Toxic effects are undesirable disturbances of physiological function caused by an overexposure to chemical or physical agents. They also arise as side effects in response to medication and vaccines. Toxicity is the capacity of a chemical to harm or injure a living organism. Toxicity entails the dimension of *quantity* or *dose;* the toxicity of a chemical depends on the degree of exposure and absorption.

Many chemicals essential for health in small quantities are highly toxic in larger quantities. Small amounts of zinc, manganese, copper, molybdenum, selenium, chromium, nickel, tin, potassium, and many other chemicals are essential for life. However, severe acute and chronic toxicity may result from an uptake of large amounts of these materials. For example, nickel and chromium in some of their forms are considered carcinogens.

The responsibility of the industrial toxicologist is to define how much is too much and to prescribe precautionary measures and limitations so that usual or recommended use does not result in the absorption of too much of a particular substance. From a toxicological viewpoint, the industrial hygienist must consider all types of exposure and the subsequent effects on the living organism.

Toxicity Versus Hazard

Toxicity and hazard differ. Toxicologists consider toxicity as the ability of a substance to produce an unwanted effect when the substance has reached a sufficient concentration at a certain site in the body; hazard is regarded as the probability that this concentration will occur at that site. Many factors contribute to determining the degree of hazard—route of entry, quantity of exposure, physiological state, environmental variables, and other factors. Assessing a hazard involves estimating the probability that a substance will cause harm. Toxicity, along with the chemical and physical properties of a substance, determines the level or degree of hazard. Two liquids can possess the same degree of toxicity but present different degrees of hazard. One may be odorless and not irritating to the eyes and nose whereas the other may produce a pungent or disagreeable odor at a harmless concentration. The material with the warning properties at harmless concentrations may present a lesser degree of hazard; its presence can be detected in time to avert injury.

Some chemical agents are not selective in their action on tissues or cells; they can exert a harmful effect on all living matter. Other chemical agents act only on specific cells. Some agents are harmful only to certain species; other species have built-in protective mechanisms.

The term *toxicity* is commonly used in comparing one chemical agent with another but is meaningless without data designating the biological species used and the conditions under which the harmful effects were induced.

A chemical stimulus can be considered to have produced a toxic effect when it satisfies the following criteria:

- An observable or measurable physiological deviation has been produced in any organ or organ system. The change can be anatomic in character and may accelerate or inhibit a normal physiological process, or the deviation can be a specific biochemical change.
- The observed change can be duplicated from animal to animal even though the dose-effect relationships vary.
- The stimulus has changed normal physiological processes in such a way that a protective mechanism is impaired in its defense against other adverse stimuli.
- The effect is either reversible or at least attenuated when the stimulus is removed.
- The effect does not occur without a stimulus or occurs so infrequently that it indicates generalized or nonspecific response. When high degrees of susceptibility are noted, equally significant degrees of resistance should be apparent.
- The observation must be noted and must be reproducible by other investigators.
- The physiological change reduces the efficiency of an organ or function and impairs physiological reserve in such a way as to interfere with the ability to resist or adapt to other normal stimuli, either permanently or temporarily.

Though the toxic effects of many substances used in industry are well known, the toxicity of others is not yet well defined. Although certain important analogies are apparent between structure and toxicity, important differences exist that require individual study of each compound.

In addition to establishing toxicity, evaluation of a chemical hazard involves establishing the amount and duration of exposure, the physical characteristics of the substance, the conditions under which exposure occurs, and the determination of the effects of other substances in a combined exposure. All of these may significantly influence the toxic potency of a substance.

The chemical properties of a compound are often one of the main factors in its hazard potential. Vapor pressure (an indicator of how quickly a liquid or solid evaporates) partially determines whether a substance has the potential to pose a hazard from inhalation. Many solvents are quite volatile and vaporize readily into the air to produce high concentrations of vapor. Hence, a solvent with a low boiling point would be a greater hazard than an equally toxic solvent with a high boiling point simply because it is more volatile and it evaporates faster.

Chemical injury can be local or systemic, and the toxicological reactions can be slight or severe. Local injury results from direct contact of the irritant with tissue. The skin can be severely burned or the surface of the eye can be injured to the extent that vision is impaired. In the respiratory tract, the lining of the trachea and the lungs can be injured as a result of inhaling toxic amounts of vapors, fumes, dusts, or mists.

ENTRY INTO THE BODY

In discussing toxicity, it is necessary to know how a substance enters the body and, if relevant, the bloodstream. For an adverse effect to occur, the toxic substance must first reach the organ or bodily site where it causes damage. Common "routes of entry" are inhalation, skin absorption, ingestion, and injection. Depending on the substance and its specific properties, however, entry (absorption) can occur by more than one route, such as inhaling a solvent that can also penetrate the skin.

Inhalation

For industrial exposures, a major, if not predominant route of entry is inhalation. Any airborne substance can be inhaled.

The respiratory system is composed of two main areas: the upper respiratory tract airways (the nose, throat, trachea, and major bronchial tubes leading to the lobes of the lungs) and the alveoli, where the actual transfer of gases across thin cell walls takes place. For particles, only those smaller than about 5 μm in diameter are likely to enter the alveolar sac.

The total amount of a toxic compound absorbed via the respiratory pathways depends on its concentration in the air, the duration of exposure, and the pulmonary ventilation volumes, which increase with higher work loads. If the toxic substance is present in the form of an aerosol, deposition

and absorption occur in the respiratory tract. For more details, see Chapter 2, The Lungs.

Gases and vapors of low water solubility but high fat solubility pass through the alveolar lining into the bloodstream and are distributed to organ sites for which they have special affinity. During inhalation exposure at a uniform level, the absorption of the compound into the blood reaches an equilibrium with metabolism and elimination.

Skin Absorption

An important route of entry for some chemicals is absorption through skin. Contact of a substance with skin results in these four possible actions:

- ➢ The skin can act as an effective barrier
- ➢ The substance can react with the skin and cause local irritation or tissue destruction
- ➢ The substance can produce skin sensitization
- ➢ The substance can penetrate skin to reach the blood vessels under the skin and enter the bloodstream

For some substances (such as parathion), the skin has been the main portal of entry in many toxic occupational exposures. For other substances (such as aniline, nitrobenzene, and phenol), the amounts absorbed through the skin are roughly equivalent to the amounts absorbed through inhalation. For the majority of other organic chemicals, the contribution from skin (cutaneous) absorption to the total amount absorbed is significant. Hence, toxic effects can occur because of cutaneous penetration.

The cutaneous absorption rate of some organic chemicals rises when temperature and perspiration increase. Therefore, absorption can be higher in warm climates or seasons. The absorption of liquid organic chemicals may follow surface contamination of the skin or clothes; for other compounds, it may directly follow the vapor phase, in which case the rate of absorption is roughly proportional to the air concentration of the vapors. The process involves a combination of deposition of the substances on the skin surface followed by absorption through the skin.

The physicochemical properties of a substance determine absorption potential through intact skin. Among the important factors are skin pH and the chemical's extent of ionization, aqueous and lipid solubilities, and molecular size.

Human skin shows great differences in absorption at different anatomic regions, primarily due to differences in thickness. The skin on the palm of the hand has approximately the same penetration potential as that of the forearm for certain organic phosphates. The skin on the back of the hand and the skin of the abdomen have twice the penetration potential of the forearm, whereas follicle-rich sites such as the scalp, forehead, and scrotum show a much greater penetration potential. High temperatures generally increase skin absorption by increasing vasodilation and sweating. If the skin is damaged by abrasion dermatitis, the normal protective barrier to absorption of chemicals is lessened and penetration occurs more easily. (See Chapter 3, The Skin, for more information.)

Ingestion

The problem of ingesting chemicals is not widespread in industry; most workers do not deliberately swallow materials they handle. Nevertheless, workers can ingest toxic materials as a result of eating in contaminated work areas; contaminated fingers and hands can lead to accidental oral intake when a worker eats or smokes on the job. They can also inhale materials when contaminants deposited in the respiratory tract are carried out to the throat by the action of the ciliated lining of the respiratory tract. These contaminants are then swallowed and significant absorption of the material may occur through the gastrointestinal tract. Approximately one quart of mucus is produced daily in an adult's lungs. This constant flow of mucus can carry contaminants out of the lungs into the throat to be swallowed with the saliva or coughed up and expectorated.

Toxicity after ingestion is generally lower than the inhalation toxicity for the same dose and substance because absorption of many substances across the intestinal wall and into the bloodstream is relatively poor. Food and liquid mixed with a toxic substance not only provide dilution, but can combine with it to form less soluble substances. Also, action of digestive acids and enzymes can chemically alter the substance and reduce its toxicity. After absorption via any route into the bloodstream, the substance may enter the liver, which metabolically alters, degrades, or detoxifies many substances. This detoxification process is an important body defense mechanism. Basically, detoxification involves chemical reactions, which in some cases change the substance to a less toxic or more water-soluble compound.

Injection

Although infrequent in industry, a substance can be injected into some part of the body. This can be done directly into the bloodstream, peritoneal cavity, pleural cavity, skin, muscle, or any other place a needle or high-pressure orifice can reach. The effects produced vary with the location of administration. In industrial settings, injection is an infrequent route of worker chemical exposure.

There is increasing attention to prevention of skin puncture and injection injuries associated with bloodborne pathogens (hepatitis B, HIV, and hepatitis C). Risk of infection is significant following accidental skin puncture by a needle or instrument contaminated with infected blood or tissue.

In the laboratory, toxic substances are injected into animals because it is far more convenient and less costly than establishing blood levels by inhalation or skin exposures. Intravenous injection sidesteps protective mechanisms in the body that prevent substances from entering the blood.

DOSE–RESPONSE RELATIONSHIP

A fundamental consideration in toxicology is the *dose–response relationship*. In animal studies, a dose is administered

to test animals and increased or decreased until a range is found where at the upper end all animals show a preselected health effect (e.g., death, injury) and, at the lower end, all animals are absent the health effect. The data collected are used to prepare a dose-response curve relating health effect incidence to dose administered (Figure 6–1).

The doses given are expressed as the quantity administered per unit body weight, quantity per skin surface area, or quantity per unit volume of respired air. In addition, the length of time during which the dose was administered should be listed.

The dose–response relationship can also be expressed as the product of a concentration (C) multiplied by the time duration (T) of exposure. This product is proportional more or less to a constant (K); or mathematically, $C \times T \approx K$. The dose involves two variables—concentration and duration of exposure. For certain chemicals, a high concentration breathed for a short time produces the same effect as a lower concentration breathed for a longer time. The CT value provides a rough approximation of other combinations of concentration of a chemical and time that would produce similar effects. Although this concept must be used very cautiously and cannot be applied at extreme conditions of concentration or time, it can be useful in predicting safe limits for some airborne contaminants in the workplace. Regulatory exposure limits are set so that the combination of concentrations and time durations are theoretically below the levels that produce injury to exposed individuals.

Threshold Concept

For most chemicals there is a *threshold of effect* or a *no-effect level.* The most toxic chemical known, if present in small enough amounts, produces no measurable effect. It may damage one cell or several cells, but no measurable effect, such as kidney dysfunction, will result. As the dose is increased, there is a point at which the first measurable effect is noted or at which the incidence of a health effect in the exposed population exceeds its incidence in unexposed populations. The (toxic) potency of a chemical is defined by the relationship between the dose (amount) of the chemical and the response produced in a biological system. A high concentration of toxic substance in the target organ causes a severe reaction and a low concentration causes a less severe or no reaction.

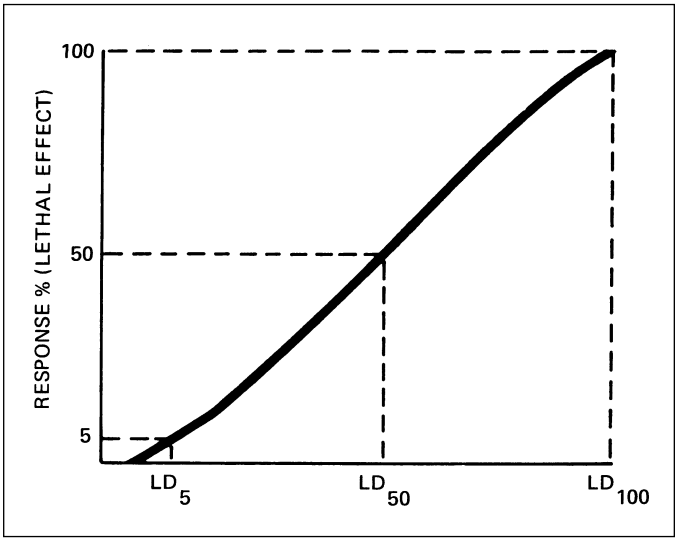


Figure 6–1. Dose-response curves for a chemical agent administered to a uniform population of test animals. (LD=lethal dose; number shown after LD indicates the percent of exposed animals that are affected. LD_{50} means that dose given at which 50 percent of exposed animals died.)

The word *toxic* relates to the dose or amount of a substance necessary to cause injury, illness, or significant adverse health effect. If that dose is low compared to the harmful dose for other substances, it is described as more "toxic." In other words, although all substances produce harmful effects at some dose, a toxic substance causes harmful effects at low doses.

Although most exposures in industry occur by way of the respiratory tract or skin, most published dose-response data are found in studies of experimental animals. In these experiments, the test substances were usually administered by mouth (in food, in drinking water, or by intubation [tube] directly into the stomach) or injection (intravenous, intramuscular, intraperitoneal, etc.).

The harmfulness of a material depends on its chemical composition, the type and rate or level of exposure, and the fate of the material in the body. For many substances, a single large dose of a toxic substance produces a greater response than the same total dose administered in small amounts over a long period of time. Each of the small amounts can be detoxified quickly but a large dose produces its detrimental action before appreciable detoxification occurs. If a substance is detoxified or excreted at a rate slower than the rate of intake, it may cause continuing (cumulative) effects.

Accumulation of a substance in the body is understood as a process in which the level of the substance increases with the duration of exposure and can apply to both continuous and repeated exposure. Biological tests of exposure show that an accumulation is taking place when rising levels of the substance are seen in the urine, blood, or expired air (Figure 6–2).

Exposure thresholds are most easily determined (and more available) for effects occurring soon after exposure. Other effects such as reproductive defects and cancer occur months or years after exposure began. Dose-related data are often imprecise in human epidemiological studies. For these and other reasons, thresholds for some carcinogens (such as asbestos) have not been identified and are considered to be zero.

Because different biological mechanisms are involved in reproductive toxicity, attempts are being made to identify exposure levels (mostly from animal studies) below which no

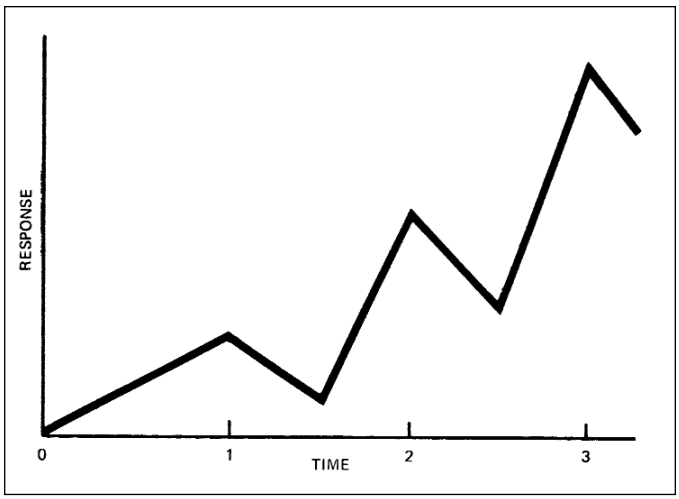

Figure 6–2. Accumulation of a substance in a body is shown in this curve; in this example the level of the substance increases with the duration of exposure.

evidence of injury or impairment can be found; these are called the *No Observable Effect Level* (NOEL).

Lethal Dose

If a number of animals are exposed to a toxic substance, when the concentration reaches a certain level, some but not all of those animals will die. Results of such studies are used to calculate the *lethal dose* (LD) of toxic substances.

If the only variable being studied is the number of deaths, it is possible to use the concept of the LD. The LD_{50} is the calculated dose of a substance that is expected to kill 50 percent of a defined experimental animal population, as determined from the exposure to the substance by any route other than inhalation.

Several designations can be used, such as LD_{50}, LD_0, LD_{100}, and so on. The designation LD_0, which is rarely used, is the concentration that produces no deaths in an experimental group and is the highest concentration tolerated in animals; LD_{100} is the lowest concentration that kills 100 percent of the exposed animals. Although LD_{50} is the concentration that kills half of the exposed animals, it does not mean that the other half are in good health.

Normally, LD_{50} units are the weight of substance per kilogram of animal body weight, usually milligrams per kilogram. The LD_{50} value should be accompanied by an indication of the species of experimental animal used, the route of administration of the compound, the vehicle used to dissolve or suspend the material, if applicable, and the time period during which the animals were dosed and observed.

The slope of the dose-response curve provides useful information. It suggests an index of the margin of safety, or the magnitude of the range of doses between a noneffective dose and a lethal dose. If the dose-response curve is very steep, this margin of safety is slight. One compound could be rated as more toxic than a second compound because of the shape and slope of the dose-response curve (Figure 6–3).

Lethal Concentration

When considering inhalation exposures, the dose by inhalation is needed. *Lethal concentration* (LC) is used for airborne materials. Airborne concentrations may be expressed as *mg/m*^{3} (*milligrams per cubic meter*) or *ppm* (*parts per million*). An LC_{50} means that when a defined experimental animal population is exposed to a calculated concentration of a substance, that concentration (expressed in mg/m^3 or ppm) is expected to kill 50 percent of the animals in a stated length of time.

The duration of exposure is very important because a half-hour exposure might produce an effect that is significantly different in severity or character from that of a 24-hour exposure.

Data accompanying LCs should state the species of animal studied, the length of time the exposure was maintained, and the length of time observation was carried out after exposure.

The dose should be delivered in a specified length of time followed by observation for another specified period of time—this may be hours or days, or even several years when testing for carcinogenesis. For example, in one study animals were exposed for a short time to nitrogen dioxide (NO_2). Initially, there was no observable response, but 36 hours after the exposure, the animals developed a chemical pneumonia and ultimately died. If the animals had been observed for only the first 24 hours after the exposure, the health effects that occurred in the second 24-hour period would have been missed.

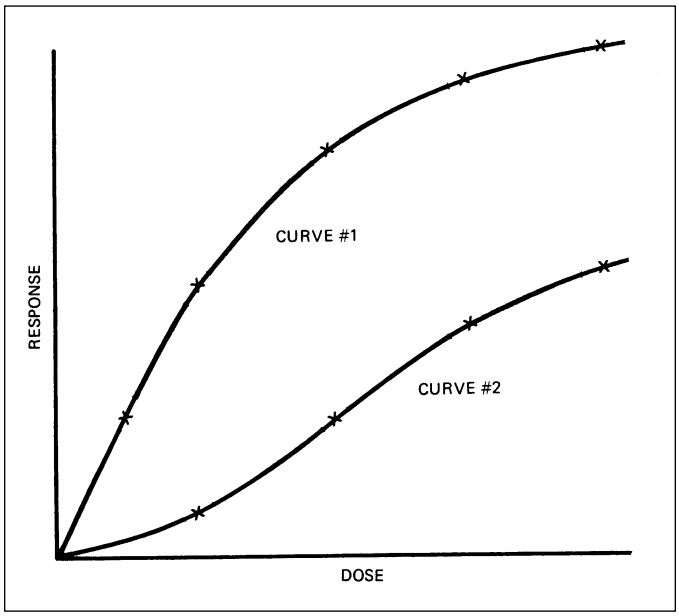

Figure 6–3. The chemical represented by curve #1 has a lower margin of safety and greater toxicity than the curve #2 chemical. In curve #1, the response increases more rapidly as dose increases.

Table 6–A. ***Brief Comparison of Acute, Prolonged, and Chronic Toxicity Tests***

	Acute	*Prolonged*	*Chronic*
Exposure lasts . . .	≤ 24 hours, usually single dose	Typically 2, 4, or 6 weeks	≥ 3 months
Typically yields . . .	Single lethal dose, clinical signs of toxicity	Cumulative dose (if any), major metabolic routes, detoxification or excretion	Potential for carcinogenic effect or other delayed effects
Exemplified by . . .	Potassium cyanide rapidly depriving tissues of oxygen	Carbon tetrachloride causing destruction of liver cells after repeated exposure over several weeks	Carbon tetrachloride causing liver cancer following prolonged exposure (and observation)

Responses

After a substance has been administered, there are criteria the toxicologist uses to evaluate the response.

Examining the organs removed from exposed animals reveals the site of action of the agent, mode of action, and cause of death. Important pathological changes in tissues can be observed following dose levels below those needed to produce the death of animals. The liver and the kidney are particularly sensitive to the action of many agents.

The effect of the agent on the growth rate of the animals is another criterion of adverse response. Relatively low levels of substances that do not produce death or signs of serious illness can result in a diminished rate of growth. The food intake must also be measured to learn whether loss of appetite was a cause of diminished growth.

Changes in the ratio of organ weight to body weight can be used as a criterion of adverse response. In some instances, such alterations are specific to the chemical being tested; for example, an increase of lung weight to body weight ratio can result from pulmonary edema (accumulation of fluid) produced by irritants including ozone and oxides of nitrogen.

Physiological function tests are useful in animal studies and in assessing the response of exposed workers. They can be especially useful in studies of populations with chronic conditions.

Substances can then be rated according to their relative toxicity based on animal data (and human data, if available). Unfortunately, animal experimental data are difficult to interpret and may not apply to human exposure, response, or pathophysiology. Nevertheless, because human dose-response data are not available for most substances, animal data are valuable in estimating the likely range of toxicity of a substance as well as in guiding further investigation.

TIMING: EXPOSURE AND EFFECT

The toxic action of a substance can be arbitrarily divided into acute and chronic effects. In addition to acute and chronic toxicity, we can distinguish acute and chronic exposures (Table 6–A).

Factors other than immediate effects often determine the type and severity of a chemical's adverse effects. For example, acute benzene toxicity (narcosis) has a different clinical picture from that of chronic toxicity (bone marrow depression, leukemia).

Acute Effects and Acute Exposures

Acute exposures and *acute effects* generally involve short-term, high concentrations, and immediate or prompt health effects (illness, irritation, or death). Acute occupational exposures are often related to an accidental exposure.

Acute exposures typically are sudden, of short duration, and are characterized by rapid absorption of the offending material. For example, inhaling high levels of carbon monoxide or swallowing a large quantity of cyanide compound produces illness very rapidly. The health effect of a chemical exposure is considered "acute" when it appears within a short time following exposure, such as within minutes or hours, and the health effect is relatively short-lived.

Chronic Effects and Chronic Exposures

In contrast to acute effects, *chronic effect* or illness is characterized by symptoms or disease of long duration or frequent recurrence. Chronic effects usually develop slowly.

Chronic exposure refers to exposure continued or repeated for a prolonged period, usually years. Standard-setting organizations now try to establish limits that control chronic as well as acute exposures.

Chronic exposure may cause a substance to be continuously present in the tissues. Chronic health effects, illness, or injury can be produced by exposure to a harmful substance that produces irreversible damage so that the injury, rather than the substance, accumulates or progresses. The symptoms of chronic effects are usually different from those seen in acute injury by the same agents. In chronic exposure settings, the level of exposure is often relatively low; the worker is often unaware of the exposures as they occur.

EFFECTS OF EXPOSURE TO AIR CONTAMINANTS

Air contaminants can be classified on the basis of pathophysiological action into irritants, allergens, systemic toxins, or site-specific or organ-specific toxins.

Responses to toxic substances depend on the concentration and duration of exposure. For example, a vapor or gas at one concentration can exert its principal action on the body as an anesthetic, whereas at a lower concentration for a longer exposure time, the same gas or vapor can injure some internal organ or the blood system without causing CNS depression or anesthesia.

Irritation

Irritation is an inflammation or aggravation of the tissue the substance contacts. Contact of some substances with the face and upper respiratory system affects the eyes, the cells lining the nose, and the mouth.

There are many industrial chemicals that at fairly low concentrations irritate tissues with which they come in contact. Irritation results from direct mechanical or chemical (most frequent) reaction with constituents in the tissue having contact. Irritation or inflammation is the major health effect of corrosives.

Many irritants are liquids; for many of these, the degree of local irritation is unrelated to their systemic toxicities. Sometimes differences in viscosity are the determining factors in the type of injury. This applies especially in the lungs, where the inhalation hazard from a substance of low viscosity, such as kerosene, is quite different and more severe than the hazard from a higher viscosity substance such as mineral oil.

To a large extent, the solubility of an irritant gas or vapor influences the part of the respiratory tract that is affected (Table 6–B).

Ammonia, which is very soluble in water, irritates the nose and throat, primarily because the moisture on the surface absorbs and reacts quickly with ammonia. Nitrogen dioxide, which is much less water soluble, acts mainly on the deeper tissues in the lungs as a result of its slower reaction with water/mucous-coated lung structures. Some irritants produce acute pulmonary edema (fluid in lungs), which usually begins as an immediate or intense inflammation that is later manifested by coughing, difficulty breathing, shortness of breath, cyanosis, or coughing up large amounts of mucus. With other chemicals, irritation can be delayed or an immediate reaction can be followed by a period of remission, typically a few hours for phosgene or 24–48 hours for nitrogen oxides. Sensitizing irritants, such as toluene diisocyanate, induce asthmatic bronchitis.

Respiratory irritants can be inhaled in gaseous or vapor form, as a mist, or as particles with a coating of absorbed liquid. Irritants are often grouped according to their site of action (Table 6–B).

Irritants can be subdivided into *primary* and *secondary irritants.* A *primary irritant* is a material that exerts little systemic toxic action, either because the products formed on the tissues of the respiratory tract are nontoxic or because the irritant action at the contact site is far greater than any systemic toxic action.

A *secondary irritant* produces irritant action on mucous membranes, but this effect is overshadowed by systemic effects resulting from absorption. Examples of materials in this category are many of the aromatic hydrocarbons and other organic compounds. The direct contact of liquid hydrocarbons with the lung can cause chemical pneumonitis. Thus, in the case of accidental ingestion of these materials, inducing vomiting is not recommended because some of the vomited hydrocarbon could be breathed (aspirated) into the lungs.

Irritation is generally reversible after short-term exposures. If a worker goes into a cloud of ammonia, immediate irritation is experienced and unless the worker is greatly overexposed, the sensation of pain and irritation will be largely gone very shortly after removal from exposure. However, temporary damage to the respiratory epithelium can make the worker susceptible to other irritants that would otherwise be tolerated. Corrosive substances, such as strong acids and caustics, by contrast, can cause irreversible tissue damage or destruction.

Allergens

Allergens are agents that cause recurrent effects after the worker becomes sensitized (allergic) to the substance. The first few exposures may cause no reaction, but once a person becomes sensitized, reactions can occur from later contact with very small quantities for very short periods of time.

Allergy to a substance almost always presents as eye, skin, or respiratory tract inflammation. Allergic skin effects appear as itching, hives, or eczema (redness, small blisters, cracking). Respiratory skin effects of allergy appear as nasal congestion, sneezing, discharge, or less commonly asthma (bronchospasm) or pneumonia. Eyes can also manifest allergy as itching, redness, or swollen eyelids. Allergy due to industrial exposures does *not* affect the nervous system, liver, kidney, heart, or most other organ systems. Most allergic effects or symptoms begin within minutes or hours following exposure depending on the agent and type of allergy. Symptoms will recur with reexposure.

In other words, allergy causes only eye, skin, or respiratory tract response after exposure to airborne levels often far below PELs, TLVs®, or other occupational guidelines. Once a person develops an allergy to a substance, it will persist for years, if not for life. The occurrence of allergy to one substance does not predict future allergy to another substance although those with allergies to one substance are more likely to develop additional allergies.

Allergy, also known medically as "hypersensitivity," is often confused with hypersusceptibility. *Hypersusceptibility* refers to the occurrence of the usual health effects caused by a substance following exposures to air levels below that associated with effects for most individuals. The substance affects its usual target but at lower doses. If exposure ends, there is no immunologic memory, in contrast to allergy.

Many agents can cause allergic contact dermatitis, including nickel, chromium salts, poison ivy or oak, and epoxy constituents. Known causes of allergic asthma following inhalation exposure include isocyanates, platinum salts, some wood dusts, animal dander, and organic anhydrides. Allergic pneumonia (hypersensitivity pneumonitis) is caused by some molds (farmer's lung) and sugar cane residue (bagassosis).

Table 6–B. ***Comparison of Several Irritants Affecting the Respiratory Tract***

Substance	*Description*	*TLV (2001)**	*Concentrations Exceeding TLV*
		A. Irritants Affecting Upper Respiratory Tract	
Formaldehyde (HCHO)	Aldehyde, colorless gas at ordinary temperatures. Soluble in water up to 55%. (Formalin is aqueous solution).	TLV = 0.3 ppm ceiling based on complaints of irritation <1 ppm, constant prickling irritation, disturbed sleep. Suspected carcinogen.	10–20 ppm causes severe difficulty in breathing, intense lacrimation, severe cough.
Acrolein (CH_2=CHCHO)	Aldehyde, colorless or yellowish liquid. Water soluble.	TLV = 0.1 ppm ceiling low enough to minimize, but not entirely prevent, irritation in exposed individuals.	1 ppm may be strongly irritating to eyes and nose within five minutes or less. 8–10 ppm lethal within four hours or less; 100 ppm and above may be lethal within a short time.
Ammonia (NH_3)	Alkali, colorless gas. Soluble in water; pungent odor detected as low as 1 ppm.	TLV = 25 ppm should protect against irritation to eyes and respiratory tract, minimize complaints of discomfort among unacclimated individuals.	Irritation of respiratory tract and conjunctiva in workers inhaling 100 ppm. Severe eye damage, lung and airway dysfunction at higher concentrations.
Sulfur dioxide (SO_2)	A colorless nonflammable gas with acid odor, pungent taste, one of the most common community air pollutants.	TLV SO_2 = 2 ppm expected to prevent irritation and accelerated loss of pulmonary function in most workers.	High acute exposure causes intense irritation, death may follow from suffocation due to respiratory paralysis or pulmonary edema. Industrial poisoning usually chronic—may develop as pulmonary dysfunction progressing to emphysema.
		B. Irritants Affecting Both Upper Respiratory Tract and Lung Tissues	
Chlorine (Cl_2)	Halogen, greenish-yellow gas with suffocating odor, which may be noticeable at 1–4 ppm. Soluble in water up to 0.8% by weight.	TLV = 0.5 ppm to minimize chronic lung changes, accelerated aging, teeth erosion.	30 ppm produces intense coughing.
Ozone (O_3)	Bluish or colorless explosive gas or blue liquid. Pleasant characteristic odor in concentrations of less than 2 ppm. Slightly water-soluble, used as disinfectant.	TLV = 0.05 ppm (heavy work), which causes no symptoms but may result in slightly reduced lung function.	Daily intermittent exposure above 5 ppm may cause incapacitating pulmonary congestion. Lung function changes are dose-dependent and reversible at lower doses.
		C. Irritants Affecting Primarily Terminal Respiratory Passages and Air Sacs	
Nitrogen dioxide (NO_2)	Reddish-brown gas with irritating odor. Decomposes in water, nitric acid (HNO_3), and nitric oxide (NO).	TLV = 3 ppm, considered sufficiently low to ensure against reduced respiratory function.	10–20 ppm may cause mucosal irritation or chronic disease. 100–500 ppm may lead to sudden death, insidious, delayed, and potentially lethal pulmonary edema (most characteristic), delayed inflammatory changes leading to death several weeks after exposure.
Phosgene (carbonyl chloride) ($COCl_2$)	Colorless, nonflammable gas. Suffocating odor when concentrated, otherwise odor suggestive of decaying fruit or moldy hay. Slightly soluble in water and hydrolyzed by it.	TLV = 0.1 ppm because of its irritating effects on the respiratory tract at levels slightly above 0.1 ppm.	3 ppm causes immediate throat irritation, 50 ppm rapidly lethal.

TLVs are from the ACGIH 2001 TLVs® and BEIs®.

SYSTEMIC TOXINS

Asphyxiants are systemic toxins that interfere with oxygenation of the tissues and the affected individual may suffocate. This class is divided into *simple asphyxiants* and *chemical asphyxiants*.

Simple Asphyxiants

Simple asphyxiants are most often inert gases that dilute or displace atmospheric oxygen from the breathing zone or air supply. Blood levels become insufficient for normal tissue respiration. Common examples are carbon dioxide, ethane, helium, hydrogen, methane, and nitrogen. However, any substance in gaseous form can replace oxygen in the breathing zone and in excessive quantity cause asphyxiation.

Asphyxiants deprive the body of the needed oxygen that must be transported from the lungs via the bloodstream to all cells. With complete deprivation of oxygen, brain cells die in 3–5 min. Total asphyxiation leads to complete absence of oxygen in the blood (anoxia). Partial asphyxiation leads to low levels of oxygen in the blood (hypoxia). If allowed to continue too long, hypoxia also can result in brain damage or death.

Chemical Asphyxiants

Through their direct chemical action, chemical asphyxiants prevent the uptake of oxygen by the blood, interfere with the transportation of oxygen from the lungs to the tissues, or prevent normal oxygenation of tissues even when the blood is well oxygenated. Carbon monoxide prevents oxygen transport by preferentially combining with hemoglobin. Hydrogen cyanide inhibits enzyme systems, particularly the cytochrome oxidase system necessary for cellular oxygen use. Hydrogen sulfide paralyzes the respiratory center of the brain and the olfactory nerve. At sufficiently high levels, all three of these chemical asphyxiants can cause almost instantaneous collapse and unconsciousness (Table 6–C).

The principal action of carbon monoxide is its interference with the delivery of oxygen to the tissues. The concentration of carbon monoxide required to cause death is small compared with the lethal amount for simple asphyxiants. Carbon monoxide occupies oxygen's usual binding site on hemoglobin, thus preventing the transport of oxygen through the bloodstream to all cells. Hemoglobin combines with carbon monoxide much more readily than it does with oxygen by a ratio of approximately 300 to 1.

Another example of a chemical asphyxiant is hydrogen cyanide. It is transported by the bloodstream to the individual cells of the body, where it blocks oxygen uptake at the cellular level by combining with the enzymes that control cellular oxidation.

Organ-Specific Effects

Most substances do not damage all organs or systems, but affect a few or one specific organ. For example, most organic hydrocarbons cause central nervous system (brain) depression; corrosive acids and alkalis injure skin, mucous membranes, eyes, and lungs. Some agents cause unique effects, such as cancer (e.g., benzene), reproductive effects (e.g., lead) or even liver damage (e.g., carbon tetrachloride) This section highlights a selection of organ-specific effects and their causative substances.

CENTRAL NERVOUS SYSTEM DEPRESSANTS

Central nervous system depressants (CNSDs) exert their principal action by causing simple anesthesia without serious systemic effects, unless the dose is massive. Depending on the concentration, the depth of anesthesia ranges from mild symptoms (e.g., headache, dizziness, lack of coordination, confusion) to complete loss of consciousness and death.

CNSDs include aliphatic alcohols (such as ethyl and propyl), aliphatic ketones (such as acetone and methyl-ethyl-ketone), aromatic hydrocarbons, ethers (such as ethyl and isopropyl), and short-chain halogenated hydrocarbons.

CARDIAC SENSITIZATION

Inhalation of certain volatile hydrocarbons can make the heart abnormally susceptible to epinephrine (adrenalin). The epinephrine then causes abnormal, dangerous cardiac rhythms, usually ventricular in origin. This has been observed with solvent misuse such as sniffing aerosols or glue, and exposure to some industrial solvents (chlorocarbons) and chlorofluorocarbon (CFC) refrigerants at levels grossly exceeding the recommended TLV.

NEUROTOXIC EFFECTS

Neurotoxic agents damage the nervous system. Metals such as manganese, lead, and mercury are examples. The central nervous system seems particularly sensitive to organometallic compounds.

A different neurotoxic effect involves acetylcholine, a neurotransmitter. In the transfer of electrical impulses (nerve conduction) from one part of the nerve to the next part, the chemical acetylcholine is essential, and the enzyme cholinesterase maintains acetylcholine at the proper levels. When acetylcholinesterase is inhibited, the acetylcholine increases and may reach a level incompatible with the orderly transfer of electrical impulses.

Nerve conduction abnormalities occur that result in nervous system failure. Some cholinesterase inhibitors include organic phosphate and organophosphate pesticides such as parathion or carbamate pesticides such as carbofuran.

Other neurotoxic effects include neurasthenia and peripheral neuropathy. Neurasthenia involves emotional irritability and loss of intellectual function; it is associated with prolonged (years) exposure to some hydrocarbon solvents (such as styrene and toluene). Peripheral neuropathy involves loss of limb strength or sensation; it is associated with exposure to agents such as lead, hexane, and acrylamide.

PULMONARY EFFECTS

In considering health effects from inhaled dust, primary concern is given to solid material that is small enough to enter

Table 6–C. ***Comparison of Some Chemical Asphyxiants***

Substance	*Description*	*TLV 2001*	*Concentrations Exceeding TLV*
Hydrogen cyanide (HCN)	Colorless liquid or gas, flammable, inhibits cellular respiration, almond-like odor.	TLV = 4.7 ppm (5 mg/m^3) ceiling, which may give a seven or eightfold margin against lethal effects.	18–36 ppm causes slight symptoms after several hours, 90 ppm fatal after 30 to 60 minutes, 270 ppm immediately fatal.
Carbon monoxide (CO)	Colorless, odorless gas, sparingly soluble in water, that combines with hemoglobin to form carboxyhemoglobin (COHb), which interferes with oxygen transport to tissues and removal of CO_2 from tissues.	TLV = 25 ppm (29 mg/m^3), based on an air concentration that should not generally result in COHb levels above 10%. Heavy labor, high temperatures, or altitudes 5,000– 8,000 feet above sea level may require 25 ppm TLV.	Fatal in 1 minute at 1% concentration (= 10,000 ppm), which causes approximately 20% COHb. Severe poisoning from short exposure often followed by complete recovery but neurological, cardiovascular, pulmonary, other complications may occur.
Hydrogen sulfide (H_2S)	Colorless flammable gas, burns to sulfur dioxide. Soluble in water but solutions unstable heavier than air. Characteristic odor of rotten eggs detectable at concentrations of 0.02 ppm or appreciably less. Higher toxic concentrations can rapidly deaden sense of smell. Inhibits cellular respiration.	TLV = 5 ppm (14 mg/m^3), based primarily on eye effects and CNS depression.	Concentrations of 300–1000 ppm cause rapid unconsciousness and death through respiratory paralysis. Associated with an unusual diversity of symptoms including chronic keratoconjunctivitis, nausea, insomnia, pulmonary edema, balance disorders, polyneuritis, and gray-green discoloration of the teeth.

the alveoli. A certain amount of filtration by the upper respiratory system prevents large particles from getting into the lung. In the workplace, particles are dispersed in a nonuniform way and in a full spectrum of sizes; only a portion of them are small enough to get into the lung.

Inert dusts previously termed nuisance dusts are now called *Particulates* (insoluble) *Not Otherwise Classified* (PNOC). The definition of inert is relative because all particulates evoke a tissue response when inhaled in sufficient amount. The TLV for PNOC has been set at 10 mg/m^3 (inhalable fraction) or 3 mg/m^3 (respirable fraction). This is provided that the particulate matter contains no asbestos and less than one percent crystalline silica.

Chronic exposure to some dusts (asbestos, silica, coal) is associated with various types of pneumoconiosis (lung disease caused by dust). (See Chapter 8, Particulates.)

Pneumoconioses associated with inert dusts are sometimes called benign pneumoconioses.

Fibrotic (formation of scar tissue) changes are produced by materials such as crystalline silica, which produces a silicotic nodule or small area of scarlike tissue. Asbestos also produces typical fibrotic damage to lung tissue (asbestosis) as well as various cancers. There is concern about the possible effects of nonoccupational exposure to asbestos.

Asbestos and smoking illustrate the concept of synergy, in which the combined risk from two separate causes of a health effect (lung cancer) far exceeds the sum of their individual risks.

In combination with smoking, exposure to airborne asbestos fibers leads to an excessive incidence of lung cancer. The incidence of lung cancer to nonsmokers exposed to asbestos, though lower, is still abnormally high. Asbestos exposure has also been shown to cause mesothelioma, which in nonasbestos-exposed people is a very rare cancer of the lining of the abdomen or the lung. (See Chapter 8, Particulates, for more information on asbestos-related diseases and other pneumoconioses.)

Some inhaled particles gain entrance to the body through the lung. Although they may not damage the lung tissues, they are absorbed into the blood and distributed throughout the body and can damage the nervous system, kidney, liver, or other organs.

The effects that result from heavy metals being absorbed through the respiratory tract vary appreciably from substance to substance. Often there is slow, cumulative absorption and retention of metal in the body; however, health effects may develop so slowly that the source or cause of the symptoms is often not initially recognized (e.g., lead, mercury).

Inorganic lead is a good example of a substance with unique effects in multiple organs. Excessive exposure to the inorganic form usually results from ingestion or inhalation of dust or fume, causing physical abnormalities that are characterized by anemia, headache, anorexia, weakness, and weight loss. With chronic, high exposures, more serious reactions include bone marrow changes and peripheral neuropathy, kidney injury, reproductive effects, and brain injury.

Organic lead, unlike inorganic lead, tends to concentrate in the brain. Some organic lead materials can easily be absorbed through the skin and add to the hazard from ingestion or inhalation. A single exposure to tetraethyl lead can

cause symptoms in a few hours and absorption of a relatively small amount can be fatal.

Although mercury poisoning was described by Paracelsus among miners several centuries ago, it has received much more attention recently. Inorganic compounds of mercury are readily absorbed from the intestine and tend to concentrate primarily in the kidneys, but can also damage the brain. Organic mercury tends to be especially concentrated in blood and the brain.

Industrial manganese poisoning, except for its action related to metal fume fever, is primarily a chronic disease resulting from inhalation of fume or dust in the mining or refining of manganese ores. It also can be caused by cutting and welding metals containing high manganese content while in a confined space without respiratory protection. Manganese poisoning is noted for its peculiar neurological effects, especially psychomotor instability.

Carcinogenesis

Although any new and abnormal tissue growth can be classed as a neoplasm, this term is most often used to describe cancerous or potentially cancerous tissue. The cells of a cancer are out of control. If neoplastic cells invade tissues or spread to new locations in the body (metastasize) the neoplasm has become cancerous or malignant. Cancer cells infrequently perform a useful function or one similar to that of the cells they destroy and replace.

It is well established that exposure to some chemicals can produce cancer in laboratory animals and humans. In common usage, *carcinogen* refers to any agent that can produce or accelerate the development of malignant or potentially malignant tumors or malignant neoplastic proliferation of cells. Carcinogen refers specifically to agents that cause carcinoma, but the current trend is to broaden its usage to indicate an agent that possesses carcinogenic potential. The terms tumorigen and oncogen are used synonymously with carcinogen.

A number of factors have been related to the incidence of cancer—the genetic makeup of the host, viruses, ultraviolet and ionizing radiation, hormone imbalance, and exposure to certain substances. Other factors such as cocarcinogens and tumor accelerators can be involved. For some substances a combination of factors must be present to induce cancers.

DEFINITIONS

Carcinogenesis has several possible definitions. A *carcinogen* can be defined as a substance that will induce a malignant tumor in humans following a reasonable exposure. A carcinogen has also been defined as a substance that will induce any neoplastic growth in any tissue of any animal at any dose by any method of application applied for as long as the lifetime of the animal.

Problems arise when all substances that would fulfill the second definition in the experimental laboratory are classified as carcinogens and it is assumed that they will cause malignancies in humans in accordance with the first definition. According to NIOSH, a substance is considered a suspected carcinogen to humans if it produces cancers in two or more animal species.

Even if we could extrapolate from a specific strain of a laboratory animal to all species including humans, taking into consideration such factors as weight, surface area, metabolic profiles, and drug-induced changes in metabolism, carcinogenic potential is often difficult to estimate because of interactions with other agents or biological susceptibilities.

Chemicals that induce cancer do so by mechanisms that are not completely defined. It is generally believed that the transformation of a cell from a normal to a carcinogenic state is multistaged and influenced by both internal and external factors. For example, some materials can produce cancer in the lungs after inhalation whereas others pass through the lung as a route of entry and produce the cancer elsewhere.

A toxicologist can look at the structure of an organic chemical and speculate that because of certain functional groups the chemical is carcinogenic but another chemical having similar functional groups is not carcinogenic. The theories that explain why a chemical is carcinogenic are very involved and, as yet, imperfect.

TYPICAL CARCINOGENS

Coal tar and various petroleum products have been identified as skin and subcutaneous carcinogens. Pitch, creosote oil, anthracene oil, soot, lamp black, lignite, asphalt, bitumen, certain cutting oils, waxes, and paraffin oils have also been implicated as potential carcinogens.

Workers can be exposed to arsenic, also recognized as a carcinogen, in the manufacture or use of roasting metallic sulfide ores as well as certain paints or enamels, dyes or tints, pesticides, and miscellaneous chemicals.

Inorganic salts of metals such as chromium, beryllium, and to a lesser extent nickel compounds are associated with cancer of the respiratory tract, usually the lungs. Other metals such as lead and cobalt are suspect, but their direct toxic effects in humans can obscure carcinogenic potential.

Leukemia is a group of diseases characterized by widespread, uncontrolled proliferation and abnormal accumulation of white blood cells and the failure of many of these cells to reach maturity. Exposures to ionizing radiation and benzene are principal occupational causes. Benzene exposure is also associated with blood dyscrasias (diseased state of the blood, generally involving abnormal or deficiently formed cellular elements), which may progress to leukemia or aplastic anemia.

Osteogenic sarcomas (bone tumors) have been detected in workers who applied radioactive luminous paint to instrument and watch dials. Angiosarcomas (a relatively rare malignant growth) of the liver have been found to be associated with human exposure to vinyl chloride monomer. Oat-cell carcinomas of the lung have been found in workers exposed to bis (chloromethyl) ether (BCME). BCME exposure can

occur as an unsought intermediate in certain reactions involving formaldehyde and hydrochloric acid. BCME is carcinogenic by inhalation, skin, and subcutaneous routes in animals.

The result of exposure to chemical carcinogens is such that people who absorb a chemical carcinogen such as benzidine are at increased risk of getting bladder cancer. With many carcinogens (Table 6–D), it is clear that there is a higher incidence of cancer in certain groups of people who are exposed to carcinogenic materials. For a more complete listing and discussion of carcinogens, consult the websites of IARC and the National Toxicology Program.

ENVIRONMENTAL FACTORS

Cancer is considered so insidious and has such severe health effects that carcinogenic substances are isolated and looked at more carefully than all others. The statement that 80–90 percent of all cancers are environmentally caused does not mean that 80–90 percent of cancers are caused by industry. The environment includes not only the air we breathe and water we drink but our diet and all elements of our lifestyle, on and off the job. The predominant causes of environmental cancer are tobacco smoke and diet.

Mutagenesis

A *mutagen* is an agent that affects the genetic material of the exposed organism. It may cause cancer, birth defects, or undesirable effects in later generations. People who work with a certain chemical may not be harmed, but their offspring can be.

The problem of time lag between exposure and effect is particularly severe for mutagenic agents. Mutations will not show up until the next generation at the earliest, and may not appear for several generations. The long latency makes it difficult to discover the connection between the exposure and manifestation of genetic damage.

Mutagens are chemical or physical agents that cause inheritable changes in the chromosomes. A mutagen might have an effect on somatic cells but not on germ (reproductive) cells. In this case, its effects are not passed on to offspring, but depend on the kind of cell affected. For example, the (somatic) cells of the bone marrow go on multiplying through life and shed the products of division into the blood, where they function for a time as red and white blood cells before they are removed and replaced. Gross interference with the genetic material of such cells may make cell division ineffective.

A mutagenic effect on somatic cells can also make them capable of more rapid growth and multiplication, so that they are formed far more rapidly than they can be removed from the blood, where they interfere with normal body functions. If the white cells are affected in this way, the outcome is a leukemia.

Similar interference with the genetic material could theoretically start up division in cells that do not normally divide during adult life. If the products of such division displace or invade normal tissues, the result is a solid tumor or cancer. In both these instances, the mutagen responsible would have manifested activity as a carcinogen.

Reproductive Toxicity

Reproduction results from a complex series of events involving both parents. It begins with each parent's genetic contribution (chromosome) and ends with expression of the genes acquired by the offspring. Every step in the reproductive process is vulnerable to effects from external physical and chemical agents. Chromosomal replication, sexual function, ovulation, conception/fertilization, embryo implantation, placental function, fetal development, labor, delivery, and even child development are components of the reproductive process. Table 6–E lists known or suspected human reproductive toxins. Reproductive abnormalities include changes in sperm count, sperm motility, libido, menstruation and cycle length, and fertility rate; these and other changes can result in miscarriage, embryo toxicity, developmental defects, and stillbirth (Tables 6–F, 6–G).

Teratogenesis (congenital malformation) results from interference with normal embryonic development by a biological, chemical, or physical agent. Exposure of a pregnant female may, under certain conditions, produce malformations of the fetus without inducing damage to the mother or killing the fetus. Such malformations are not hereditary. In contrast, congenital malformations resulting from changes in the genetic material are mutations and are hereditary.

TYPICAL TERATOGENS

Agents currently identified as human teratogens include infections such as rubella, metals such as lead and mercury, chemicals including PCBs, and ionizing radiation.

PREGNANT WOMEN IN THE WORKPLACE

A teratogen, by definition, is different from a mutagen in that it must affect a developing fetus. This is extremely important today because of the very considerable pressure to address the topic of pregnant women in the workplace.

The fetus is protected from some toxic chemicals because the placenta prevents them from entering the fetal bloodstream; however, many toxic chemicals, such as lead, easily cross the placenta. Damage to the fetus (embryo) is most likely to occur in early pregnancy, particularly during the first 8–10 weeks. During much of this critical period, many women are not even aware that they are pregnant.

It can be extremely difficult to establish specific cause-and-effect relationships between a teratogen and the birth defect it can produce. Animal studies must be supplemented with epidemiologic data and it may be decades before researchers know with certainty what substances hold how much risk for which unborn infants.

The fact that there are pregnant women in the workplace

Table 6–D. ***Carcinogens with Possible Occupational Relevance****

Substances Known to Be Carcinogenic		
4-aminobiphenyl	Bis (chloromethyl) ether and technical-grade chloromethyl methyl ether	Erionite
Arsenic and certain arsenic compounds	1-(2-chloroethyl)-3-(4-methylcyclohexyl)-1-nitrosourea (MeCCNU)	2-naphthylamine
Asbestos	Chromium and certain chromium compounds	Thorium dioxide
Benzene		Vinyl chloride (monomer)
Benzidine		
Radon		
Substances That May Reasonably Be Assumed to Be Carcinogenic		
Acetaldehyde	Diglycidyl resorcinol ether	Polychlorinated biphenyls
2-acetylaminofluorene	3,3'-dimethoxybenzidine and 3,3'-dimethoxybenzidine	Polycyclic aromatic hydrocarbons (such as benz(a)anthracene and benzo(a)pyrene)
Acrylamide	3,3'-dimethylbenzidine	Nitrilotriacetic acid
Acrylonitrile	Dimethylcarbamoyl chloride	B-propiolactone
2-aminoanthraquinone	4-dimethylaminoazobenzene	Propylene oxide
O-aminoazotoluene	Dimethyl sulfate	Polybrominated biphenyls
1-amino-2-methylanthraquinone	Dimethylvinyl chloride	Silica, crystalline (respirable) in the form of quartz, cristobalite, and tridymite
Amitrole	1,1-dimethylhydrazine	Sulfallate
O-anisidine hydrochloride	Epichlorohydrin	1,3-propane sultone
Benzotrichloride	Ethyl acrylate	Tetrachloroethylene (perchloroethylene)
Beryllium and certain beryllium compounds	1,4-dioxane	Thiourea
Bromodichloromethane	Ethyl methanesulfonate	Selenium sulfide
1,3-butadiene	Formaldehyde (gas)	O-toluidine and o-toluidine hydrochloride
Butylated hydroxyanisole	Ethylene oxide	Toxaphene
Cadmium and certain cadmium compounds	Hexamethylphosphoramide	2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD)
Carbon tetrachloride	Hydrazine and hydrazine sulfate	Toluene diisocyanate
Chlorendic acid	Ethylene thiourea	2,4,6-trichlorophenol
Chlorinated paraffins (C_{12}, 60% chlorine)	Kepone (chlordecone)	Ceramic fibers
Chloroform	Lead acetate and lead phosphate	Chlordecone
3-chloro-2-methylpropene	Hexachlorbenzene	Chloro-o-toluidine
4-chloro-o-phenylenediamine	2-methylaziridine (propyleneimine)	Chloro-o-toluidine hydrochloride
P-cresidine	4,4'-methylene bis (2-chloroaniline) (MBOCA)	Dinitropyrene
DDT	Hydrazobenzene	Danthron
2,4-diaminotoluene	4,4'-methylendianiline and its dihydrochloride	Glasswool
1,2-dibromo-3-chloropropane	Methyl methanesulfonate	Glycidol
1,2-dibromoethane (EDB)	Lindane and other hexachlorocyclohexane isomers	Furan
1,4-dichlorobenzene	Michler's ketone	Hexachloroethane
1,4-dichlorobenzidine and 3,3'-dichlorobenzidine dihydrochloride	Nickel and certain nickel compounds	Nitroanisole
1,2-dichloroethane	4,4'-methylene bis (N,N-dimethyl) benzenamine	Nitrochrysene
Dichloromethane (methylene chloride)	2-nitropropane	Nitropyrene
1,3-dichloropropene (technical grade)	4,4'-oxydianiline	Tetranitromethane
Diepoxybutane	N-methyl-n'-nitro-n-nitrosoguanidine	Trichloropropane
Di(2-ethylhexyl)phthalate		Vinyl cyclohexene diepoxide
Diethyl sulfate		
Occupational Exposures Associated with a Technological Process That Are Known to Be Carcinogenic		
Coke oven emissions	Mineral oils	
Soots	Tars	

* Known carcinogens are substances for which evidence from human studies indicates that there is a causal relationship between exposure to the substance and human cancer. Substances that may reasonably be expected to be carcinogens are those for which there is limited evidence of carcinogenicity in humans or sufficient evidence of carcinogenicity in experimental animals. (Adapted from Eighth Annual Report on Carcinogens, 1998 National Toxicology Program.)

and that they can be exposed to teratogens leads to a problem in setting occupational health standards. An embryo of a few weeks or a fetus of a few months should be given consideration and should not be exposed to a toxic environment. Although one way to solve this problem is to restrict the activities of fertile women in the workplace, this practice is no longer legally acceptable (*Auto Workers vs. Johnson Controls*). Also, the potential for adverse effects on the male reproductive system cannot be overlooked. *The workplace should be such that fertile men and women are able to work there without likelihood of harm.*

BASIS FOR WORKPLACE STANDARDS

Chemical analogy, in-vitro testing, animal experimentation, and human epidemiologic data are the bases for establishing

Table 6–E. ***Selected Occupational Agents Known or Strongly Suspected to Cause Human Reproductive Toxicity***

Developmental Effects	*Female Reproductive Toxicity*
Carbon disulfide	Alkylating/antineoplastic agents
Carbon monoxide	Arsenic
Ethylene glycol monoethyl ether	Carbon disulfide
Ethylene glycol monoethyl ether acetate	Ethylene oxide
Ethylene glycol monomethyl ether	Ionizing radiation
Ethylene glycol monomethyl ether acetate	Lead
Ionizing radiation	Mercury
Lead	Solvent exposure
Mercury (compounds)	*Male Reproductive Toxicity*
Methyl bromide	Carbon disulfide
Polychlorinated biphenyl (PCB)	Cyclohexanone
Ribavirin	1,2-dibromo-3-chloropropane (DBCP)
2,3,7,8-tetrachlorodibenzo para dioxin (TCDD)	Dinitrobenzene
Arsenic	Ethylene glycol ethers
Cadmium	Ethylene dibromide
Chlordecone	Chlordecone
	Estrogens
	Heat
	Ionizing radiation
	Epichlorohydrin
	Lead

workplace standards for substances. They are described in the following sections.

Chemical Analogy

When dealing with a new chemical, animal or human toxicity data are usually unavailable. Therefore, the nature of response to a chemical can be assumed to be analogous to that produced by contact with a substance with a similar chemical and biological structure. Chemicals that are similar have been assumed initially to produce similar biological responses. Computerized modeling uses structure-activity data, chemical analogy, and other data to derive estimates of toxicity and toxicokinetics.

In-Vitro Testing

In-vitro means "in a test tube." As a result of increasing costs and social pressures to eliminate use of animals for toxicological testing, laboratory methods are being developed to study toxicity and health effects. Depending on the effect or property being studied, different test materials or biological media may be used. For example, bacteria (*Salmonella*) are grown on a plate and exposed to a chemical to determine its mutagenicity (Ames test). Similarly target organ cells (e.g., skin, liver) can be grown in culture and exposed to a chemical to determine the reaction at the molecular or cellular level. Other tests being developed or in use involve human or animal tissue and cells, microbial agents (protozoa, helminths), artificial human organs or tissue and even DNA.

Animal Experimentation

Before introducing chemical agents into the workplace, it is advisable to know their toxic effects. Then preventive measures can be designed to protect workers and emergency procedures can be put in place to minimize accidental exposure. Because there is often little or no information available about new chemicals, an important method of developing such new information quickly is animal experimentation.

EXPOSURE STANDARDS

The toxicological effects of vapors, gases, fumes, and dusts are initially determined in the laboratory can be estimated by actually exposing animals to known concentrations for controlled periods of time.

Groups of animals can be exposed to controlled concentrations for eight hours a day, five days a week, for weeks, months, or years. Animals must be observed daily to ascertain any untoward physiological responses during exposure and post-exposure periods. On terminating chronic experiments, all animals are sacrificed and the internal organs are weighed and examined histopathologically. In this manner, the toxicologist gains information regarding no-effect levels as well as levels that produce injury.

SCREENING PROCEDURES

Toxicological screening should ideally include both acute toxicity studies, studies of repeated administration at short intervals, and long-term studies performed during the lifespan of the animal, and in some instances over several generations.

Because biological variations influence the reaction to a foreign substance in different species, it is difficult to duplicate in animal experiments the precise situation to which humans can be exposed. In the development of a specific test program, preliminary studies are necessary to select species that absorb and metabolize related classes of chemicals in ways similar to humans.

A route of administration different from that usually occurring in humans, such as parenteral (injected, i.e., intravenous, intramuscular, etc.) administration instead of inhalation or ingestion, can give misleading results.

Chronic toxicity studies involve repeated administration of test substances. However, chronic effects can also be expected from a single exposure to a substance if the body stores the material so that it remains in the organism for long periods of time or if the health effect is delayed or permanent. Repeated administration of the test substance is useful in the investigation of such problems as cumulative toxicity, tolerance, and enzyme-induction phenomena.

PROBLEM AREAS

Animal testing provides only an estimate of the toxicity of a chemical for humans. It is very difficult to extrapolate an LD_{50} or an LC_{50} to an acceptable Threshold Limit Value.

Because the primary concern is the prevention of harm to humans, the limitations inherent in animal-derived data

Table 6–F. ***Measures of Human Reproductive Function Readily Obtainable Before Fertilization***

	Affected Individual		
Endpoint	*Male*	*Both*	*Female*
Sexual function	Erection Ejaculation	Libido Behavior	
Endocrine system		Luteinizing hormone Follicle-stimulating hormone Steroid hormones (androgens, estrogens, and progestins)	Cervical mucus quality
Germ cells	Sperm number Sperm motility Sperm shape Chromosomal integrity Fertilizing ability		
Fecundity (ability to conceive)	Testicular integrity Semen quality	Integrity of external genitalia	Ovarian integrity Blockage of oviduct Menstrual regularity Amenorrhea Anovulatory cycles
Secondary sexual characteristics		Breast development Facial and axillary hair growth Sebaceous glands	
Reproductive lifespan		Age at puberty	Age at menopause

(From U.S. Congress, Office of Technology Assessment. *Reproductive Health Hazards in the Workplace,* Chapter 3, Table 3–1. Washington, DC: U.S. Government Printing Office, OTA-BA-266, Dec. 1985.)

Table 6–G. ***Measures of Human Reproductive Function Readily Available After Fertilization***

	Affected Individual		
Endpoint	*Female*	*Both*	*Offspring*
Endocrine system	Human chorionic gonadotropin Steroid hormones, especially progesterone		
Health during pregnancy	Hemorrhage Toxemia	Fetal death Spontaneous abortion	Morphology Chromosomal aberrations
Perinatal period		Premature birth Postmature birth	Death Chromosomal aberrations Birth defects Birth weight Apgar score
Postnatal period	Lactation		Infant death Childhood morbidity Childhood malignancies Development Behavior
Reproductive lifespan	Age at menopause

should be recognized. Whether human response will resemble that of the most reactive or the least reactive species tested is often not known. Finally, whether the animal response is an exact parallel to human response cannot always be predicted.

Human Epidemiological Data

Records of human experience for exposures to many substances are available. This is particularly true for older chemicals such as carbon monoxide and lead. Epidemiological data can be descriptive, retrospective, or prospective; it pertains to health effects that are measured in groups of exposed humans.

Descriptive studies identify a change or difference in prevalence of a disease in a subgroup of the population.

Retrospective studies reveal a relationship between a substance and a certain effect caused by exposure that occurred months or years before the initiation of data collection.

Prospective studies can define more precisely the time relationship and the magnitude of risk. Prospective studies are

present and future continuing studies that measure health effects as the exposures occur in work areas.

Epidemiological analysis may reveal the relationship between time of occurrence of an adverse effect and age at the time of the first exposure. Epidemiological study and analysis attempts to identify or clarify the influence of variables other than the agent under study. For example, cigarette smoking in the study of lung cancer among asbestos workers is such a variable.

Finally, if a specific chemical is removed from the environment, it should be followed by epidemiological evidence of a decline in the frequency of the effect.

FEDERAL REGULATIONS

The federal regulations with implications for industrial toxicology include the Federal Occupational Safety and Health Act of 1970, the Toxic Substances Control Act of 1976, and various NIOSH, OSHA, and voluntary professional standards. These are covered in the following sections.

Occupational Safety and Health Act (OSHAct)

The Occupational Safety and Health Act (*OSHAct, enacted in 1970*) is administered by the Occupational Safety and Health Administration (OSHA), which has the regulatory authority to protect workers from physical hazards and hazardous substances and forms of energy (such as noise and radiation) in the work environment. OSHA monitors health and safety in the workplace, setting standards for worker exposure to specific chemicals, for permissible exposure levels (PELs), and for monitoring procedures. It also provides research, information, education, and training in occupational safety and health. By establishing the National Institute for Occupational Safety and Health (NIOSH), the act provided for studies to be conducted so that regulatory decisions can be based on the best available information.

In 1983, OSHA enacted the Hazard Communication Standard, 29 *CFR* 1910.1200, which sets standards for worker notification and training for chemicals in the workplace. This also is known as the "Hazcom" or "right-to-know" Regulation. For more information on hazard communication, see Chapter 28, Government Regulations, and Chapter 29, History of the Federal Occupational Safety and Health Administration.

OSHA has adopted exposure limits (PELs) for more than 400 substances. Many are based on Threshold Limit Values (TLVs®) suggested for industrial chemical exposures by the American Conference of Governmental Industrial Hygienists (ACGIH).

The ACGIH TLVs® were directed primarily at substances that caused physiological reactions such as poisoning, irritation of eyes and respiratory tract, and skin rashes. The original TLVs were not established on the basis of carcinogenic, teratogenic, or mutagenic properties, and synergistic effects of chemical mixtures were not included in tests used to determine the TLVs. Since OSHA began (1971), new standards for carcinogenic and other chemical agents have been promulgated by OSHA. ACGIH has also been updating and adding to its original list of TLVs. See Appendix B for a complete listing of the ACGIH TLVs®.

The American National Standards Institute (ANSI), through its former Committee on Acceptable Concentrations of Toxic Dusts and Gases, also published standards on levels of materials in the air in work areas. OSHA has adopted some ANSI standards because ANSI was considered to be a consensus standard-setting group.

TSCA

The Toxic Substances Control Act of 1976 (*TSCA*) is administered by the Environmental Protection Agency (EPA) and covers almost all chemicals manufactured in the United States, excluding certain compounds covered under other regulations such as the Federal Insecticide, Fungicide and Rodenticide Act (FIFRA). The act requires that chemical manufacturers and processors develop adequate data on the health and environmental effects of the chemicals they produce. The EPA is required to establish standards for the testing of chemicals.

Companies are required to notify the EPA 90 days before manufacturing any new chemical and to provide test data and other information about the safety of the product. The EPA has the authority to ban or regulate such chemicals if test information is insufficient and if the chemical is to be produced in substantial quantities with wide distribution. The EPA is required to ban or restrict the use of any chemical presenting an unreasonable risk of injury to health or the environment.

Toxic Substances List

The Occupational Safety and Health Act requires the annual publication of a list of all known toxic substances by generic, family, or other useful grouping, and the concentrations at which such toxicity is known to occur. OSHA also requires employers to monitor employee exposure to toxic materials and to keep records of such exposure.

The Registry of Toxic Effects of Chemical Substances (RTECS) is a compendium of toxicity data extracted from the scientific literature by the U.S. Department of Health and Human Services. It is intended to serve as the required toxic substances list.

The purpose of the Toxic Substances List is to identify all known toxic substances in accordance with standardized definitions that can be used to describe toxicity. The entry of a substance on the list does not automatically mean that it is to be avoided but that the listed substance has been found to be hazardous at the doses or exposure levels listed.

The absence of a substance from the list does not necessarily indicate that a substance is not toxic but rather that the dose that causes the toxic effect is not known.

There has been no attempt at an evaluation of the degree of hazard that might be expected from substances on the list; that is a goal of the hazard-evaluation studies.

HAZARD EVALUATION

Hazard evaluation involves a measurement of the quantity available for absorption by the user, the amount of time available for absorption, the frequency with which the exposure occurs, the physical form of the substances, toxicological properties and potency, and the presence of other substances (toxic or nontoxic), additives, or contaminants.

Ventilation, appropriate hygienic practices, housekeeping, protective clothing, and pertinent training for safe handling may eliminate or reduce hazards that might exist.

Hazard evaluation is performed by engineers, chemists, industrial hygienists, toxicologists, and physicians trained in toxicology, industrial hygiene, and occupational medicine who strive to recognize, measure, and control these hazards.

NIOSH/OSHA Standards

Since the passage of the OSHAct, both NIOSH and OSHA have been committed to establishing permissible standards for the workplace that are far more complete than the TLVs® issued by the ACGIH.

A complete substance-specific standard includes the exposure limit of the substance that has been determined to provide a safe, healthful work environment; the methods for collecting, sampling, and analyzing the substance; the engineering controls necessary for maintaining a safe environment; appropriate equipment and clothing for safe handling of the substance; emergency procedures in the event of an accident; medical surveillance procedures necessary for the detection of illness or injury from inadvertent overexposure; and the use of signs and labels to identify hazardous substances.

NIOSH CRITERIA DOCUMENTS

Except in the case of emergency standards, the normal first step in the standard-setting process is the creation of a criteria document for the substance by NIOSH. Such documents are forwarded to OSHA for consideration as permanent OSHA standards.

NIOSH also develops recommended exposure limits (RELs) for hazardous substances in the workplace. Unless noted otherwise, RELs are time-weighted average (TWA) concentrations for up to a 10-hour workday during a 40-hour workweek. RELs are published in NIOSH criteria documents along with appropriate measures to prevent adverse health effects.

NIOSH criteria documents incorporate animal and human data, when available, on carcinogenicity, mutagenicity, teratogenicity, and effects on reproduction. When possible, attempts are made to correlate these adverse reactions with exposures and effects.

Current Intelligence Bulletins (CIBs) are issued by NIOSH for more rapid dissemination of new scientific information about occupational hazards. A CIB may draw attention to a hazard previously unrecognized or may report new data suggesting that a known hazard is either more or less dangerous than was previously thought (see Bibliography).

OSHA STANDARDS

The U.S. Secretary of Labor is responsible for promulgating standards. In some cases, a recommended standard is referred to an advisory committee for study and review in accordance with provisions of the act. OSHA standards are adopted at after extensive review including public hearings. Regardless of the status of the proposed standards in the criteria documents, these documents constitute valuable and readily available sources of information and should be consulted whenever there is interest in a substance for which a criteria document has been written.

Although the standard-setting process is extremely thorough, it is also lengthy and very costly, and has resulted in the promulgation of relatively few regulations (permanent standards).

ACGIH THRESHOLD LIMIT VALUES—TLVS®

In addition to regulated PELs established and enforced by OSHA, many voluntary guides for exposure to airborne contaminants have been proposed. The most widely followed or referenced are those issued annually by the American Conference of Governmental Industrial Hygienists (ACGIH), and are termed Threshold Limit Values (TLVs).

The ACGIH TLVs® are not recommendations of a government agency, but are the product of a committee whose members are associated with government or academia.

Appendix B presents the *2001 Threshold Limit Values* (*TLVs®*) *for Chemical Substances and Physical Agents and the Biological Exposure Indices* (*BEIs®*), reprinted with permission. This information is also available directly from the American Conference of Governmental Industrial Hygienists, Inc. (ACGIH®)

The *Threshold Limit Values* (*TLVs®*) *for Chemical Substances and Physical Agents and the Biological Exposure Indices* (*BEIs®*) book is published annually by the ACGIH and is available for a nominal cost. It is copyrighted by the ACGIH and is reproduced here with permission. For information about this publication, contact ACGIH at Kemper Meadow Center, 1330 Kemper Meadow Drive, Cincinnati, OH 45240-1634, (513) 742-3355, http:www.acgih.org; e-mail: mail@acgih.org.

Limitations of TLVs®

The TLV Committee intended the TLVs® they issued to be used as *guides* in the control of health hazards, *not as fine lines between safe and dangerous concentrations*. The committee noted many reasons for the inadequacy of these numbers for such purposes. Despite this admonition, however, the TLV list gradually became incorporated into many state and federal regulations. Because the basic concepts underlying exposure and measurement are the same for TLVs and regulated PELs, it is worth examining the nature of TLVs in some detail.

One of the fundamental tasks confronting the industrial hygienist is assessing the possible degrees of exposure to a variety of substances in the work environment. It is accepted that there is a threshold level (exposure) for almost all substances below which no measurable impairment of health occurs. Because the most common route of entry for a chemical in the workplace is inhalation, the practice for many years has been to sample the air being breathed by the workers and compare the result with a suitable standard.

Although air standards and guides such as those developed by OSHA, ACGIH, and NIOSH are most widely used in industrial hygiene practice, certain shortcomings are inherent in any air standard. This limits their applicability to some situations. Some of the more common recognized problems include the following:

1. Difficulty in acquiring a truly representative breathing zone sample
2. Uncertainties about the extent of absorption of the amount inhaled
3. Nonroutine or nonrepetitive work; air samples can characterize work operations only on the day the sample is taken
4. Variations in particle size, absorption, and particle solubility
5. Accidental or deliberate contamination of sample

The TLV list is basically an alphabetical listing of substances with the recommended limits expressed either in parts per million by volume or milligrams per cubic meter; see Appendix B. It is the practice to express the TLV for all substances expected to be present in the air as particulate suspensions in milligrams per cubic meter. For substances expected to be present as gases or vapors, the TLV is expressed in parts per million, and for convenience the equivalence in milligrams per cubic meter is also presented.

Formulas are available for determining TLVs® for the inhalable-thoracic and respirable-particulate fractions, obtained by means of a suitable particle-size–discriminating device. The asbestos TLV is unique, and is expressed in fibers per cubic centimeter of air.

Time-Weighted Average

It is implicit in all TLVs® that measurements are made in the breathing zone of a worker and are obtained in such a way that a TWA can be calculated. In general, for an eight-hour workday,

$$\text{TWA} = \frac{C_a T_a + C_b T_b + \ldots\ C_n T_n}{8}$$

where T is the time of exposure period and C is the concentration of contaminant during that period. This concept has proven to be a useful means of estimating the long-term chronic effects of exposure to most substances in the workplace. Although the TWA does not necessarily predict the amount of a substance that will be absorbed, it does measure the amount that can be inhaled during a workday; considerations of the extent of absorption aid in the selection of a value that affords the desired degree of protection.

It is inherent in the definition of a TWA that concentrations higher than the recommended value can be permitted for some periods of time as long as these levels are offset by periods of lesser concentration. The degree of permissible excursion is related to the TLV of the substance. The relationship between threshold limit and permissible excursion is a general rule that may not apply in certain cases (Figure 6–4).

Ceiling Values

For some substances, it is not advisable to permit concentrations substantially above the recommended TWA; the TLV committee designates these substances with the letter *C,* which stands for *ceiling value*. Most substances designated with a C tend to be irritants for which a TLV has been set slightly below the level where irritation will be noticed by the most sensitive individuals. *Exposures should never exceed the ceiling value.*

The durations of sampling necessary to determine whether the exposures are within the limits for each group usually differ. A single brief sample that is applicable to a C limit is not appropriate for calculating a TWA.

The TLV list also contains another listing of values for many substances that are called short-term exposure limits (STELs).

Mixtures

When two or more hazardous substances that act on the same body organ system are present, their combined effect, rather than that of either component, should be given primary consideration. In the absence of information to the contrary, the effects of the different hazards should be con-

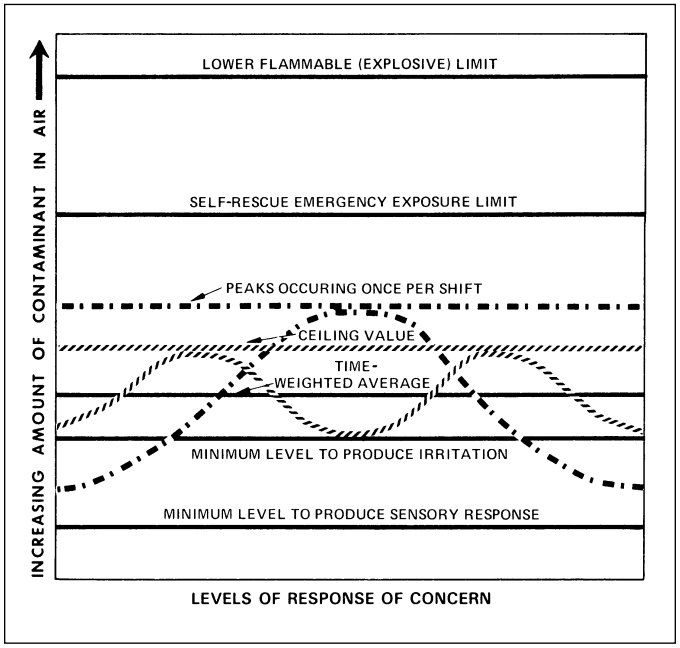

Figure 6–4. Knowledge of the type of injury that would result from exposure to various contaminant levels is important to health and safety professionals.

sidered additive. Exceptions can be made when there is a good reason to believe that the chief effects of the different harmful substances are independent, as when purely local effects on different organs of the body are produced by the various components of the mixture.

The formula for additive effects is as follows:

$$\frac{C_1}{T_1} + \frac{C_2}{T_2} + \frac{C_3}{T_3} + \ldots = 1$$

where C = the observed atmospheric concentration
T = the corresponding Threshold Limit Value

If the sum of the fractions is greater than one, then the Threshold Limit Value has been exceeded.

Antagonistic action or potentiation may occur with some combinations of contaminants. At present, such cases must be determined individually. Potentiating or antagonistic agents may not necessarily be harmful by themselves. Potentiating effects of exposure by routes other than that of inhalation are also possible, such as the effect of ingested alcohol on an inhaled narcotic (trichloroethylene).

When a given operation or process emits a number of harmful dusts, fumes, vapors, or gases, it is often feasible to attempt to evaluate the hazard by measuring a single (surrogate) substance. In such cases, the threshold limit used for this substance should be reduced by a suitable factor, the magnitude of which depends on the number, toxicity, and relative quantity of the other contaminants ordinarily present.

Examples of processes that are typically associated with multiple harmful atmospheric contaminants are welding, automobile repair, painting, reinforced plastic fabrication, shipbuilding, biotechnology, and chemical manufacturing.

Carcinogens

Because causal mechanisms and dose-response relationships are not well understood for many carcinogens, the ACGIH considers them separately in the TLV® booklet. It rates substances based on the quality and weight of data available which assesses a substance's carcinogenic potential.

If no data are available for a particular substance, no rating is assigned. The ratings are as follows:

- A1—Confirmed Human Carcinogen
- A2—Suspected Human Carcinogen
- A3—Confirmed Animal Carcinogen With Unknown Relevance to Humans
- A4—Not Classifiable as a Human Carcinogen
- A5—Not Suspected as a Human Carcinogen

(See Appendix B, for definitions of these ratings of the carcinogenicity of substances.)

Physical Factors

It is recognized that such physical factors as heat, ultraviolet and ionizing radiation, and work under high atmospheric pressure or at a high altitude cause adverse health effects following sufficient exposure. Certain physical stresses may also alter the response to a toxic substance. Although most threshold limits have built-in safety factors to guard against moderate deviations from normal environments, the safety factors of most substances are not large enough to account for gross deviations. For example, continuous work at temperatures above 32 C (90 F) or work at altitudes above 3,000 m would be considered gross deviations. In such instances, judgment must be exercised in the proper downward adjustments of the TLVs®.

Unlisted Substances

Many substances used or created (including by-products) in industrial processes do not appear on the TLV list. For many, the committee does not have sufficient information from which to derive a TLV, even on a tentative basis. Also, some substances of considerable toxicity have been omitted primarily because only a limited number of workers, such as employees of a single plant, have potential exposure to possibly harmful concentrations.

Basic Data Used for TLVs®

If possible, the ACGIH TLV committee selects a value based on human experience. Epidemiological studies, which include environmental data and morbidity and mortality data, are the best possible basis for a TLV, but in most cases, such studies do not exist. In the absence of epidemiological studies, individual cases involving human exposures are considered, but usually the most useful literature available is from animal toxicological studies. The preferred studies for determining acceptable exposure limits are those based on long-term inhalation tests involving several animal species at concentrations both above and below the lowest effect level.

However, scientists often must rely on short-term inhalation data or, in many cases, toxicity studies in which the substance was introduced into the experimental animals by routes other than inhalation. The least useful toxicological data are those based on short-term oral intake, intended to measure the acute toxicity, or the ability of the substance to kill the exposed animals. It is not surprising, therefore, that the publication of new information often results in dramatic changes in some TLVs®.

Documentation

The policy of the TLV committee is to prepare a justification for each proposed TLV. These are published in a document titled *Documentation of Threshold Limit Values,* available from the ACGIH (see Bibliography). In these documents, the principal data that the committee considered significant are reviewed and references are cited. The justification and documentation are discussed in the following categories:

- chemical and physical properties
- occupational exposure
- animal studies
- reproductive and developmental studies
- genotoxicity studies
- pharmacokinetic/metobolism studies
- human studies

Table 6–H. *Classification of Criteria for ACGIH TLVs® Applicable to Humans and Animals**

Applied Criteria			
Morphologic	*Functional*	*Biochemical*	*Miscellaneous*
Systems or organs affected: lung, liver, kidney, blood, skin, eye, bone, CNS, endocrine, exocrine, reproductive	Changes in organ function: lung, liver, kidney, reproductive	Changes in amounts of biochemical constituents, including hematologic	Nuisance:
Carcinogenesis	Irritation	Changes in enzyme activity	Visibility
Roentgenographic changes	Mucous membranes (epithelial linings, eye, and skin)	Immunochemical allergic sensitization	Cosmetic
	Narcosis	Hormone activity	Comfort
	Odor		Aesthetic
			(Analogy)
Potentially Useful Criteria			
Altered reproduction	Behavioral changes:	Radiomimetic effects	
Body-weight changes	Cerebral functions	Teratogenesis	
Organ/body weight changes	Conditioned and unconditioned reflexes—learning	Mutagenesis/Genotoxicity	
Food consumption	Audible and visual responses		
	Endocrine glands		
	Exocrine glands

- ➢ TLV® recommendation
- ➢ other recommendations
- ➢ carcinogenic classification
- ➢ TLVs of other nations
- ➢ references

This document should be consulted whenever a particular TLV is to be applied, for it is important to be aware of the basis for each standard. In most cases, a particular value is selected on the basis of one or more of the consequences of overexposure listed in Table 6–H.

One of the advantages of the TLV list is its relative timeliness. The list contains a section titled "Notice of Intended Changes"; as the name suggests, all changes, including additions, are listed for a period of at least two years. During this period, the TLV committee solicits comments from interested parties concerning the suggested changes. By comparison, OSHA PELs and substance-specific standards usually require many years for adoption or change—if at all.

Threshold Limit Values® are intended only for use in the practice of industrial hygiene as guidelines or recommendations in the control of potential health hazards. The TLVs® should be interpreted and applied only by a person trained in industrial hygiene. They are not intended for use, or for modification for use, as a relative index of hazard or toxicity, in the evaluation or control of community air pollution nuisances, in estimating the toxic potential of continuous, uninterrupted exposures or other extended work periods, as proof or disproof of an existing disease or physical condition, or for adoption by countries in which working conditions differ from those in the United States and where substances and processes differ. These limits are not fine lines between safe and dangerous concentrations. See Chapter 15, Evaluation, for further discussion of the use of TLVs®.

BIOLOGICAL TESTING

A useful means of assessing occupational exposure to a harmful material is the analysis of biological samples obtained from exposed workers. Biological sampling, however, should not be considered a substitute for air sampling. Ethical considerations prohibit what some have called the use of the worker as an "integrated air-sampling device." Biological analysis may provide an indication of the body burden of the substance, the amount circulating in the blood, or the amount being excreted. Virtually every tissue and fluid in the body can be analyzed, but for practical reasons, most bioassays are confined to specimens of urine or blood. For substances such as carbon monoxide and many solvents, the analysis of exhaled breath samples indicates the level of previous exposure. Occasionally, analysis of samples of hair, nails, feces, or other tissues may be useful.

Whereas air monitoring measures the composition of the external environment surrounding the worker, biological monitoring measures the amount of chemical absorbed via any route (lungs, skin, mucosa, etc.) are measured. In addition, the effects of added stress (such as increased work load resulting in a higher respiration rate with increased intake of the air contaminant) are reflected in the results. The total exposure (both on and off the job) to harmful materials is included.

For some chemicals, biological assays, in addition to air measurements, can be much more reliable indicators of health risks than measurements of air contaminants alone (Table 6–I).

Analyses that can be performed on biological samples include the following:

- ➢ Analysis for the unchanged substance (such as lead, arsenic, mercury) in body fluids and tissues

Table 6–I. ***Body Tissues and Fluids Suitable for Biological Analysis***

Analysis of Urine Samples May Be Useful for the Following Compounds		
Acetone	2-ethoxyethanol acetate (2-ethoxyacetic acid)	Pentachlorophenol
Aluminum	Ethyl benzene (mandelic acid)	Phenol
Aniline	Fluoride/Hydrogen fluoride	Selenium
Antimony	Furfural (furoic acid)	Styrene (mandelic acid)
Arsenic/ Arsine	N-hexane (2-5-hexanedione)	Tellurium
Benzene (phenol)	Hydrogen cyanide	Tetrachloroethylene (trichloroacetic acid)
Benzidine	Isopropyl alcohol (acetone)	Tetrahydrofuran
Cadmium	Lead	Thallium
Carbon disulfide (2-thiothiazolidine-4-carboxylic acid)	Manganese	Toluene (hippuric acid)
Chlorinated benzene (4-chlorocatectol)	Mercury	1,1,1-trichloroethane (trichloroacetic acid, trichloroethanol)
Chromium H_20-soluble compounds	Methanol (or formic acid)	Trichloroethylene (trichloroacetic acid, trichloroethanol)
Cobalt	Methyl ethyl ketone	Triethylamine (triethylamic and TEA n-oxide)
Cyanide (thiocyanate)	Methyl isobutyl ketone	Uranium
Cyclohexane (cyclohexanol)	Nickel	Vanadium pentoxide
Dichloromethane	Nickel carbonyl (nickel)	Xylene (methyl hippuric acid)
Dimethylacetamide (methylacetamide)	Nitrobenzene (p-nitrophenol)	Zinc
Dimethyl formamide (N-methylformamide)	Parathion (nitrophenol)	
2-ethoxyethanol (2-ethoxyacetic acid)		
Analysis of Blood Samples May Be Useful for the Following Compounds:		
Acetone	Cyclohexane	Pentachlorophenol
Aniline (methemoglobin)	Dichloromethane (carboxyhemoglobin)	Styrene
Cadmium dust, fume	Ethylene oxide	Tetrachloroethylene
Carbon monoxide (carboxyhemoglobin)	Lead	Toluene
Cholinesterase inhibitors (RBC cholinesterase)	Manganese	Trichloroethylene (or trichloroethanol)
Cobalt	Mercury	Xylene
	Nitrobenzene (methemoglobin)	
Breath Analysis May Be Useful for the Following:		
Benzene	N-hexane	1,1,1-thrichloroethane
Dichloromethane	Tetrachloroethylene	Trichloroethylene
Ethyl benzene		

* Note: Metabolites are given in parentheses where they are the best indicators of exposure and absorption of a compound.

- ➢ Analysis for a metabolite of the substance in body fluids or tissues, such as phenol in urine resulting from exposure to benzene
- ➢ Analysis to determine the variations in the level of a naturally occurring enzyme or other biochemical substance normally present in body fluids or tissues, such as depression of cholinesterase activity as a result of exposure to organic phosphate compounds

The rates of absorption, metabolism, and excretion for a particular substance determine when it is most appropriate to analyze samples in relation to duration and time of exposure. For rapidly excreted or exhaled substances, peak concentrations are found during or immediately after exposure. Peak excretion rates for metabolites of some organic solvents and some inorganic substances may occur minutes to hours after exposure. Biological levels of metals with cumulative properties (such as lead or mercury) may reflect the response to several days' or weeks' prior exposure. The "half-lives" of various chemicals in the body have been established and are an important consideration in biological testing for exposure.

People with virtually identical exposure histories can show a wide variation in response due to subtle differences in their rates of absorption, tissue storage, or metabolism. Greater significance should be given to the variations in an individual's level from period to period than to the variations between different individuals within a group.

Some harmful substances can be stored for long periods of time in various parts of the body. The substances are unlikely to be evenly distributed throughout the body. In many cases, the organ with the highest concentration of the material is the liver or kidney.

Many materials, including organic compounds, undergo detoxification in the body. The body converts the material to something else that may reduce its ability to cause injury. Occasionally, the conversion enhances the toxicity, but in any event, the process helps the body to dispose of the material. The conversion products may appear in the urine or blood as metabolites (see Table 6–I).

Many organic chemicals of high molecular weight and low vapor pressure are not found in workroom air at elevated concentrations under normal conditions of work, but the same substances can be absorbed through the intact skin, giving rise to excessive absorption that cannot be measured by air sampling. In such cases, a suitable biological analysis

can be an excellent means of detecting the failure of skin-protection measures.

For a few regulated substances, OSHA has set biological limits (e.g., blood lead). For many others, the ACGIH has adopted a set of advisory biological limit values called the Biological Exposure Indices (BEIs®). These indices use urine, blood, or expired air sampled under strictly defined conditions. The user should become familiar with the extensive documentation that accompanies these indices in the ACGIH *Documentation of Threshold Limit Values* (2001) and *Threshold Limit Values® for Chemical Substances and Physical Agents and Biological Exposure Indices®* (2001). (See Chapter 15, Evaluation, for a more detailed discussion of Biological Exposure Indices.)

Because the collection of blood, urine, or breath samples requires the use of medical personnel, most programs of biological monitoring become a cooperative effort between the safety, industrial hygiene, and medical departments.

The analysis and interpretation of biological samples is obviously of great importance and because the quantities involved are almost always very slight, great care must be taken in performing such analyses. Ordinarily, existing plant laboratories are not equipped or trained to perform these analyses in a satisfactory manner, and it is advisable to use a laboratory that has proven capability in this area.

Urine, Blood, and Breath Analyses

Tests for the level of metabolites of toxic agents in the urine, blood, and breath have found wide use in industrial toxicology as a means of evaluating exposure of workers. The concentration of the metabolic product is related to the exposure level of the toxic agent. Because normal values of such metabolites have been established, an increase above normal levels indicates that an overexposure has occurred. This provides a valuable screening mechanism for estimating the hazard from continued or excessive exposure. Because lead, for example, interferes with porphyrin metabolism, erythrocyte protoporphyrin can be a useful measure and the results are useful as an indicator of lead effect (and absorption).

One of the best documented examples of the effectiveness of biological sampling is that of analysis for exposure to lead and its compounds. It is almost universally agreed that the level of lead in the blood is the best index of the probability of damage resulting from lead exposure.

For many other substances there is no known biological test as useful as the measurement of lead in blood, whereas for other substances the correlation between bioassay tests and symptoms is so poor as to render a biological analysis of little value. The aim of an industrial hygienist or safety professional is to control exposure to harmful materials; both air sampling and biological monitoring contribute valuable information regarding exposure and health impact.

The industrial hygienist or safety professional is charged with maintaining a safe, healthful environment and should probably do air sampling; indeed, it is required by law in many cases.Where available and indicated by exposure risk, biological testing may also be required or appropriate.

If inhaled gases and vapors are fat-soluble and are not metabolized, they are cleared from the body primarily through the respiratory system. Examples of these are the volatile halogenated hydrocarbons; the volatile aliphatic, olefinic, and aromatic hydrocarbons; some volatile aliphatic saturated ketones and ethers; esters of low molecular weight; and certain other organic solvents such as carbon disulfide.

For industrial solvents that continue clearing from the body in exhaled breath for several hours after exposure, analysis of progressive decrease in the rate of excretion in the breath can be very helpful in showing not only the nature of the substances to which the worker was exposed, but also the magnitude of the exposure and probable blood levels. By use of gas chromatography or infrared analysis of breath samples, the identification of the substance can be established, permitting comparison of the exposed workers' breath decay rate with worker's published excretion curves. There is, however, considerable individual variation and it is not easy to set standard values.

SOURCES OF TOXICOLOGAL INFORMATION

The health and safety professional can turn to several sources for information when a question arises about the toxicity and hazard of a material.

Material Safety Data Sheet

Material Safety Data Sheets (MSDSs) are a prime source of information on the hazardous properties of chemical products, although the quality of such information is highly variable. The OSHA Hazard Communication Standard requires that all chemical manufacturers and importers supply an appropriate MSDS to their customers. The MSDS is usually developed by the chemical manufacturer. Additionally, all users of the product (employers) must have an MSDS for every hazardous chemical used in the workplace.

Although OSHA does not specify the format of the MSDS, it does require certain specific information. A sample form approved by OSHA for compliance with the Hazard Communication Standard is shown in Figure 6–5.

There are eight categories of information on the MSDS:

SECTION I

Name and address of the manufacturer (the originator of the MSDS)

- ➢ Emergency telephone number, which can be used to contact a "responsible party" for information about the product
- ➢ Information telephone number, to be used in non-emergency cases to contact the manufacturer
- ➢ Signature of the person responsible for the MSDS and the date it was developed or revised

Material Safety Data Sheet

May be used to comply with OSHA's Hazard Communication Standard, 29 CFR 1910.1200. Standard must be consulted for specific requirements.

Figure 6–5. (Concluded)

SECTION II: HAZARDOUS INGREDIENTS

- ➢ Common name used as identification on the label (the code name or number, trade, brand, or generic name)
- ➢ Chemical name: the scientific designation of a chemical in accordance with the nomenclature systems of the International Union of Pure and Applied Chemistry (IUPAC) or the Chemical Abstracts Service (CAS)
- ➢ CAS number: the identification number that is unique to a particular chemical and is assigned by the Chemical Abstracts Service

SECTION III: PHYSICAL AND CHEMICAL CHARACTERISTICS

- ➢ Physical and chemical data such as boiling point, vapor pressure, vapor density, solubility appearance, melting point, and evaporation rate

SECTION IV: FIRE AND EXPLOSION HAZARD DATA

- ➢ Information needed for planning fire and explosion prevention, including flash point, flammable limits, and special fire-fighting procedures

SECTION V: REACTIVITY DATA

- ➢ Outline of the stability of the product and the potential for hazardous polymerization and decomposition and a list of materials and conditions to avoid during use

SECTION VI: HEALTH HAZARDS

- ➢ Explanation of the most common sensations or symptoms a person might experience from acute and chronic *overexposure* to the material or its components, emergency and first aid procedures, any TLVs® or PELs are listed, and, if the chemical is a carcinogen, the source of this designation

SECTION VII: SAFE HANDLING AND USE

- ➢ Designated special handling and disposal methods and storage and spill precautions

SECTION VIII: CONTROL MEASURES

- ➢ Manufacturer recommendations for the use of ventilation, personal protective equipment, and hygienic practices

Many data sheets now also contain detailed information regarding labeling, transport, toxicity, and regulatory requirements. All required sections must be completed. If the required information is not available or not applicable, this must be shown on the form. Additionally, if the ingredients of a chemical mixture are trade secrets, their identity can be withheld, but their hazardous properties must be given.

These forms are required to be readily available to employees. Training in their use should be included in employee training required under the Hazard Communication legislation (see Chapter 28, Government Regulations).

Information Resources

The Internet now provides immediate access to current toxicology data and hazardous substance information. For all but the most common and well-studied substances (e.g., acetone, sodium hydroxide), reliable databases (Internet-accessible) should be queried first for relevant data and guidelines. However, beware of data obtained from websites, the authors of which are not listed and/or are not a government agency or academic institution.

Listed below are recommended websites—all with search capabilities.

SUMMARY

The word *toxicity* is used to describe the ability of a substance to have an adverse effect on the health or well-being of a human. Whether any ill effects occur depends on the properties of the chemical, the dose (the amount of the chemical acting on the body or system), the route by which the substance enters the body, and the susceptibility or resistance of the exposed individual.

There are four routes of entry or means by which a substance may enter or act on the body: inhalation, skin absorption or contact, ingestion, and injection. Of these, inhalation is the most important occupational exposure route.

When a toxic chemical acts on the human body, the nature and extent of the injurious response depends on the dose received—that is, the amount of the chemical that actually enters the body or system and the time interval during which this dose is administered. Response can vary widely and might be as slight as a cough or mild respiratory irritation or as serious as cancer and death.

The practice of industrial hygiene is based on the concept that for each substance there is a level of exposure below which significant injury, illness, or discomfort rarely or never occurs. The industrial hygienist protects the health of workers by assessing potential chemical and physical agent exposures and controlling the environmental conditions so that the risk of exposure is minimized.

Chapter 7

Gases, Vapors, and Solvents

by George P. Fulton, MS, CIH
revised by S. Katharine Hammond, PhD, CIH

A potential threat to the health, productivity, and efficiency of workers in most occupations and industries is their exposure to gases and vapors from solvents, chemical products, by-products of chemical use, and chemical processes. No one fully comprehends the total effect, yet all of us are exposed and we all are affected.

Exposures to volatile chemicals occur throughout life, from conception to death. For example, organic solvent vapors inhaled by a mother can reach the fetus. Exposures also occur in the course of daily living, ranging from the inhalation of vapors from a newspaper freshly off the press, to exposure to cleaning solvents by all routes of entry, to a worker manufacturing computer chips, to a researcher in a laboratory, to a farm worker hoeing weeds. It may occur at home or at work. Effects from the exposure may range from a simple objection to an odor to death at high concentrations. In between, there is a whole spectrum of effects.

Solvents convert substances into a form suitable for a particular use. Solvents are significant because many substances are most useful when in solution.

Organic and inorganic compounds are used in the home as cleaning agents, paint thinners, coatings, and spot removers; in the office as typewriter key cleaners, desktop cleaners, and wax removers; in commercial laundries as dry cleaning liquids; on the farm as pesticides; in laboratories as chemical reagents and drying, cleaning, and liquid extraction agents; in shops as cleaners, solvents, by-products from processes such as welding, and paints. Many consumer products packaged in cans and drums contain mixtures of organic chemicals.

Because of the nearly infinite number of combinations possible for the variables involved—hundreds of different compounds, degree of concentration, duration of exposure, combined effects with other solvents, gases and vapors, and the health and age of an exposed person—generalizations about effects of exposure on a particular person are difficult to make. The problem lies not so much in the effect itself, but rather in determining which effects are harmful and at what level.

PROPERTIES OF GASES, VAPORS, AND SOLVENTS

Two of the three fundamental states of matter, gases and liquids, are discussed in this chapter; the solid phase is discussed in the next chapter. A gas is a formless fluid that completely fills its container and that exerts an equal pressure in all directions. Gases spread rapidly throughout a room by diffusion.

Gases are materials that are in the gaseous state at normal temperature (25 C) and pressure (1 atmosphere)—NTP. Chemicals that are liquids at NTP will exist partially in the gaseous phase, and that portion is known as a vapor. If a liquid is spilled, or otherwise has a large surface area, some will evaporate, and, over time, equilibrium may be established between the gas and liquid phases. The vapor pressure is a measure of the concentration of the chemical in the air at equilibrium; the higher the vapor pressure, the higher the concentration of the chemical at equilibrium. Vapor pressure is very temperature dependent, so that as the temperature rises, the airborne concentration of an equilibrium mixture will rise. Although there is often insufficient time or material for equilibrium to be established, the vapor pressure remains a good measure of the tendency of a liquid to evaporate, and, other factors being equal, a solvent with a higher vapor pressure will have a higher airborne concentration than a solvent with a lower vapor pressure.

Solvents are liquids in which something, called a solute, can be dissolved; solids may also be suspended in solvents. The solute may have been a solid, a gas, or another liquid before being dissolved in the solvent. Solvents are very useful both to transport solutes and to clean materials. In many cases, such as paint application, solvents work best if they evaporate relatively quickly, leaving behind an even application of the solid material; however, this very property may lead to high vapor concentrations in the air.

Although the term "solvent" is often used to describe organic solvents, water is a solvent as well. Common acids and bases are aqueous solutions. The common inorganic acids include the hydrogen halides (HF, HCl, HI, HBr), the oxygen acids (nitric [HNO_3], phosphoric [H_3PO_4], and sulfuric [H_2SO_4]), and others such as hydrogen sulfide (H_2S) and hydrogen cyanide (HCN). These are commercially available as compressed gases, liquids, aqueous solutions of various concentrations, or, in some cases, as solids. These acids may be strong (completely ionized in aqueous solution) or weak (parent acid in equilibrium with its acid anion; the parent acid predominates).

Vapor phase water is not considered hazardous, and the solutes that dissolve in water are polar or ionic, and so generally have low vapor pressures; therefore, there is less potential hazard from inhalation of vapors from aqueous solutions in general. However, the gases that dissolve in water to form acids will off-gas from solution due to the equilibrium between the gas phase and the solution. The more volatile acids, such as HCl, do so readily; the less volatile acids, such as H_2SO_4 and H_3PO_4, do so only at elevated temperatures. As temperatures are increased, equilibrium is driven to the gas phase; the simple acids are driven off as the gas and the oxygen acids can decompose to produce oxides such as NO/NO_2 and SO_2/SO_3. As the pH is lowered (more acidic), volatility from solution is increased; as the pH is raised (more alkaline), the acid anion is stabilized in solution and it is essentially not volatile.

Another important characteristic of solvents, in addition to their volatility, is their polarity. Some solvents are highly polar, like water, while others are nonpolar, such as hexane, and others are of intermediate polarity. A fundamental principle, "like dissolves like," states that more polar or ionic solutes will dissolve more readily in polar solvents than in nonpolar solvents. For example, more salt will dissolve in water than in hexane, that is, salt is more soluble in water than in hexane. Conversely, grease dissolves better in gasoline than in water.

Solubility is very important in understanding the hazards presented by various solvents as solubility affects absorption into the body, distribution throughout the body, storage in various tissues, and elimination of chemicals. Thus, more fat soluble, or lipophilic, chemicals pass through the skin than those chemicals that are soluble in water only, while substances that are soluble in both water and fat are most readily absorbed. Clearly dermal absorption will be more important for the latter compounds. Solubility is also important in evaluating the potential effect of a chemical on the central nervous system. The blood-brain barrier appears to be much more effective at excluding ionized molecules than those that are fat soluble. Water soluble compounds tend to be excreted fairly rapidly, while fat soluble substances are often stored in the adipose tissue.

Where a solvent system is in use, three distinct possible routes of exposure must be considered. First, if an opportunity exists for skin contact, dermal absorption may be important. If the vapor pressure is high, or the temperature is high, inhalation of vapors may be important. Finally, one must also consider the possibility of exposure to an aerosolized mist of the solution, in which case there is also exposure to the solutes. Because of the high volume of breathing and the large surface area of the lungs, which are designed for maximum interchange between blood and air in the lungs, inhalation is usually the most important route of exposure. However, in some cases the dermal route predominates.

CRITICAL EXPOSURE FACTORS

The hazard presented by use of a chemical is a function not only of its inherent toxicity, but also of the potential for exposure. While one substance may be extremely toxic, and therefore very well controlled so that the exposure is negligible, a greater hazard may then exist in the same workplace due to an inherently less toxic chemical which is totally uncontrolled, and to which the worker is exposed at high levels.

Mode of Use and Potential for Exposure

The most important factors in exposure potential are how the material is used and what controls (engineering or personal protective equipment), if any, are in place. Processes that use gaseous reactants (as in a semiconductor chip manufacturing process) are often completely enclosed; the gases are often too reactive to coexist with air and the purity of the product demands it. In the event of a system failure, a compressed gas at pressures of several hundred pounds per square inch (psi) poses greater risk than a liquefied gas with a pressure of a few psi. Painting operations pose risk of exposure to solvents, reactive chemicals such as the isocyanates, or suspected carcinogens such as hexavalent chromium (used in primers). Spray painting poses a greater exposure risk for the worker than brush or roller application. When inhalation exposures are controlled, dermal exposure may be the major route of entry. Many organics readily permeate the skin or glove materials; some, such as dimethyl sulfoxide, are of limited toxicity but may be a vehicle for transporting other toxic materials into the body.

Temperature and Volatility

The airborne concentration of a solvent vapor depends on the vapor pressure, which is a measure of the volatility of the solvent. The vapor pressure of any chemical compound is directly related to the temperature. For solvents that are liquids at room temperature, this can make a significant difference in exposure potential. For example, methyl ethyl ketone (MEK) has a vapor pressure of 100 mm Hg at 25 C and 400 mm at 60 C. Thus, for two similar processes using the same solvent, the one taking place at lower temperature poses less potential for exposure.

The boiling point and vapor pressure increase with increasing numbers of carbon atoms provided the functional group remains the same; for example, among the three ketones, acetone, methyl ethyl ketone, and methyl isobutyl ketone (3, 4, and 5 carbon atoms, respectively), the boiling points are 56, 80, and 128 C, respectively. However, compounds with the same number of carbon atoms but different functional groups will have very different boiling points and vapor pressures; for example, the compounds with three carbon atoms have boiling points ranging from –44 F for propane (a hydrocarbon), through 133 F for acetone (a ketone), 207 F for propanol (an alcohol), to 256 F for methyl cellosolve, or 2-methoxy ethanol.

Concentration

The effect of concentration may be manifested in several ways. From the point of view of chemical kinetics, reaction rates depend on some factor of concentration; for a given concentration x, the rate is proportional to x, x^2, or some other factor depending on the reaction mechanism. Nitric oxide (NO, TLV 25 ppm) at higher concentrations reacts rapidly with oxygen to produce nitrogen dioxide (NO_2, TLV 3 ppm), but at very low concentrations the rate is very slow. The vapor pressure of a solute over a solution varies directly as the mole fraction (concentration) of the solute and the vapor pressure of the solute when it is pure, according to Raoult's law. In both cases, reducing concentration reduces the potential for exposure by limiting the amount of toxic product formed or volatilized. Some chemicals, such as sulfuric acid, are available in a variety of concentrations; the standard grade is approximately 98 percent acid. The vapor pressure is so low at room temperature that it poses minimal risk. The grade marketed as oleum, or fuming sulfuric acid, is much more reactive and off-gases sulfur dioxide; it poses significant risk to the worker. Chemical protective clothing for those working with highly reactive materials must be selected carefully; butyl rubber is satisfactory for sulfuric acid, but has significantly diminished breakthrough times for oleum.

Reactivity

Chemical reactivity can enhance or reduce health hazard potential. Other physical hazards, such as fire, become significant for pyrophoric materials such as silane (SiH_4) and yellow phosphorus. Acids or bases can react with volatile compounds to stabilize them. In a strongly alkaline solution (high pH), cyanide salts cannot form volatile hydrogen cyanide (HCN); in an acid solution (low pH), volatile amines (ammonia or organic amines) are converted to nonvolatile ammonium salts in solution. Liquid metal halides (tungsten or rhenium hexafluoride) react rapidly with moisture in the air to form gaseous hydrogen fluoride (HF).

Exposure Guidelines

Several guidelines exist to assist industrial hygienists in interpreting the hazard posed by specific concentrations of gases and vapors in the workplace. The most commonly used in the United States are TLVs (Threshold Limit Values®), PELs (Permissible Exposure Limits), and RELS (Recommended Exposure Limits).

TLVs are established by a committee of the American Conference of Governmental Industrial Hygienists and composed of professionals working voluntarily. The ACGIH has published its TLVs for over 50 years. Threshold Limit Values (TLVs) refer to "airborne concentrations of substances and represent conditions under which it is believed that nearly all workers may be repeatedly exposed day after day without adverse health effects." (ACGIH, 2001). For some gases and vapors, short-term exposure limits (STELs) have also been established when exposure to higher concentrations for 15 minutes may lead to serious health consequences. See Appendix B for a listing of the TLVs and STELs. The ACGIH cautions that "these values are *not* fine lines between safe and dangerous concentrations"; they should be used as guidelines in evaluating exposures in particular workplace. Each year some of the TLVs are revised, and often new chemicals are added to the list. Although some countries have adopted the TLVs as legal limits, they were not intended for that purpose, and do not have the weight of law in the United States.

PELs, by contrast, are legal exposure limits in the United States and are established by the Occupational Safety and Health Administration (OSHA). OSHA initially adopted the 1968 TLVs® as PELs, and has since issued revised PELs for only 27 substances. The revised PELs include much more recent data, details on health effects, and often include more details on required monitoring and protections, including biological monitoring in some cases.

The National Institute for Occupational Safety and Health studies compounds of concern and issues Recommended Exposure Limits (RELs), along with reports on the scientific data upon which RELs are based, the *Criteria* documents. RELs may be used by OSHA in setting new PELs. In the meantime, RELs provide important guidance to the practicing industrial hygienist.

Each of these occupational exposure limits has its limitations. TLVs have been criticized because some feel that industry has had too much influence in their establishment, and the levels appear to be insufficiently protective given the scientific data presented; ACGIH has taken several steps to try to alleviate these concerns.The rulemaking procedure for PELs is arduous and subject to multiple hearings, comment periods, and legal appeals; this lengthy process has restricted the ability of OSHA to revise PELs as new health data have arisen in the past three decades. Thus, while TLVs have been established for more than 720 chemicals, PELs exist for only 412 chemicals. OSHA does state that the employer has a general duty to provide a safe workplace, and interprets this to imply that TLVs should be also be considered. Therefore, the industrial hygienist is best advised to make use of all available occupational exposure limits, PELs, TLVs, and RELs, and to understand the basis upon which such recommendations are made.

SOLVENTS

Organic Chemistry

Organic chemistry is the chemistry of the compounds of carbon. The carbon atom can form single, double, and triple covalent bonds to other carbon atoms and to atoms of other elements. A *molecular chain* (or *skeleton*) consists of a line of carbon atoms that can have branches of carbon atoms, or functional groups. These functional groups can contain oxygen (O), nitrogen (N), phosphorus (P), and sulfur (S), among others. A *functional group* in an organic molecule is a region where reactions can take place. Double and triple bonds and the presence of atoms other than carbon make up typical functional groups.

Organic compounds are named according to the number of carbon atoms in the basic skeletal chain. The location of the functional groups is designated by the number of the carbon atom to which it is attached. The common organic solvents can be classified as aliphatic, cyclic, aromatic, halogenated hydrocarbons, ketones, esters, alcohols, and ethers. Each class has a characteristic molecular structure, as shown in Table 7–A.

Compounds with only carbon and hydrogen atoms are called *hydrocarbons*. *Hydrocarbons* with all single bonds are alkanes, and are also known as saturated hydrocarbons, as they contain the maximum number of hydrogen atoms. Hydrocarbons forming chains are known as aliphatic or paraffin hydrocarbons, while those forming rings are identified with the prefix *cyclic-* or *cyclo-*. One very important cyclic hydrocarbon is benzene, which contains six carbon atoms and is very stable; compounds which contain benzene are described as aromatic compounds.

Halogenated hydrocarbons have chlorine, fluoride, iodine, and/or bromine atoms attached to a hydrocarbon. Ketones, esters, alcohols, and ethers all have an oxygen atom attached to a carbon atom, and examples are given in Table 7-A.

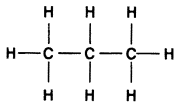
Isomers are molecules that have the same number and kinds of atoms, but the atoms are arranged differently, and thus have different physical and chemical properties. For example, both ethanol and dimethylether have two carbon atoms, six hydrogen atoms, and one oxygen atom, but the atoms are arranged differently, and the two compounds have quite different properties, e.g., dimethylether is a gas at room temperature, while ethanol is a liquid. A good working knowledge of the nomenclature, the characteristic molecular structure, and the different toxicities is helpful in making a proper assessment of an exposure.

Nomenclature itself can often be misleading. For example, trichloroethane and trichloroethylene are chlorinated hydrocarbons differing in the types of bonds and the arrangement of chlorine atoms. Trichloroethane is saturated whereas trichloroethylene has a carbon–carbon double bond. Trichloroethane is a saturated compound in which the three chlorine atoms may be attached to the same carbon atom (1,1,1-trichloroethane), or two may be attached to one carbon and one to the other carbon atom (1,1,2-trichloroethane); trichlorethylene has a double bond between the carbon atoms and there is only one possible arrangement of the chlorine atoms, two on one carbon and one on the other. These three compounds, 1,1,1-trichloroethane, 1,1,2-trichloroethane, and trichlorethylene, have very different toxicities and very different TLVs, 350 ppm, 10 ppm, and 50 ppm, respectively. On the other hand, 1,1,1 trichloroethane has been identified as an ozone-destroying chemical (see Air Pollution, later), and production was banned in the United States after Jan. 1, 1996. This example illustrates the importance of correctly identifying the chemical being used. These chemicals are easily confused due to slight difference in names, which might not be apparent to a worker with inadequate training.

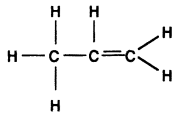
Common names may not impart any information as to the structure of a molecule (muriatic acid as compared to hydrochloric acid) and can even be misleading (ethylene dichloride is actually the completely saturated 1,2-dichloroethane); systematic names, using the International Union of Pure and Applied Chemistry rules, unambiguously describe the structure of a molecule. The *CRC Handbook of Chemistry and Physics* describes this system in detail.

Table 7–A. ***Major Classes of Organic Compounds***

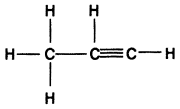
Aliphatic Hydrocarbons



alkane, C_nH_{2n+2}
propane



alkene, C_nH_{2n}
propene



alkyne, CnH_{2n-2}
propyne (methyl acetylene)

Aromatic Hydrocarbons

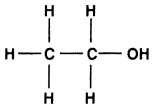
benzene, C_6H_6

toluene, $C_6H_5CH_3$
(methyl benzene)

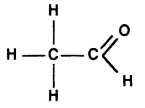
Cyclic Aliphatic Hydrocarbons

cyclohexane

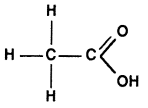
Oxygen-containing Functional Groups



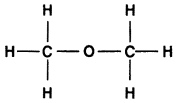
alcohol, ROH
ethanol



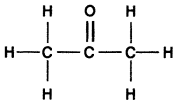
aldehyde, RCOH
ethanal (acetaldehyde)



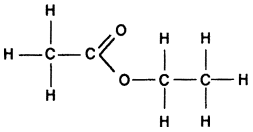
acid, RCOOH
ethanoic acid (acetic acid)



ether, ROR′
dimethy ether

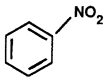


ketone, R(C = O)R′
dimethyl ketone (acetone)

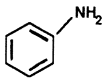


ester, RCOOR′
ethyl acetate

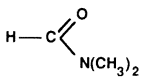
Nitrogen-containing Functional Groups



nitro-compound, RNO_2
nitrobenzene



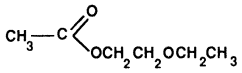
amine, RNH_2
aniline



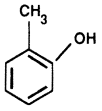
amide, RCONR′R″
dimethyl formamide (DMF)

Miscellaneous Functional Groups

glycol ether
2-methoxyethanol

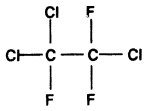


glycol ether ester
2-ethoxyethyl acetate
ethyl cellosolve



phenol, ROH
o-cresol

Halogenated Hydrocarbons



1,1,2-trichloro-1,2,2-trifluoroethane
(Freon TF)

Even a scientifically trained user often has only a vague and sometimes completely erroneous knowledge of the chemical preparation in use. It is a good practice to verify the specific name and composition of the solvents involved with direct evidence from the label, from the manufacturer's Material Safety Data Sheet, or from the laboratory. Only after verification of name and composition should one attempt to evaluate the potential effect or hazard of a solvent.

Manufacturers now are required by government regulations to provide information on the composition of their trade name materials. The minimum information is that contained in the Material Safety Data Sheet (MSDS) (Figure 7–1). Manufacturers can withhold proprietary information from an MSDS for general use, but are required to furnish it in cases of medical necessity.

Hawley's Condensed Chemical Dictionary, Windholz's *The Merck Index,* Gleason's *Clinical Toxicology of Commercial Products,* and the NFPA *Fire Hazard Properties of Flammable Liquids, Gases, and Vapors* provide general information and descriptions of many solvents, including trade name materials. These are helpful references for classifying and understanding the composition of a solvent.

HAZARDS OF GASES, LIQUIDS, SOLVENTS, AND VAPORS

Compressed Gas

The use of compressed gas cylinders has inherent dangers in their handling. If the tank were to fall and the valve snap off, the cylinder can become a projectile; therefore, one should always cap the valve before transporting cylinders of compressed gas, and the cylinders should be securely stored with double chains to prevent falling. They should also be protected from heat, which may cause a liquid to volatilize or react, and so generate greater pressures inside than the cylinder was designed to withstand. Attention should be paid to the reactivity of the gases with the regulators and lines. For this reason, copper should be avoided in systems with acetylene or ammonia. Regulators should be dedicated to use with single gases, and mixed use with potentially reactive gases should be strictly avoided. Often flammable gas cylinders are reverse threaded to prevent mixing with oxygen inside the regulator.

Gases

Commercially, gases are available as compressed or liquefied gases. Certain gases, such as nitrogen, helium, and some others that are available as liquefied gases, are used as a source of high-purity gas from boil-off or as a cryogenic fluid at the gas's boiling point (77 K or –196 C for liquid nitrogen). Table 7–B gives common industrial gases, cylinder pressures, and physical state. All of these readily volatilize, although some organometallic compounds typically available as liquefied gases must be heated to give an adequate working pressure.

Cryogenic Liquids

Cryogenic liquids pose several safety concerns in addition to frostbite from extreme cold. Spills of cryogenics rapidly vaporize, producing a gas that is initially significantly more dense than air, resulting in potential oxygen deficiency hazards in pits, vaults, and enclosed spaces. Given sufficient time, the gas reaches thermal equilibrium with its surroundings and disperses throughout the available space. Liquid nitrogen, the most common cryogenic fluid, boils at a lower temperature than liquid oxygen, providing a location for oxygen to condense out of the atmosphere into dewars (double-walled flasks with a vacuum between the walls) with the nitrogen. This creates a potential explosion hazard if the oxygen comes in contact with an oxidizable material. Cryogen dewars and cryogenic systems must have proper pressure relief to prevent pressure buildup and possible rupture as the liquid vaporizes. Full containment of a liquefied gas is usually not possible; helium requires about 18,000 pounds per square inch (psi) and nitrogen requires 43,000 psi. Table 7–C lists common cryogenic liquids.

Flammability, Explosions, and Reactivity

Some gases are very pyrophoric. Silane is used extensively in the semiconductor industry, but is a well-recognized fire hazard as it will ignite spontaneously when exposed to air; silane has been responsible for several serious fires causing millions of dollars of damage. Perchloric acid is a strong oxidizing agent which can cause fire and explosions. Some solvents, e.g., some ethers, are unstable over time, and degrade into explosive compounds.

Depending on their flash points, liquids may be flammable or combustible, as described by the National Fire Protection Association (see NFPA 30, *Flammable and Combustible Liquids Code* and NFPA 325, *Fire Hazard Properties of Flammable Liquids, Gases and Volatile Solids*).

FLASH POINTS

The flash point of a liquid is the lowest temperature at which it gives off enough vapor to form an ignitable mixture with the air near the surface of the liquid or in a vessel capable of flame propagation away from the source of ignition. Some evaporation takes place below the flash point, but not in sufficient quantities to cause an ignitable mixture. Flash points can be determined by using either closed-cup or open-cup testers. Open-cup flash points are determined with the liquid in the open air and are generally 10 to 20 percent higher than closed-cup flash point figures for the same substance. When open-cup flash point figures are given, they are usually identified by the initials *OC*.

FLAMMABLE LIQUIDS

A liquid with a closed-cup flash point below 100 F (37.8 C) and a vapor pressure not exceeding 40 psi absolute (psia) at 37.8 C is a Class I liquid. Class I liquids are subdivided as follows:

- Class IA liquids include those with a flash point below 73 F (22.8 C) and a boiling point below 100 F (37.8 C).

Table 7–B. *Selected Compressed and Liquefied Gases*

Gas	Formula	Form	*Cylinder Pressure (psig)*
Ammonia	NH_3	Liquid	114
Argon	Ar	Gas	225–6,000
Arsine	AsH_3	Liquid	190–205
Carbon dioxide	CO_2	Liquid	830
Helium	He	Gas	225–6,000
Hydrogen	H_2	Gas	225–3,500
Hydrogen chloride	HCl	Liquid	613
Hydrogen fluoride	HF	Liquid	0.6
Methane	CH_4	Gas	1,500–2,300
Neon	Ne	Gas	225–1,900
Nitrogen	N_2	Gas	225–6,000
Nitrous oxide	N_2O	Liquid	745
Oxygen	O_2	Gas	225–2,200
Phosphine	PH_3	Liquid	400–590
Silane	SiH_4	Gas	150–1,200

Reprinted with permission from Matheson Gas Products, *Matheson Gases & Equipment,* 1993.)

- ➢ Class IB liquids include those with a flash point below 73 F (22.8 C) and a boiling point at or above 100 F (37.8 C).
- ➢ Class IC liquids include those with a flash point at or above 73 F (22.8 C) and below 100 F (37.8 C).

COMBUSTIBLE LIQUIDS

Liquids with a closed-cup flash point at or above 100 F (37.8 C) are called combustible liquids, which are subdivided as follows:

- ➢ Class II liquids include those with a flash point at or above 100 F (37.8 C) and below 140 F (60 C).
- ➢ Class IIIA liquids include those with a flash point at or above 140 F (60 C) and below 200 F (93.4 C).
- ➢ Class IIIB liquids include those with a flash point at or above 200 F (93.4 C).

FIRE POINT

The fire point of a liquid is the lowest temperature at which vapors evolve fast enough to support continuous combustion. The fire point temperature is usually about 5 F above the flash point temperature.

FLAMMABLE RANGE

A prominent factor in rating the fire hazard of a flammable liquid or gas is its flammable range, sometimes called the explosive range. For each flammable liquid or gas, there is a minimum concentration of its vapor, in air, below which propagation of flame does not occur on contact with a source of ignition because the mixture is too lean. Propagation of flame is the self-sustaining spread of flame through the body of the flammable vapor-air mixture after introduction of the source of ignition; a vapor-air mixture at or below its lower explosive limit can burn at the point of ignition without propagating. There is also a maximum concentration of vapor, in air, above which propagation of flame does not occur because the mixture is too rich. The mixtures of vapor with air that, if ignited, just propagate flame are known as the lower and upper flammable (or explosive) limits, and are usually expressed in terms of percentage by volume of vapor in air.

Table 7–C. *Common Cryogenic Liquids*

Cryogen	Boiling Point (C)
Argon	–186
Helium	–287
Hydrogen	–252
Neon	–245
Nitrogen	–196
Oxygen	–183

(Reprinted with permission from Lide DR, Frederickse HPR, eds. *CRC Handbook of Chemistry and Physics,* 75th ed. Boca Raton, FL: CRC Press, 1994.)

The flammable (or explosive) range includes all the concentrations of a vapor in air between the lower explosive limit (LEL) or lower flammable limit (LFL) and the upper explosive limit (UEL) or upper flammable limit (UFL). The lower flammable limit is important because if this percentage is small, it takes only a small amount of the liquid vaporized in air to form an ignitable mixture.

It also should be noted that if the concentration of vapor in the vapor-air mixture is above the upper flammable limit, introduction of air (by ventilation or other means) produces a mixture within the flammable range before a safe concentration of vapor below the lower flammable limit can be reached.

For a large number of common liquids or gases, the LEL is a few percent and the UEL is 6-12 percent, although there are notable exceptions. The LEL and UEL for hydrogen are 4 and 75 percent and for anhydrous hydrazine they are 4.7 and 100 percent, respectively. For specific materials, consult the material safety data sheet or NFPA 325. For hazardous vapors, if the airborne concentration is kept below the PEL or TLV, the concentration is less than the LEL (note that a concentration of 1 percent by volume is 10,000 ppm).

REQUIREMENTS AND GUIDELINES

The occupational safety requirements for the handling and use of flammable and combustible liquids and gases are given in Subpart H of 29 *CFR* 1910. These rules are based on the 1965–1970 editions of the NFPA guidelines current at the time the OSHA standards were first written. Best management practice suggests that current NFPA guidelines should be followed to the extent feasible. Compliance with Subpart H is a minimum.

TOXICOLOGICAL EFFECTS

Site of Action

For some toxicants, the site of action is at the point of exposure, i.e., the skin or the respiratory tract. For others, the target organ is more distant, or the effect is systemic.

Water-soluble gases are more likely to be upper respiratory tract irritants (e.g., HF, ammonia, sulfuric acid), while the less soluble gases (nitrogen dioxide, ozone, phosgene) pass through the upper airways and penetrate to the bronchioles and alveoli where they may have a delayed reaction and cause acute pneumonitis and pulmonary edema hours later. Chemicals which might otherwise deposit in the upper respiratory tract may penetrate into the deep lung if they are adsorbed to particles.

Asphyxiation

Oxygen is essential to life, and delivery of oxygen to the cells is equally vital. Gases and vapors can interfere with the supply of oxygen in two fundamental ways: simple asphyxiants exert no direct action, but act passively by merely replacing oxygen in the air so that the concentration of oxygen falls below the 18 percent minimum required for life. Any gas or vapor, even nitrogen, can act as a simple asphyxiant if its concentration is high enough. By contrast, chemical asphyxiants react with essential cellular molecules to disrupt the transport or use of oxygen. Carbon monoxide forms a very stable complex with hemoglobin, and so blocks the readily reversible interaction of hemoglobin with oxygen that is crucial to carrying oxygen to the cells. Chemical asphyxiants may also interfere with the cell's ability to use the oxygen which is delivered, e.g., cyanide and hydrogen sulfide inhibit cytochrome oxidase enzymes and so disrupt the normal reactions of the cell.

Organic and Inorganic gases

Simple gases (low-molecular-weight hydrocarbons such as methane, ethane, and propane), nitrogen, hydrogen, the inert gases (helium, neon, and argon), and some compounds (CO_2) have no significant toxicity of their own. They are simple asphyxiants; they dilute oxygen in the atmosphere. These elements and compounds have either no or very minimal odor and thus have poor warning properties.

The oxides of carbon, nitrogen, and sulfur can be produced by use of oxygen acids, combustion, welding, chemical cleaning or electroplating, or a variety of other processes. Decomposition of organic material may produce toxic (hydrogen sulfide) or flammable (methane) atmospheres. Others, such as ammonia, boron halides, phosphine, arsine, and silane, are used as reactants in industrial and manufacturing processes. Others, such as the reactive, volatile metal halides, are used in research.

In all of these cases, reactivity of the gas is important. The oxides may react with moisture in the mucous membranes to form acids; ammonia, an alkaline gas, acts as a primary irritant. Boron or volatile metal halides react spontaneously in moist air to form gaseous hydrogen halides. Phosphine and silane are spontaneously flammable in air. Arsine and phosphine are also highly toxic.

Exposure control relies primarily on engineering controls. Dilution ventilation *may* be sufficient for the simple asphyxiants. Local exhaust ventilation is suitable for many processes. The more reactive or highly toxic compounds require complete control (exhaust ventilation, gas sensors, all-welded construction for gas lines, excess flow-controllers, automatic shut-down systems, etc.) to ensure protection of the workers.

Inorganic Acids and Bases

Strong acids and bases are corrosive and can burn the skin and mucous membranes. Health effects are variable and concentration-dependent, most often on the site of contact with tissue; they include irritation of mucous membranes or respiratory tract by HCl, chemical burns by the concentrated solutions, oxidation by HNO_3 (an oxidizing acid), and dehydration by H_2SO_4. The highly toxic acids H_2S and HCN act differently from other acids; they complex with metal-containing enzymes (cytochromes), preventing cellular oxygen metabolism.

Concentrated HF is particularly corrosive to tissue and bone. Pain from HF solutions stronger than 50 percent is felt within a few minutes; lower concentrations may not produce pain for several hours. Serious tissue damage may result without the person being aware of it. HF burns require immediate action: Irrigate the exposed area to flush away as much HF as possible and seek medical attention immediately. Treatment is dependent on the severity of the burn; mild cases can be managed with magnesium oxide but more severe burns may require infiltration of the affected tissue with calcium gluconate.

Engineering controls and protective equipment should be used to limit exposure. Use of personal protective equipment is essential for working with concentrated acids. Chemical compatibility of the protective clothing with the acid must be considered to ensure protection of the worker (see Johnson, Swope, Goydan, et al, 1991).

Other Aqueous Solutions and Systems

These are known for their irritant effects after prolonged exposure. Contact dermatitis from aqueous solutions is quite common, usually appearing as "dishpan hands." Excessive levels of mists in the air (resulting from heating, agitation, and spraying) can cause throat irritation and bronchitis. Many other effects and hazards are possible if chemicals react with their containers. Bretherick (1990) and Lewis (1997) cite a number of examples. As a rule, aqueous systems, because of their low vapor pressure and ease of control, are a lesser problem, but they cannot be dismissed as potential hazards.

Solvents and Solvent Vapors

Organic solvents can have an array of toxic effects on humans; some effects are similar for all solvents, and other effects are specific to particular solvents or their metabolites. While the common effects generally occur at relatively high concentrations of solvent vapors, the specific effects tend to become manifest at lower concentrations.

Direct contact of solvents with the skin can cause irritation, defatting of the skin, and dermatitis. Some solvents, especially less polar (lipophilic) solvents, can penetrate the skin, so dermal exposure to solvents can be an additional route of exposure. Some recent experiments have demonstrated that solvent vapors can also be absorbed through the skin.

At very high concentrations (thousands of ppm), solvent vapors may cause simple asphyxiation by displacing oxygen. This is most likely to occur in confined spaces. At high concentrations (typically hundreds of ppm) solvents tend to have a rapid effect on the central nervous system which results in dizziness, disorientation, confusion, euphoria, and giddiness; prolonged exposure at high levels can lead to loss of consciousness, paralysis, convulsion, and, ultimately, death from respiratory or cardiac arrest.

In addition to these effects of solvents in general, specific solvents may have specific toxicities. Organ systems that are affected by some solvents include the liver, the kidney, the central nervous system, and the peripheral nervous system.

PHYSIOLOGICAL EFFECTS

Some of the effects are outlined in the following paragraphs. For detailed information on specific organic solvents, consult Clayton and Clayton's *Patty's Industrial Hygiene and Toxicology,* Gerarde's *Toxicology and Biochemistry of Aromatic Hydrocarbons,* The American Conference of Governmental Industrial Hygienists *Documentation for the Threshold Limit Values,* the American Industrial Hygiene Association (AIHA) *Hygienic Guide Series,* and the NIOSH *Registry of Toxic Effects of Chemical Substances* or the NIOSH criteria document on the subject solvent (see Bibliography).

Hydrocarbons

ALIPHATIC HYDROCARBONS

The aliphatic compounds take their name from the Greek word *aliphe,* meaning fat, because fats are derivatives of this class of hydrocarbons (see Table 7–A).

Aliphatic hydrocarbons are further classified as alkanes, alkenes, cycloalkanes, cycloalkenes, alkynes (acetylenes), and arenes (an aliphatic group is bonded to an aromatic ring). Petroleum and natural gas are the most important sources of alkanes, alkenes, and cycloalkanes. Coal tar is an important source of arenes. High-molecular-weight alkanes are broken down (cracked) catalytically to increase the yield of gasoline from petroleum. Ethylene (H_2CCH_2) is an important by-product of cracking and is used to make plastics and ethanol (CH_3CH_2OH).

The saturated aliphatic hydrocarbons, C_nH_{2n+2}, known as alkanes, are those with all bond positions saturated by bonding with hydrogen. Compounds in this series have the characteristic *-ane* suffix, as in isobutane, 2-methylpentane, and 2, 2-dimethylpentane. They are as inert biochemically as they are chemically. Even as air pollutants, they are among the least reactive and do not pose a significant problem. The alkanes are good solvents for natural rubber. They act primarily as CNS depressants.

A relatively high level is required for toxic effects. The TLVs generally range from 100 ppm and higher. The exception is n-hexane (or normal hexane, the straight-chained isomer), with a TLV of 50 ppm. Repeated exposures to excessive concentrations may cause peripheral neuropathy, although other isomers have not been found to have this health effect.

The unsaturated aliphatic hydrocarbons, the alkenes (C_nH_{2n}) and the alkynes (C_nH_{2n-2}), with double and triple bonds respectively, are similarly inert in the body. However, they are more chemically reactive than the saturated hydrocarbons. As air pollutants, they are reactive and create a control problem. The primary health problem associated with the aliphatics is dermatitis.

Crude oil (petroleum) is mainly a very complex mixture of aliphatic compounds. It contains alkanes, alkenes, cycloalkenes, and arenes, as well as small amounts of nitrogen and sulfur compounds, which vary depending on the source.

Petroleum is separated into mixtures of hydrocarbons by fractional distillation. Gasoline is the fraction of petroleum boiling between room temperature and 200 C and is mainly made up of C_5 to C_{11} hydrocarbons, with C_8 predominating. It has been estimated that there are as many as 500 different hydrocarbons in gasoline alone. About 150 of them have been separated and identified.

CYCLIC HYDROCARBONS

The cyclic hydrocarbons act much in the same manner as the aliphatics, but they are not quite as inert. A significant percentage of cyclic hydrocarbons are metabolized to compounds with a low level of toxicity.

The lower molecular weight cycloalkanes (cyclopropane and cyclobutane) have been used as anesthetics. The cycloalkanes typically are CNS depressants, but as molecular weight increases, the margin of safety between anesthesia and adverse health effects decreases. The unsaturated cyclic hydrocarbons generally are more irritating than the saturated forms. This may be due in part to the reactivity of the carbon–carbon double bond. For example, cyclopentane causes slight reddening and drying of the skin and cyclopentene causes moderate to severe irritation of the skin and eyes.

AROMATIC HYDROCARBONS

These get their names from *aroma,* meaning pleasant odor. The molecules are usually characterized by one or more six-carbon rings (benzene) or fused rings (naphthalene or larger rings). This classification once served to distinguish petroleum and coal-tar hydrocarbon solvents. Now, however, aromatics are derived from both sources.

Benzene and other aromatics do not undergo the addition reactions shown by alkenes and alkynes, but do undergo aromatic substitution reactions in which an atom or group of atoms replaces one of the hydrogen atoms on the ring. Aromatic substitution reactions of benzene produce a wide variety of useful products (see Table 7–A). The aromatic hydrocarbon benzene is notorious for its effect on the blood-forming tissues of the bone marrow and as a cause of aplastic anemia. Gerarde (see Bibliography) has shown that, in animals, injury may result from a single exposure. Benzene is now indicated as a leukemogenic agent. This has greatly reduced the extent of its use as a solvent. Toxic levels of benzene are easily absorbed through the skin and inhaled. Benzene should not be used for cleaning processes or for any process requiring skin contact or where the concentration in the air is not controlled by proper ventilation. The 2001 TLV® for benzene is 0.5 ppm, with an A1 (confirmed human carcinogen) classification. However, NIOSH recommended that the PEL be reduced to 0.1 ppm, averaged over an 8-hour period, and that benzene be regulated as an occupational carcinogen.

The aromatic hydrocarbons in general are local irritants and vasodilators that cause severe pulmonary and vascular injury when absorbed in sufficient concentrations. They also are potent narcotics. The primary problems with common aromatic solvents other than benzene are dermatitis and effects on the central nervous system (CNS). Benzene can also be a contaminant of industrial toluene and xylene.

HALOGENATED HYDROCARBONS

The halogens are a group of five elements: fluorine, chlorine, bromine, iodine, and astatine. The halogens are a remarkable family of elements, marked by their great chemical activity and unique properties. Stability, nonflammability, and a wide range of solvency are but a few of the characteristics imparted by their application (see Table 7–A). Halogenated hydrocarbons are organic compounds in which one or more hydrogens have been replaced by fluorine, chlorine, or bromine, or rarely, iodine. The effects of the halogenated hydrocarbons vary considerably with the number and type of halogen atoms present in the molecule. Carbon tetrachloride at one end of the scale is highly toxic, causing acute injury to the kidneys, liver, CNS, and gastrointestinal tract. The 2000 TLV® for carbon tetrachloride is 5 ppm (A2 classification—suspected human carcinogen); however, NIOSH recommends that the PEL be reduced to a short-term exposure limit (STEL) of 2 ppm averaged over a 1-hour period and that the chemical be regulated as an occupational carcinogen.

Chronic exposure to carbon tetrachloride also damages the liver and kidneys and is suspected of causing liver cancer. Carbon tetrachloride has become the classic liver toxicant for use in studies on the effects of damage to the liver. As with benzene, this solvent should not be used for open cleaning processes where there is skin contact or where the concentration in the breathing zone may exceed recommended levels. Its use should be avoided altogether.

Replacing some of the chlorine atoms with fluorine as in 1,1,2-trichloro-1,2,2-trifluoroethane (Freon TF) produces a compound with a low level of toxicity. Its present eight-hour TLV is 1,000 ppm with 1,250 ppm as a ceiling limit. The depressant effect on the CNS and cardiac arrhythmias occur at concentrations much greater than the TLV. Because it is nonflammable and of low toxicity, it may be a suitable substitute for the more hazardous chlorinated solvents; however, environmental considerations such as ozone depletion preclude its application in many cases.

The chlorinated hydrocarbons, in general, are more toxic than the common fluorinated hydrocarbon solvents, although there are significant exceptions such as perfluoroisobutylene (TLV = 0.01 ppm, ceiling). Specific effects and toxicities vary widely, but the most common effects from the chlorinated hydrocarbons of intermediate toxicity (trichloroethylene, for example) are CNS depression, dermatitis, and injury to the liver. There is disagreement as to the carcinogenicity of 1,1,1-trichloroethane; the ACGIH TLV® carcinogen classification is A4, not suspected as a human carcinogen, but other organizations, such as NIOSH, consider 1,1,1-trichloroethane to be a carcinogen.

In addition, the chlorinated hydrocarbons, especially trichloroethylene, are noted for their synergistic effects with alcohol consumption. These include flushed, red face and personality changes. These effects must be taken into account when evaluating industrial exposure.

Perchloroethylene (tetrachloroethylene), commonly used in dry cleaning, textile processing, and other industrial processes, has been suggested as a potential human carcinogen. Recent animal lifetime exposure studies (National Toxicology Program, 1986) did show an increased tumor incidence. Earlier animal data, in some cases, are confounded by simultaneous exposure to epichlorohydrin (a known mutagen); human epidemiology is confounded by concomitant exposures to other chlorinated solvents, smoking, and other factors. In its *Seventh Annual Report on Carcinogens, 1994* the National Toxicology Program stated that there is sufficient evidence for the carcinogenicity of perchloroethylene in experimental animals and cited an International Agency for Research on Cancer (IARC) working group conclusion that there are insufficient data to evaluate its carcinogenicity in humans (National Toxicology Program, 1994).

Refrigerants (Freon, chlorofluorocarbons or CFCs, and hydrochlorofluorocarbons or HCFCs) are a subclass of the halogenated hydrocarbons. The majority of these are methane or ethane derivatives, with a few higher carbon analogues and

some other inorganic and organic gaseous compounds. The materials in current use are generally of low toxicity and exposure limits and guidelines tend to be high; the TLV for trichlorofluoromethane (R-11) is a ceiling of 1,000 ppm. The TLV for chlorodifluoromethane (R-22) is 1,000 ppm. New refrigerants have come on the market as a result of the EPA incentives to produce nonozone-depleting refrigerants. There are no exposure standards or guidelines for these compounds other than those suggested by the manufacturer. Safety of some of the new refrigerants has come under question as benign tumors have been seen in long-term animal studies. Refrigerant safety has been reviewed by Calm (1994) and engineering controls have been addressed by ASHRAE (see Bibliography).

NITROHYDROCARBONS

These vary in their toxicological effects, depending on whether the hydrocarbon is an alkane or an aromatic hydrocarbon. Nitroalkanes are known more for their irritant effects accompanied by nausea; effects on the CNS and liver become significant during acute exposures. 2-Nitropropane is listed as a confirmed animal carcinogen, but with an assigned TLV of 10 ppm. The nitroaromatics (such as nitrobenzene with a TLV of 1 ppm) are much more acutely hazardous. They cause the formation of methemoglobin and act on the CNS, the liver, and other organs.

Oxygen-Containing Functional Groups

These are found in the alcohols, aldehydes, ketones, carboxylic acids and their esters, anhydrides, and the ethers.

ALCOHOLS

One of the most important classes of industrial solvents is characterized by the presence of a hydroxyl group (-OH). Saturated alcohols are widely used as solvents. All alcohols are formed by the replacement of one or more hydrogen atoms by one or more hydroxyl groups.

These polar compounds are classified on the basis of both the number of hydroxyl groups and the nature of the radicals attached to the hydroxyl groups. The monohydric alcohols, which contain one hydroxyl group, are known simply as alcohols; dihydric alcohols have two hydroxyl groups and are known as glycols; trihydric alcohols have three hydroxyl groups and are called glycerols or polyols.

The alcohols are noted for their effect on the CNS and the liver but they vary widely in their degree of toxicity.

Methanol (CH_3OH) and ethanol (CH_3CH_2OH) are the two most important industrial alcohols. Methanol is made by catalytic hydrogenation of carbon monoxide and may one day replace gasoline and natural gas as a fuel because it can be made from coal. Ethanol is made by fermentation of starch (or other carbohydrates) and by hydration of ethene.

Methanol causes several types of injuries, notably impairment of vision and injury of the optic nerve. Methanol slowly produces toxic metabolites. For this reason, its chronic toxicity is greater than that of ethanol.

Ethanol is used industrially in a denatured form. It is quickly metabolized in the body and largely converted to carbon dioxide, and is the least toxic of the alcohols. Any toxicity it causes can be more related to the denaturants (such as benzene or methanol). The undesirable effects of ethanol primarily are related to its recreational use, which affects the drinker's physical safety and can compound the effects of other solvents or medications.

Alcohol is a depressant, not a stimulant. Medically, alcohol depresses the CNS, slowing down the activity of the brain and spinal cord. A large enough dose of alcohol can sedate the brain to a point where involuntary functions such as breathing are lost, causing death.

Propanol is metabolized to toxic by-products and is more toxic than ethanol when taken internally but less toxic than the higher homologues.

ALDEHYDES

These are well-known causes of skin and mucosal irritation and CNS effects. Dermatitis from the aldehydes is common. The aldehydes also are characterized by their sensitizing properties. Allergic responses are common.

KETONES

These have become increasingly important solvents for acetate rayon and vinyl resin coatings. Ketones are stable solvents with high dilution ratios for hydrocarbon diluents. They are freely miscible with most lacquer solvents (low-molecular-weight alcohols, aromatics, and esters) and diluents, and their compatibility with lacquer ingredients gives an acceptable finish to many products. Generally, ketones are good solvents for cellulose esters and ethers and many natural and synthetic resins.

The common ketones (such as acetone or methyl ethyl ketone, MEK) generally exert a narcotic-type action. All are irritating to the eyes, nose, and throat, so high concentrations are not usually tolerated. Methyl ethyl ketone in conjunction with toluene or xylene has been reported to cause vertigo and nausea. Lower tolerable concentrations may impair judgment and thereby create secondary hazards. The lower saturated aliphatic ketones are rapidly excreted and for this reason cause only minor systemic effects. Methyl n-butyl ketone received widespread attention during the 1970s, when it was pinpointed as the etiological agent producing a high incidence of peripheral neuropathy in one working population.

ESTERS

These are produced by the reaction of an organic acid with an alcohol. The particular properties of the esters are, therefore, partly determined by the parent alcohol. Esters often have pleasant odors. Esters in low concentrations are used as artificial fruit essences, flavorings, or components of perfumes. The esters are good solvents for surface coatings. Esters in high concentrations are noted for their irritating

effects to exposed skin surfaces and to the respiratory tract. They also are potent anesthetics. Cumulative effects of the common esters used as solvents are not significant except for conditions resulting from irritation. Esters of some mineral acids, such as dimethyl sulfate, are highly toxic.

ETHERS

These are made up of two hydrocarbon groups held together by an oxygen atom. They are made by combining two molecules of the corresponding alcohol. Compared with alcohols, ethers are characterized by their greater volatility, lower solubility in water, and higher solvent power for oils, fats, and greases. Because of their nonreactivity with solutes and ease of recovery, ethers are widely used for extraction. Mixtures of the lower alkyl ethers with alcohols make efficient solvents for cellulose esters. The epoxides (cyclic ethers) differ from other ethers, which are chemically inert, because their unstable three-membered rings make them highly active chemically. Because the epoxides react with the unstable hydrogen atom from water, alcohols, amines, and similar substances, they form a wide range of industrially important compounds.

The primary reactions to the saturated and unsaturated alkyl ethers, such as ethyl and divinyl ether, are anesthesia and irritation of the mucous membranes. However, the greatest safety hazard of these ethers is their tendency to form explosive peroxides. Once opened, ethers should be used within a short period of time, stored so that peroxides are destroyed as they are formed, or checked for the presence of peroxides. The ethers vary in their rate of peroxide formation; diisopropyl ether is one of the most rapid. Halogenated ethers (such as bis-chloromethyl ether) generally are highly toxic and the reader should refer to the more comprehensive references for information on these materials (see Bibliography, especially Clayton and Clayton, the AIHA *Hygienic Guide Series,* and the OSHA standards).

GLYCOLS, GLYCOL ETHERS, AND THEIR ESTERS

The glycols, like the cellosolves and the carbitols, are colorless liquids of mild odor. They are miscible with most liquids (organic and aqueous) and owe this wide solubility to the presence of the hydroxyl, the ether, and alkyl groups in the molecule. The glycol dialkyl ethers are pure ethers with a mild and pleasant odor. They are better solvents for resins and oils than are the monoethers. As a rule, these compounds are more volatile than the monoethers with the same boiling point.

The glycol ethers exert their effects on the brain, the blood, the reproductive system, and the kidneys. Of these, 2-methoxyethanol (ethylene glycol monomethyl ether), 2-ethoxyethanol (ethylene glycol monoethyl ether), and their acetates are the most toxic. They are rapidly absorbed through the skin and elicit neurological symptoms, including changes in personality. They also affect the reproductive system in both men and women. The higher-molecular-weight glycol ethers (such as propylene glycol and ethylene glycol monobutyl ether), on the other hand, are much less toxic. Work with 2-methoxyethanol, 2- ethoxyethanol, or their acetates should be conducted so as to preclude any skin contact. OSHA is proposing to reduce the PELs for 2-methoxyethanol and its acetate from 25 ppm to 0.1 ppm and for 2-ethoxyethanol and its acetate from 200 and 100 ppm, respectively, to 0.5 ppm.

Recent epidemiological studies in the semiconductor industry have associated spontaneous abortion (Swan et al, 1995; Correa et al, 1996) and reduced fecundability (Eskenazi et al, 1995) among fabrication workers who used 2-methoxyethanol, 2-ethoxyethanol, or their acetates, despite the fact that airborne concentrations were under 0.1 ppm (Hammond et al, 1996), that is, under the proposed OSHA standard.

OTHER FACTORS

Other factors must be taken into consideration. For example, handling procedures and type of clothing determine the degree of skin contact and so will affect dermal absorption. Even the degree of a user's respect for the hazard potential can be a decisive factor.

Ignition temperature, flash point, and other factors determining the potential for fire and explosion also must be considered. Although concentrations that are safe from a toxicological viewpoint are much lower than the lower flammable limits of flammable solvents, concentrations at potential points of ignition may be far higher than concentrations in the user's breathing zone.

Evaluation of hazard potential requires assessment of the consequences of exposure, the degree of exposure, and all factors contributing to the exposure.

AIR POLLUTION

In 1970 the Clean Air Act was passed by the U.S. Congress, and the U.S. Environmental Protection Agency began regulating criteria air pollutants. Four of the six criteria pollutants are gases: carbon monoxide, sulfur dioxide, ozone, and nitrogen oxides.

For the first 20 years, the U.S. EPA regulated only six criteria pollutants, the four gases, lead, and particulate matter. The 1990 Clean Air Act listed 189 hazardous air pollutants, most of which are vapors, and authorized the U.S. EPA to add additional hazardous air pollutants to its list. The concentrations of these are not regulated, but EPA will at some future time issue regulations to reduce emissions from sources, which will be required to use the Maximum Available Control Technology to reduce pollutant releases. Although the initial regulations will target major sources, small sources will be studied if further reductions are deemed necessary.

Solvents and other chemicals may become hazardous to the public in the form of air pollutants when released outdoors. Hydrocarbons are a major factor in the formation of photochemical smog. In the presence of sunlight, they react with atomic oxygen and ozone to produce aldehydes, acids,

oxides of nitrogen and sulfur, and a series of other irritant and noxious compounds.

The greatest portion of hydrocarbons contributing to air pollution originates from automobiles, but a significant amount also comes from the tons of solvents exhausted daily from industrial cleaning and surface-coating processes.

Nitric oxide (NO) is produced by the reaction of nitrogen with oxygen in high-temperature combustion, as in automobiles and fuel-burning power plants. Nitric oxide is photochemically oxidized to nitrogen dioxide (NO_2), a corrosive and an irritant. Nitrogen dioxide is an energy trap, reacting with sunlight to form nitric oxide and atomic oxygen:

$$NO_2 + h\upsilon \rightarrow NO + O$$

Atomic oxygen is highly reactive, forming ozone and initiating a host of secondary photochemical reactions. The nitric oxide produced can again react to produce more nitrogen dioxide, propagating the process. The yellow-brown haze seen over many cities is made up of nitrogen dioxide and its reaction products. Ozone in the troposphere (the atmosphere less than 10 km altitude) detracts from air quality and damages the lung.

Some compounds are more reactive to sunlight and contribute heavily to the smog problem. The use of such solvents is being curtailed in more and more areas, especially large cities. Other solvents are less reactive and are exempt from stringent control. Here, they are listed in decreasing order of photochemical reactivity as a general guide.

- Alkenes (unsaturated open-chain hydrocarbons containing one or more double bonds)
- Aromatics (except benzene)
- Branched ketones, including methyl isobutyl ketone
- Chlorinated ethylenes, including trichloroethylene (except perchloroethylene)
- Normal ketones (for example, methyl ethyl ketone)
- Alcohols and aldehydes
- Branched alkanes
- Cyclic alkanes
- Normal alkanes
- Benzene, acetone, perchloroethylene, and the saturated halogenated hydrocarbons

Opinion is divided as to the exact order of reactivity and many solvents have yet to be tested. The trend is toward the development and use of nonreactive solvent blends.

Upper Atmosphere Effects

In addition to the smog-related materials discussed previously, fluorocarbons such as trichlorotrifluoroethane and related materials catalyze the destruction of ozone in the upper atmosphere. Ozone in the stratosphere (the atmosphere 10–50 km in altitude) absorbs solar ultraviolet radiation at the 290-nanometer (nm) wave length. Should the destruction of ozone by fluorocarbons and other materials prove to be significant, the amount of solar ultraviolet radiation reaching the earth's surface will increase. This would impair agricultural production and increase the incidence of skin cancer. In 1987, the industrialized nations met and signed the Montreal Protocol on Substances that Deplete the Ozone Layer. The Montreal Protocol calls for the reduction of use and elimination of the major ozone-depleting chemicals.

Global Warming

Carbon dioxide, the product of combustion of carbon-based fuels, contributes to the greenhouse effect. Put simply, solar radiation penetrates the atmosphere and is absorbed by the earth; a portion is radiated back into space, and a portion is consumed in life processes and atmospheric chemical reactions, thus setting up a thermal equilibrium. Carbon dioxide absorbs the shorter wavelength energy re-radiated into space; this energy is then manifested as heat. It has been estimated that an increase of CO_2 concentration to 370 ppm from the present value of about 320 ppm would increase the temperature 0.5 C. In reality, other factors, such as cloud cover, atmospheric water vapor and particulates, and weather patterns all affect the process and may offset the warming trend of carbon dioxide.

EVALUATION OF HAZARDS

A prime question regarding any process using a volatile chemical is whether the concentration of the solvent in the air exceeds acceptable limits. Getting the answer to this is not as difficult as it may seem.

A knowledge of the chemical, its properties, and the process in which it is used should give the investigator some idea of the potential hazards.

If a chemical of high-hazard potential is being used, if the equipment and ventilation system are poorly designed, or if performance of the system is questioned, then there is a greater probability of physiological injury and immediate action should be taken to evaluate and reduce the hazard before it becomes a problem.

The evaluation procedure, where the industrial hygienist assesses the degree of risk in the workplace, is based on the following factors:

- The toxicity of the substance
- The concentration in the breathing zone
- The manner of use
- The length of time of the exposure
- The controls already in place and their effectiveness
- Any special susceptibilities on the part of the employees

Samples can be collected in the field and returned to the laboratory for analysis or (and this is the trend) they may be collected and analyzed on the spot with direct-reading instrumentation (Figure 7–2).

In this way, a much greater number of samples and much more information can be obtained and evaluated immediately. Data loggers are used to obtain a continuous record of concentration. The data may be analyzed by programs resident in the instrument itself, or downloaded to a computer for further analysis. Standard features include

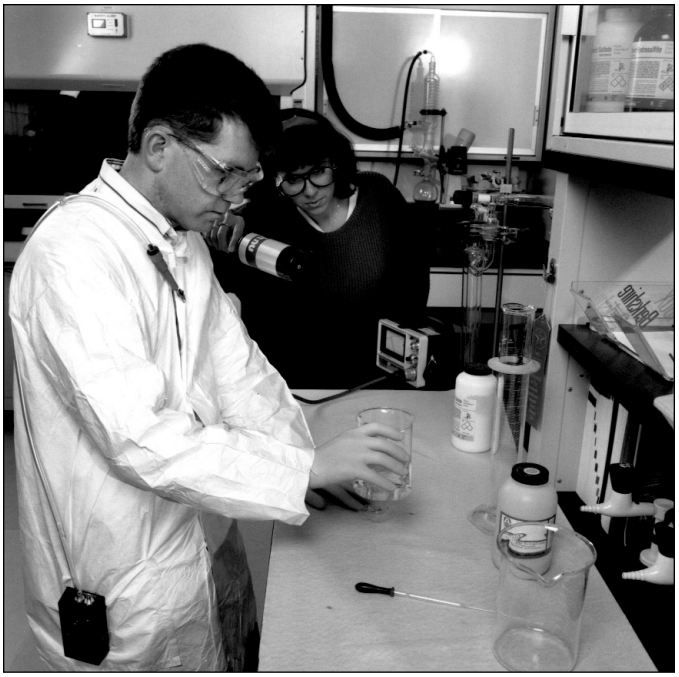

Figure 7–2. The industrial hygienist assesses the degree of risk in the workplace based on the toxicity of the substance, the concentration in the breathing zone, the manner of use, the duration of the exposure, the controls already in place and their effectiveness, and any special susceptibilities of the employees in the workplace. (Courtesy Fermilab Visual Media Services.)

plots of concentration over time and calculations of time-weighted averages over specified time periods. Peak concentrations are readily observed from these graphs; such peaks would have been obscured with integrated samples such as charcoal tubes. Peak concentrations are especially important when the vapor is an irritant or is highly odorous, or if a subjective complaint is involved. The concentration above the norm must be reduced to achieve satisfaction as quickly as possible.

Because correct operation of direct-reading field instruments often requires considerable laboratory backup for maintenance, testing, and calibration, they are not as expedient as they seem. The cost for a field evaluation may be much more than the cost of a laboratory analysis, but this may be offset because much more information is obtained.

See Chapter 15, Evaluation, Chapter 16, Air Sampling, and Chapter 17, Direct-Reading Instruments for Gases, Vapors, and Particulates for more information.

CONTROL OF HAZARDS

Responsibility of Health and Safety Personnel

Personnel concerned with health and safety should recognize that the use of toxic gases and solvents can be a major threat to health and that hazard assessment and control are necessary to prevent detrimental physiological effects.

Exposure evaluation and workplace inspection should be a routine part of any health and safety program. Exposure evaluations should be performed for new processes to ensure that controls are adequate to protect workers. Surveys or searches should also be made for evidence of disease. Dermatitis, unusual behavior, coughing, or complaints of irritation, headache, and ill feeling are all outward signs of potential disease that warrant further investigation. Positive findings justify the effort and provide convincing evidence for educating personnel to the need for corrective actions.

Note conditions and practices that contribute to excessive exposure and call them to the attention of responsible personnel. Train users to handle chemicals properly to prevent injurious exposures. Set guidelines to direct operating personnel in the selection, use, and handling of chemicals. Prohibit general use of highly toxic chemicals, highly flammable solvents, or solvents that are extremely hazardous, unless special evaluation or authorization is obtained.

Finally, provide technical assistance to help the user select the least hazardous chemicals, design and obtain proper ventilation, eliminate the risk of fire, eliminate skin contact, and evaluate situations when workers might be exposed to excessive levels.

Process Controls

SELECTION OF CHEMICALS

One of the most effective means of controlling chemical exposure is to use the least hazardous material. By simply substituting a less toxic or less volatile solvent, for example, one can minimize or eliminate a hazard. The fact that a certain chemical has been specified does not mean that it is the only one or even the best one for a particular use. At times, the one specified is the most familiar one.

This fact is more apparent if one compares the TLVs and the vapor pressures or distillation ranges of different solvents in each class. Toluene and xylene are solvents that can usually be substituted for benzene, for example. If an aromatic hydrocarbon is not required, then it can be replaced with less toxic aliphatic mineral spirits. Low-molecular-weight glycol ethers are used in semiconductor manufacturing processes as a solvent for photoresists, but higher-molecular-weight analogues that have little, if any, reproductive toxicity can be suitable in some situations. The potential for fire can be minimized by the introduction of nonflammable 1,1,2-trifluoro-2,2,1-trichloroethane or 1,1,1-trichloroethane.

The best all-around solvent is water. It is nontoxic and nonflammable and (with the proper additives) it forms an aqueous solvent system that is a good solvent for many organic materials. For the cleanup of inorganic soils, aqueous solvent systems are still the best. The disadvantages are corrosivity of many aqueous solutions and the slow evaporation rate of water. Also, additives may leave a residue on a manufactured item, necessitating further cleaning.

Aliphatic hydrocarbons are good for dissolving nonpolar organic materials such as oils and lubricants. The aliphatics,

however, are not effective cleaners for dissolving or removing many tenacious inorganic materials.

Aromatic hydrocarbons are especially effective on resins and polymeric materials. Between the aromatic and aliphatic hydrocarbons in solvent power are the cyclic hydrocarbons. Halogenated hydrocarbons are effective solvents for a wide range of nonpolar and semipolar compounds.

The nitrohydrocarbons have not been used to a large extent as cleaning agents. Their greatest use has been as solvents for esters, resins, waxes, paints, and the like. Because the ketones, alcohols, esters, ethers, aldehydes, and glycols are more water soluble than the other classes, they are good solvents for the more polar compounds. These solvents are often used as cleaning agents alone or combined with other solvents, especially water. They are useful as solvents for paints, varnishes, and plastics.

Remember that for nearly every process there is an effective solvent or solvent blend that has low toxicity and low flammability. For example, several companies have switched to water containing an alkaline cleaner as a replacement for naphtha and other such organic solvents for cleaning hydraulic tubing, tanks, and other containers. Inhibited 1,1,1-trichloroethane has replaced carbon tetrachloride as a household spot remover. As a guide, the following suggestions might be used:

- ➢ Use an aqueous (water) solution if possible.
- ➢ When possible, consider a different process altogether, one that does not involve chemicals.
- ➢ Solvents that are toxic are to be used only with properly engineered local exhaust systems. Solvents such as trichloroethylene, toluene, and ethylene dichloride are in this category.
- ➢ Highly toxic or highly flammable solvents, such as benzene, carbon tetrachloride, and gasoline, should be prohibited as general cleaning solvents.

Definite dividends will result from this policy. The number of employees who might have exposures exceeding the TLV can be reduced significantly. The number of small fires resulting from the use of flammable bench solvents also can be reduced.

Engineering Controls

ENCLOSURE AND VENTILATION

The major route of entry for chemicals into the body is the lungs (see Chapter 2, The Lungs). The lungs have a surface area of about 85,000–115,000 sq in. (55–75 m^2); much of this area is permeated with thin-walled capillaries. Chemicals in the breathing zone are drawn into the lungs during breathing, quickly absorbed into the bloodstream, and distributed to other parts of the body. The most effective way to prevent inhalation of gases and vapors is to keep them out of the breathing zone. This is done by using closed systems and local exhaust ventilation. All open vessels should be kept covered except when in use. Systems should be designed to prevent leakage and spillage and to collect and contain the solvent in the event of a leak or spill. Proper ventilation must be installed for any process using solvents. Even storage areas require adequate general ventilation to prevent accumulation and buildup of flammable or toxic concentrations. (See Chapters 19 through 21 on industrial and general ventilation.)

If subambient temperature storage of solvents is recommended, they should be stored only in refrigerators constructed and designated for that use (explosion-proof or explosion-safe). Such refrigerators have had their ignition sources removed. Refrigerators used for storage of food and beverages should not be used for any other purpose.

Local exhaust ventilation is necessary to capture the vapors at their point of origin and thus prevent excessive concentrations in the breathing zone. If a highly toxic solvent or gas is being used, or if general ventilation is poor, a local exhaust system, completely enclosing the process, or both is necessary to remove the vapors. All control measures should maintain concentrations of hazardous chemicals in the breathing zone well below the OSHA-specified levels. Present trends in worker's compensation insurance and federal regulations justify designs that are well on the safe side. Ventilation systems are a topic in themselves and the reader should refer to Chapters 19 through 21 and to the ACGIH Industrial Ventilation Manual or American National Standards Institute (ANSI) series Z9 standards on industrial ventilation (see Bibliography). Remember that the local exhaust ventilation system of removing vapors at their point of origin is usually the most satisfactory means of control.

Personal Protective Equipment

RESPIRATORS

Do not use respirators as the primary or only means of protection against hazardous chemical vapors because too many factors limit their use. They can be used as emergency or backup protection. Respiratory protective equipment, especially the air-purifying type, is limited by leakage around the mask edges, surface contamination, impaired efficiency with use, and need for adequate oxygen. Unless it is correctly used and properly cared for, a respirator may present a greater danger to an employee than no protection at all. Too often, such equipment gives a false sense of security and the wearer becomes careless and may be exposed to highly hazardous levels. Respirators should be controlled through a program that provides for proper selection, fitting, testing, education, and maintenance under the surveillance of competent personnel. Such a program is mandatory under present federal occupational safety and health standards. (See Chapter 22, Respiratory Protection.) Make sure that the level of gases or vapors in the air does not exceed the protective factor of the respirator. Air-purifying respirators should not be used for operations where the solvent is air-sprayed unless there is supplementary mechanical ventilation. OSHA has issued a new respirator standard; among the new requirements is one in which the employer must develop a schedule for changing cartridges and canisters for air purifying respirators. See Chapter 22 for more details.

PROTECTIVE CLOTHING AND GLOVES

Another major route of entry for hazardous chemicals is through the skin. Dermatitis is the leading industrial disease, and solvents are second only to cutting oils and lubricants in causing this disease. (See Chapter 3, The Skin and Occupational Dermatoses.) Skin contact occurs through direct immersion, splashing, spilling, contact with chemical-soaked clothing, improper gloves, and contact with solvent-wet objects. Some solvents such as benzene, carbon tetrachloride, and methyl alcohol can be absorbed in amounts great enough to cause physiological injury to organs other than the skin. The most effective way and often the only way to prevent harm is to keep the solvent from the skin. This can be done by using mechanical handling devices, such as tongs and baskets, and by using impermeable protective clothing, such as aprons, face shields, and gloves.

The use of gloves requires caution. A common mistake is to recommend "rubber" or neoprene gloves for use as hand protection against a solvent, regardless of the kind of solvent in use. Many solvents can quickly penetrate latex rubber or neoprene gloves and come in contact with the skin.

The permeability of gloves to certain solvents and chemicals is the most important characteristic to consider when selecting gloves for protection. Chemical manufacturers include permeability information with their product, often in the form of permeability tables or computer software for glove selection. They suggest appropriate glove materials for particular chemicals. The abrasion resistance of glove materials is also given in tables and this information is often more widely available. Note both permeability and abrasion resistance when considering the type of gloves to use with certain solvents.

Permeability measurements should be made on the complete glove if the effect of weak or thin spots is to be detected. A rough comparison of the permeability of gloves plus an indication of some of the other characteristics can easily be made by turning the gloves inside out, filling them three-fourths full of solvent, sealing the cuff, and measuring the loss of weight, the stretch, and other parameters.

More precise methods for measuring glove permeability are available, but require the use of an analytical laboratory. A standard method has been published by the American Society for Testing and Materials.

The time required for a chemical to penetrate a glove is affected by the glove's thickness and its composition. In some cases, the time to break through can be as brief as five minutes. For example, it has been shown that benzene breaks through a 0.03-mm polyethylene glove in five minutes. Conversely, the same glove material had a two-hour breakthrough time when tested against butyl acetate.

Note that gloves made of the same material and nominal thickness, but from different manufacturers, may have significantly different breakthrough times. This difference may result from differences in formulation of glove materials or manufacturing procedures used.

Neoprene is good for protection against most common oils, aliphatic hydrocarbons, and certain other solvents, but is not satisfactory for use against the aromatic hydrocarbons, halogenated hydrocarbons, ketones, and many other solvents. Natural rubber is not effective against these solvents.

Polyvinyl alcohol (PVA) gloves provide adequate protection against the aromatic and chlorinated hydrocarbons, but they must be kept away from water, acetone, and other solvents miscible in water to prevent deterioration. Butyl rubber gloves can be a suitable compromise when polyvinyl alcohol cannot be used.

Regular periodic cleaning and drying of gloves is as important as using the proper type. Keep an extra pair of gloves available for use while the cleaned pair is being aired and dried. When the gloves become soiled with hard-to-remove hazardous materials such as insecticides and epoxy resins, it is often better to discard the glove than to try to clean it. In some situations, gloves must be replaced after only a few minutes' work. If the outside of any glove becomes thoroughly wetted, remove it promptly.

Disposable gloves are useful for light laboratory or assembly work, but are too easily torn or punctured for heavier work. Latex medical gloves provide good manual dexterity, but they tear easily and are permeable to many solvents. Their use is not recommended in an industrial setting. If they are used, an effective practice is to change immediately after a splash or contamination or change gloves frequently even if direct contact has not occurred. There is no set recommendation for the use of gloves; what works well for one group of workers may not work for another. In many cases, a certain amount of trial and error is required. Gloves are subject to small tears that may go unnoticed, but drastically reduce their efficiency. Gloves may also increase the absorption of solvents if they do penetrate the glove, and the solvent is then trapped in close contact with the skin and cannot evaporate.

Barrier creams are the least effective way of protecting skin. Barrier creams are not a substitute for gloves, except when there is only occasional and minor contact with a solvent, or around rotating machinery when gloves cannot be worn because of the catching hazard. Barrier creams are *not* as effective as an impervious glove. (See Chapter 3 for more information on barrier creams.)

Good personal hygiene is important whenever chemicals are used. Remove spills and splashes from skin immediately with soap and water. This includes showering and replacing solvent-soaked or splattered clothing with clean clothing immediately and as often as necessary.

PROTECTIVE EYEWEAR

Workers at risk for a splash of chemicals in the eyes must wear appropriate protective eyewear. It must be noted that protective eyewear should not be used as the sole protection, but in conjunction with engineering control, guards, and good manufacturing practice. OSHA, in 29 *CFR* 1910.133, requires eye and face protection when injury can be prevented by its use.

The standard practice is given by ANSI Z87.1, *Practice for Occupational and Educational Eye and Face Protection.*

For chemical splash or irritating mists, eye protection should be selected from unvented chemical goggles, indirect-vented chemical goggles, or indirect-vented eyecup goggles. Direct vented goggles and spectacle-type eye protection do not provide protection against liquid exposures and should not be used. For severe exposures, a face shield should be used in conjunction with goggles; a face shield by itself does not provide adequate protection against liquid splashes. Where both an inhalation and splash hazard exists, full-face respiratory protection is preferable over a half-mask and goggles.

Traditionally, the recommendation has been that contact lenses should not be worn in eye hazard areas. However, the new ANSI standard removed the prohibition on contact lenses. (See Chapter 5, The Eyes, for more information.)

SUMMARY

Critical exposure factors include how the material is used and what controls (engineering or personal protective equipment) are in place, temperature and volatility, concentration, and reactivity. Guidelines for exposure are discussed. In this chapter, solvents are classified as aqueous or organic systems. Gases as cryogenic liquid and simple and chemical asphyxiants and their characteristics are discussed. Flammable and combustible liquids, flash points, flammable range, and requirements and guidelines are given. The physiological effects of aqueous systems, organic compounds, aliphatic hydrocarbons, cyclic hydrocarbons, aromatic hydrocarbons, halogenated hydrocarbons, nitrohydrocarbons, oxygen-containing functional groups, inorganic acids, and organic and inorganic gases as well as hazard potential, evaluation, and control are covered.

Chapter 8

Particulates

by Richard J. Kelly, MS, CIH

Particulate matter is probably the type of environmental chemical hazard most on the minds of U.S. citizens. Lead in paint, asbestos in schools, radon progeny in homes, Hanta virus in sheds, and diesel smoke are all current issues in the lay press. Industrial hygienists see many other emerging particulate matter issues, including exposures to beryllium, free crystalline silica, endotoxins, toxic fungal spores, and cadmium.

The objective of this chapter is to familiarize the reader with the basic concepts of anticipating, recognizing, and evaluating occupational particulate matter hazards. Basic concepts of aerosols, aerosol behavior, sampling, analysis, filtration, lung deposition, and biological responses are introduced, with many specific examples discussed in detail and within a historical context. Regulatory and consensus guidelines are reviewed whenever appropriate. Air, surface, bulk, dermal, and biological sampling are described, and the relative roles of each are discussed. Many tables that will provide quick reference for common particulate matter concerns are included. An extensive bibliography is provided, including sources for equipment, sampling tools and supplies, and reference materials.

BACKGROUND

In the field of industrial hygiene, *particulate matter* (*PM*) is traditionally defined as small (less than 100 micrometers in diameter) pieces of solid materials, liquid droplets, or microbiological organisms. On the other end of the spectrum, particles smaller than about 0.001 µm start to act like gases, and thus are not treated as particulate matter. This range of particle sizes under consideration is five orders of magnitude. The adjective *particulate* is often used as a noun in the industrial hygiene literature in lieu of the full term "particulate matter" (PM). While this is incorrect English, it is common enough that it is generally accepted "jargon" in the occupation.

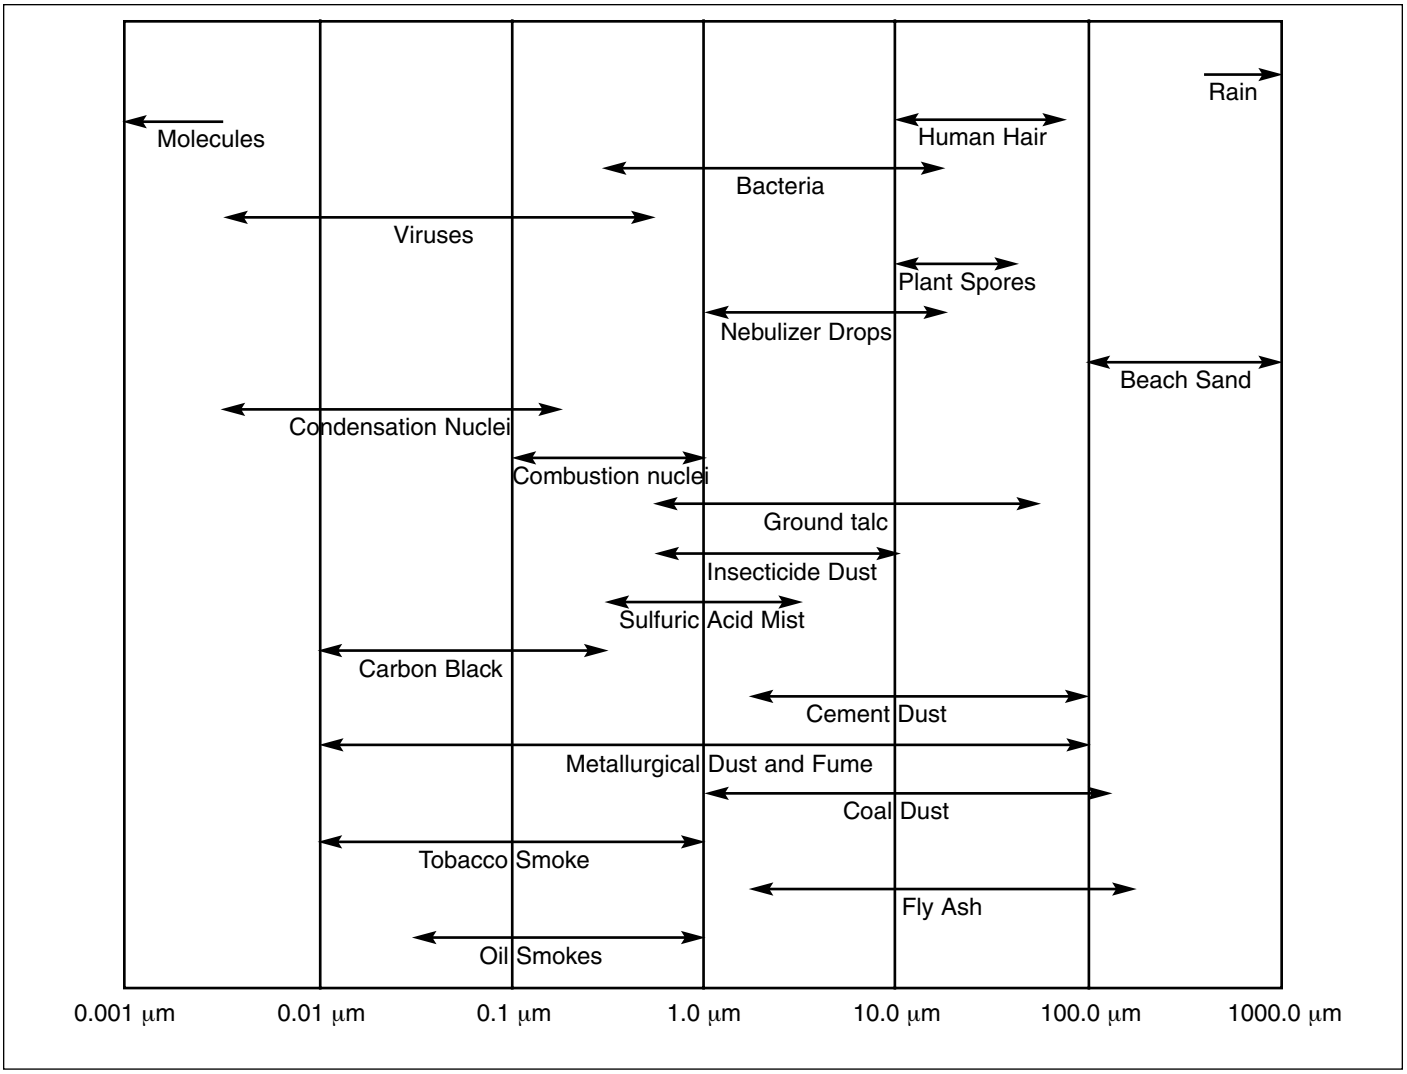

Figure 8–1. Size range of various particulate matter clouds.

Most often, particulate matter is regarded as a hazard when suspended in air, forming an *aerosol,* which can then be inhaled. Only particles less than approximately 100 micrometers in diameter have the potential to remain suspended in the air for any length of time to form a hazardous aerosol. Indeed, the primary route of exposure for most hazardous particulate matter is inhalation, with toxicity occurring subsequent to removal of the particulate matter from the aerosol by deposition in the lungs. Substantial exposure to particulate matter can result in a wide variety of biological responses ranging from acute to chronic and mild to life-threatening. Figure 8–1 represents the size range of different types of occupationally significant particles.

The hazards associated with occupational inhalation of aerosols have long been recognized. Pliny the Elder (AD 23–79) wrote of lead inhalation hazards during scraping of lead-containing paint. Agricola (1491–1555) and Ramazzini described the hazards of aerosols in mining, and they were a major topic of writings by Alice Hamilton as the industrial revolution flourished and the field of industrial hygiene evolved in the very early 20th century.

While exposure to particulate matter as an aerosol is the most common route, some types of PM may be hazardous by ingestion or skin contact. Sir Percival Pott identified cancer caused by skin contact with soot among chimney sweeps as early as 1775. Lead particles that have settled out of the air onto eating surfaces can be absorbed through the gastrointestinal tract to cause systemic poisoning. Recently it has been suggested that chronic beryllium disease may be triggered by contact of insoluble beryllium-containing dust with the lips, mouth, or even eyes. Thus, the range of potentially hazardous routes of exposure posed by particulate matter is broader than often recognized.

The least toxic airborne particles have been traditionally classified as "nuisance dusts," or more recently by the American Conference of Governmental Industrial Hygienists as "*Particulates* (*insoluble*) *Not Otherwise Classified* (*PNOC*)." OSHA has a somewhat parallel term, *Particulates Not Oth-*

Table 8–A. ***General Types of Particulate Matter (PM)***

Type of PM	*Sub-Type*	*Defining Characteristic*	*Examples/Sources*
Dusts	General	Produced by mechanical action on larger pieces of the material (e.g., grinding, cutting, tearing)	Lead dust while scraping paint Quartz dust when jack hammering
	Fibers	Dust classified because of its shape as long thin tendrils	Asbestos Ceramic fibers Fiberglass
	Biological (not micro-organisms)	Typically organic dusts created by disturbance of plant or animal materials	Wood dust Cotton dust Animal dander
	Radioactive	Radiotoxicity is often more significant than chemical toxicity	Radon progeny Radioactive waste Uranium
Mists	General	Droplets of liquid. Always defined in the context of an aerosol. Created by mechanical action breaking liquid into small particles	Droplets from bubbling dip tanks Paint overspray
	Fog	Droplets of liquid caused by recondensation of vapor	Boiling acids in chemical digestion
Fume	All	Formed by the evaporation and rapid condensation of metal vapor into very small particles	Welding Arc or torch cutting Foundry work
Biological agents	All	These include living and non-living agents that may be allergenic, toxigenic or infectious	Bacteria (and related organisms) Viruses Fungal spores Prions
Smokes	All	Smokes are the products of incomplete combustion of organic materials. Created by vaporization of organic material with subsequent condensation. Sometimes used interchangeably with "fumes"	Diesel exhaust Coke or coal powered furnaces Human tissue during laser surgery Second-hand cigarette smoke

erwise Regulated (*PNOR*). As implied by the older nomenclature, these particles are supposed to cause only minor health effects at relatively high exposures, leaving no important long-term lung damage or impairment. In fact, until the 1980s this nomenclature was directed almost exclusively toward pneumoconiosis-producing dusts. The current ACGIH definition is broader, adding reference to particles which will not have a systemic effect.

Particulate matter typically encountered in the occupational environment can be divided into a number of "types," based primarily on how the PM was created, its shape, and its composition. Table 8–A lists the broader classifications and some subclassifications of PM.

There are thousands of types of inorganic and organic particulate matter that may be found in the occupational environment. Table 8–B lists some of the more ubiquitous PMs, as well as certain types of PMs that are of current special interest in industrial hygiene and air pollution.

Many of the classic chronic respiratory tract diseases that have been attributed to inhalation of PM result in a type of illness that is broadly called a *pneumoconiosis*. Derived from Greek, this simply means "dust in the lungs." This term has been rather widely used to describe a number of lung diseases, many of which do not share mechanisms, symptoms, or prognoses. Some "diseases" classified as pneumoconiosis are not known to result in any clinical symptoms, whereas others are potentially fatal as a result of the formation of collagenous fibrotic scarring. Some are reversible upon cessation of exposure, some often remain stable if exposure is stopped, and others may progress even without further exposure.

Attempts to define pneumoconiosis were made as early as 1916. There was no universally accepted definition of pneumoconiosis until 1950. A more recent definition of pneumoconiosis is "the accumulation of dust in the lungs and the tissue reaction to its presence." This assumes that the dust is solid and relatively insoluble when deposited in the alveolar region of the lungs.

Classically, the severe forms of pneumoconiosis are associated with lung fibrotic changes. Different exposures result in distinct patterns of fibrosis on chest x-ray images. There are several defined subforms of fibrosis associated with pneumoconiosis, including hyaline-nodular fibrosis pneumoconiosis, coal miners pneumoconiosis, mixed dust pneumoconiosis, and diffuse interstitial fibrotic pneumoconiosis. Interpretation of chest x-ray films for signs of pneumoconiosis is a complex specialty, and such trained physicians are referred to as "B" readers.

Table 8–C lists many of the agents that have been associated with a type of pneumoconiosis.

Table 8–B. ***Selected Hazardous Particulate Matter***

Agent	*Typical Industries/Occupations for Exposure*	*Summary of Health Effects*
Arsenic and inorganic compounds	Agriculture; wood treatment; semiconductor wafer fabrication (gallium arsenide); alloy production; pesticide manufacture; lead smelting	Inhalation of inorganic arsenic compounds can cause chronic poisoning with weakness, nausea, respiratory tract symptoms and damage to the peripheral nervous system; cancer
Asbestos	Asbestos abatement; demolition; building maintenance; custodial work; brake repair and replacement	Inhalation increases the risk of lung cancer, mesothelioma (a cancer of the lining of the lungs and peritoneum), asbestosis
Bacteria	Office work; hospitals; sewer repair and maintenance; biological research; social service industries; grade school teaching	Exposure to airborne bacteria may cause indoor air quality problems, humidifier fever, alveolar inflammation or infection.
Beryllium and compounds	Aerospace; nuclear industries; electronics; mining and processing; tool manufacturer; refractory ceramic industries; chemical research; sporting goods manufacturing; machining	Chronic exposure to beryllium metal, oxides, and other insoluble compounds may cause "chronic beryllium disease" and cancer. Very high exposure to soluble compounds may cause acute beryllium disease
Cadmium and compounds	Metal brazing; alloy making; welders; metal coating; construction	Acute exposure may cause potentially fatal pulmonary edema. Chronic exposure may cause systemic illness or cancer
Chromium and compounds	Metal plating; chemical research; welding; stainless steel production and use; machining	Chromium in the hexavalent oxidation state is the most toxic. Exposure may be to dust in some operations and mist in electroplating. Exposure to chromium hexavalent compounds may cause a range of irritation effects, allergic sensitization, and lung cancer
Cotton (primary)	Cotton and flax workers	Byssinosis, which results in progressive difficulty in breathing, probably caused by an allergic or pharmacological agent in the bract associated with fresh cotton
Cobalt and compounds	Alloy making; pigment manufacture; machine tool sharpening; electroplating; aerospace; blue glass manufacturing	Inhalation may cause asthma-like illness, which may progress to fibrosis. A specific form of pneumoconiosis associated with cobalt and some other metals, especially metal carbides, is called "hard metal disease"
Diesel exhaust	Operation of diesel powered industrial trucks; toll takers; construction	Potential increase in asthma and lung cancer
Isocyanates (e.g., TDI, MDI, HDI)	Paint sprayers; polyurethane manufacturing; organic chemical synthesis; construction	Effects range from transient irritation of the respiratory tract to chronic sensitization and reduction in lung function. Exposure may occur as a mist or vapor
Lead and compounds	Painting; demolition; lead abatement; battery manufacture and maintenance; welding and cutting; brazing; building maintenance; radiation users; machining	One of the most common industrial illnesses is chronic lead poisoning, which damages the peripheral and central nervous systems, sometimes irreversibly
Manganese and compounds	Steel manufacturing; alloy making; paint manufacture; chemical research	Inhalation may cause severe damage to the central nervous system, sometimes mimicking Parkinson's disease
Mold (fungal) spores	Office work; farming; biological research; mining; earth-moving trades (geographically specific); grain milling; migrant farm work; cotton mill workers; silo operators; saw mill operations; mushroom farming; cork production; sugar cane harvesting	Exposure to mold spores may cause allergy (hypersensitivity reaction), poisoning (if the spores contain mycotoxins), or infection. Some spores infect healthy hosts; others infect mostly compromised hosts. A combination of these responses is possible
Nickel	Nickel refining; stainless steel manufacture; alloy production; welding and cutting; chemical research; electroplating; battery manufacture; machining	Nickel and some compounds are probable human respiratory tract carcinogens. Other systemic toxicity has been reported
Pesticides	Pesticide manufacture; pesticide application; farming; gardening; fumigation	There are a wide variety of pesticides with varying toxicity. Many former pesticides have been banned either because of toxicity or biopersistence. One common class, the organophosphates, can cause damage to the peripheral and central nervous system as well as a host of other body systems

(Continues)

Table 8–B. ***Selected Hazardous Particulate Matter (Concluded)***

Agent	*Typical Industries/Occupations for Exposure*	*Summary of Health Effects*
Radon progeny	Mining; work in underground vaults; work at homes with cellars or concrete office buildings	Radon is a radioactive gas, but when it decays it forms single ions of other radioactive species that bind electrostatically with other dust to form radioactive particles
Silica-quartz, cristobalite and tridymite	Sand blasters; concrete demolition; building demolition; hard rock mining; building maintenance; cement manufacture	Exposure to these specific crystalline forms of silicon dioxide typically produces a chronic lung nodular fibrosis called "Silicosis" which impairs lung function. This effect can occur in a matter of months at very high exposure levels
Sodium hydroxide	Electroplating; chemical metal cleaning; metal etching; plastic production; soap manufacture; chemical laboratory work	Sodium hydroxide is not volatile, so all exposure occurs to the dust or mist. These are extremely alkaline and may cause local tissue irritation or destruction
Thallium and compounds	Pesticide manufacture; pesticide application; chemical laboratory work; optics fabrication; alloy making	Thallium is very toxic and the effect is cumulative. Early symptoms of exposure include fatigue and myalgia, with later symptoms including those associated with nervous system damage
Thorium and compounds	Gas mantle fabrication; alloy making; welding rod production; welding; chemical laboratory work; ceramic production	The main hazard posed by this material is due to the accumulation of the radioactive thorium. Although not a high activity material, it still must be controlled due to its radioactivity
Uranium and compounds	Uranium mining; nuclear industries; uranium refining; uranium fuel reprocessing; uranium enrichment; low levels may also be present in other rare earth compounds	Naturally occurring uranium is a mixture of three isotopes. The isotopic ratio does not affect the chemical toxicity but influences the radiotoxicity. Soluble uranium compounds pose the highest toxic hazard and generally the lowest radiohazard. The target of the chemical toxicity is the kidney. Radiotoxicity increases the risk of cancer
Wood dust	Saw milling; lumbermen; furniture makers; carpenters	Depending on the wood, inhalation of dust may cause toxic, irritant, or allergic effects. Severe sensitization can occur in some cases, notably with mahogany and western red cedar. Inhalation of some hardwood dusts may contribute to nasal cancer.
Zinc oxide fume	Welding; torch or arc cutting—all where zinc is present	Most common metal fume associated with "metal fume fever," a transient flu-like illness occurring 2-24 hours after exposure and lasting hours to several days

BASIC CONCEPTS, PROCEDURES, AND EXAMPLES

Particle Deposition Mechanisms

When a particle passes through a filter and is not effectively removed from the aerosol, the filter has failed to do its job. When a particle is inhaled but is subsequently exhaled without deposition in the respiratory tract, it will have no toxic effect. If it is deposited in the lung, *where* it is deposited may determine if it will contribute to an illness. When attempting to collect a particle for analysis, if it is not deposited on the filter or other sampling medium, the sampling effort will be inaccurate.

The removal of a particle from a moving aerosol is called particle deposition. There are five primary mechanisms of particle deposition, and they are all applicable to filters, lungs, sampling media, or any other surfaces that are exposed to a moving aerosol.

1. *Inertial impaction*—As a particle moves within an aerosol, it gains momentum that is proportional to its mass. The individual atoms or molecules of the gas phase of the aerosol effectively have no momentum. When a moving gas phase of an aerosol is forced to change direction abruptly, it does so, albeit with the possible formation of eddies and turbulence. However, a particle with significant mass and inertia follows Newton's Law that states "a mass in uniform motion tends to remain in motion unless acted upon by an outside force." Thus, while the gas responds very readily to abrupt changes in direction, the particle

Table 8–C. ***Agents Associated with Pneumoconiosis***

Asbestos (asbestosis)	Aluminum w/silica (Shaver's disease)	Beryllium (chronic beryllium disease)
Barium	Bentonite	Cement
Cerium	Coal (black lung)	Diatomite
Fullers earth	Hematite	Iron (siderosis)
Kaolin	Mica	Mixed dust
Silica (silicosis)	Tin (stannosis)	Titanium

tends to resist this change in direction and deviate from the air stream. This may cause the particle to *impact* on the surface, stick there, and be removed from the aerosol. Impaction is directly proportional to the density of the particle, the square of its diameter, and the velocity of the moving aerosol. It is most effective for large and dense particles in high velocity air. It is a common principle used in the collection of industrial hygiene PM samples.

2. *Interception*—Particles not deposited by inertial impaction may be deposited by interception. In this case, the particle follows the air stream fairly well (because it is small, of low density, or in a more slowly moving air stream), but still contacts the surface of the filter or lung. It sticks, and has effectively been removed from the aerosol. Interception is most effective for mid-sized particles. A special case of interception, sieving, is an important deposition mechanism for very large airborne particles.
3. *Sedimentation (Settling)*—All particles are acted upon by gravity and tend to move toward the center of the earth. If the particle settles onto a surface, it may stick and be removed from the aerosol. In a vacuum, the particle would accelerate continuously until it reached the surface, independent of its mass or shape. In the real world, particle movement is resisted by aerodynamic drag created by the particle moving downward through the gaseous phase, and convection upward within the gaseous phase. In a still environment, where drag is the primary force resisting sedimentation, the terminal rate of settling (Vt) for most particles can be can be estimated by Equation 1, which combines Newton's Second Law of gravitational acceleration with Stokes' Law pertaining to drag forces of particles moving in a viscous medium. When the increasing particle velocity creates a drag equal and opposite to the force imposed by gravity, the particle attains its terminal settling velocity.

   The effectiveness of sedimentation in a still aerosol is proportional to the particle's mass, and large particles settle out much faster than small particles.

Equation 1

$$Vt = \frac{(\text{particle density})(\text{gravity})(\text{Cunningham correction})(\text{diameter}^2)}{18\ (\text{air viscosity})\ (\text{dynamic shape factor})}$$

The terminal settling velocity (Vt) in centimeters per second is found when:

- ➢ Particle density is in grams per cubic centimeter
- ➢ An average value of the gravitational constant in CMS units of 980 cm/second^2
- ➢ Particle diameter is in centimeters
- ➢ Standard air viscosity can be assumed to be 1.8 x 10^{-4} g/(cm • s)
- ➢ Cunningham correction factor is looked up (unitless)
- ➢ The dynamic shape factor is looked up or approximated from Table 8–D (unitless)

4. *Electrostatic attraction*—Charged collection surfaces will tend to attract and hold oppositely charged particles. Most airborne particles carry some net charge, and can be effectively removed by electro-attractive forces if presented with a surface with the opposite net charge. While not known as a major mechanism of deposition in the respiratory tract, some air filters are designed to hold sustained electrostatic charges, and this can greatly increase the efficiency at which they remove particles from aerosols. Also, some industrial hygiene sampling methods still use electrostatic attraction to collect particles, and unintended electrostatic effects hamper other sampling methods.
5. *Diffusion* (*Brownian movement*)—Very small particles do not see the gas in which they are suspended as a continuum. Instead, they react to individual atoms of the gas or uneven impact by groups of air molecules over time. As a result the particles wander around in a seemingly random path, an effect termed Brownian motion (or movement). Many people have seen this happen to small bacteria in liquid suspension through a microscope. As the particles flow with the air, they tend to wander from the airflow lines, and may bump into a collection surface and be removed from the aerosol. The effectiveness of diffusion as a deposition mechanism is indirectly related to the square of the particle diameter and to the velocity of the aerosol. Thus, slow movement of small particles favors deposition by diffusion. The six deposition methods are shown diagrammatically in Figure 8–2.

The net deposition of particles on an air-cleaning filter, sampling device, or in the lungs is almost always the result of action of two or more of these deposition mechanisms. Figure 8–3 shows the relative contribution of many of these mechanisms to collection of particles on a specific filter, as a function of both effective aerodynamic diameter and aerosol flow velocity. It is evident that impaction becomes of increasing importance as both particle size and air flow rate goes up, gravitational settling predominates for larger particles at low flow rates, and diffusion is the only active mechanism for particles less than 0.1 µm, regardless of the flow rate.

As might be expected, there is a particle size range that is least efficiently collected because none of the deposition mechanisms are highly effective at that size. The exact nadir point in the collection efficiency of a filter varies somewhat with the flow velocity and filter type, but generally lies

Table 8–D. ***Dynamic Shape Factors***

Shape/Type	Typical Dynamic Shape Factors
Sphere	1.0
Cubic	1.08
Clustered spheres (e.g., aged fume)	1.15
Quartz particles	1.36
Talc particles	2.04
Fibers	<<1.0

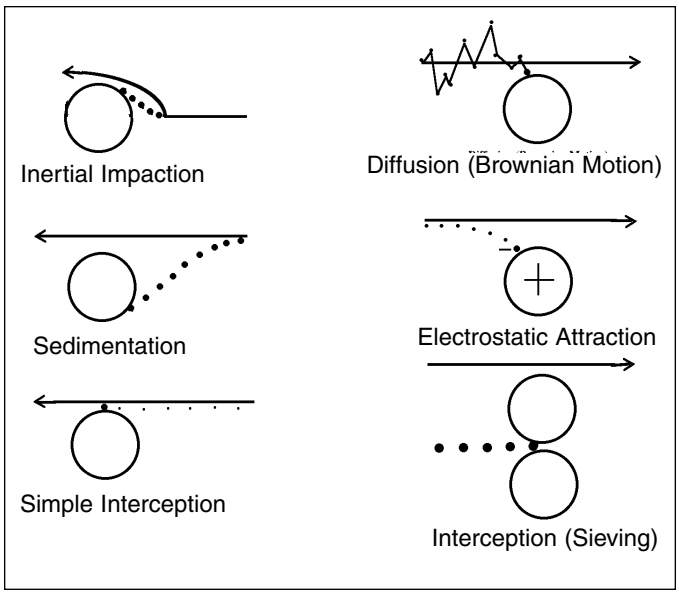

Figure 8–2. Particle deposition mechanisms.

between about 0.1 and 0.4 μm in aerodynamic equivalent diameter. Historically, high efficiency particulate air (HEPA) filters, developed to support nuclear material production facilities and used extensively in respirators, have been tested and certified at a presumed nadir point of 0.3 μm using a narrowly dispersed mass of dioctylphthalate oil droplets. Better understanding of filtration principles and improvements in technology allow some filters, such as *ultra high efficiency air* (*ULPA*) filters to be tested using a nearly monodisperse aerosol with an aerodynamic equivalent diameter of about 0.12 μm. At usual flow rates, this is a slightly more challenging test than the 0.3 μm HEPA test.

This low point or nadir in collection filtration occurs because the effectiveness of impaction and interception tails off rapidly below a diameter of about 0.5 μm, and diffusional mechanisms do not become effective until about 0.1 μm. Thus, particles between 0.1 and 0.4 μm are collected inefficiently by diffusion and impaction. This effect for a certain type of air cleaning filter is shown in Figure 8–4.

PARTICLE SIZE DISTRIBUTIONS

Employees are not exposed to single particles, but rather to large masses of particles suspended in air, commonly called a particle cloud. Particle clouds have a variety of characteristics that often must be understood to fully evaluate and control the hazard they may present.

Particle clouds may be fairly monodisperse, consisting mostly of particles that fall within a very narrow size range, or polydisperse, containing a wide range of particle sizes. Fresh welding fume or fog from condensed boiling acid are examples of fairly monodisperse particle clouds. Both of these types of PM result from vaporization and recondensation, which has a tendency to form uniformly sized particles. Fresh welding fume is typically very small, on the order of 0.01 μm in diameter. The fog caused by acid digestion, often called "fume" by chemists, tends to be formed of larger particles, several micrometers in diameter.

The majority of occupational aerosol-generating activities make polydisperse particle clouds. Sand blasting usually leaves some of the large incident particles (>100 μm) unbroken, yet also forms very small fines. The size distribution of particles is very broad. The same is true for many demolition activities, such as concrete breaking, and many construction activities. For a given agent, the distribution of particle sizes can range over several orders of magnitude.

Another characteristic of particle clouds is that they may be unimodal or multimodal, that is, they can have either a single peak when size is plotted against count, or they can have multiple peaks. This may occur with a single agent in a number of ways, or may result from the mixing of several different forms of aerosol clouds. For example, in the case of welding fume, although fresh fume tends to be composed of very small, spherical particles, as the fume "ages" it has a strong predilection to agglomerate or "flocculate" into irregularly shaped, extended, and enlarged groups of small spheres. A person working near the process may be exposed to both larger agglomerates and fine primary fume, a distribution with two peaks.

Alternatively, bimodal or trimodal distributions of particle sizes may occur when several operations are occurring in the same area of a workplace. In a foundry, a pouring location that generates very fine fumes may be located close to a polishing operation that creates mid-sized metal particles and also to a needle gunning operation that forms very large particles. Thus the chemical composition may be the same, but when evaluated with a size-selective instrument, three distinct modes or peaks are detected. More commonly, chemically heterogeneous multimodal particle clouds are found, such as in a machine shop, where large particles of cutting fluid are mixed with mid-sized particles of metal from grinding operations, and with very small particles of organic smoke from an electronic discharge machining operation. Idealized examples of particle cloud distributions are shown in Figure 8–5.

It is unusual to find a normally distributed particle cloud. When you plot the number of particles on the y-axis and the diameter of the particles on the x-axis, it rarely results in a normal, bell-shaped distribution. This is unfortunate, as basic descriptive statistical techniques are easily applied to normally distributed variables. In normal-normal distributions, the mean (which is the same as the mode and median) is the measure of central tendency, and the standard deviation is the measure of the dispersion. A large mean implies that the average particles are large, and a small standard deviation indicates a fairly monodisperse distribution of particle sizes.

If you measure and plot particle sizes found in a polydisperse distribution, the most common picture that emerges is

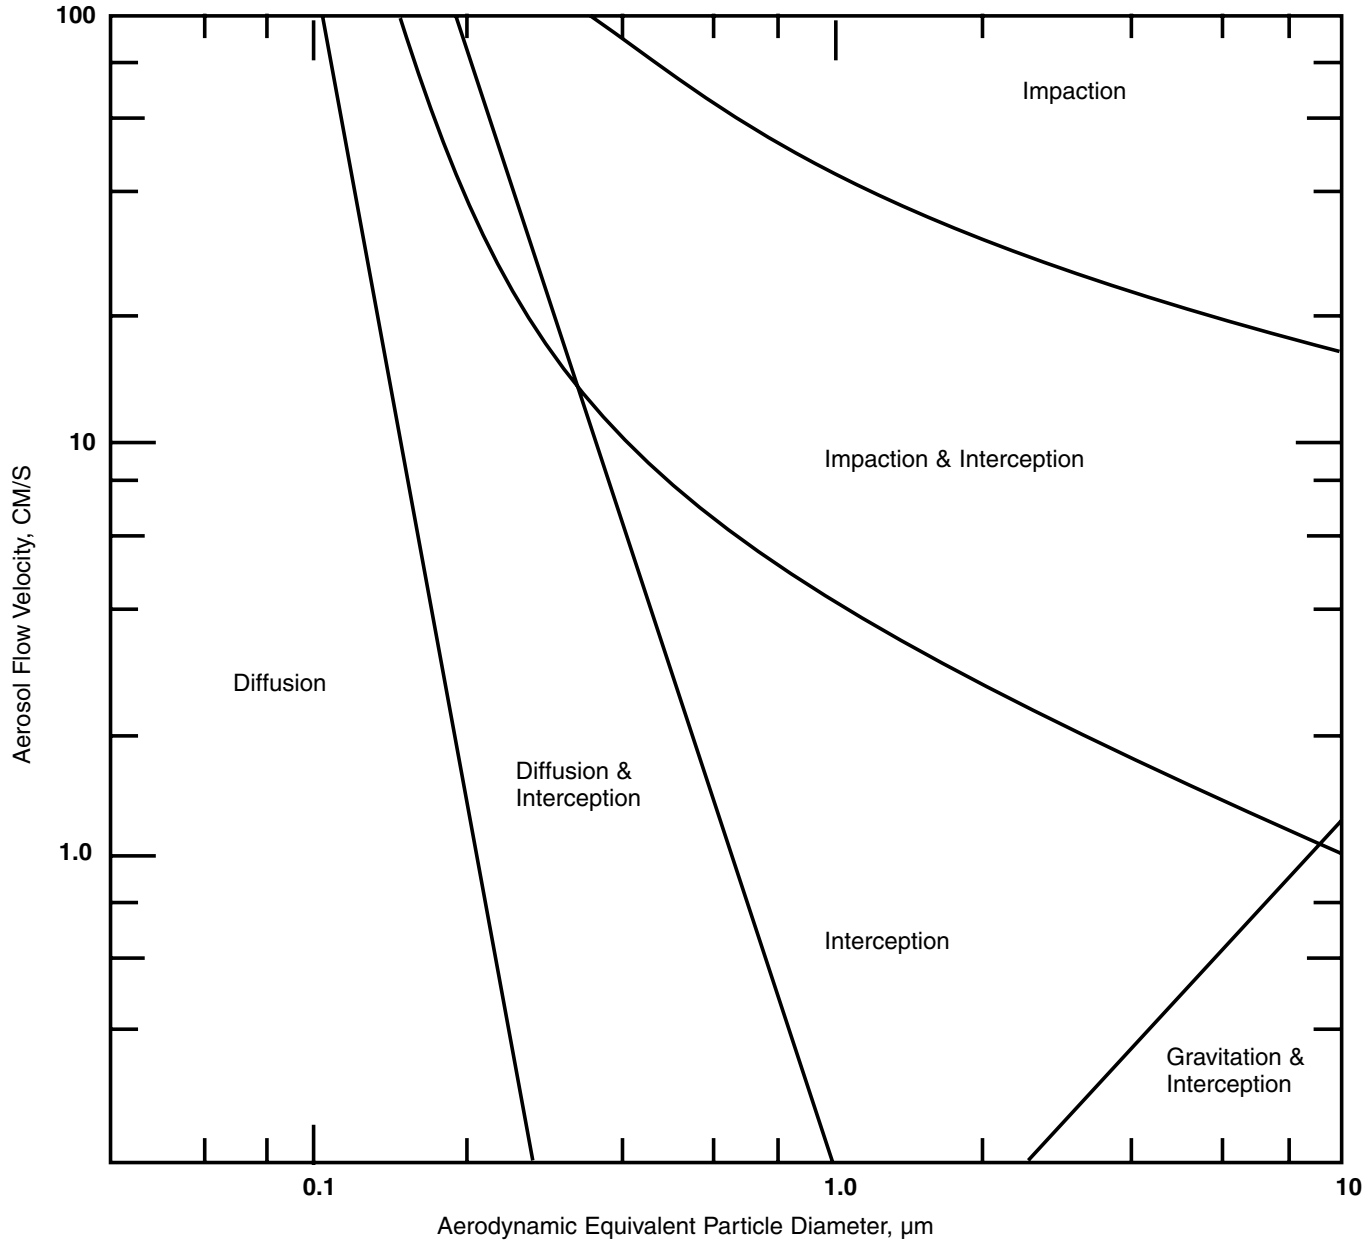

Figure 8–3. Relative contribution of deposition mechanisms as a function of particle size and aerosol flow velocity.

a highly skewed curve, with the majority of particles falling to the right side of the curve (smaller particles), then there is a peak, followed by an elongated, asymptotic slope to the right (larger particle sizes). This may occur for a variety of reasons, including the selective loss by sedimentation or impaction of the larger particles.

Fortunately, it is often possible to convert the skewed distribution into a fairly normal shaped curve by plotting the log of the particle sizes against their count. The resulting distribution, called a *log-normal distribution,* is bell-shaped in appearance and can be described in terms synonymous with those applicable to a normal distribution. The mean of a log-normal distribution is called the geometric mean, and corresponds to the mean in a normal-normal distribution. The geometric standard deviation can be calculated, which is analogous to the standard deviation calculated to define set intervals in normal distributions. The only difference is that instead of adding and subtracting the geometric standard deviation from the geometric mean to define known subsets of the data (as is done in normal-normal distributions), the mean is multiplied or divided by the geometric standard deviation. Thus, a log-normal distribution of a particle cloud with a geometric standard deviation of 10 μm in diameter and a geometric

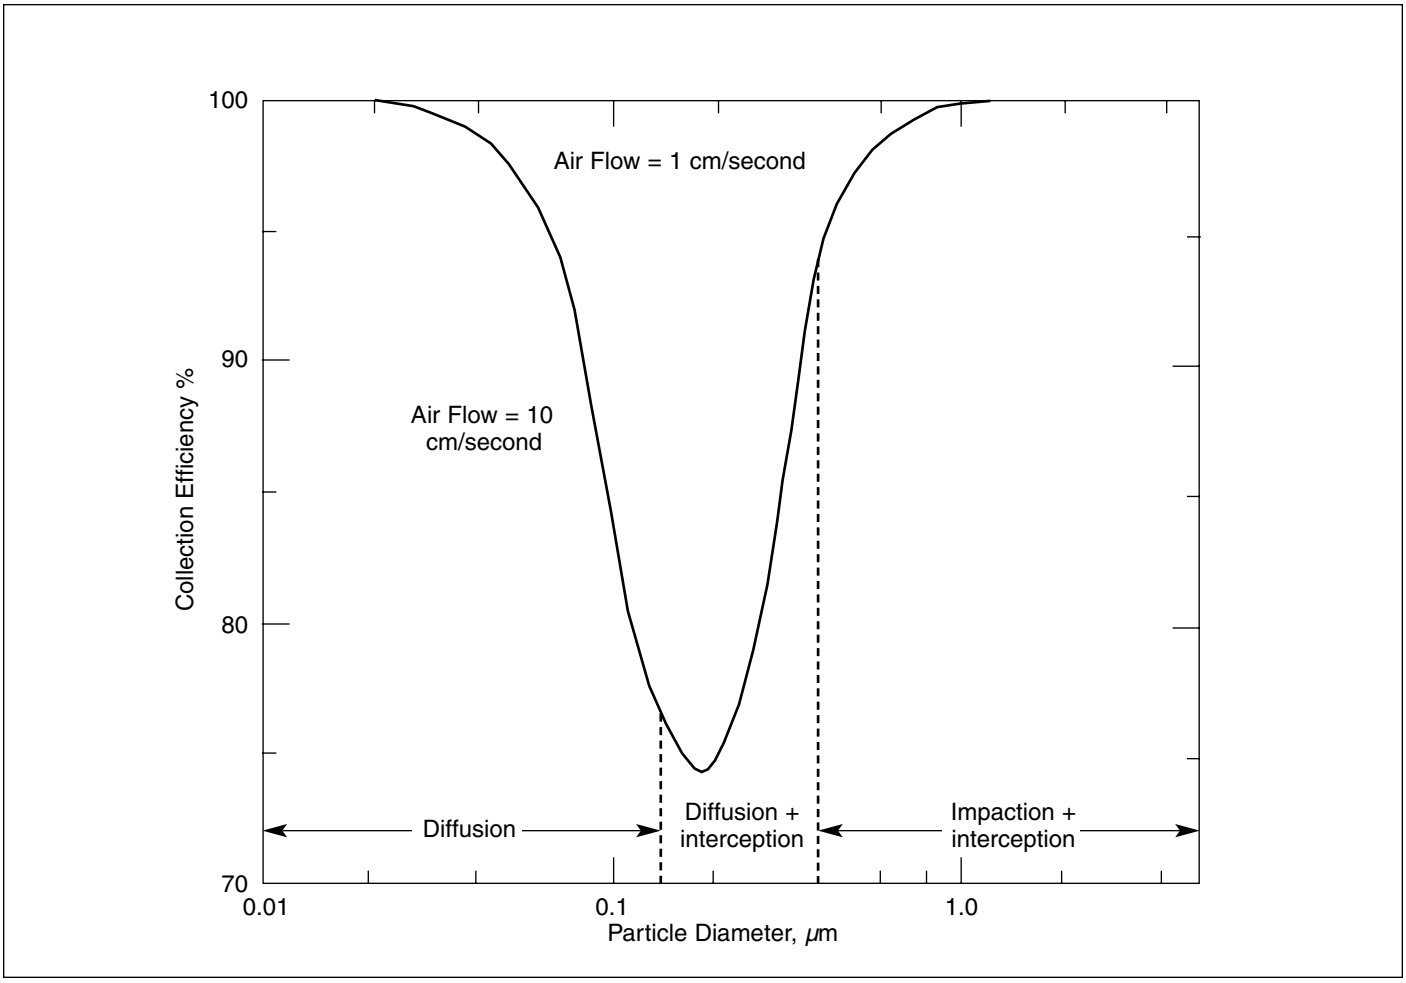

Figure 8–4. Filtration efficiency vs particle size and velocity.

standard deviation of 2 indicates that 67 percent of the particles fall within the size range of 10 x 2 and 10/2, or 5–20 μm. Ninety-five percent of the particles fall within about +/– two geometric standard deviations of the geometric mean, 2.5 to 40 μm. This is a moderately disperse particle cloud.

The geometric mean of a log-normal distribution can be calculated directly, by *log transforming* the data (calculating the $\log_{10}$ of the diameter of each particle), and dividing by the number of particles. It can also be picked directly off a special type of plot, a cumulative log-probability plot. Using this unusual type of graph paper, log-normal distributions plot as straight lines. The geometric mean and geometric standard deviations can be measured directly from this plot, as shown in Figure 8–6.

Sometimes particle clouds are described in terms of the *geometric mass equivalent diameter* instead of the geometric count diameter as described above. This is particularly true when the mass of the particles deposited, rather than the number, determines toxicity. Soluble lead or arsenic compounds are examples of PMs that are toxic when in a soluble form, no matter where they deposit in the respiratory tract. To calculate this, one multiplies the volume of each particle by its mass before plotting or manipulating the data. The geometric mass equivalent distribution has the same geometric standard deviation as the geometric count distribution, but the mean particle size is always much larger than the mean particle diameter of the count distribution. This occurs simply because mass is a third-power function of diameter, and most of the mass in a polydisperse cloud of PM will reside in the larger particles. The extremely fine particles, which appear prominently in the count distribution, are almost irrelevant in the mass distribution.

In contrast, the mass of inhaled asbestos is largely unimportant. It is the count, the number of fibers inhaled, that relates to the probability of developing disease. Thus, the count distribution would be appropriate for the characterization of a cloud of asbestos fibers. Figure 8–6 shows the number and mass distributions of a particle cloud plotted on cumulative log-probability graph paper. Also shown is the surface area distribution, which is not often relevant to the toxicology of the PM, but significant for some types of direct-reading particle enumerators (e.g., forward light scattering photometers).

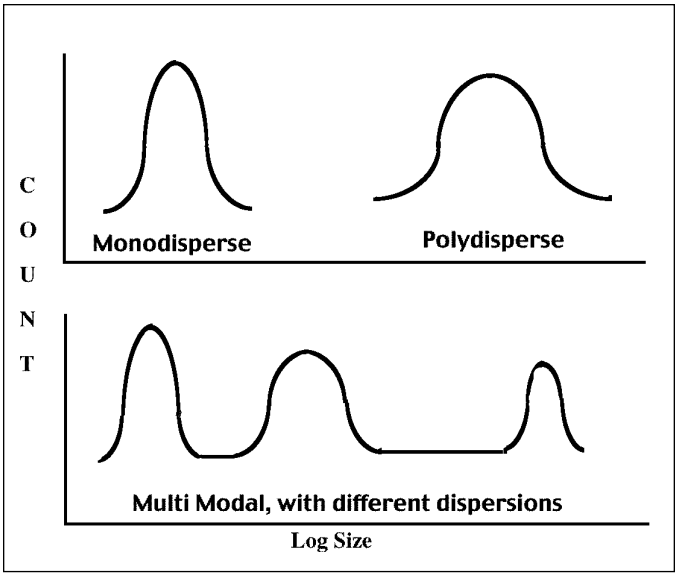

Figure 8–5. Ideal monodisperse, polydisperse, unimodal, and multimodal particulate matter clouds (log-normal plots).

CRITICAL FACTORS IN DETERMINING ACCEPTABLE EXPOSURE

The nature of the health problems caused by inhalation of PM is influenced by a number of factors:

- ➢ Chemical and biological composition of the particles and stability of their nuclei (radioactivity)
- ➢ Crystalline, structural, and isotopic forms of the particles
- ➢ The shape of the particles
- ➢ The size of the particles
- ➢ Dose: concentration of particles in the work environment and exposure duration
- ➢ Preexisting health or genetic status of the workers
- ➢ Concurrent exposure to other toxic agents

Chemical and Biological Composition

The chemical composition is often a primary driver for the toxicity of a material. As reflected in their respective Threshold Limit Values (TLVs)® and OSHA Permissible Exposure Limits (PELs), beryllium is considered more hazardous than lead, which is more toxic than iron. Smoke from petroleum asphalt is considered less toxic than smoke from coal tar, because the latter typically has a much higher concentration of potentially carcinogenic polynuclear aromatic hydrocarbons.

Inhalation of free respirable crystalline silica may cause severe lung disease, silicosis. Rocks and soil that contain silicon dioxide chemically bound to other elements are termed silicates, which may have some toxicity of their own, but not generally on the order of free crystalline silica. A major exception is asbestos, which is a silicate with great potential for toxicity.

Exposure to *Bacillus anthracis* is potentially much more dangerous than exposure to *Bacillus subtilis,* even though they are closely related bacteria, because inhalation of *B. anthracis* can cause anthrax, a potentially fatal disease. Inhalation of *B. subtilis* is unlikely to cause any infection in healthy adults.

Inhaled radiological materials vary in toxicity for a number of reasons, but in most cases, a primary factor is the specific activity of the radioactive atom. Species with high specific activities emit a lot of ionizing radiation per unit of time and mass, and thus more rapidly affect tissue causing genetic and somatic cell damage. Also important is the type and energy of the radioactive particle (or photon) emitted when the atom decays.

Thus, plutonium, which has a high specific activity and releases very densely ionizing alpha particles, is considered to be one of the most radiotoxic atoms in existence. Natural uranium has a much lower specific activity and is correspondingly much less radiotoxic. A tritium compound, because of the very low energy beta particle it emits when it decays, is considered a minor hazard when inhaled in moderate amounts.

The type of molecule to which a radioactive atom is bound also affects its radiotoxicity. Soluble uranium compounds are much less carcinogenic than are insoluble or minimally soluble forms. The former, once deposited in the alveolar portion of the lungs, is rapidly removed by dissolution and often excreted promptly. Insoluble compounds of uranium, in contrast, can remain on the alveolar surface for a much longer period of time, all the while depositing ionizing energy into cells in the vicinity of the particle.

Crystalline, Structural, and Isotopic Nature

The chemical composition of various particles may be virtually identical, but other qualities of the molecules or atoms making up the particles may render them more or less toxic. The best-known example of this is silica (silicon dioxide). The most toxic form, "free crystalline silica" (quartz, cristobalite, and tridymite) are all well-defined, three-dimensional crystalline structures, not bound chemically to other elements. Inhalation of very fine particles of this free crystalline form of silicon dioxide causes "silicosis," a nodular, potentially progressive, and often-severe form of pneumoconiosis.

At the other extreme, rapidly cooled liquid silicon dioxide forms an amorphous (noncrystalline) structure called glass. This happens naturally in the formation of minerals such as pumice and obsidian, the latter displaying the appearance associated with manmade glass. Other examples of free silica that are not crystalline include diatomaceous earth, fumed silica, and silica gel. Although chemically identical to quartz and the other free crystalline silicas, amorphous silica lacks any repetitive crystalline structure. As a result of this difference, glass, natural or manmade, is of low toxicity and is generally regulated as only a "nuisance dust." In between these two extremes are other forms of silicon dioxide that have different levels of crystalline organization, and thus intermediate toxicity and Threshold Limit Values.®

Among organic PM, particularly smokes and soots, molecules with identical chemical compositions may have widely varying toxicity depending on the exact chemical

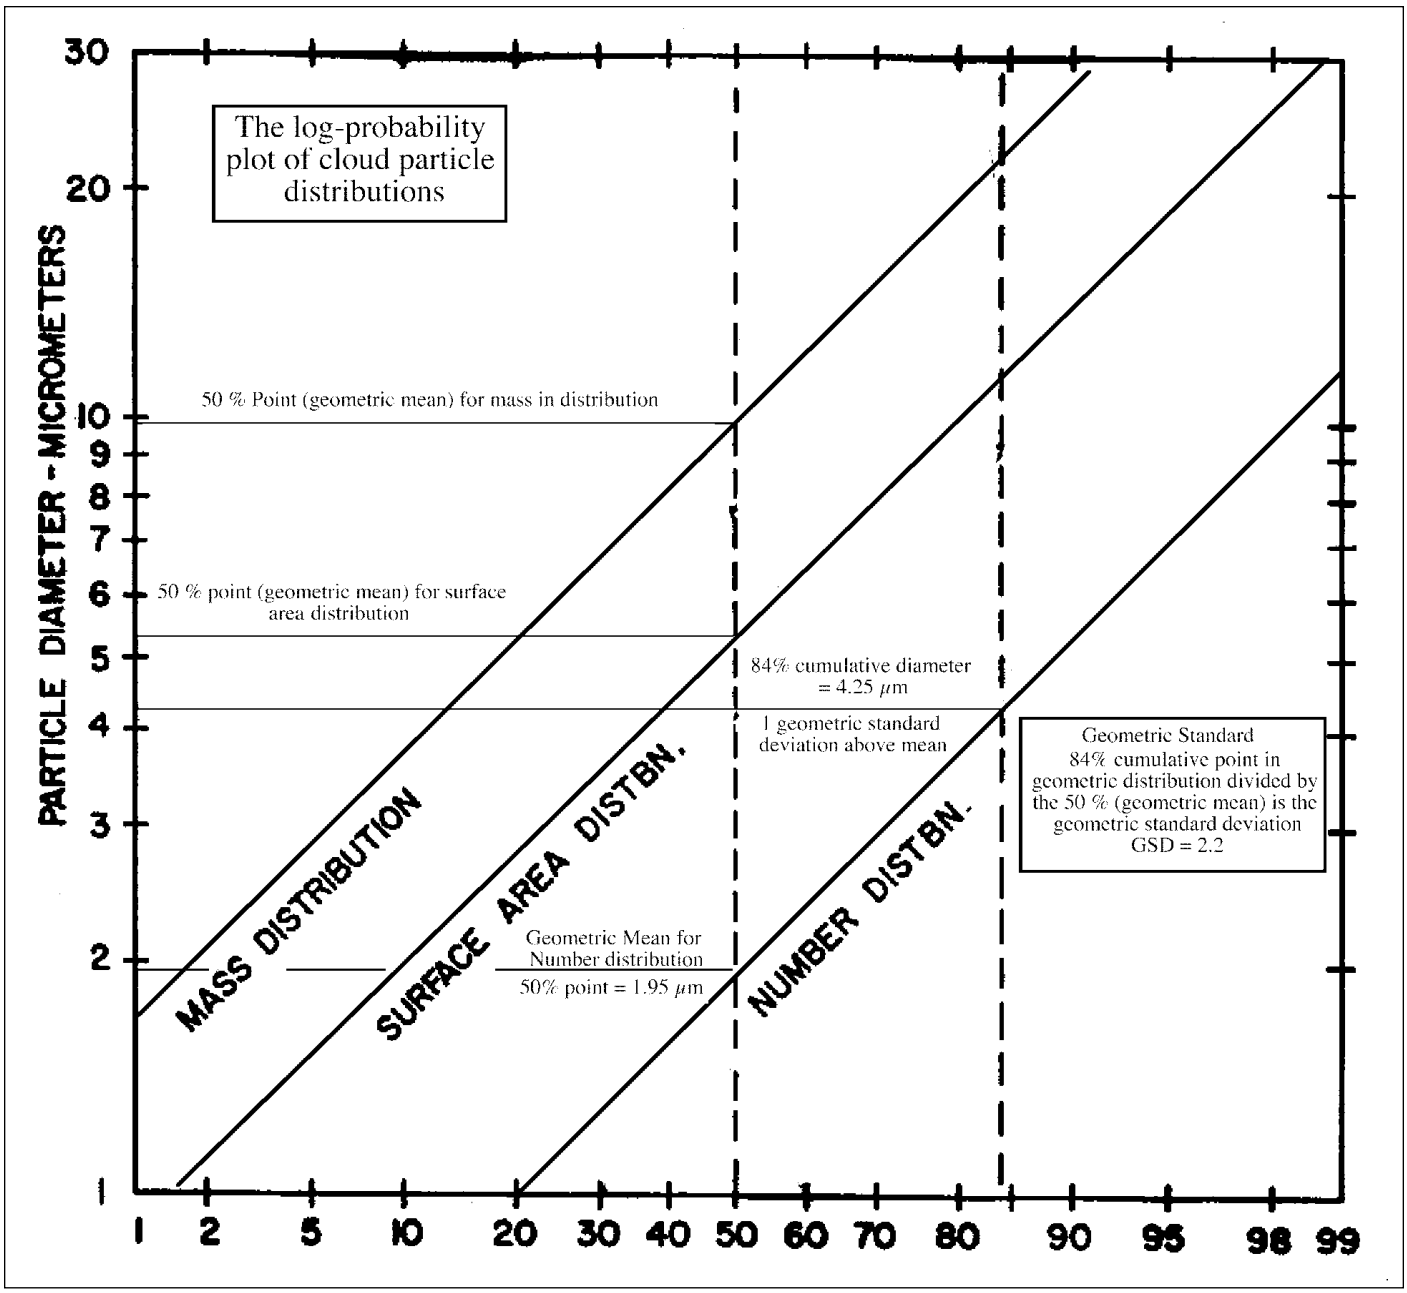

Figure 8–6. Cumulative log-probability plot of log-normally distributed particle cloud.

arrangement of the atoms which make up the organic molecule. For example, the polynuclear aromatic compound benzo-a-pyrene is a known mutagen and carcinogen. By slightly rearranging the atoms that shape benzo-a-pyrene, breaking the polynuclear structure, the material looses its mutagenic and carcinogenic potency.

Among organic molecules, even much less dramatic structural changes can vastly change the toxicity of a compound. For example, some organic pharmaceuticals have a chiral center, which may be either left or right handed. These pharmaceuticals are often effective (and toxic) because they contain or consist entirely of one isotopic *enantiomer,* either the left handed or right handed variety. The variation in structure is very subtle, but has a big impact on the drug effectiveness and potential for toxicity.

Some radioactive atoms have two or more distinct radioactive isotopes, varying structurally only in the number of neutrons in the nucleus of the atom. For example, naturally occurring uranium consists of three isotopes, U-238 (99.28%), U-234 (0.0006%), and U-235 (0.714%). The U-235 is the fissile isotope, capable of powering nuclear reactors and nuclear bombs. Because of its high specific activity, it is also the most radiotoxic isotope, with an additional significant contribution by U-234. Remove U-235, as is done to produce

fuel for reactors, and the remaining material, almost exclusively U-238, is primarily controlled as a kidney toxin, not a radiotoxic material. In contrast, U-235 enriched uranium is predominantly a radioactive hazard.

Shape of the Particles

By convention, there are six varieties of asbestos: chrysotile (a serpentinite mineral), amosite (in mineralogical terms, cummingtonite-grunerite), crocidolite (reibeckite), fibrous tremolite, fibrous anthophyllite, and fibrous actinolite (all of the latter members of the amphibole series of minerals). While all of these minerals vary in chemical composition, all of them share a general shape—they are fibrous. More specifically, they are "asbestiform," a type of fibrous habit that is much less common than the general term "fibrous." When shredded apart from their rock form, they exist in bundles of long, skinny fibers that are much longer than they are wide. As you further tear the bundles apart, you just get smaller and smaller bundles with the same general morphology. Ultimately, when all of the adhering particles are separated, the unit piece of an asbestos fiber, the *fibril,* retains the same general shape, long and narrow. Asbestos fibers are said to have a high *aspect ratio*. In mineralogical terms, asbestos always has an aspect ratio of at least 10:1; that is, it is 10 times longer than it is wide. Current OSHA analysis regulations define asbestos as having an aspect ratio of >3:1; the EPA defines it as >5:1. These regulatory aspect ratios are arbitrary and may introduce errors by being too low, especially the 3:1 OSHA/NIOSH ratio.

Each asbestiform mineral has a chemically identical non-asbestiform mineral. These non-fibrous analogues to asbestos do not present the same hazards of lung cancer, asbestosis, and mesothelioma as do the asbestiform varieties. Thus it is the shape of the asbestos fibers, which is actually determined by the crystalline structure (see above), that to a large extent defines their toxicity. Unfortunately, these non-asbestiform polymorphs (and other minerals) occur with asbestos in the earth's crust, and tend to form cleavage fragments called "pseudofibers" that meet the 3:1 aspect ratio criterion. By OSHA/NIOSH rules, they get counted as asbestos when they are not asbestos and generally do not pose the hazards presented by asbestos.

Because asbestos fibers can travel through the lung lengthwise, like an arrow, they can penetrate much deeper into the lung than a non-fibrous particle with a diameter equal to the length of the fiber. As a result, asbestos fibers many tens of micrometers long can make it to the alveolar region of the lungs, which would almost never happen with more regularly shaped particles of this size. Once deposited in this relatively undefended region of the lungs, it is believed that the fibers trigger an ineffective immune response by resident macrophages, which not only fail to remove the relatively insoluble fiber but die in the process, setting off a chain of immunological events, which results in scarring of the lungs and cancer.

In some arenas, the relative toxicity of the six forms of asbestos remains in debate. The TLVs® suggest differing exposure limits. Many mineralogists and some countries take the position that "white" asbestos, chrysotile, is less toxic than the brown or blue forms (amosite or crocidolite). This argument is based on some epidemiological and autopsy data, but also on the very different morphology of the serpentenite chrysotile from the amphibole species of asbestos. Airborne chrysotile fibers tend to be rather curly and twisted, less likely to travel through the air as an arrow and reach deeply into the lungs. Crocidolite and amosite, in contrast, form very straight fibers. A third argument in favor of establishing differing exposure limits between these families of minerals relies on the fact that chrysotile is more biosoluble than the other forms of asbestos, and thus will have less residence time in the alveoli to cause disease.

However, OSHA is resolute that all of the forms of asbestos present approximately the same hazard and should be treated identically. As a result, few industrial hygienists pay any attention to the TLVs for asbestos, and simply follow the OSHA regulations, which makes no differentiation among the asbestos types in terms of exposure limits.

Note that the term "asbestos" is a term of commerce, not science. There are other fibrous minerals, such as a fibrous zeolite called erionite and fibrous attapulgite, that may pose similar health hazards as asbestos. The costly lesson provided by the epidemic of asbestos-related disease has led industrial hygienists and toxicologists to worry about exposure to certain manmade fibers which share the characteristics of very small diameter, high aspect ratio, length, and low biological solubility.

Size of the Particles

The toxicity of some agents depends very strongly on the size of the individual particles to which employees are exposed. Obviously, as mentioned at the beginning of this chapter, to be of inhalation concern, a particle must not be too big, as it would not stay suspended in the air long enough to be inhaled, nor too small, as it then takes on the characteristics of a gas rather than a particle.

Industrial hygienists are not generally concerned with the actual diameter of a particle. Instead, they are concerned with the *equivalent aerodynamic diameter* (*EAD*) of a particle, sometimes called the *aerodynamic equivalent diameter (AED).*

This value predicts how a particle will behave when inhaled or challenged with a respirator or sampling filter. The aerodynamic equivalent diameter removes all of the aerodynamic variability induced by the shape of the particle and the density of the particle, and relates it to a spherical particle of unit density. Almost all of the exposure standards that require measurement of a size fraction of a dust actually require the measurement of the aerodynamic equivalent size of the dust rather than its physical size.

For moderately sized spherical particles (1–10 μm physical diameter), the AED can be pretty well estimated by the simple equation provided below.

Equation 2 (Spherical particles)

$$\text{AED} = \text{actual particle diameter} \times (\text{particle density})^{0.5}$$

- ➢ AED = Aerodynamic Equivalent Diameter in µm
- ➢ Actual particle diameter in µm
- ➢ Particle density in units of grams/centimeter^3

Thus, the AED is related to the actual diameter by multiplication with the square root of the particle density. In the example provided in Equation 2, it was assumed that the particle was spherical. With the exception of mists and very fresh fume and smoke, most PM is not spherical, and a correction must be made for the differential resistance to airflow induced by shape. This has been called the Dynamic Shape Factor, and has been introduced earlier in this chapter. The net AED for a non-spherical particle in the middle size range (1–10 µm) can be estimated in many cases by adding the dynamic shape factor to Equation 2.

Equation 3

$$\text{AED} = \begin{matrix}\text{particle}\\ \text{diameter}\end{matrix} \times \left(\begin{matrix}\text{particle}\\ \text{density}\end{matrix}\right)^{0.5} \times \begin{matrix}\text{dynamic}\\ \text{shape factor}\end{matrix}$$

- ➢ AED = Aerodynamic Equivalent Diameter in µm
- ➢ Actual particle diameter in µm
- ➢ Particle density in units of grams / centimeter^3
- ➢ Dynamic shape factor estimated from Table 8–D (unitless)

Thus, a talc particle, which tends to be in the shape of a flake, has a high *dynamic shape factor*, increasing drag as it moves through air, making it appear aerodynamically larger than it is physically. A fiber, which travels lengthwise as it moves in an aerosol and thus resembles an arrow, has a low dynamic shape factor, and moves in a manner more of a function of its diameter rather than its length. Typical dynamic shape factors for differently shaped particles are provided in Table 8–D.

The usefulness of these simple methods for determining AED starts to degrade progressively with very small and relatively large particles. Large particles tend to flow through the air with the creation of a lot of turbulence rather than laminarly, in effect making the particles AED smaller than it appears by calculation. Very small particles enter another flow regime, where they start to see the air as individual molecules rather than a continuum, and are subject to "slippage" between the molecules with reduced drag. Thus, they have an AED that is larger than these simple calculations would suggest. More sophisticated calculations, with consideration of Cunningham Slip Correction Factors and Reynolds' numbers can be made to partially correct for these effects, but such calculations are beyond the scope of this chapter.

In practice, aerodynamic equivalent diameter is usually determined empirically. When it is important to know the full size distribution of the dust, it is often sampled through a multi-stage separator, each stage collecting a certain aerodynamic "cut" or fraction of dust. Devices such as multi-stage cascade impactors can be used very effectively to show the count or mass distribution of a particle cloud. In one research project, the particle size distribution created by laser machining of a carbon composite versus that created by mechanical machining were compared by use of a cascade impactor. Simply by looking at the filters on the six stages in each impactor, it was obvious that mechanical machining produced a cloud dominated by large particles, whereas laser machining, which works mostly by a vaporization-condensation mechanism, produced only very fine particles.

The aerodynamic equivalent diameter of the particle is important because it determines where in the respiratory tract the particle is most likely to be deposited. As described in Chapter 2, the lung has different clearance mechanisms and particle residence times in different sections. In the nose, nasal turbinates, and throat (collectively the Head Airways Region or nasopharyngeal region) inhaled air moves rapidly through small diameter passageways with several sharp changes in direction. The larger particles, especially those with AEDs greater than 25 µm, are subject to removal by impaction in this area, and are either ejected through blowing the nose, or passed into the GI tract, completely avoiding the lungs. In the thoracic region of the lungs, also known as the tracheobronchial region (which includes the bronchi and larger bronchioles), the air slows down because of the greater cross section of flow, and impaction and inertial settling remove smaller particles, between 1 and 20 µm AED. Particles deposited in this region are usually reliably removed from the lung in a matter of hours by the mucociliary escalator, and thus have a limited residence time in the lung.

Finally, very small particles, those with AEDs significantly less than 10 µm, have an increasingly good chance of penetrating all the way to the terminal bronchioles and the alveolar sacs in the air exchange region of the lungs. In this region,

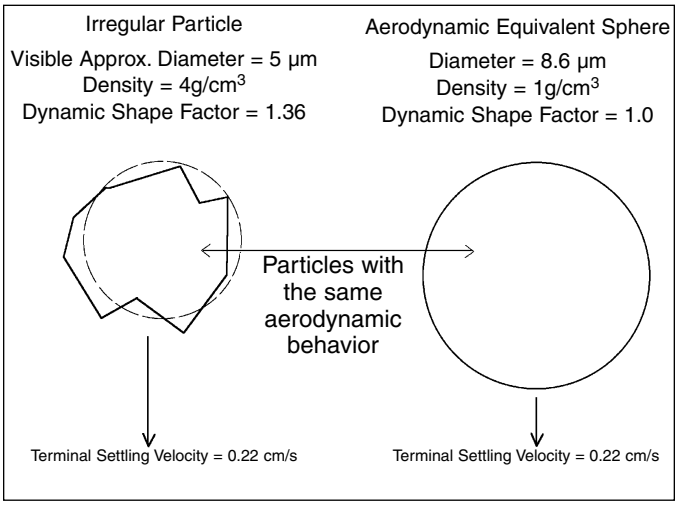

Figure 8–7. Real particle diameter and shape and aerodynamic equivalent diameter.

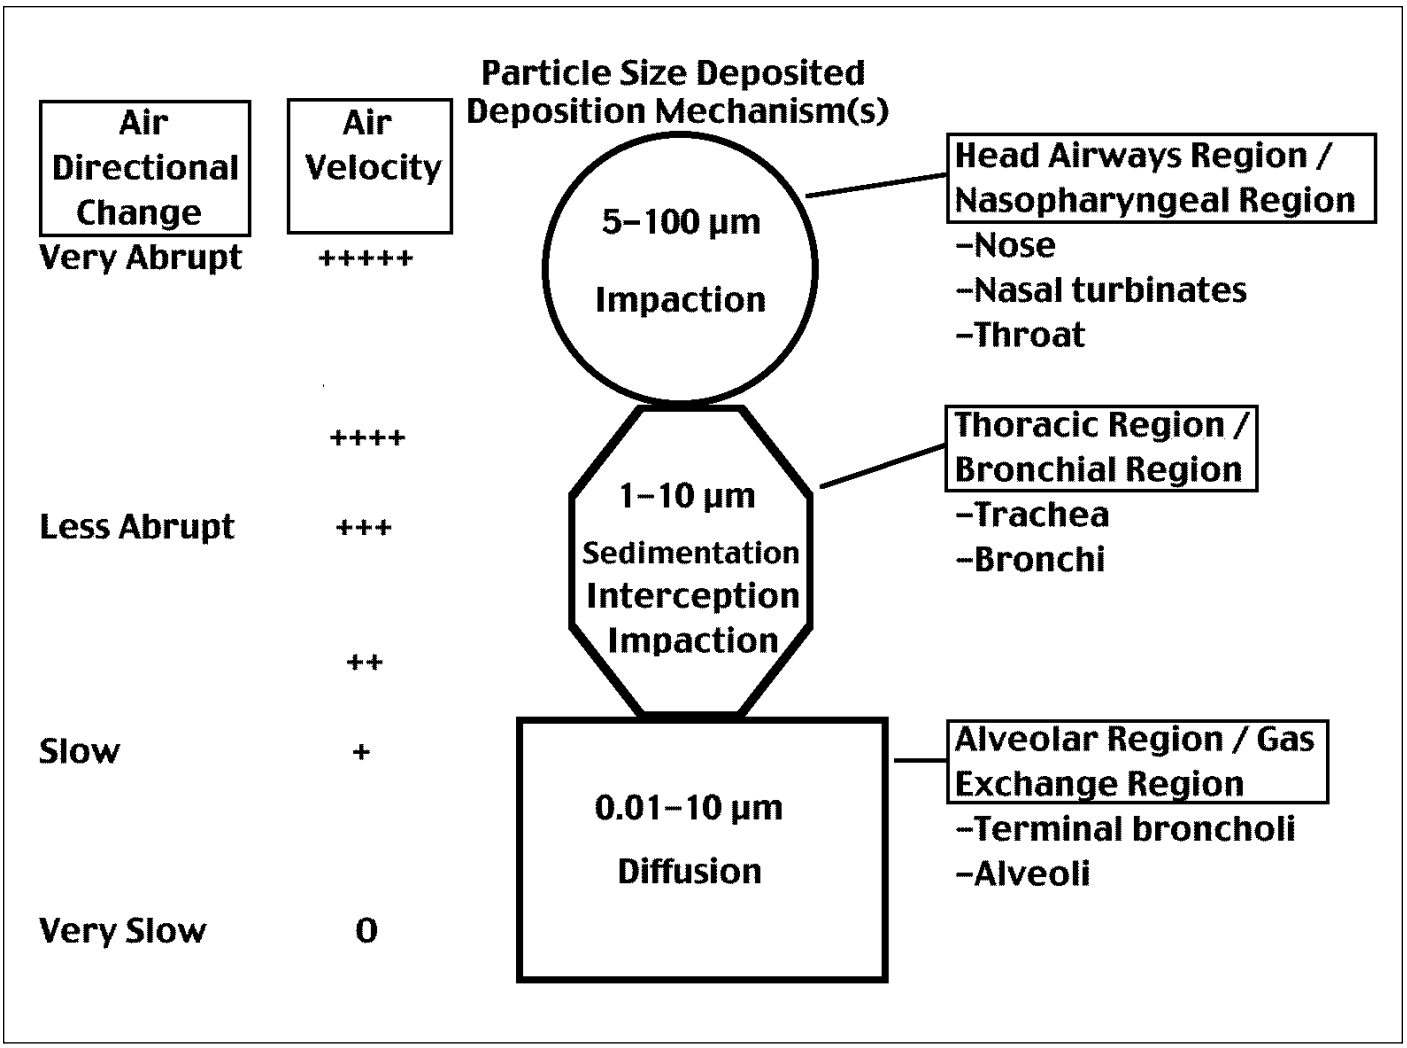

Figure 8–8. Respiratory tract particle deposition as a function of aerodynamic equivalent diameter (AED).

they may be deposited by diffusion (Brownian motion). Here, the only option for removing the particle is to dissolve it or let the macrophage physically transport it to a nearby lymph node. Particles deposited in the alveoli are attacked by resident macrophages, which attempt to engulf and dissolve them using a variety of digestive enzymes. Particles that are effectively moved from the alveoli by macrophages without dissolution pass into the lymphatic drainage where they may accumulate to cause illness or partially gain access to the systemic circulation. Particles that dissolve naturally are transported directly into the bloodstream by diffusion across the very thin capillaries that line the alveolar sacs. Particles that do not dissolve and are harmful to macrophages are often the serious pneumoconiosis-inducing particles, and they simply accumulate in the alveoli.

Real health consequences may arise when the particle is toxic and the macrophages are ineffective at removing it. One example of such a case has already been presented—asbestos. The macrophages do not destroy the asbestos particle, and in the process of trying, actually die and degrade, apparently triggering a cascade of biological responses that may be responsible for much of the fiber's toxicity. Quartz (the common form of free crystalline silica) is another highly insoluble compound, the toxicity of which is completely dependent on its penetration to the alveolar portion of the lungs. Quartz deposited in the nose, throat, bronchi, or larger bronchiole is completely non-toxic. Only when it is small enough to come to rest in the alveoli does it trigger the start of silicosis and cancer, probably by killing macrophages somewhat like asbestos. Many, but not all of the non-benign pneumoconiosis producing dusts act through this type of mechanism.

On the other hand, many particles demonstrate similar toxicity no matter where they are deposited in the respiratory tract. A soluble lead compound, for example, is likely to rapidly dissolve and enter the blood no matter where it is deposited in the respiratory tract. This is true of arsenic and many other soluble particulate matters. The poisoning occurs regardless of where the PM deposits in the respiratory tract.

Dose: Concentration of PM in the Work Environment and Exposure Duration

"All substances are poisons; there is none which is not a poison. The right dose differentiates a poison and a remedy." This statement, written by Paracelsus (1493–1541) is an important starting point in understanding the concept of dose and dose-response relationships. At some dose, everything, including water, becomes toxic. Common table salt will kill half the people who consume four grams per kilogram of body weight in a short period of time. On the other extreme, botulism toxin will kill half of the people who consume 10 nanograms per kilogram, a toxicity range of 400 million.

Most of the pneumoconioses require many years of exposure for toxic effects to manifest themselves. The same is true of carcinogenic PM, such as polynuclear aromatic hydrocarbons and cadmium fume. Some metals, such as arsenic and lead, typically result in poisoning that occurs after exposure of at least several months. A few hours of heavy overexposure to some metal fumes from welding or cutting, such as zinc, can result in a transient illness known as metal fume fever.

Of course, all of these timeframes are affected by the concentration of the contaminant in the workplace air. Silicosis, a classic pneumoconiosis, can occur in a matter of months when the exposure level is very high. High exposure to cadmium fume can cause acute pulmonary edema, which can be fatal in days. At very high levels, lead toxicity may manifest itself in less than a week.

What is a safe level for exposure to a potentially toxic PM in the workplace? This depends on many factors. First we must consider the concentration of PM in the workplace air. In almost all cases, higher concentrations are more dangerous than lower concentrations. Industrial hygienists have an assortment of mandatory regulations and voluntary guidelines to follow to determine what is a "safe" exposure level. Federal OSHA Permissible Exposure Limits (PELs) regulate most U.S. exposure levels. PELs carry the force of law. Some of the larger states have developed their own (typically equal to or lower than federal OSHA) PELs for some toxic PMs.

The National Institute of Occupational Safety and Health (NIOSH) has developed a number of Recommended Exposure Limits (RELs), which are promulgated to guide OSHA in future rule making. Finally, the American Industrial Hygiene Association publishes voluntary guidelines called WEELs, "Workplace Exposure Evaluation Levels."

OSHA is very slow to adjust to new data and new views, and is subject to extreme political pressures. Thus, PELs, in particular, rarely change.

Many responsible employers also follow the guidelines established by the American Conference of Governmental Industrial Hygienists called Threshold Limit Values®, or TLVs®. These are updated yearly, and often provide more current values for controlling employee exposure.

Lacking a PEL, REL, WEEL, or TLV®, some manufacturers or employers will develop their own recommended exposure limits, based on toxicity testing or their handling experience.

Occupational exposure limits (OELs) for chemical compounds are defined against several different time bases. Most TLVs and PELs are defined as eight-hour time weighted average exposures. Many RELs are based on a 10-hour exposure period. Historically, the TLVs have also included Short Term Exposure Limits (STELs), which were a 15-minute average of exposure, but this concept has largely been dropped in recent years. Only a few compounds retain STEL limits. Another common limit is the "Ceiling" limit, abbreviated simply as "C," which is a concentration of the chemical agent which is usually intended as an absolute limit, a value never to be exceeded even for a short time.

OSHA retains as a historical artifact the concept of "Peak Above Ceiling," which is a limit that allows short periods of exposure above the ceiling value. The time basis for the peak above ceiling varies from agent to agent. Among PM, only beryllium and its compounds, chromic acid and chromates, and fluoride-containing dust are subject to the peak above ceiling limit. Finally, the OSHA standard for asbestos provides an "excursion" limit, which is a 30-minute average exposure.

For radioactive particles, the airborne limits are termed "Derived Air Concentrations" or DACs, which are published by the International Conference on Radiation Protection (ICRP). These figures are airborne limits that are back-calculated from the pre-established limit for radiation dose to the lungs and other tissues. Unlike chemical exposure limits, which are usually expressed as eight-hour average exposure limits, the DACs are year-long averages. Exposure slightly above a DAC on one or several days is not important if exposure is well below the DAC on the majority of workdays.

For many particulate matters, the level of exposure multiplied by the long-term duration of exposure (the *dose*) reveals the real measure of safety provided by the occupational exposure limit. For example, in diseases that are cumulative without a safe "threshold," as is generally thought to be true for asbestos-induced cancers, it is not the daily exposure that is important. It is the average exposure over the employee's career that establishes his or her residual risk of developing asbestos-related cancer. According to OSHA, exposure at the current limit of 0.1 fiber per cubic centimeter of air averaged over an 8-hour day for a working lifetime will increase an individual's risk of developing asbestos-related cancer by about 0.3–0.4 percent. Against the total likelihood of developing cancer over an individual's life of 22 percent, this residual risk is considered acceptable.

Other particles have only a short-term effect on the exposed individuals, not a cumulative effect. Where an occupational limit is set to control irritation, as in the case of sodium hydroxide dust or mist, if it is effective on one day, it should be equally effective on every day. Exposure at that level for many years is not likely to result in any long-term

disease. It is worth noting that exposure limits set to minimize irritation usually assume that the employee is regularly exposed to the irritating agent. Inexperienced or transient workers are often severely affected at levels that are below the ceiling or short-term exposure limit.

In between are chemicals for which toxicity is somewhat cumulative, but not linearly cumulative as assumed for many carcinogens. Lead is a good example. Everybody is exposed to lead every day in minute amounts through the air we breathe, the food we eat, and the water we drink. Yet because the dose is small, virtually nobody develops lead poisoning. This occurs because the lead is slowly but continuously eliminated from the body. An equilibrium concentration of lead in the body is achieved which is below the level necessary to cause disease. As the dose increases, the body's ability to keep up with the accumulation of lead lags, and the body burden of lead climbs. Assuming a constant dose, eventually the body will reach a new equilibrium of lead burden, which may exceed a safe level. At this point, signs and symptoms of lead poisoning appear.

Many occupational exposure limits carry poorly defined residual risks, and in the case of the TLVs®, the ACGIH states that the limits "refer to airborne concentrations…under which it is believed that nearly all workers may be repeatedly exposed day after day without adverse effects. Because of individual suceptibility…(some people) may be affected more seriously…by development of an occupational illness."

The environmental limits for exposure of the general population to PM are generally much lower than the occupational limits. For example, the limit for beryllium in the environment is 0.01 $\mu g/m^3$, 200 times less than the occupational exposure limit. This arises from a variety of considerations, including the potential of exposure to the sick, young, and elderly in the general population, 24 hour-a-day exposure, and a general attitude that residual risk rates for the public should be much lower than residual risk rates acceptable in the occupational setting.

Preexisting Health or Genetic Status of the Worker

Occupational exposure limits for particulate matter are generally set for "healthy workers." They do not, in most cases, take into account the variable susceptibility of individual employees because of preexisting health problems or genetic endowment. Many of the *expanded OSHA standards* do require some medical evaluation of workers before significant exposure to a specific PM (e.g., asbestos, lead, cadmium, and arsenic).

The ACGIH and the Centers for Disease Control and Prevention recommend blood lead levels much lower for pregnant or potentially pregnant women than for other women, not to protect them against lead health effects, but to protect the fetus from the teratogenic and fetotoxic effects of the mother's elevated blood lead level. In a comprehensive industrial hygiene program, all women who become pregnant or are trying to become pregnant would have their workplace evaluated for potential exposure to teratogenic or fetotoxic exposures, including radiation exposure when applicable. However, a court decision has made it clear that a woman cannot be forcibly discharged or even shifted from one job to another to protect her fetus, as long as her exposure and biological monitoring results fall below the minimum OSHA standards. It should also be noted that lead may have a variety of adverse effects on the male reproductive system as well, most notably on fertility and sperm function.

However, for the vast majority of PM hazards, there is no requirement to perform preexposure medical assessment of the workers to determine if they have conditions that might make it imprudent to be exposed to the PM in question. No generally applicable regulation requires prescreening for individuals who are to be exposed to beryllium, chromium, cobalt, barium, diesel exhaust, nickel, pentachlorophenol, thallium, or dozens of other occupational particles.

Concurrent Exposure to Other Toxic Agents

Often, exposure to particulate matter or other types of airborne hazardous materials do not occur in isolation. Rather, exposure occurs to more than one type of PM or PM plus gases, vapors or infectious agents. While in many cases these multiple exposures do not interact, in some cases they may interact additively or synergistically.

An example of a noninteractive concurrent exposure would be lead and asbestos. While they are both primarily occupational hazards as aerosols, their target organs, health effects, and pharmacokinetics are very different. Lead is primarily neurotoxic, even though it gains access to the body through the lungs. Asbestos is toxic mostly in the lungs, and causes lung diseases such as cancer and asbestosis. Lead is somewhat cumulatively toxic, but it has a threshold below which there is no risk of developing lead poisoning. Asbestos is usually assumed to be fully cumulatively toxic (especially the less soluble forms amosite and crocidolite) with no threshold. When both exposures are measured simultaneously, the results are treated independently, and if both exposures are below the appropriate limits, then the operation is in compliance.

Other exposures are known or assumed to be additive. For example, it is prudent to assume that co-exposure to any of the pneumoconiosis-producing dusts listed in Table 8-C would be additive, as they produce variably related conditions. Thallium and lead have very similar toxicological profiles, so again it would be appropriate to consider these concurrent exposures as additive. The more closely the particulate matter-related health effects are, the more appropriate it is to judge them to be additive. When both exposures are measured simultaneously, the TWA fractions of the respective exposure limits found for each agent are added together, and if the value exceeds 1.0, then an overexposure situation is assumed to exist.

Equation 4

$$\frac{\text{Measured exposure agent 1 (TWA)}}{\text{TLV*–TWA for agent 1}} + \frac{\text{Measured exposure agent 2 (TWA)}}{\text{TLV*–TWA for agent 2}}$$

* PEL, REL, or WEEL may be used instead of TLV®, as is most appropriate

An example of application of additive calculation for measured concurrent exposures to lead and a soluble thallium compound is provided below:

$$\frac{\text{Lead: Measured exposure is 0.03 mg/m}^3\text{ (TWA)}}{\text{PEL-TWA = 0.05 mg/m}^3} + \frac{\text{Thallium: Measured exposure is 0.05mg/m}^3\text{ (TWA)}}{\text{PEL-TWA = 0.10 mg/m}^3}$$

The sum of these is 1.1. As this exceeds 1.0, the measured worker is assumed to be overexposed to the additive metals (lead and thallium in this case). If taken separately, each metal would be below its corresponding PEL, and an overexposure would not exist. Note that this type of additive analysis can be conducted for three, four, or even more agents sampled at the same time. It may even include a mixture of PM, vapors and even physical agents. This is a determination which must be made on a case-by-case basis by an industrial hygienist.

Other PM exposures are synergistic. For reasons not totally clear, the health consequences of concurrent inhalation of cigarette smoke and asbestos exposure are much greater than the sum of the parts. Both attack the lung and both cause cancer, but when exposure occurs at the same time, there is a very large synergistic increase in the risk of developing lung cancer.

Lung infection and exposure to pneumoconiosis-producing dusts often seem to act synergistically. Silicosis predisposes workers to the development of active tuberculosis that progresses along with the pneumoconiosis and makes the pneumoconiosis much worse. Emphysema often adds to the problem when there is concurrent silicosis and tuberculosis. While some cases of silicotuberculosis may result from activation of latent disease, it appears that other cases arise due to concurrent exposure to silica and *Mycobacterium tuberculosis.*

Concurrent pneumoconiosis from kaolin and infection with tuberculosis causes synergistic fibrosis. The same thing can happen with asbestosis. However, in the latter two cases, unlike silicosis, the presence of these other pneumoconioses does not seem to actually enhance susceptibility to tuberculosis. Concurrent proliferation of *Candida albicans* (a normally present but quiescent fungal infection in humans) and asbestosis appears to be synergistic. Some types of co-infection cause coal miners' pneumoconiosis to change from a fairly benign disease to a very serious and progressive illness.

A number of co-infections probably are promoted by pneumoconiosis-producing dusts or act synergistically to cause more severe forms of the pneumoconiosis.

There is no routine mathematical way to account for synergistic effects.

BIOLOGICAL REACTIONS

There is a wide range of biological responses to deposited particulate material. Some of these are described below.

- ➢ Acute sensory irritation of the upper and middle air passageways, including a burning sensation in the upper airways and coughing from laryngeal stimulation. Continued exposure may result in bronchioconstriction.
- ➢ Pulmonary irritants stimulate sensory receptors in the lungs and induce rapid shallow breathing, dyspnea, and breathlessness. If the exposure is high enough or prolonged, more severe responses including airway constriction and pulmonary edema may occur. Secondary infection may complicate severe cases.
- ➢ Lung edema without sensory irritation. For example, cadmium oxide can be fatal by this mechanism in high doses.
- ➢ Some irritants can cause acute or chronic bronchitis, which is the overproduction of mucus, and lead to cough and dyspnea (e.g., vanadium compounds, endotoxin).
- ➢ Allergic sensitization resulting in extrinsic allergic alveolitis or asthma arises from many exposures, including isocyanates, certain wood dusts, complex biomolecules, mite feces, pollen, cotton bract (byssinosis), mold spores [mushroom pickers lung, maple bark strippers lung, [cheese washers lung], thermophilic actinomycetes [farmers lung], dried sugar cane (bagassosis).
- ➢ Fibrosis, which is a type of scarring of the lung tissue, results in loss of flexibility, difficulty breathing, and in severe cases, damage to the right side of the heart as it tries to compensate for reduced blood oxygenation. Many of the pneumoconioses result in fibrosis. There are many different types of fibrosis, some localized and some very diffuse, as discussed previously. They may present a restrictive or obstructive pulmonary function profile, or a mixture of the two.
- ➢ Emphysema, which results in obstructive lung function. Particulate matter examples include cadmium oxide and cigarette smoke. Many gases result in emphysema as well.
- ➢ Systemic toxicity resulting from dissolution of inhaled particles in the lung or in the digestive tract after being removed from the upper and middle airways. Examples include lead, arsenic, thallium, pentachlorophenol, fluoride salts, manganese, soluble radioactive compounds, and toxic fungal spores.
- ➢ Lymphatic toxicity from particles physically moved to the lymphatic system from the alveoli by macrophages. Insoluble radioactive particles may cause this type of damage.
- ➢ Oncogenesis, the initiation or promotion of cancer. Examples are many, and include arsenic, asbestos, beryllium, chromium +VI compounds, coke oven emissions, nickel, free crystalline silica, cigarette smoke, and at least certain hard wood dusts.
- ➢ Infection (e.g., *Coccidioides immitis, Mycobacterium tuberculosis, Legionella* species, *Hanta virus*).

➢ Metal fume fever, which typically resembles flu, and results from overexposure to fresh metal particles, especially fume, of zinc, magnesium, and copper or a number of other metals or their corresponding oxides. It tends to occur in employees who have not been recently exposed to these fumes. Symptoms start four to 12 hours after inhalation, and are self-limiting in almost all cases.

Note that some types of particles can cause a range of lung toxicity depending on the specific compound containing the active element, the particle size, and the exposure rate. Thus, arsenic can cause pulmonary edema, systemic poisoning, or lung cancer. Second-hand cigarette smoke can cause emphysema, bronchitis, or lung cancer. Asbestos can cause asbestosis or lung cancer.

SAMPLING AND ANALYSIS OF PARTICULATE MATTER

Most samples taken to assess exposure to PM are air samples. Most often, the particles are removed from the aerosol by filtration, impaction, electrostatic attraction, or wetting, with subsequent analysis of the collected particles in a laboratory by chemical or microscopic methods. Although less common than when sampling for gases and vapors, direct-reading real time instruments are also used to measure airborne PM as well, commonly by detecting their scattering of light.

However, other types of particle sampling are also common in industrial hygiene. Surface sampling in areas where hazardous aerosols are present is a fairly common tool, recognized by OSHA as industrial hygiene sampling data, with the same rules about record retention as apply to air samples. Occasionally PM from clothing or skin surfaces will be collected as an indication of dermal exposure. This method is commonly used in research on particles that pose substantial transcutaneous hazards, such as some pesticides.

Bioassays exist for many particulates that provide an indication of actual absorbed dose or biological changes resulting from absorbed dose. This may be done by analysis of urine or blood. The American Conference of Governmental Industrial Hygienists has established a number of recommended bioassays for PM, mostly for metals.

It is actually rather common to use two or more of these sampling methods to monitor or evaluate the exposure of a particular individual. Personal air samples are an excellent indicator of PM exposure on that shift, biological monitoring may provide a measure of exposure across many shifts, and surface sampling provides information on the effectiveness of engineering and administrative controls over the longer term.

Sampling for Particulate Matter

Air sampling for particulate matter is a fundamental industrial hygiene activity. The vast majority of occupational exposure limits are based on the results of air sampling. Air sampling can be integrated over various periods of time, ranging from samples which last days or weeks for environmental measurements or point source release of radioactive particulate matters, to direct-reading real time sampling intended to measure ceiling or peak exposures. For occupational exposure purposes, the eight-hour time-weighted average is the most commonly measured value.

Integrated industrial hygiene air samples are most typically collected onto filters placed in the *breathing zone* of the worker (within ~12 inches of their nose and mouth), with air drawn through the filter at a rate of 0.5 to 3 liters per minute. This way, the filter goes where the worker goes, and collects particles based on the airborne concentration of PM wherever that employee moves over an eight-hour shift. Although common in the past, now a liquid impinger is only occasionally used to collect particles in modern industrial hygiene practice. Before the 1960s, asbestos and coal dust were usually collected in impingers, but now they are collected on filters.

Less common now, although a standard in the past, is the *general area* sample, typically taken with a plug-in pump. One version of this type of instrument is operated by a 1/5–1/3 horsepower vacuum pump, and draws air through a 25 to 47 millimeter diameter filter at rates varying from a fraction of a cubic foot per minute (CFM) to a couple of CFM. This is sometimes casually referred to as a "high-volume" (or simply hi-vol.) sampler. Another version of an area sampler, a true high-volume sampler, uses a vacuum cleaner motor to draw air through a filter as large as 8 x 10 inches at a rate of 20 to hundreds of CFM. Sampling devices that collect specific size fractions of PM are used extensively in the environmental or community setting. Samplers such as the PM 10 collect particles at 50 percent efficiency with AEDs less than 10 μm, and the PM 2.5 and PM 1.0 act similarly for those smaller particles.

General area sampling is used extensively in specific settings, asbestos abatement in particular. Typically, samplers are set up around the perimeter of an isolated asbestos dust containment area as a means of verifying the adequacy of the controls. With phase contrast microscopy (the primary OSHA analytical method for counting asbestos fibers) the samples, which may be collected in as little as one to two hours and analyzed on site in a matter of 30 minutes, provide rapid feedback on the effectiveness of the dust containment. Following an asbestos abatement action in a full containment, it is typical to take one or more *clearance samples* as a means of verifying the complete decontamination of the air and surfaces in the contained area. These area samples, collected on 25 or 37 mm filters at 10 to 16 liters per minute (depending on the analytical procedure), are usually taken using "aggressive techniques," traditionally using a leaf blower and fans to stir up any settled or residual dust. Thus the result(s), whether analyzed by phase contrast or by transmission electron microscopy are a hybrid sample, partially reflecting what was actually in the air, and partially counting what was on the surface but capable of being made airborne.

Figure 8–9. Tools of industrial hygiene.

Microbiological Sampling

General area samples are still commonly used for sampling airborne bacteria and fungal spores. Traditionally, samples were collected by impingement in a liquid with a device called the "all glass impinger-30," with subsequent dilution and plating out and culturing of the suspension or direct optical counting of the collected bioparticles. While this method is still in use, especially for bacteria, in the 1970s and 1980s, it became more common to collect viable bacteria and fungal spores on a petri plate filled with a growth medium loaded into a modified single stage "Anderson" impactor. Buoyed by the publication of an ACGIH guideline for using this method in 1986, the collection of viable microorganisms by drawing air through a 400-hole sixth stage of a multistage cascade impactor became the norm. When air from each hole hits the growth medium, a viable bacterial or fungal spore can impact and eventually grow.

Originally, these samplers were built by cannibalizing multistage cascade impactors. In time, appropriate single stage impactors became available commercially. Eventually, NIOSH developed written sampling methods for these impactors (NIOSH 0800 and 0801). Standard collection agars have come to be tryptic soy and tryptic soy with five percent sheep blood for bacteria (sometimes with mold inhibiting additives), and with malt extract, rose bengal, potato dextrose, dichloran glycerol, Czepak Cellulose, and corn meal for molds. Almost all of the single-stage, 400-hole agar impactors are designed to operate at 1 CFM (28.3 LPM). Smaller personal versions of single stage impactors are commercially available.

Other viable spore collection devices that acted similarly, such as the RCS sampler, were marketed successfully, although in its original version, the RCS unit was inefficient for smaller bacteria and spores.

Once cultured under specified conditions, the number of colonies was counted and the total airborne loading of viable bacteria or fungal spores was determined, in units of *total colony forming units per cubic meter* (CFU/m^3).

In time, it became apparent that live culture/total colony count method had several limitations, including its relative difficulty of use, lack of typing of the fungus or bacteria, and the varying presence of potentially large numbers of airborne microorganisms, which were dead and would not grow once collected, but retained their potential allergenic or toxigenic properties.

It is still common for aeromicrobiological sampling to be performed by area sampling rather than personal sampling. While the viable sampling methods are still in common use with some modification, methods of collecting all cells and spores whether viable or not, were developed, This included the Burkhart Spore Trap and most recently, the Air-O-Cell cassette. The cassette, usable with any pump capable of providing the required 15 liters of air per minute flow rate, impacts particles onto a sticky surface; the particles are then analyzed optically by a trained microbiologist to determine not only the number of organisms, but the genus and in some cases the species of the organisms.

It is quite unusual for an industrial hygienist to be asked to sample for infectious airborne bacteria, fungal spores or viruses, primarily because it is difficult to culture captured organisms, and the sensitivity of the methods is too low to detect meaningful levels of infectious agents. For example, soilborne spores of *Coccidioides immitis* when inhaled can lead to coccidiomycosis, a potentially severe lung infection, but air sampling is almost impossible, leading to false negative results. *Legionella,* the bacteria responsible for the outbreak of lung disease among the Legionnaires in 1978 as well as Pontiac fever is often sampled in bulk water sources such as cooling tower water, but almost never in the air. Tuberculosis is clearly transmissible person to person. A standard sampling and analysis protocol requires that the collected and cultured organisms then be inoculated into sensitive animals like guinea pigs to demonstrate infectivity. Anthrax and Q fever are common bacterial diseases transmitted by the air from animals to people (potentially over miles in the case of anthrax), and while there have been instances where these have been sampled by cascade impactor or impinger, it is rather unusual. Q fever has been sampled in animal rendering plants for occupational purposes. Some viruses, including measles, have been sampled as part of larger mists or dusts in hospitals and other health care settings but this is not routinely done by industrial hygienists.

In some industries and many indoor air quality evaluations, it is common to sample for "endotoxin," which is a family of lipopolysaccharides in the outer membrane of gram-negative bacteria. Inhalation of endotoxin can induce flu-like or asthma-like symptoms or more serious lung illnesses. Oddly, while these molecules may cause short and intermediate term adverse health effects, they may also stimulate the immune system so as to render the exposed employee relatively resistant to some types of cancer.

Endotoxin can occur in bacteria growing in humidifier water in buildings, and in cotton dust, agricultural dusts, and machining oils. It is often collected on polycarbonate capillary pore filters or in impingers.

Radon and Radon Progeny

Radon is one of the "noble gases," which generally refuse to react with other compounds and therefore are almost always found as gases. Radon is a naturally occurring gas that is usually formed by the radioactive decay of uranium. Even though the gas is radioactive, it is not usually an occupational hazard, as it is not significantly absorbed as a gas when in contact with surface of the lungs.

However, as radon radioactively decays by the release of an alpha particle (nucleus of a helium atom), it turns first into radioactive polonium, then through several other radioactive isotopes including two forms of radioactive lead, and finally into Lead 206, which is not radioactive and makes no pretense of nobility. These intermediate radioactive materials are not gases, are charged, and rapidly attach themselves to oppositely charged particles in the air. Very quickly, a radioactive particle is formed, and when inhaled, is subject to lung deposition with subsequent radioactive decay through a series of other radioactive forms. These particulate matter decay products have traditionally been called *radon daughters,* or more recently, *radon progeny.*

Deposition of radioactive particles in the lungs presents the risk of inducing respiratory tract cancer. Airborne radon tends to accumulate where uranium is stored or inside poorly ventilated basements. Indeed, radon accumulation from naturally occurring uranium in the soil is common inside houses and some workplaces where the soil uranium concentration and soil gas permeability is high. Many thousands of homes across the United States have radon levels above the guidance level set by the EPA of four picocuries per liter. However, the classic workforce subject to radon daughter exposure is mining. This is an obvious hazard in uranium mining (or processing or handling), but also occurs with some regularity in other types of mining where uranium is present in fairly high concentrations. Excess lung cancer has been demonstrated in mines where radon daughters are present at elevated levels, although oddly enough, to date excess cancer rates have not been associated with living in houses with equally high levels of radon daughters. It is likely that some additive or synergistic effect is occurring among miners.

Most radon or radon daughter sampling is done using area methods. While radon daughters are sometimes measured directly by collection on a filter and counting under a gas proportional or thin-window solid state scintillation counter, in many settings the radon itself is collected by diffusion onto treated, activated charcoal-containing sorption media. The charcoal is then analyzed by a method such as liquid scintillation counting to directly determine the radon content. While the radon concentration itself is of no importance, in many settings the radon is in equilibrium with the many radon daughters, and the hazard posed by the radon daughters can be inferred from the radon levels. Control the radon level, and effectively the radon daughters are controlled.

Diesel Exhaust

Diesel exhaust has been shown to be carcinogenic, as it contains high concentrations of oncogenic polynuclear hydrocarbons. The particles are very small and thus respirable.

Table 8–E. *Filter Particulate Matter Collection Media Used in Industrial Hygiene*

Plain Filters	**Diameters / Pore sizes**	**Uses**
Cellulose	37 mm /undefined	Radioactive particles
Mixed cellulose ester	25–47 mm / 0.45–1.2 µm	Welding fume, asbestos, lead, cadmium, beryllium, sodium hydroxide mist
PVC	25–47 mm / 0.8–5.0 µm	Gravimetric dust, chromium paint overspray, silica, aluminum oxide, cotton dust
Glass fiber	13–47 mm / 1.0 µm	PCB mist, carbaryl, chloramphenicol
Polycarbonate	25–47 mm / 0.4–0.8 µm	Asbestos for TEM
Silver membrane	25–37 mm / 0.45–0.8 µm	Coke oven emissions
Teflon	13–47 mm / 0.45–5.0 µm	Assorted polynuclear aromatic hydrocarbons (as in soot, diesel exhaust, petroleum asphalt fumes, cigarette smoke)
Nylon	25–37 mm, 1.0 µm pore size	
Quartz	37–47 mm / undefined	Diesel particles
Coated Filters	**Characteristics**	**Examples**
Glass fiber/sulfuric acid	Stabilized MOCA on filter	4-amino biphenyl
		4,4-methylene dianiline
		MOCA
Mixed cellulose ester/ sodium carbonate		Arsenic trioxide
Glass fiber/1-(2-pyridyl) piperazine	Chemical reaction with isocyanates to stabilize them on filter	Toluene, diisocyanates, methylene, diphenylisocyanate, 1 and 2 naphthylamine
Unusual Filters	**Characteristics**	**Examples**
OSHA versatile sampler	Combination vapor/particle collectors. Filter portion may be glass or quartz fibers	Pesticides, organo-tin compounds, TNT, DNT, phthalate esters, glycols
Polyurethane foam (PUF) tubes	Very thick plugs of foam are used to collect mist phase of mixed vapor/mist	Pesticides, PCBs, dioxins, polynuclear aromatic hydrocarbons (area samplers)

Much attention is being paid to the levels of diesel exhaust and similar high PNA particulate matter (asphalt fumes, environmental tobacco smoke) in the field of air pollution. Concern for these agents is to starting to appear more often in the industrial hygiene literature. NIOSH has developed an analytical method, 5040, meant to sample for total elemental carbon as a simple surrogate for diesel exhaust carcinogenic compounds. The analysis involves thermal optical methods that are fairly specific for carbon. The diesel particulate matter standard and equipment are intended to be used in the effluent line, and thus may be exposed to high heat levels. The filter of choice is the 37-mm, heat-treated quartz fiber filter, and respirable sampling using a cyclone is recommended. The Mine Safety and Health Administration has also developed a set of specifications for sampling diesel particulate matter in mining environments, but the availability of sampling devices to meet these criteria is currently very limited. Many methods are available to sample and analyze specific polynuclear aromatic hydrocarbons (PAHs), the presumed primary carcinogens in these partial combustion products. A practice that may come into common acceptance is to analyze for 15 of the predominant PAHs in diesel exhaust and sum these. The ACGIH has already proposed this type of standard for oil mist.

Size-Selective Particle Sampling and Analysis

There is growing emphasis in industrial hygiene to use particle size-selective sampling to better characterize the level of exposure to relevant dust rather than total dust.

This can be done in a couple of ways. The oldest size-selective analysis, which is still used, observes each particle microscopically and counts only those that meet the preestablished size criterion. Starting in the 1920s, dust was collected by hand operated pumps into 1 liter *water-filled impingers*. Under the microscope, only particles with an approximate diameter of less than 10 µm were counted, in an effort to estimate the size fraction that was thought to be a toxicologically significant respirable fraction.

Asbestos remains as one of the few PMs that is routinely analyzed by size-selective microscopic counting. Optical (or electron) microscopy visualizes the collected fibers. The actual size of each particle determines if it gets measured. Under OSHA and the asbestos "A" NIOSH optical counting rules, the fiber must be >5 µm long and have an aspect ratio of at least 3:1. Under the more recent EPA electron microscope counting rules the fibers must be >0.5 µm long and meet a 5:1 aspect ratio. Neither of these procedures establishes an independent fiber diameter counting rule.

Most of the optical asbestos (and other fiber) methods used historically and around the world selected 5 μm in length as the minimum countable fiber. When the membrane filter collection method was formally adopted by the U.S. Public Health Service in 1969, the optical microscopy size-selective counting rules (which were subsequently adopted by OSHA and the ACGIH) were based on limiting the time burden on the analyst. Counting all of the short fibers would be highly time consuming. This is how the 5-μm limit was set, despite other published accounts suggesting prescient toxicology was taken into account or some other scientific logic drove this decision. As it turns out, recent toxicological evidence does suggest that fibers shorter that 5 μm do have reduced toxicity.

Fibrous glass or other manmade vitreous fibers (MMVF) have a mass per volume standard under OSHA—they are treated as a nuisance dust and evaluated gravimetrically. However, more recently, the ACGIH has established a TLV® for fibrous glass in units of fibers per cubic meter of air, like asbestos (they still retain their gravimetric standard, however).

The usual analytical procedure for MMVF is the NIOSH 7400 method, using the "A" counting rules, as for asbestos. However, this makes it necessary to count "OSHA fibers" no matter how large in diameter. Many fibrous glass products tend to be composed mainly of fibers that are quite large in diameter, and thus will be nonrespirable. Recall, a fiber tends to flow in an aerosol with an AED equal to about three times its actual width, which in the case of a 3-μm wide fiber is 9 μm. Thus, many nonrespirable and presumably nonharmful fibers are counted. This can result in what is probably an unreasonable overcount. Use of the "B" counting rules under the NIOSH 7400 method or the AIA RTM 1 method allows the discounting of fibers larger than 3-μm in diameter, thus avoiding overcounting associated with very large-diameter and likely fairly harmless particles.

Other size-selective sampling and analytical methods use some sort of mechanical separator in front of the collection medium to limit the size of the collected particles to a specified effective aerodynamic diameter. Over the years, several types of selective separators have been used. After collection of the appropriate size fraction, analysis can then proceed by chemical, gravimetric, or other means.

The best known example is the use of a separator to limit collection to the respirable mass fraction. In 1952, the British Medical Research Council first proposed exactly what defined the "respirable mass fraction," intended for use with pneumoconiosis producing dusts. This method was an area sampling method and used a *horizontal elutriator* to remove the nonrespirable fraction. The U.S. Atomic Energy Commission (AEC) in 1961 followed this with a modified curve for use in nuclear facilities. By 1968, the ACGIH developed its own respirable dust curve, very similar to the one used by the AEC, and specified its use for free crystalline silica-containing dust. Size selectivity was to be provided by a cyclone, a 10-mm nylon Dorr-Oliver cyclone for personal samples, and a 2-in. cyclone for high volume area samples. As it turned out, when the Occupational Safety and Health Act was passed in the United States in 1970, and OSHA was assembled a year later, it adopted verbatim the ACGIH TLVs®, including the respirable dust curve, as it applied to free crystalline silica-containing dust.

* This table indicates the percentage of particles of a given aerodynamic equivalent diameter (AED) in a polydisperse particle cloud that should pass through the size-selective sampler and be collected on the sample medium. Larger particles are not collected for analysis.

In the 1991 and 1992 respectively, the ISO (International Organization for Standardization) and CEN (the European Standardization Committee) had settled on a slightly modified respirable dust curve, which in 1993 was adopted by the ACGIH. NIOSH joined in the consensus at the same time. At this time, the ACGIH/ISO/CEN/NIOSH respirable dust curves are the same (Table 8–F).

The biggest change in this curve from the one adopted by OSHA in 1971 was the slight shifting of the 50 percent cut point from 3.5 μm to 4.0 μm. In theory, the new curve is more conservative, collecting a larger fraction of dust as respirable than the older curve. In practice, this small shift makes no practical difference, as both OSHA and the ACGIH recommend the continued use of the 10 mm Dorr-Oliver cyclone operated at 1.7 liters per minute, as established many years before. The resulting separation function is adequate for either curve.

Other respirable dust cyclonic separators are available as well. One company has long sold an aluminum cyclone that was originally designed to meet the old BMRC curve at 1.9 liters of air per minute. However, when operated at 2.5 liters of air per minute, it produces a respirable curve which very closely resembles the current ACGIH/ISO/CEN/NIOSH curve adopted in 1993. A slightly faster flow rate is recommended to better match the OSHA curve. Because it is composed of conductive metal, it is not subject to the disruptive effect of localized charge accumulation seen in nonconductive nylon cyclones. Conductive plastic respirable PM mass separators are also available which are advertised to reduce some of the other sources of bias inherent in the traditional Dorr-Oliver cyclone. These cyclones operate at 2.75 liters a minute to effect the respirable dust curve.

Table 8–G. ***Some TLVs® with Respirable Particulate Mass (RPM) Standards***

Particulate Matter	*TLV RPM (mg/m^3)*	*Comments*
Cadmium	0.002	RPM TLV, but not part of OSHA standard
Coal Dust (Anthracite)	0.4	Under OSHA, limit is: $\frac{2.4\ mg/m^3}{\%\ SiO_2 + 2}$
(Bituminous)	0.9	where quartz is <5%, otherwise use OSHA quartz formula
Diquat Dibromide	0.1	An herbicide, also has nonrespirable TLV
Graphite	2.0	All forms except fibers
Kaolin	2.0	Under OSHA, standard still only exists in mppcf units.
Mica	3.0	Under OSHA, standard still only exists in mppcf units
Paraquat	0.1	A pesticide, also nonrespirable TLV
Particulates not otherwise classified (PNOC)	3.0	Under OSHA, 5 mg/m^3
Silica:		
Free crystalline (quartz, tridymite, cristobalite)	0.05	In Federal OSHA, the quartz standard is given by:
Tripoli	0.1	$\frac{10\ mg/m^3\ (total\ respirable\ dust)}{\%\ SiO_2 + 2}$
Fume	2.0	
Fused	0.1	which is equal to essentially 0.1 mg/m^3 for pure quartz. Tridymite and cristobalite limits are given as 1/2 the quartz standard. Limits for amorphous forms are given by:
Diatomaceous earth	3.0	$\frac{80\ mg/m^3\ (total\ respirable\ dust)}{\%\ SiO_2}$
Soap Stone	3.0	Also nonrespirable TLV
Talc	2.0	Not containing asbestos. Under OSHA, standard still only exists in mppcf units.

Table 8–G lists a number of types of particulate matter for which the ACGIH has established respirable particulate mass standards. Some of the same chemicals with respirable TLVs® also have nonrespirable particulate mass standards.

The ACGIH has also established a PM subfraction called "Thoracic Particulate Mass" (TPM). TPM includes particles smaller than about 25 µm in AED, and represents those particles that make it past the head airways region and are available for deposition in either the tracheobronchial or alveolar regions. See Table 8–H. At this time, no TLVs are assigned to the Thoracic Particle Mass fraction. However, cotton dust and coke oven emissions have been suggested as possible candidates for TPM standards.

The ACGIH has also established an "Inhalable Particle Mass" (IPM) criterion. It is slowly moving away from traditional "total dust" collection, which is poorly defined and subject to a number of errors, toward the IPM criterion. (See Table 8–I.)

As an improved version of "total dust" sampling, this procedure is applicable for particles that can cause adverse health effects regardless of where they deposit in the respiratory tract. Formally recognizing the general belief that particles larger than 100 µm are not inhalable, the acceptance of the curve is undefined above 100 µm AED.

Special sampling devices are sold to implement the IPM sampling procedures, just as cyclones are sold to implement the respirable particle mass criteria. A few of the chemicals already assigned to inspirable particulate matter TLVs® include:

➢ Diquat
➢ Grain dust

Inhalable mass samplers are often handled differently from typical "total dust" sample cassettes. In one common protocol developed by the Institute of Occupational Medicine in Scotland, a 25-mm filter is used inside a special holder. It is operated at 2.0 L/min to simulate the inhalable mass criteria. The cassette and filter are weighted pre- and post-sampling as a unit, reducing any loss of particles on the interior walls of the cassette, sometimes a severe problem when sampling for total dust with nonconductive polycarbonate cassettes. Also, this prevents the loss of any larger particles that might fall off the filter when it is removed for analysis using more traditional techniques.

There is one other significant size-selective separator still used in industrial hygiene. It is unique to the measurement of lint-free dust from primary cotton operations. Dust is sampled on a filter for gravimetric analysis, but first it must be passed through a vertical elutriator designed to provide a 50-percent acceptance size of 15 μm AED. This device is an area sampler only and cannot be used for personal samples. The interested reader is referred to the Transactions of the National Conference on Cotton Dust, page 33, JR Lynch, May 2, 1970.

For environmental PM sampling, particles size selectors with 10, 2.5, and 1 μm AED 50 percent cut points are used. These devices are not normally used in the occupational environment, although personal separators for PM 2.5 and 10 are commercially available, mostly for use in community air pollution work.

Dual-Phase Monitoring

On occasion, it is necessary to make a decision to sample either the particle phase of a mixed vapor/particle agent or the vapor phase. For example, when sampling with chemically treated filters for certain isocyanates in paint mist, only the particles will be collected and the vapor will be undetected. Another sample can be taken in a liquid filled impinger and almost all of the vapor and mist will be collected, with the possible exception of the very smallest mist, which can sometimes penetrate impingers.

Polychlorinated biphenyls (PCBs) are another agent which can expose employees to either a mist (if agitated or condensed) or vapor (if heated). NIOSH has a method that specifically addresses this by using a 13-mm glass fiber filter for mist, inline with an appropriate vapor sorbent tube.

Oil mist is usually collected on a filter, as in the NIOSH 5026 method. Depending on the vapor pressure of the oil, mass can be lost after collection by evaporation. A method that allows the evaporating oil to be adsorbed onto a collection tube after the filter would be desirable for high vapor pressure oils.

Isokinetic Sampling

Sometimes, it is necessary to sample PM in a moving airstream, such as after a HEPA filter bank ventilating a nuclear reactor. This introduces new aerodynamic problems into the sampling procedure that must be accounted for in order to obtain a valid sample of the PM in the airstream.

After the air has flowed through a HEPA filter, it is common to place a sampling tube in the duct, perpendicular to the air flow, to draw the air and deliver the particulate matter to a filter outside of the ventilation system. In some cases this might be a very sophisticated multiport air intake, designed specifically for that duct or stack. In other cases, it is a single tube, often of copper.

There are two critical factors to consider when performing the type of sampling described above. First, the airflow in the sampling line must be isokinetic with the airflow in the duct or stack. That is, the velocity of the air in the duct must be the same as the velocity of air in the sampling tube. If the sample velocity is less than the duct velocity, it will tend to result in overestimation of the particle mass in the ductwork. On the contrary, if the airflow in the sampling tube exceeds the airflow in the duct, it will tend to cause underestimation of the particle concentration. The effect of nonisokinetic sampling in a duct or stack can be quite severe. These effects occur primarily with the larger particles, due to inertial forces, as shown diagrammatically in Figure 8–10. Errors start to show up at particle AEDs of 3 μm, and become increasingly severe above 6 μm.

The other potential problem sampling in ducts and stacks is the use of a sampling tube with sharp bends. The sampling tube must face straight into the airflow, and it must curve slowly to achieve exit from the duct. Any sharp bends will cause particle accumulation at the bend by inertial impaction, which will cause the particles not to reach the filter and thus underestimate the particulate matter mass. Finally, the air collection filter should be as close to the outside of the duct or stack as possible. Running the particle laden air through extended lengths of tubing before the filter, as is sometimes done, will certainly result in particle loss and underestimation of particle mass.

Finally, if the collection medium is subject to pressure changes as dust accumulates, this may slow the flow of air in

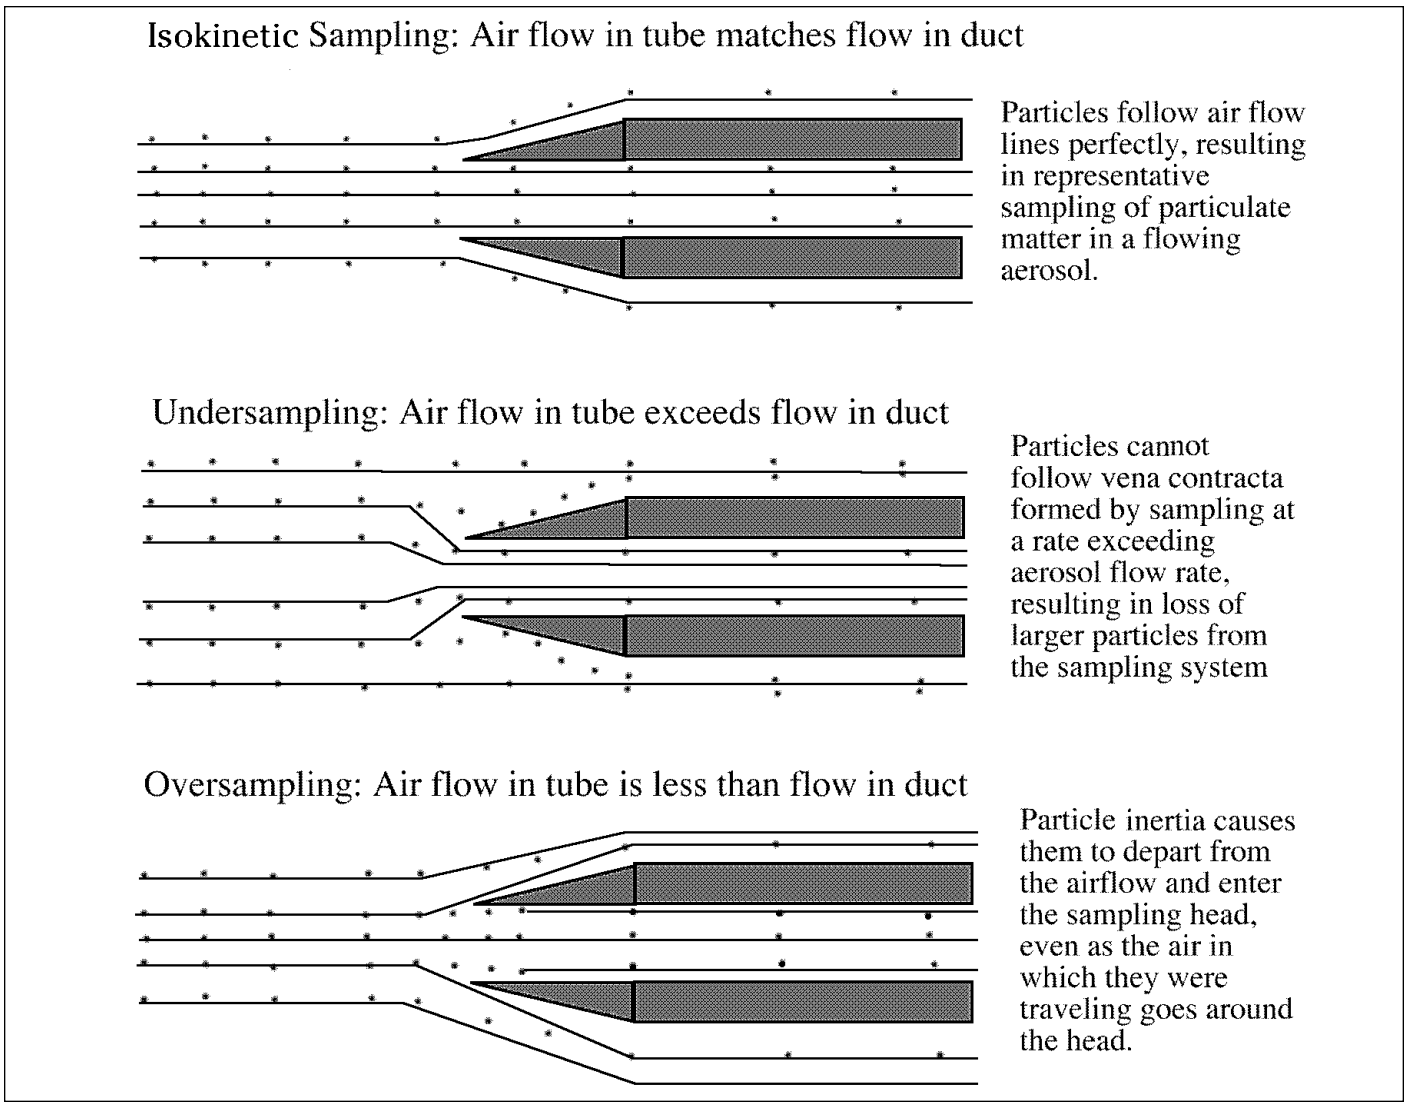

Figure 8–10. Sampling error introduced by nonisokinetic sampling.

the system and drop the sampling flow rate below the isokinetic level. This can be avoided by using a sampling medium that does not change resistance substantially with loading (e.g., water collection), or controlling the flow either actively or via a critical flow orifice.

If the temperature or airflow rate in the duct or stack is subject to change during sampling, it will be very difficult to maintain isokinetic conditions without constant attention. In a nicely flowing system, in contrast, once the system is set, it should operate reliably on its own.

Surface Sampling for Particulate Matter

Surface sampling in some workplaces is useful as an adjunct to air sampling. Typically, surface sampling is conducted for several reasons.

First, surface sampling is conducted to determine adequacy of housekeeping and engineering controls in minimizing the spread of highly toxic PM. Surface sampling is not needed where the contaminant is of low toxicity, as a visual observation will usually suffice. However, for materials with high toxicity and correspondingly low occupational exposure limits, surface sampling should be considered. In the facilities owned or operated by the Department of Energy, surface sampling of beryllium work areas is required. In U.S. Housing and Urban Development (HUD) housing (also used more broadly in other settings), surface sampling for lead dust is required. A little utilized but potentially very useful type of swipe is the *Ames test* swipe. Here, if there is no specific analysis for the potentially mutagenic material (e.g., soot), subjecting the surface dust to revertant mutation assay provides some semiquantitative data about the potential spread of that material.

Federal OSHA has no specific requirements for surface sampling for particulate matters, but does require that if such sampling is conducted in the workplace, it be treated the same as air sampling data with respect to records retention.

Other settings where surface sampling for PM is useful include the following:

- ➢ When working on laboratory fume hoods, to verify that no potentially explosive perchlorate residue is present in the hood, plenum, duct, or fan.
- ➢ Prior to releasing excess equipment for reuse, utilization, sale, or donation. For example, it would be inappropriate to donate a machine tool contaminated with beryllium or other highly toxic metal to a local high school.
- ➢ When it is necessary to determine what metals are/were used in an area, surface samples can be analyzed for many metals by inductive coupled plasma emission spectroscopy or similar tool.
- ➢ Where the contaminant has a high percutaneous toxicity, as in the case of some organophosphate pesticides.
- ➢ Where the surface dust is a major component of the source term for airborne exposure.
- ➢ Following certain types of abatement actions (lead in particular) to verify the adequacy of the decontamination and contamination control procedures.
- ➢ Whenever working with potentially radioactive PM.

A variety of surface sampling techniques are available to the industrial hygienist. The traditional method is a dry "swipe" sample, where the surface is rubbed over a known area with a mixed cellulose ester filter or a special swipe tab often called a "smear tab." These are quick and easy, and it is common to combine samples from several related areas onto one swipe, but this is also the least reliable, most user-specific surface sampling technique.

A move up from the dry swipe is the wet swipe, where the Whatman filter or swipe tab is prewetted with water or another liquid prior to application to the surface to be tested. This procedure is a little more precise than the dry swiping methods, but still subject to a lot of variability.

The Housing and Urban Development (HUD) procedure for lead dust sampling introduced most industrial hygienists to the process of wet wiping, using a large, wet wiping medium and a specified wiping technique. While still very much semiquantitative, this procedure is generally regarded as an advancement over prior wipe sampling methods, with the possible exception of the radiological control community. An American Society for Testing Materials (ASTM) draft procedure for lead wipe sampling was proposed in 1993, which evolved into an ASTM Provisional Procedure in 1996 (ASTM 46-96). Many other wipe sampling methods for lead have been published, including EPA 3050.

Where visible quantities of dust are present, surface samples can be obtained simply by collecting the dust and sending that in for analysis. A common variation on this is the surface *microvacuum* technique. Microvacuuming is usually performed by using a standard 25-mm or 37-mm mixed cellulose ester filter attached by hose to a relatively high flow rate pump. A short extension tube, cut off at a 45-degree angle on the front end, is attached to the front nipple on the cassette. A known area of surface is carefully vacuumed onto the filter, and the entire cassette is submitted to the laboratory for analysis. Sometimes the desired result is mass of contaminant per mass of total dust (i.e., percent or ppm) or mass of contaminant per given surface area (e.g., micrograms per square foot). The ASTM has developed two specific standards for microvacuuming for asbestos fibers, ASTM D 5755 and 5756.

A variation on this procedure that is somewhat more elegant is the "Smair Ring." This machined ring takes the place of the top cap on a three-piece air filter cassette. Numerous small holes are drilled into the side at specific angles, designed so that when the ring is placed flat against the surface to be sampled, high velocity jets of air were driven onto the surface to dislodge dust and create a vortex effect, efficiently removing the dust and loading it onto the surface. The only drawbacks to the Smair ring are its relatively high cost, limited commercial availability, and its ineffectiveness on uneven surfaces. Other devices similar to a Smair Ring have been developed and marketed.

Direct-reading surface sampling tools also exist. Lead on surfaces can be detected by the use of sodium rhodizinate-based swipes meeting the specifications of the NIOSH 7700 method. Although lacking the sensitivity and specificity of the more traditional field collection/lab analysis method, the advantage of instantaneous results, at least for screening purposes, is substantial in some settings. Similar single-use surface sampling tubes are available for mercury droplets, nickel dust, cadmium dust, and chromate dust.

All surface samples of PM should be regarded as qualitative or at best semiquantitative, and used as an adjunct to air sampling and other aspects of a comprehensive industrial hygiene program. See Chapter 17 for more information on direct-reading instruments.

Dermal Monitoring

A related type of PM monitoring is dermal monitoring, typically for particles that present significant skin absorption hazards, such as pesticides. NIOSH 9201 is a method that was developed to measure chlorinated and organonitrogen pesticides from patches of fabric attached to the clothing of workers. One product available to implement this method is the "*Dermal PUF (polyurethane foam) patch*." It is a section of polyurethane foam fabric that is clipped to the worker's clothing or taped directly to the skin. After sampling, the patches are removed and sent to a laboratory for analysis of the pesticide.

Analysis of hand washing rinsate is another technique sometimes used to evaluate dermal exposure. Increasingly common, at least in research, is the use of ultraviolet fluorescent powders added to pesticides or other chemicals that can then be imaged and recorded photographically. This is an old trick used in the training of radioactive material handlers: have the trainees handle fluorescent powder instead of radioactive powder and at the end of the exercise, demonstrate with a long wave ultraviolet light the spread of contamination and problems in their practices.

ANALYSIS OF AIR SAMPLES

Once the particle is removed from the airstream and collected onto a filter or into a liquid, it then must be analyzed. Historically, the most common methods of analysis were optical microscopy, gravimetric (weighing), and sometimes wet-chemical analysis. While these methods are still fairly common, more sophisticated analytical procedures have been developed for all metals, free crystalline silica, certain organic materials, isocyanates, and certain other materials.

Metals (Spectroscopic Analysis)

Wet-chemical analysis of most metals ended with the advent of the flame emission photometer, a device that siphons dissolved metal ions into a flame and measures the characteristic optical emission lines of the metal. The intensity of the lines is proportional to the concentration of the metal.

The flame photometer was improved by the introduction of the flame atomic absorption photometer. Here, the flame-excited metal ion is exposed to a collimated beam of light created by a source that produces the emission lines characteristic of that metal. The ions in the flame absorb the intense light in proportion to their concentration. This method has the advantage of being more stable and sensitive than flame photometry, but is also more expensive and limited, as it requires separate light sources for each element to be analyzed. A further improvement, still in broad use, is the graphite furnace atomic absorption spectrophotometer, where the flame is replaced by a graphite furnace.

The next major improvement in metal analysis, which is the workhorse instrument in most sophisticated labs that perform many different types of metal analyses, is the inductively coupled plasma atomic emission spectrometer (ICPAES). Here, the flame is replaced with very high temperature gas plasma, created by induction from the fields created by a radiofrequency generator. Other than changing the excitation source and computerizing the operation of the device, an ICPAES operates largely like an old flame photometer. The liquid containing the digested metal ions is siphoned into the plasma, and as it is turned into plasma it produces characteristic emission lines. A monochrometer allows selection of a particular line, and the intensity of that line is proportional to the concentration of metal analyte. Typically, it is possible to automatically scan the different lines to determine many metals at the same time, and to compare the intensity of several lines produced by a metal to assure that no positive or negative interference is occurring. A further improvement of this device eliminates the monochrometer and photometer, and replaces them with a spectrometer consisting of a light dispersion element (e.g., reflective diffraction grating) and a charge coupled device that allows simultaneous measurement of all lines of all elements.

The last big step in analytical instruments for metals is the inductively coupled plasma-mass spectrometer (ICP/MS). In this device the metal ion is first run through radiofrequency induced plasma, and then directed into a mass spectrometer, which weighs the atom to determine its exact atomic number and concentration. Like the ICPAES, this instrument can analyze many metals all at the same time. For many metals, this is the most sophisticated and sensitive routinely used analytical instrument. It should be noted that in many cases, such sophistication and sensitivity are unnecessary and needlessly expensive. For routine analysis of a single analyte like lead, a simple atomic absorption spectrophotometer is perfectly adequate and much less expensive than an ICP/MS. The ICPAES and ICP/MS are very helpful when you need low detection limits, do not know the exact metal composition of the PM you are sampling, or require the analysis of several metals on the same filter.

Free Crystalline Silica

Free crystalline silica (e.g., quartz, cristobalite, and tridymite) can be analyzed by a couple of methods. One involves infrared spectrophotometry, as in the NIOSH 7602, 7603, and MSHA P-7 methods. Colorimetric methods are still occasionally used. However, the most common and reliable analytical method is powder x-ray diffraction, as in NIOSH 7500 and OSHA ID 142. This method is more sensitive and precise and can analyze all three free crystalline silica species at the same time. It can be used for personal air samples, settled dust samples, bulk samples, or high volume air samples. In the past, it was considered necessary to submit either high volume samples or at least settled dust samples along with the air samples, in order to allow proper calibration of the instrument. In recent years, many laboratories no longer require the cosubmission of high-volume or settled-dust samples, although if the concentration of silica in the source material is not known, it is a prudent practice to submit a settled-dust sample or bulk sample to ascertain this value.

Unfortunately, both of the main analytical methods available for free crystalline silica are quite imprecise by industrial hygiene standards. The variability among labs or even within labs is quite high, with a relative interlaboratory standard deviation up to about 40 percent for the infrared method. The variability is much improved, albeit still poor (SD in the range of 20 percent) for the x-ray diffraction method. Among common analytes, only the analysis of asbestos approaches the level of analytical imprecision characteristic of silica analysis (asbestos analysis SD about 20 percent at best).

Asbestos

Asbestos is still measured mostly by optical techniques. From about 1925 until 1969, asbestos-containing dust in the United States was usually collected in a water-filled impinger. An aliquot of the impinger fluid was placed in a special well slide and fibers were counted through an optical microscope. Results were expressed in terms of millions of particles per cubic foot of sampled air (mppcf). (Note: There are a few OSHA standards that still exist only in terms of mppcf, namely soapstone, talc, cement, and mica.)

Following the lead of the British and publication of the membrane filter method in the United States (Lynch & Ayer, 1968), in 1968 the United States adopted a filter sampling method that still allowed optical analysis. A wedge of the filter, with fibers embedded, is cut from the whole, placed on a slide, and the filter wedge is rendered transparent by the application of a drop of solvent. The fibers are then counted through the eyepiece of a phase-contrast microscope using a Porton-type reticule. Fields are semi-randomly selected, and if the particle is at least 5 μm long, has an aspect ratio of 3:1 or greater, and falls within the bounds of the engraved reticule, it is counted. The results are now expressed in units of fibers per cubic centimeter of air (f/cc, occasionally f/mL), very difficult to relate to the older mppcf units. Many attempts have been made to correlate the two units, but the conversion factors have typically been found to be of limited applicability. Still, the original OSHA standard in terms of f/cc is based on one conversion factor from mppcf.

The National Institute of Occupational Safety and Health and OSHA adopted essentially the same method after OSHA's creation in the 1970s. Originally called Physical and Chemical Analytical Method 239 (P&CAM 239), over time several changes to the method have been made (changing to a Walton-Beckett reticule, replacement of the liquid clearing solution with a vapor phase clearing chemical, adjustment of acceptable flow rates, resolution testing of the microscope), and the method was renumbered NIOSH 7400 in 1984. It has been through several revisions since, but retains the designation NIOSH 7400. Currently, the most recent revision is 1994. OSHA adopted the new NIOSH 7400 in lieu of the P&CAM 239 method almost verbatim when it revised the asbestos exposure standard in 1986. In this case, they called it the OSHA Reference Method.

Other less commonly used optical analytical methods for asbestos also exist, including the OSHA 160 method and the Asbestos International Association Membrane Filter Reference Method RTM 1.

The analysis of asbestos by optical methods is usually quite imprecise and often inaccurate. Especially at low fiber loading on the filter, the imprecision of the NIOSH 7400 method is severe, as shown in Figure 8–11. Assuming proper procedures are used, the equipment is adequate and well set up, and the analysts well experienced, the variability seen at the low end of the fiber loading curve is largely intrinsic to the method and random in nature. Imposed on the inevitable error is the tendency of less skilled analysts to over-count fibers at very low loading. At excessive fiber loading not shown in Figure 8–11, systematic undercounting of fibers starts to occur, eventually reaching the point where the filter is not analyzable. The method is best used by controlling fiber loading to levels between 100 and 1,300 fibers/mm^2 of filter surface area, which can be back-calculated from the expected airborne asbestos concentration, given that the usable surface area of the 25-mm filter used for asbestos collection is 385 mm^2. For example, if the expected fiber concentration is 1.0 f/cc, in order to get the desired loading on the filter, the sample volume should be from 38 to 490 liters.

The inaccuracy of optical methods of asbestos analysis arises from the fact that the analyst counts all fibers that meet the method specifications, not just asbestos fibers. In addition, the limited resolution of optical microscopes (about 0.25 μm for most phase-contrast microscopes) means that the narrowest and potentially most toxicologically significant fibers are systematically undercounted. While a significant percentage of the fibers of amosite (20–60%) will usually be visible under the optical microscope, only a small fraction of those of chrysotile and crocidolite asbestos will be visible. This fraction, depending on the analytical methods used, may be as low as 1–5 percent.

If they are present, fibrous glass, cellulose, and mineral wool fibers get counted as asbestos fibers. Within the rules for NIOSH 7400 and for the OSHA Reference Method, there are no provisions for discriminating among different types of fibers, even though a skilled microscopist can readily tell a cellulose fiber from an asbestos fiber. The method authors are well aware of this limitation, and the NIOSH 7400 method is actually termed the analysis of "Fibers," not asbestos.

The counting of particles with an aspect ratio as low as 3:1 results in the enumeration of "pseudofibers." While true asbestos minerals have aspect ratios of 10:1 or more, many minerals, including many nonasbestiform polymorphs of asbestos and other minerals like talc, form cleavage fragments or scrolls which are somewhat fibrous but clearly not asbestiform, but must be counted under the NIOSH/OSHA methods.

Finally, the NIOSH "A" counting rules and the OSHA method require counting all fibers meeting the length and aspect ratio rule, regardless of their diameter. The Asbestos International Association method RTM 1 discounts fibers wider than 3 μm. The rarely used "B" counting rules offered in NIOSH 7400 makes the same concession. Research has suggested that fibers, regardless of length, tend to demonstrate AEDs that are about three times their width. Three times 3 μm is 9 μm, and when multiplied by the density of asbestos which exceeds 1, makes such wide particles essentially nonrespirable and toxicologically of low significance.

These nonspecific analytical methods were developed primarily with work settings such as asbestos mines, mills, and asbestos manufacturing facilities as the target. In these settings, most of the airborne fibers are asbestos. In modern times, at least in the United States, these are not major industries. Asbestos exposure and therefore asbestos monitoring are now mostly associated with building maintenance and renovation and asbestos abatement. In these settings, asbestos exposure usually occurs along with other fibrous or pseudofibrous materials, often making the measured

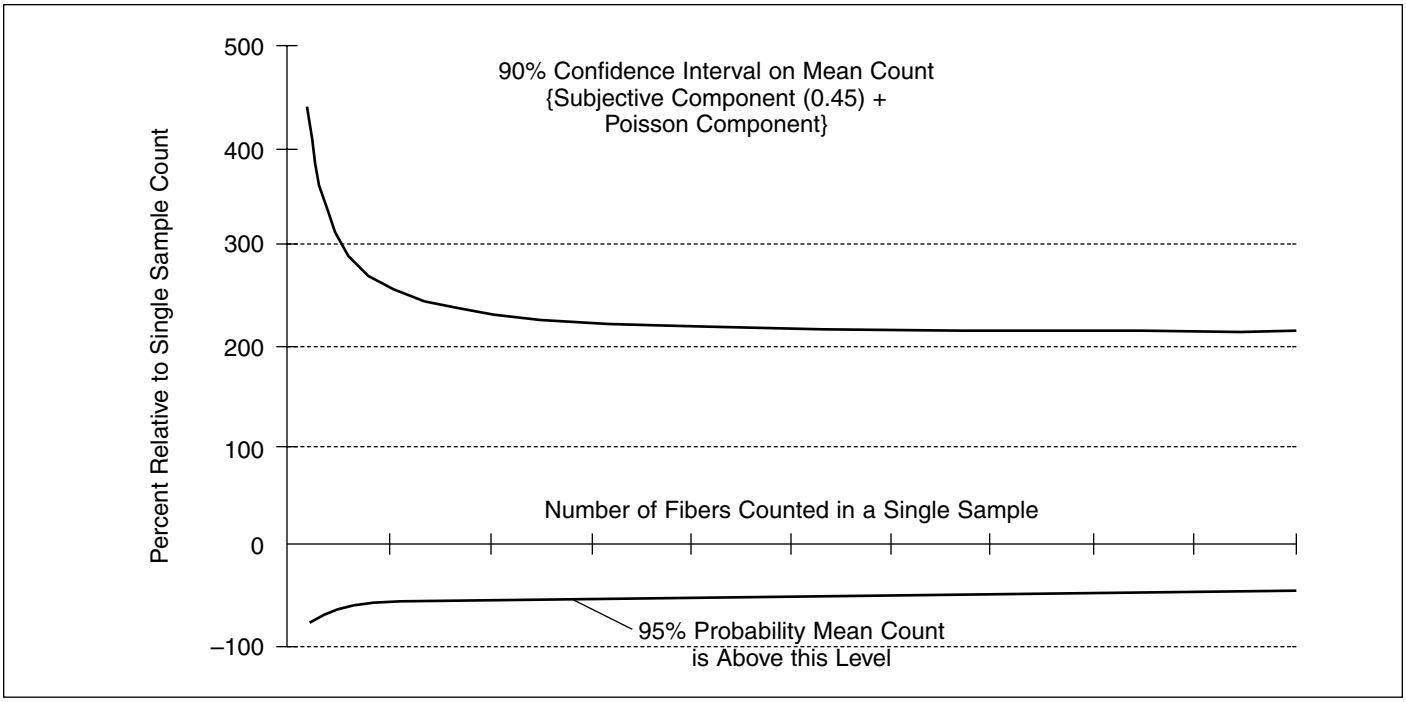

Figure 8–11. Variation in precision of NIOSH 7400 with fiber loading.

"asbestos" exposure a severe overestimate. Perhaps the worst example of this occurs during controlled removal of sheet rock with asbestos-containing surface coating or joint spackling. Fiber exposures when measured by phase-contrast microscopy (PCM) in accordance with the NIOSH or OSHA methods can be very high, but if subjected to analyses that allows discrimination between asbestos and nonasbestos fibers, few of the fibers counted by optical microscopy may turn out to be asbestos.

Several methods are used to get around the inherent nonspecificity of phase contrast optical fiber counting. In some cases, experienced optical microscopists can simply discount obvious nonasbestos fibers and count only those fibers that are likely to be asbestos. This method, however, it subject to the experience of the microscopist, and is more of an art than science. Alternatively, procedures have been developed (OSHA ID 160) which allow phase contrast counting microscopy to be used in tandem with polarized light mineralogical analysis (PLM), morphological observations, scanning electron microscopy (SEM), and transmission electron microscopy (TEM). This procedure is designed to be used by OSHA compliance officers when they sample for asbestos in a multifiber aerosol environment.

The Asbestos International Association has developed a scanning electron microscope procedure, RTM 2, as has the International Agency for Research on Cancer, but these are rarely used. The most common method for differential fiber counting is transmission electron microscopy. It is routine to consider fiber morphology in determining if they are asbestos under the electron microscope. Also, individual fibers beamed with electrons emit soft x-rays characteristic of elements in the fiber. If the asbestos under analysis is chrysotile, a magnesium silicate, very large peaks should represent magnesium and silicon only. If the fiber also contains a large peak for iron, it could be crocidolite, aamosite, or actinolite. Many other interfering fibers would lack one or more of these major components. This qualitative analytical tool is called *energy dispersive x-ray fluorescence*.

A more definitive differential technique with the electron microscope is electron diffraction patterns. Selected area electron diffraction (SAED) patterns are quite specific for chrysotile and fairly specific to the amphibole series. Combined with morphological observations and qualitative analysis, TEM can provide nearly definitive asbestos differentiation.

One of the earliest TEM methods specifically designed for asbestos analysis was the EPA method of 1978, named after its principal author, A. Samudra. These early TEM analytical methods expressed asbestos concentrations in gravimetric terms, nanograms per cubic meter (ng/m^3). This archaic unit, analogous to the use of mppcf in the early days of optical asbestos analysis, was replaced in the early 1980s.

A long-useful electron microscope method published in by the EPA in 1984 is usually called the *Yamate* method, after its principal author George Yamate. Here and in subsequent TEM methods the unit of measure is "asbestos structures per cubic centimeter of sampled air (s/cc)." This included asbestos fibers, bunches of asbestos fibers, clustered fibers, sets of fibers sticking out of other materials, etc.

When the Asbestos Hazard Emergency Response Act (AHERA) was signed into law the EPA developed a new TEM method, usually just called the AHERA method (40 *CFR* Part

763), which differs in some ways from the Yamate method. It is more than just an analytical method, as it is tied in with sampling protocols required of schools in other parts of the AHERA-driven regulations. Still, it can be teased away from these additional school requirements and used in various ways in nonschool settings. NIOSH also has a TEM method numbered 7402. The AHERA and NIOSH 7402 methods are probably the most commonly used TEM analytical procedures for asbestos.

TEM analysis is also the fix to undercounting narrow, toxicologically important fibers in optical analysis. TEM can visualize all asbestos fibers, even the narrowest, with no difficulty. Thus, TEM analysis of asbestos can be both highly specific and highly sensitive. At low fiber loading, it can still suffer from the inherent statistical variability associated with counting discrete data instead of measuring continuous data. This can be improved by counting more than the recommended number of microscopic fields, or better, by providing a filter with a higher fiber loading.

Historically, the biggest drawback of TEM analysis has been high cost and slow turnaround. As the asbestos abatement and handling industries have evolved from a novelty job to just another commodity, the time and money costs of TEM analysis have plummeted. It is still more expensive than PCM analysis, but unless the PCM lab is on-site, the turnaround time for TEM almost matches that of PCM. Another major problem with fiber type-specific analysis protocols is that they are generally not addressed in the OSHA regulations. However, since even the OSHA laboratory in Salt Lake City makes use of fiber-type specific counting, it is clear that there is some leeway here if the methods are sound and carefully applied.

Radioactive Particles

Radioactive particles are collected on filters, with the exception of activated charcoal sampling of radon as described in the sampling section of this chapter. Filters can be submitted for analysis by several means, almost all of them taking advantage of the readily detectable alpha, beta, or gamma emissions.

In many jobs, people handling radioactive materials are handling only one element at a time. Thus, simple counting of total emissions gives a picture of the total amount of that radioactive material on the filter. Knowing the radioelement, the amount of radioactive material in the air can be compared to the derived air concentration, which is a year-long weighted exposure limit. This is often termed *gross alpha, beta, gamma analysis*. Only if the radioisotope analyzed is in question or completely unknown (as might occur in working in multielement contaminated legacy facilities or waste disposal sites) is more sophisticated analysis necessary to differentiate radioactive materials based on the energy and type of their emission (radiospectroscopy).

Analysis of filters is often performed nondestructively by counting with a gas-proportional counter or more often, a solid state scintillation detector. Solid-state scintillators emit a burst of photons when hit by a radioactive emission within their range of sensitivity, and a sensitive photomultiplier tube typically detects this. Because only one surface of the filter is exposed to the detector crystal, compensation must be made for the geometry, and the results are typically increased by a factor of two or more to determine the complete emission rate. The exact correction value is determined empirically with a standard source.

In place of the solid state scintillator is often a Geiger-Mueller (GM) tube, which is useful for gamma and higher energy beta emissions. Geiger-Mueller tubes do not typically perform well for alpha particle emitters, so when measuring alpha emission, the solid state detector would be more appropriate.

An alternative type of analysis, which does destroy the filter, is liquid scintillation counting. In this equipment, the filter or particles removed from the filter are placed in small vials, to which is added a fluor. The fluor will act like a solid-state scintillation crystal and will give off a burst of light when stimulated by a radioactive decay. This light is detected by a photomultiplier tube, and after passing through a coincidence gate to compensate for thermal noise and cosmic radiation, and compensation for internal "quenching," is counted as a radioactive decay. One of the big advantages of this method is it can detect very low energy emissions, such as the weak beta particle released by tritium-containing particles (an isotope of hydrogen with three neutrons in the nucleus of the atom).

Many of these types of instruments come in simple versions, some of which are field-portable, and more sophisticated laboratory versions, sometimes with radiospectroscopic capability.

Under some circumstances, it is advantageous to analyze radioactive particles by chemical means rather than by radiodetection means.

Gravimetric Analysis

A shrinking list of particles are still analyzed gravimetrically, that is, by simply weighing the PM collected.

With the advent of more sophisticated and specific analytical tools, gravimetric analysis is used most often when sampling for "nuisance dust" or PNOC. Materials still analyzed gravimetrically are shown in Table 8–J.

Note that many agents that can be analyzed gravimetrically could also be measured by much more specific means. Fibrous dust can be analyzed microscopically, oil mist chemically, the metals by ICPES. In a mixed-dust environment, it is much better to use the specific analysis than the gravimetric analysis.

Several compensations must be made in order to be able to weigh dust collected on a filter. These must accommodate the unknown weight of the filter as it arrives from the manufacturer, and the potential for water absorption by the filter or collected dust during the sampling or analysis procedure. Without knowing something about the "tare" weight of the filter, it is

Table 8–J. ***Materials Still Commonly Analyzed Gravimetrically***

Cement	Coal dust (<5% silica)	Cotton
Emery	Fibrous glass*	Glycerin
Graphite	Gypsum	Grain dust
Kaolin	Limestone	Magnesite

Oil mist	Palladium	Paper fibers
Plaster of paris	Soapstone	Starch
Sucrose	Talc (<1% asbestos)	Titanium dioxide
Wood dust	Zinc oxide	

* Recent TLV analyzes fibrous glass microscopically as well as gravimetrically.

impossible to weigh it and know how much of the mass is filter and how much is collected PM. If the original weight of the filter is known prior to sampling, it may change if it or the collected PM is hydroscopic and gains weight from atmospheric water vapor, again making analysis difficult or impossible.

In the traditional procedures, the collection filter is desiccated by vacuum, and then immediately tared to obtain a base weight. It is assembled into a sampling cassette, with the tare weight written in a log corresponding to a numbered cassette, or written directly on the cassette, or both. The filter is then used to sample for dust in the field and returned to the laboratory. The filter is vacuum-desiccated a second time. The dry filter is then immediately weighed on a highly sensitive Mettler-type balance or a Cahn-type electrobalance. The difference in the final weight and the tare weight is the total dry dust collected. When divided by the sample volume, the airborne concentration of dust is determined.

Commercially preweighed filters tared to 10 ng are also available, but these are not run through the desiccation process on either end of the analysis. The use of hydrophobic PVC filters minimizes the effect of atmospheric water on the filter, but does not compensate for atmospheric water absorbed into the particulate matter on the filter.

A more convenient although probably less precise method of measuring PM gravimetrically is the use of stacked matched-weight filters. Starting with low-water absorbing filters (PVC typically), the manufacturer or laboratory weighs out many of the same filters, pairing sets which happen to weigh about the same. These "matched weight" filter sets are stacked and loaded into a single filter cassette. The filter is used to sample for gravimetric analysis and submitted to the laboratory. In the lab, both the collection filter and the "control" filter are weighed without any special pretreatment. The difference in weight is the total dust collected. An assumption is made that any weight gain of the filter caused by water absorption affects both filters equally and the blank value can be used to adjust the sample filter result.

Matched-weight filters are much more easily analyzed than the more traditional desiccation/tareing procedure. But because of a lack of compensation for water absorption by the collected particles, and small variation in weight between the "matched" sets of filters (commercially, 25-100 µg), this method is generally considered less accurate. When sampling and analyzing for an agent like nuisance dust or PNOCs, which have comparatively high occupational exposure limits, these effects become unimportant, and matched-weight filter sampling is common and accepted. If sampling for an agent with a lower exposure limit, with the intention of gravimetric analysis, the desiccation/tared filter method is preferred.

Biological Organisms

Biological organisms most often of interest to the typical industrial hygienist are limited to bacteria, fungi, and viruses. Analysis of some biological organisms has improved dramatically just within the last couple of years. The analysis of fungal spores is a good example. Traditional sampling methods pick up only viable spores by collection by inertial impaction onto a growth medium or into a special type of impinger. The spores are grown on the collection or plating medium (in the best case, a couple of different media) in a controlled environment until the individual spores establish colonies. The plates are allowed to grow as long as possible, but curtailed before the colonies start to merge or overlap. Then, the plates are placed on a gridded, illuminated stage called a *plate counter* and the total number of *colony-forming units* (*CFUs*) is counted either with the naked eye or a low-power magnifying glass.

In 1986 the ACGIH established an occupational exposure standard, using the direct impaction of viable particles onto growth agar with analysis of total viable CFUs/m^3. One could also take samples inside a workplace and outside to determine if there were more viable spores in the building than in the ambient air (an occurrence referred to as *amplification*). Inherent in this standard is the assumption that a colony is a colony, and thus a spore is a spore, and the genera and species do not matter. In fact, this early attempt at establishing a standard considered fungal spores primarily as an allergenic bioaerosol, in particular as contributors to indoor air quality problems. While this standard was useful in many circumstances, and the ACGIH should be applauded for leading the effort to establish standards for fungal spore occupational exposure limits in office environments, it soon became apparent that the standard is too simple for many settings.

The first problem surrounds the issue of viability. Many airborne spores are dead, including up to 90 percent of the spores of *Stachybotrys chartarum* (formerly *Stachybotrys atra*), a still-controversial but almost certainly toxic spore. These dead spores will never grow on any growth media, and thus their number will be greatly underestimated by viable sampling yet the spores remain toxic.

Further different genera and even different species require different growth media to prosper. The standard microbio-

logical media suggested in the 1986 standard are good at supporting growth of many common fungi, but not all of them, and not some of the more problematic. Once again, *S. chartarum* serves as a good example. The media commonly used are poor substrates for the proliferation of this toxigenic fungus. When sampled in a mixed spore environment, it is almost certain that *S. chartarum* will be poorly detected, even if living spores are collected. Other spore types will grow much more vigorously, and the culturing period will have to be suspended long before any growth of *S. chartarum.* It is necessary to use a high-cellulose growth medium for *S. chartarum,* traditionally Czepak 10-percent cellulose agar, or more recently, corn meal agar. Another way to avoid the viability problem is nonviable sampling, which can be done with a Burkhart Spore Trap or other similar instruments or by using an Air-O-Cell cassette. The collected spores are then counted under a microscope, usually with determination down to the genus level, and their viability or ability to grow on available media is irrelevant. However, the analysis typically requires a much more sophisticated analyst than is needed for simple colony enumeration without genus identification.

The second major problem with earlier fungi sampling procedures is the lack of specificity. Generally, industrial hygienists just counted all of the colonies appearing on the petri dish, and compared the net count per cubic meter to the ACGIH standard. On some occasions, when the expertise was available, the genus of the colonies might be determined, although separate standards were not available for genera and not much was known of their specific pathogenic properties.

The lack of specificity resulted in two problems. When comparing outside to inside samples using gross colony counts, the colony count might be the same, but the genera on the two samples might differ radically. When this occurs, it is usually true that the outside spores, usually "phyloplane fungi," are being removed from the incoming air by filtration in the air supply units, and the different set of organisms seen in the building is due to internal growth sources, often with much more hazardous fungi. A problem with amplification of spores inside the building might go unnoticed.

Gross colony counting also ignored the obvious problem, that different fungal spores have different health consequences. While it is possible to become allergic to almost any type of fungus, some genera and species are more likely to cause problems than others. Even more important, fungal spores vary radically in terms of acute and chronic toxicity, even within the same genus. There are at least 160 identified species of penicillium mold, some of which are not known to produce any *exomycotoxins,* but others produce potent toxins. Inhalation of spores of toxic species can cause significant toxic responses, whereas nontoxin producing species only cause allergy and other types of irritation. The same problem exists with other large genera, such as *Aspergillus* and *Fusarium.*

While determination of genus by optical microscopic examination (including the analysis of genus by observation of spores captured in a Spore Trap or in an Air-O-Cell cassette) is relatively straightforward for a microbiologist, determination of the exact species in large genera is much more complicated. Often it requires growth on multiple media, extensive microscopy, and a highly skilled analyst. This takes time and is expensive. Recently, several U.S. laboratories have started to offer speciation based on matching the DNA of cultured spores to banked DNA segments. The results are reported as the species. This procedure is almost certain to largely replace standard optical microbiological speciation at least for highly diverse genera.

Still, the practicing industrial hygienist is left without hard guidelines or occupational exposure limits on a species by species basis. Other countries have adopted guidelines, at least for certain settings (e.g., schools). Canada has a zero tolerance policy for known exotoxigenic species in schools and some other public buildings. Some European countries also have occupational exposure limits. In the United States, the rules remain rather vague: if amplification of a mold is found inside a building, work to track down the source and remediate it. If amplification of a potentially toxigenic species is found, consider more aggressive action, such as hiring experts in the area of detecting these organisms and specialized remediation firms. In extreme cases, many buildings, public and private, all across the United States have been evacuated until serious mold problems could be mitigated.

Actually, with toxin-forming species of fungi, even speciation by DNA matching leaves a certain level of uncertainty in assessing hazards. Any given species, indeed any given colony of potentially toxigenic mold, may or may not produce and release toxins under the conditions of growth. Most toxins are released into the environment when the mold sporulates, which it does when conditions for vegetative growth start to deteriorate. Depending on factors poorly understood, these spores might contain high levels of toxins or very low levels of toxins. Thus, the ultimate air sampling to determine the hazard posed by airborne mold might be to subject the collected spores to chemical analysis for mycotoxins known to be associated with the species. Unfortunately, this is still primarily a research tool or a semiquantitative agricultural tool, not widely available in a sensitive form to the industrial hygiene community. Another untapped analytical resource is cytotoxicity testing, where the mold extract is added to a growing colony of animal cells, and any adverse effect of the mold-extract on cell growth or survival provides a general indicator of the mold's toxicity. This procedure has the advantage that you do not have to know or guess at the toxins present to effectively use the method, as is necessary for chemical toxin analysis.

A major component of noninfectious airborne bacteria that may contribute to their ability to cause allergic extrinsic alveolitis or other less serious lung effects is endotoxin, a portion of the cell wall of gram-negative bacteria. As

described previously, this is collected on filters or in impingers. Subsequently, the endotoxin can then be analyzed chemically or biologically.

For the most part, bioassays are used, the most common being the *Limulus amebocyte lysate* (*LAL*) test. This procedure is simple, sensitive, and quick. The LAL determines the approximate bioactivity of the endotoxin present in the sample rather then the physical amount. The bioactivity is the most important characteristic. The analytical method has some constraints depending on the source of the sampled bacteria or fragments, contaminants, and specifics of the analytical process. One highly touted specific method is the *Kinetic Limulus Assay with Resistant-Parallel-Line Estimation* (*KLARE*). The results are reported in terms of "*endotoxin units* (*EUs*)," which is useful for comparison to control samples. There is no widely accepted guidance standard to which to compare the results.

A very standardized method has been proposed recently (Milton, 1995).

Organic Particles

A wide range of analytical tools, including gas chromatography and high-performance liquid chromatography are used to analyze organic particles collected on filters. Table 8–K lists organic PM commonly analyzed by these other types of chemical analyses.

Gas chromatography-mass spectrometry is sometimes used where very high sensitivity is needed or the composition of the dust is diverse or unknown. Tandem GC mass-mass spectroscopy is used for extreme sensitivity against a high background of similar organic molecules (e.g., mycotoxins in spores).

Direct-Reading Particle Detectors

Direct-reading particulate matter samplers are available and commonly used under conditions that do not change very much or for process control. Direct-reading instruments are the sample collection device and the sample analysis device, all in a field portable format. The results are provided immediately, as there is no delay for laboratory analysis.

A few grab-sampling *detector tubes* can be used for particles, such as oil mist, nickel, chromic acid, ethylene glycol, and sulfuric acid mist. More commonly, electro-optical particle enumeration devices are used. The earliest generation of these devices (many similar devices are still in use today) were forward (usually) light-scattering photometric dust monitors. The aerosol is passed continuously through the device, illuminated by a light, and the amount of forward-scattered light is detected and used as an index of particle concentration. Assuming fairly regular shape and refractive index of the particles, a pulse height analyzer can estimate the size of each particle as it passes through the

light. Thus, a curve of the particle size against number can be generated with the more sophisticated versions of this type of instrument.

More recent devices use lasers rather than noncoherent light sources, but the principle is generally the same. Scattering of light at a 90-degree angle by particles in the aerosol is used to enumerate and size the particles. The range of particles detectable by laser instruments exceeds the range of noncoherent, polychromatic light-scattering photometers. Some more sophisticated devices display specific size fractions (respirable, thoracic, inhalable dust, PM 10, PM 2.5, PM 1.0), detect only fibers, interface with computers and perform data logging, time-weighted average calculations, and may be alarmed.

In general, these instruments should not typically be considered as a substitute for traditional sampling, but as a surrogate, especially useful when sampling nuisance dusts or well characterized dust or when monitoring for time varying levels of dusts to detect peaks or point sources. They can be particularly useful in detecting leaks from lead or asbestos abatement work containments. Used properly, they greatly enhance the industrial hygienist's ability to monitor particle exposure. Personal sampling versions are available, but they cannot discriminate among different chemical types of dust in a mixed dust aerosol. Recently, very large stationary equipment that counts, sizes, and chemically analyzes PM has been developed for environmental testing. In time, this type of equipment may become available to the industrial hygiene community.

A few gravimetric real time particle detectors are available. One is a modified multistage cascade impactor, with each stage, starting from the top, collecting a smaller and smaller average AED particle size. Each stage is equipped with a piezoelectric balance, and the change in weight on each stage is recorded and displayed constantly.

Historically, other direct-reading devices have operated by electrostatic deposition of dust onto a piezoelectric sensor, the resonant frequency of the sensor being the dependent variable which changes as the dust loading changes. Other devices used the attenuation of beta particles through an impaction membrane to provide an indication of dust accumulation. As more dust accumulated, the ability of beta particles to pass through the membrane and dust cake declined in direct proportion to the deposited dust. Konimeters were used to deposit dust on the surface of a sticky slide, which was then examined in the field through a built-in microscope.

BIOLOGICAL MONITORING FOR INDIVIDUALS EXPOSED TO PARTICULATE MATTER

Another tool in the industrial hygiene arsenal to assess occupational exposures to PM is biological monitoring. Biological monitoring gives an index of absorbed dose, whether by inhalation, percutaneous absorption, or ingestion. The *determinant* in biological monitoring can be the chemical itself or one of its metabolites (in urine, blood, or expired air), or a reversible biochemical change in the body indicative of a biological response to the exposure. Depending on the determinant, specimen, and time of sampling, biological monitoring may be representative of the intensity of recent exposure, an average daily exposure, or chronic cumulative exposure.

Tests that can detect permanent physiological impairment or disease are not usually classified under the category of biological monitoring, but rather fall under the broader heading of *medical surveillance*.

OSHA has promulgated a number of expanded standards for PM, which include requirements for biological monitoring, including lead, arsenic, and cadmium. The lead biological monitoring procedure is particularly interesting, as it evaluates both the level of lead in the blood as a primary determinant, and the body's response to the lead in the blood in terms of the formation of zinc protoporphyrin. Both of these are usually used as indicators of long term chronic exposure.

The ACGIH has published a list of Biological Exposure Indices® (BEIs®), which are widely used as guidelines in assessing employees' exposure and response to occupational stressors. There are a number of BEIs for PM. Some of these are shown in Table 8–L.

Although still largely limited to Department of Energy owned or operated sites, a very unusual blood test for beryllium will probably spread rapidly to other sites where beryllium and insoluble beryllium compounds are used. This test, called the Beryllium Lymphocyte Proliferation Test (BLPT) helps to identify workers who have become sensitized to beryllium. To develop chronic beryllium disease an individual must first become sensitized. Not all sensitized employees will go on to develop any level of disease, but many will eventually develop granulomas in the lungs detectable by bronchoscopy or sensitive ergospirometry. A subset of these employees who develop medically detectable chronic beryllium disease (CBD) will, over time, develop clinical illness—shortness of breath upon exertion, chest tightness, and chest pain which may progress to debilitating or even fatal illness. Beryllium exposure also seems to increase the risk of developing lung cancer.

Unlike in many other lung diseases classically termed *pneumoconioses*, the macrophage probably plays a relatively small role in CBD, that of presenting the beryllium, bound as a hapten to some other biological molecule, to a T lymphocyte, probably of the T4 subtype. Unlike asbestosis and silicosis, where much of the lung damage is caused by the resident macrophages, the T4 memory lymphocytes appear to sustain the immunological process that leads to CBD.

NIOSH has recommended many other biological monitoring and medical surveillance protocols for individuals exposed to PM, such as platinum in urine or blood, pen-

Table 8–L. ***Biological Monitoring For Personnel Exposed to Selected Particulate Matter***

Agent	*Determinant*	*Sampling Time*
Arsenic and inorganic compounds	Inorganic arsenic and methylated metabolites in urine	End of workweek
Cadmium and inorganic compounds	Cadmium in urine Cadmium in blood	Not critical Not critical
Chromium VI+, water soluble fume	Total Cr in urine	Before and after shift End of workweek
Cobalt	Cobalt in urine or Cobalt in blood	End of workweek
Fluorides	Fluorides in urine	Before and after shift
Lead	Lead in blood	Not critical
Organophosphorous which may inhibit cholinesterase	Cholinesterase activity in red blood cells	Discretionary
Parathion	Total p-nitrophenol in urine Cholinesterase in red blood cells	End of shift Discretionary
Pentachlorophenol	Total PCP in urine Free PCP in plasma	Prior to last shift in week End of a shift
Vanadium Pentoxide	Vanadium in urine	End of workweek

tachlorophenol metabolites in blood, and reduced immunological competence after exposure to 4-aminodiphenyl.

SUMMARY

Particulate matter is usually an occupational hazard when suspended in air to form an aerosol. However, there are exceptions to this, and skin exposure or ingestion can be significant routes of exposure in some occupational settings. Exposure to particulate matter is assessed primarily by air sampling, although often with special reference to equivalent aerodynamic subfractions of the particle cloud.

Adjuncts to air sampling include surface sampling, skin or clothing sampling, biological sampling, and medical surveillance. While many aspects of an aerosol control program are stipulated in OSHA regulations, many other features are provided only in guidance form by the ACGIH, NIOSH, or other consensus organization.

The hazard posed by a cloud of particulate matter depends on a variety of factors, including its chemical composition, crystalline structure, isotope, solubility, shape, concurrent exposures, and particle size. It is often necessary to consider two or more of these factors when sampling for a particular agent.

Many industrial hygiene sampling and analytical methods are burdened with imprecision, inaccuracy, biases, and other technical problems that the industrial hygienist must understand to place the results in proper perspective.

Chapter 9

Industrial Noise

by John J. Standard, MS, MPH, CIH, CSP

The sounds of industry, growing in volume over the years, have heralded not only technical and economic progress, but also an ever-increasing incidence of hearing loss and other noise-related hazards to exposed employees. Noise is not a new hazard. Indeed, noise-induced hearing loss was observed centuries ago. In 1700, Ramazzini in "De Morbis Artificium Diatriba" described how workers who hammer copper "have their ears so injured by that perpetual din . . . that workers of this class become hard of hearing, and if they grow old at this work, completely deaf." Before the Industrial Revolution, however, comparatively few people were exposed to high levels of noise in the workplace. The advent of steam power during the Industrial Revolution first brought general attention to noise as an occupational hazard. Workers who fabricated steam boilers were found to develop hearing loss in such numbers that the malady was dubbed boilermakers' disease. The increasing mechanization that has occurred in all industries and in most trades has since aggravated the noise problem. Noise levels in the workplace, particularly those maintained in mechanized industries, are likely to be more intense and sustained than any noise levels experienced outside the workplace.

The recognition, evaluation, and control of industrial noise hazards are introduced in this chapter. Basically, this involves assessing the extent of the noise problem, setting objectives for a noise abatement program, controlling exposure to excessive noise, and monitoring the hearing of exposed employees.

COMPENSATION ASPECTS

The trend toward covering hearing losses under state workers' compensation laws has stimulated interest on the part of employers in controlling industrial noise exposures. Compensation laws that cover loss of hearing due to noise exposure have been enacted in many states; compensation is being awarded in other states even though

hearing loss is not specifically defined in many compensation laws.

Occupational hearing loss can be defined as a hearing impairment of one or both ears, partial or complete, that results from one's employment. It includes acoustic trauma as well as noise-induced hearing loss.

Acoustic trauma denotes injury to the sensorineural elements of the inner ear. Acoustic trauma is produced by one or a few exposures to sudden intense acoustic forms of energy resulting from blasts and explosions or by direct trauma to the head or ear. The worker should be able to relate the onset of hearing loss to one single incident. For details on ear anatomy, see Chapter 4, The Ears.

Noise-induced hearing loss, on the other hand, describes the cumulative permanent loss of hearing—always of the sensorineural type—that develops over months or years of hazardous noise exposure.

Noise-induced hearing loss usually affects both ears equally in the extent and degree of loss. It should also be kept in mind that the onset of hearing loss, its progression, its permanency, and the characteristics of the audiograms obtained, vary depending on whether the injury is a noise-induced hearing loss or acoustic trauma.

To establish a diagnosis of noise-induced hearing loss and a causal relationship to employment, the physician considers the following factors:

- The employee's history of hearing loss—onset and progress
- The employee's occupational history, type of work, and years of employment
- The results of the employee's otological examination
- The results of audiological and hearing studies performed (preplacement, periodic, and termination)
- The ruling out of nonindustrial causes of hearing loss

It has been estimated that 1.7 million workers in the United States between 50 and 59 years of age have compensable noise-induced hearing loss. Assuming that only 10 percent of these workers file for compensation and that the average claim amounts to $3,000, the potential cost to industry could exceed $500 million.

Estimates show that 16.9 percent of the working population are employed in jobs where the noise level exceeds 85 dBA (Table 9–A).

At present, no test can predict which individuals will incur a hearing loss. If enough people are placed in an environment where the predominant noise level exceeds 85 dBA for a sufficient period of time, some individuals incur a hearing impairment greater than that due to presbycusis (loss of hearing due to aging). The number of workers subjected to noise hazards exceeds that of those exposed to any other significant occupational hazard.

The audiometer provides an easily reproducible means of measuring the status of an individual's hearing with appreciable accuracy. Partial hearing losses are easily measurable by commercially available audiometers.

PROPERTIES OF SOUND

Sound can be defined as any pressure variation (in air, water, or some other medium) that the human ear can detect.

Sound produces a sensory response in the brain. The perception of sound resulting in the sensation called hearing is the principal sensory response; however, under certain conditions, additional subjective sensations ranging from pressure in the chest cavity to actual pain in the ears can be produced (see Chapter 4, The Ears). There are certain effects produced by sounds that appear to be universally undesirable for all people. These effects include the following:

- The masking of wanted sounds, particularly speech
- Auditory fatigue
- Damage to hearing
- Annoyance

Noise

What we call noise is usually sound that bears no information and whose intensity usually varies randomly in time. The word *noise* is often used to mean unpleasant sound that the listener does not want to hear. Noise interferes with the perception of wanted sound and is likely to be physiologically harmful.

Noise does not always have particular physical characteristics that distinguish it from wanted sound. No instrument can distinguish between a sound and a noise—only human reaction can.

A variety of methods have been devised to relate objective physical measurements of sound to subjective human perception. The purpose of this section is to outline both the objective physical properties of sound and its important subjective aspects.

The term *sound* usually refers to the form of energy that produces a sensation perceived by the sense of hearing in humans, whereas *vibration* usually refers to nonaudible acoustic phenomena that are recognized by the tactile experience of touch, or feeling. However, there is no essential physical difference between the sonic and vibratory forms of sound energy.

The generation and propagation of sound are easily visualized by means of a simple model. Consider a plate suspended in midair (Figure 9–1). When struck, the plate vibrates rapidly back and forth. As the plate travels in either direction, it compresses the air, causing a slight increase in its pressure. When the plate reverses direction, it leaves a partial vacuum, or rarefaction, of the air. These alternate compressions and rarefactions cause small but repeated fluctuations in the atmospheric pressure that extend outward from the plate. When these pressure variations strike an eardrum, they cause it to vibrate in response to the slight changes in atmospheric pressure. The disturbance of the eardrum is translated into a neural sensation in the inner ear and is carried to the brain, where it is interpreted as sound (Figure 9–2).

Sound is invariably produced by vibratory motion of some sort. The sounding body must act on some medium to pro-

* SIC=Standard industrial classification. Source: OMB (1987).

Reprinted from NIOSH Criteria Document, *Occupational Noise Exposure – Revised Criteria,* 1998. Cincinnati: NIOSH, 1998.

Based on data collected by NOES (NIOSH 1988a,b, 1990). Not all two-digit SIC sectors and not all four-digit SIC industries within each two-digit SIC sector were surveyed. The NOES covered 39 of 83 two-digit SIC sectors, and the NOES estimates were representative of only the four-digit SIC industries actually surveyed. For example, within agricultural services (SIC 07), the estimates are for crop preparation services (SIC 0723), veterinary services for animal specialties (SIC 0742), lawn and garden services (SIC 0782), and ornamental shrub and tree services (SIC 0783) only, because no surveys were done for soil preparation services (SIC 0711), crop planting and protecting (SIC 0721), crop harvesting (SIC 0722), cotton ginning (SIC 0724), veterinary services for livestock (SIC 0741), livestock services (SIC 0751), animal specialty services (SIC 0752), farm labor contractors (SIC 0761), farm management services (SIC 0762), and landscape counseling and planning (SIC 0781).

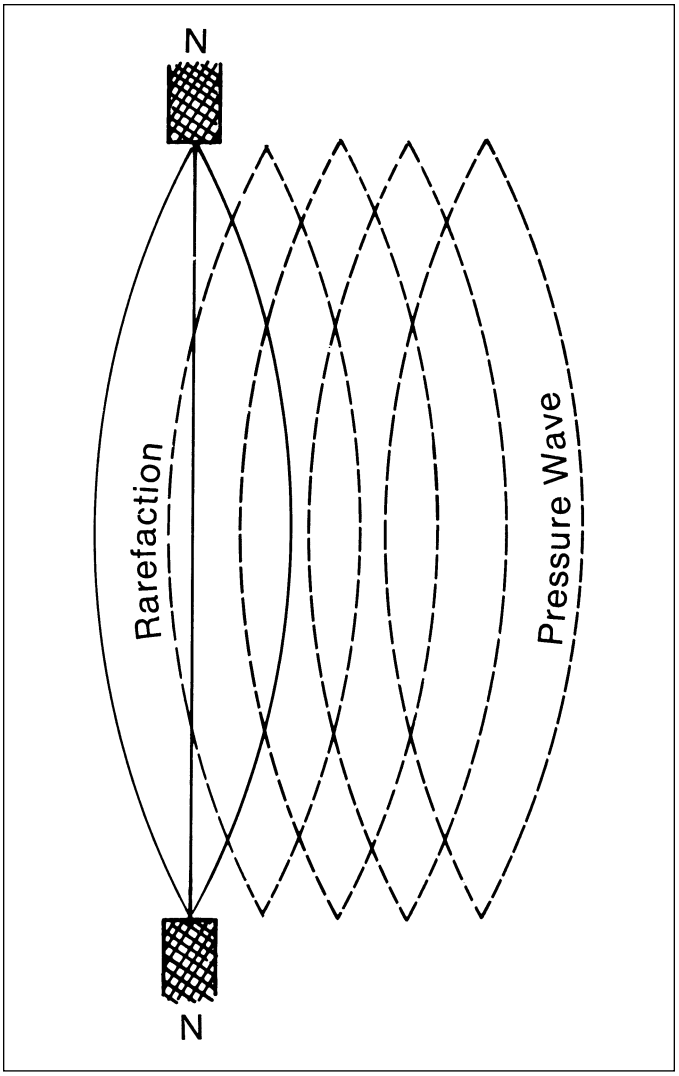

Figure 9–1. As the vibrating plate moves back and forth, it compresses the air in the direction of its motions. When it reverses direction, it produces a partial vacuum, or rarefaction, imparting energy to the air, which radiates away from the plate as sound.

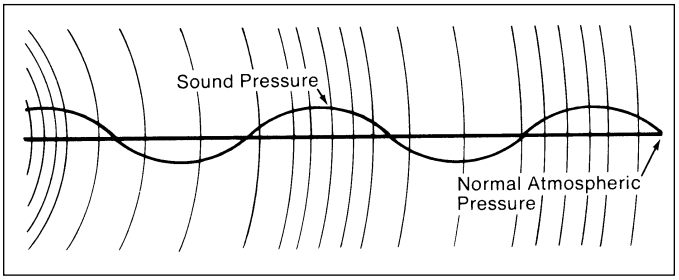

Figure 9–2. Air is an elastic medium and behaves as if it were a succession of adjoining particles. The resulting motion of the medium is known as wave motion, and the instantaneous form of the disturbance is called a sound wave.

duce vibrations that are characteristic of sound. Any type of vibration can be a source of sound, but by definition, only longitudinal vibration of the conducting medium is a sound wave.

Sound Waves

Sound waves are a particular form of a general class of waves known as elastic waves. Sound waves can occur in any elastic medium such as air, water, or steel. One sound wave may have three times the frequency and one-third the intensity (amplitude) of another sound wave. However, if both the waves cross their respective zero positions in the same direction at the same time, they are said to be in phase (Figure 9–3).

Frequency

Using sound propagating through air as an example, *frequency* is the number of times per second that an air molecule at the sound source is displaced from its position of equilibrium, rebounds through the equilibrium position to a maximum displacement opposite in direction to the initial displacement, and then returns to its equilibrium position. In other words, frequency is the number of times per second a vibrating body traces one complete cycle of motion (Figure 9–4). The time required for each cycle is known as the period of the wave and is simply the reciprocal of the frequency. The phrase formerly used to describe frequency, cycles per second, has now been replaced by *Hertz,* abbreviated *Hz.*

Frequency is perceived as pitch. The audible range of frequencies for humans with good hearing is between 20 Hz and 20,000 Hz. Most everyday sounds contain a mix-

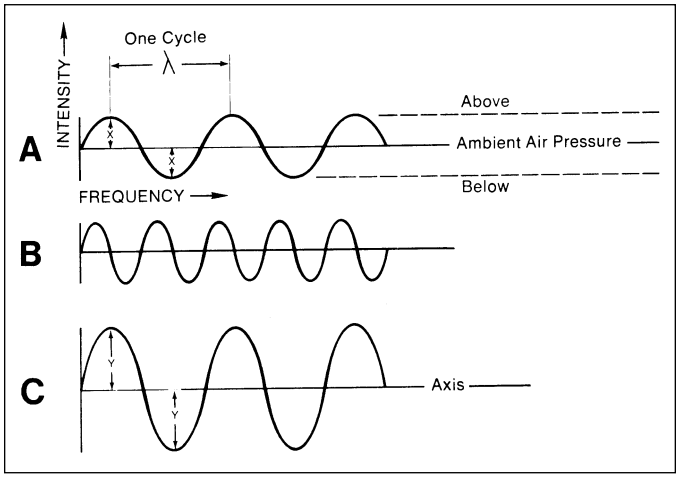

Figure 9–3. The curves shown are pictorial representations of sound waves. Pitch is related to frequency and loudness is related to the intensity of a sound. Curve B represents a sound that has a higher frequency—a higher perceived pitch—than the sound represented by curve A because the variations in air pressure, as represented by a point on the curve, cross the axis more often. The intensity of a sound can be shown by the height of the curve. Curve C represents a sound that has a greater intensity—a greater perceived loudness—than the sound represented by curve A (distance Y is greater than distance X).

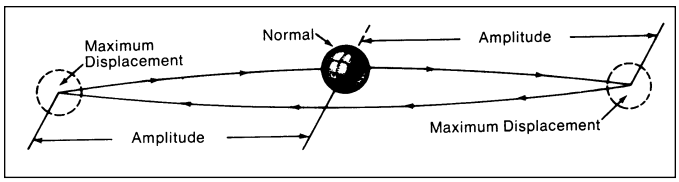

Figure 9–4. Relative positions of an air molecule during one complete cycle of motion.

ture of frequencies generated by a variety of sources. A sound's frequency composition is called its spectrum. The frequency spectrum can be a determining factor in the level of annoyance caused by noise; high-frequency noise generally is more annoying than low-frequency noise. Also, narrow frequency bands or pure tones (single frequencies) can be somewhat more harmful to hearing than broadband noise.

Wavelength

Wavelength is the distance measured between two analogous points on two successive parts of a wave. In other words, wavelength is the distance that a sound wave travels in one cycle. The Greek letter lambda (λ) is used to express wavelength, and it is measured in feet or meters (Figure 9–3).

Wavelength is an important property of sound. For example, sound waves that have a wavelength that is much larger than an obstacle are little affected by the presence of that obstacle; the sound waves bend around it. This bending of the sound around obstacles is called *diffraction*.

If the wavelength of the sound is small in comparison with the size of an obstacle (small wavelengths are characteristic of high-frequency sounds), the sound is reflected or scattered in many directions, and the obstacle casts a "shadow." Actually, some sound is diffracted into the shadow, and there is significant reflection of the sound. As a consequence of diffraction, a wall is of little use as a shield against low-frequency sound (long wavelength), but it can be an effective barrier against high-frequency sound (short wavelength) (Figure 9–5).

Velocity

The velocity at which the analogous pressure points on successive parts of a sound wave pass a given point is called the speed of sound. The speed of sound is always equal to the product of the wavelength and the frequency:

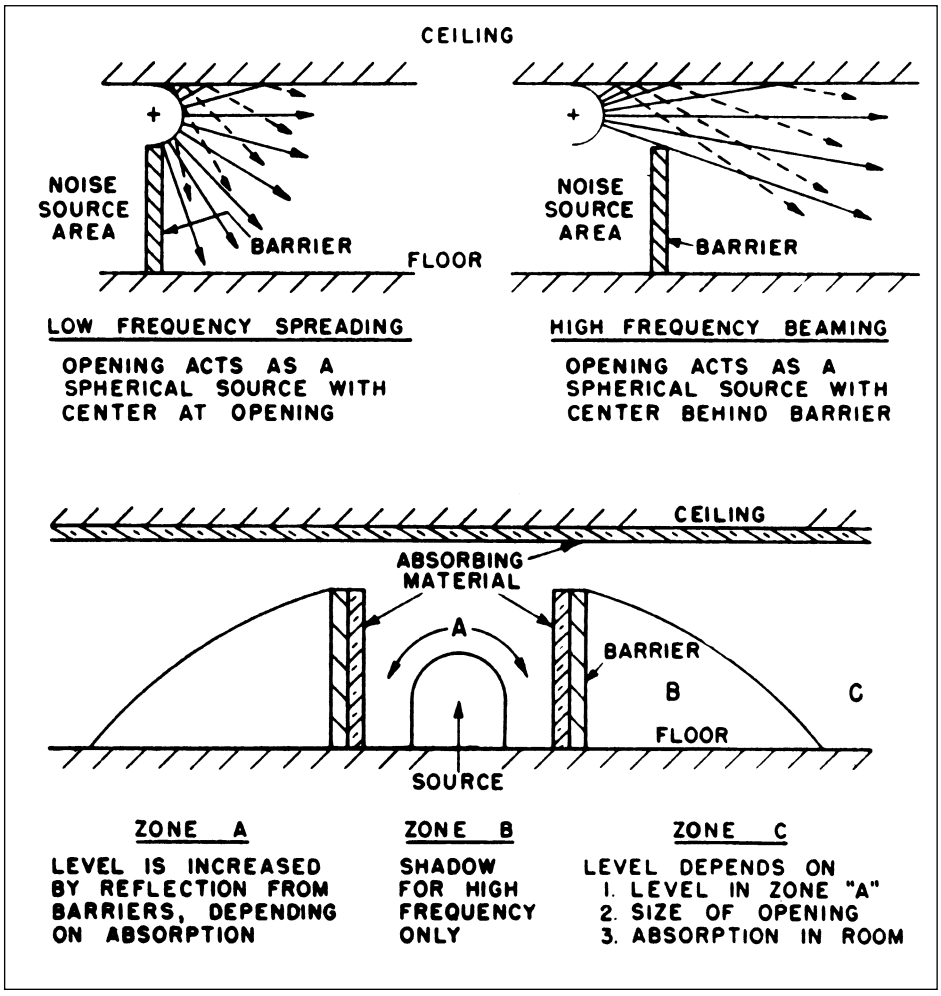

Figure 9–5. The effects of a barrier as a shield to contain noise of low or high frequency.

$$c = f\lambda \quad (1)$$

where c = speed of sound (feet or meters per second)
f = frequency of sound (Hz)
λ = wavelength (feet or meters)

The speed with which the sound disturbance spreads depends on the mass and elastic properties of the medium. In air at 72 F, the speed of sound is about 1,130 ft/sec (344 m/sec). Its effects are commonly observed in echoes and in the apparent delay between a flash of lightning and the accompanying thunder.

In a homogeneous medium, the speed of sound is independent of frequency; that is, in such a medium, sounds of all frequencies travel at the same speed. However, the speed of sound varies with the density and compressibility of the medium through which it is traveling. Speed increases as medium density increases and medium compressibility decreases. For example, the speed of sound is approximately 1,433 m/sec in water, 3,962 m/sec in wood, and 5,029 m/sec in steel. Sound, therefore, can be transmitted through many media before it is eventually transmitted through air to the ear of the receiver.

Sound Pressure

Sound is a slight, rapid variation in atmospheric pressure, caused by some disturbance or agitation of the air. The sounds of normal conversation amount to sound pressure of only a few millionths of a pound per square inch, yet they can be easily heard because of the remarkable sensitivity of the human ear. The sounds that can damage our hearing have sound pressures of only a few thousandths of a pound per square inch.

Most common sounds consist of a rapid, irregular series of positive pressure disturbances (compressions) and negative pressure disturbances (rarefactions) measured against the equilibrium pressure value. If we were to measure the mean value of a sound pressure disturbance, we would find it to be zero because there are as many positive compressions as negative rarefactions. Thus, the mean value of sound pressure is not a useful measurement. We must look for a measurement that permits the effects of rarefactions to be added to (rather than subtracted from) the effects of compressions.

The *root-mean-square (rms) sound pressure* is one such measurement. The rms sound pressure is obtained by squaring the value of the sound pressure disturbance at each instant of time. The squared values are then added and averaged over the given time. The rms sound pressure is the square root of this time average. Because the squaring operation converts all the negative sound pressures to positive squared values, the rms sound pressure is a useful, nonzero measurement of the magnitude of the sound wave. The units used to measure sound pressure are micropascals (μPa), newtons per square meter (N/m^2), microbars (μbar), and dynes per square centimeter (d/cm^2). Relations among these units are as follows: 1 Pa = 1 N/m^2 = 10 μbar = 10 d/cm^2.

Decibels and Levels

Even though the weakest sound pressure perceived as sound is a small quantity, the range of sound pressure perceived as sound is extremely large. The weakest sound that can be heard by a person with very good hearing in an extremely quiet location is known as the *threshold of hearing*. At a reference tone of 1,000 Hz, the threshold of hearing for an average person is taken to be a sound pressure of 20 μPa. The *threshold of pain,* or the greatest sound pressure that can be perceived without pain, is approximately 10 million times greater. It is therefore more convenient to use a *relative scale* of sound pressure rather than an absolute scale.

For this purpose, the bel, a unit of measure in electrical-communications engineering, is used. The decibel, abbreviated dB, is the preferred unit for measuring sound. One decibel is one-tenth of a bel and is the minimum difference in loudness that is usually perceptible. By definition, the decibel is a dimensionless unit used to express the logarithm of the ratio of a measured quantity to a reference quantity. In acoustics, the decibel is used to describe the level of quantities that are proportional to sound power.

Sound power (W) is the amount of energy per unit time that radiates from a source in the form of an acoustic wave. *Sound power level* (L_W), which is expressed in decibels relative to the reference power of 10^{-12} watt (W_0), expresses the total amount of sound power radiated by a sound source, regardless of the space into which the source is placed. The relationship is shown below.

$$L_W = 10 \log \frac{W}{W_0} \quad (2)$$

where W = sound power (watts)
W_0 = reference power (10^{-12} watts)
log = a logarithm to the base 10

Consider for example, a large chipping hammer having a sound power of 1 watt. Expressing this sound power in decibels,

$$L_W = 10 \log \frac{W}{W_0} = 10 \log \frac{1}{10^{-12}} = 10 \log 10^{12} = 120 \text{ dB} \quad (3)$$

As sound power is radiated from a point source in free space, the power is distributed over a spherical surface, so that at any given point there exists a certain sound power per unit area. This is designated as intensity and is measured in units of watts per square meter. Although intensity diminishes as distance from the source increases, the power that is radiated, being the product of the intensity and the area over which it is spread, remains constant.

Sound power cannot be measured directly. It is possible to measure intensity, but the instruments are expensive and must be used carefully. Under most conditions of sound

radiation, sound intensity is proportional to the square of sound pressure. Sound pressure can be measured more easily, so sound level meters are built to measure *sound pressure level* (L_p) in decibels.

The sound level meter directly indicates sound pressure level referenced to a sound pressure of 20 μPa, the approximate threshold of hearing. The equation for sound pressure level is:

$$L_p = 10 \log \frac{p^2}{p_0^2} = 20 \log \frac{p}{p_0} \quad (4)$$

where p = measured root-mean-square (rms) sound pressure
p_0 = reference rms sound pressure (20 μPa)

Note that the multiplier is 20 and not 10 as in the case of the sound power level equation. This is because sound power is proportional to the square of sound pressure and because $10 \log p^2 = 20 \log p$.

Table 9–B shows the relationship between sound pressure in micropascals and sound pressure level in decibels for some common sounds. The table also illustrates the advantage of using decibel notation rather than the wide range of pressure (or power). Note that a change of sound pressure by a factor of 10 corresponds to a change in sound pressure level of 20 dB. Also note that any range over which the sound pressure is doubled is equivalent to 6 dB whether at low or high levels. For example, sound pressures of 20 μPa and 40 μPa are equivalent to the following sound pressure levels:

$p = 20\mu Pa$:

$$L_p = 20 \log \frac{p}{p_0} = 20 \log \frac{20}{20} = 20 \log 1 = 0 \text{ dB} \quad (5)$$

$p = 40\mu Pa$:

$$L_p = 20 \log \frac{p}{p_0} = 20 \log \frac{40}{20} = 20 \log 2 = 6 \text{ dB} \quad (6)$$

Although a doubling of sound pressure represents an increase of 6 dB in the sound pressure level, doubling the *sound power* results in an increase of 3 dB in the sound power level:

$$W = 1 \text{ watt: } L_W = 10 \log \frac{1}{10^{-12}} = 120 \text{ dB} \quad (7)$$

$$W = 2 \text{ watt: } L_W = 10 \log \frac{2}{10^{-12}} = 123 \text{ dB} \quad (8)$$

Again, as seen in the above examples, doubling the sound power increases the sound power level 3 dB, whereas doubling the sound pressure increases the sound pressure level 6 dB. These results are not contradictory because doubling the sound power is equivalent to doubling the *square* of the sound pressure. Remember, sound power is proportional to the *square* of sound pressure.

Table 9–B. ***Sound Pressure and Sound Pressure Level Values for Some Typical Sounds***

Sound Pressure (μPa)	*Overall Sound Pressure Level (dB, re: 20 μPa)*	*Example*
20	0	Threshold of hearing
63	10	
200	20	Studio for sound pictures
630	30	Soft whisper (5 feet)
2,000	40	Quiet office; audiometric testing booth
6,300	50	Average residence; large office
20,000	60	Conversational speech (3 ft)
63,000	70	Freight train (100 ft)
200,000	80	Very noisy restaurant
630,000	90	Subway; printing press plant
2,000,000	100	Looms in textile mill; electric furnace area
6,300,000	110	Woodworking; casting shakeout area
20,000,000	120	Hydraulic press; 50-hp siren (100 ft)
200,000,000	140	Threshold of pain; jet plane
20,000,000,000	180	Rocket-launching pad

* A change of sound pressure by a factor of 10 corresponds to a change in sound pressure level of 20 dB.

There is a common tendency to confuse sound power with sound pressure. Sound power and sound pressure can be illustrated simply with an analogy between light and sound.

Light bulbs are rated in terms of their power consumption (60-W bulbs, 25-W bulbs, etc.). From experience, we know that, in a given location, the intensity or illumination of a 60-W bulb is greater than that of a 25-W bulb at a given distance. Analogously, a sound source of 60 W produces a greater sound pressure level than a 25-W source at a given distance.

Sound power is somewhat analogous to the power rating of the light bulb. A "weak" sound source would produce low sound levels, whereas a "stronger" sound source would produce higher sound levels. Sound power level is independent of the environmental surroundings. Sound pressure, on the other hand, is related to intensity and is analogous to the illumination produced by the light bulb. The magnitude of the sound pressure from a given sound source depends on the distance from the source. As discussed earlier, sound pressure is readily measured by a sound level meter, but sound power cannot be measured directly.

It is important to note that the decibel scale of measurement is not used only in the description of sound pressure level and sound power level. By definition, the decibel is

a dimensionless unit related to the logarithm of the ratio of a measured quantity to a reference quantity. The decibel has no meaning unless a reference quantity is specified. Because of the mathematical properties of the logarithmic function, the decibel scale can compress data involving entities of large and small magnitude into a relative scale involving a small range of numbers. The decibel is commonly used to describe levels of such things as acoustic intensity, hearing thresholds, electrical voltage, electrical current, and electrical power, as well as sound pressure and sound power.

Because decibels are logarithmic values, it is not proper to add them by normal algebraic addition. For example, 60 dB plus 60 dB *does not* equal 120 dB but only 63 dB.

In order to show how to combine decibel levels of sound sources, we present some examples.

Example 1

Two sources are radiating noise in a free field. One source has a sound power level of 123 dB and the other source has a sound power level of 117 dB (re: 10^{-12} W). What is the combined sound power level of these two sources?

Solution:

$$L_W = 10 \log \frac{W}{W_0} \tag{9}$$

or

$$\frac{W}{W_0} = 10^{L_W/10} \tag{10}$$

$$\frac{W_1}{W_0} = 10^{L_{W_1}/10} = 10^{123/10} = 10^{12.3} = 1.995 \times 10^{12} \tag{11}$$

$$\frac{W_2}{W_0} = 10^{L_{W_2}/10} = 10^{117/10} = 10^{11.7} = 5.012 \times 10^{11} \tag{12}$$

$$\frac{W_1}{W_0} + \frac{W_2}{W_0} = 2.496 \times 10^{12} \tag{13}$$

The combined sound power level of the two sources, L_W (total), can then be calculated as

$$\begin{aligned} L_W\,(\text{total}) &= 10 \log\left(\frac{W_1}{W_0} + \frac{W_2}{W_0}\right) \\ &= 10 \log\,(2.496 \times 10^{12}) \\ &= 10\,(12.40) \\ L_W\,(\text{total}) &= 124 \text{ dB} \end{aligned} \tag{14}$$

The same process can be used for sound pressure levels.

Example 2

Suppose the sound pressure level of each of three individual noise sources is measured at a point such that with only the first source running, the Lp = 86 dB, with only the second source running it is 84 dB, and with only the third source running it is 89 dB (re: 20 μPa). What will the sound pressure level at the point be with all three sources running concurrently?

$$L_p = 10 \log\left(\frac{p}{p_0}\right)^2 \tag{15}$$

or

$$\left(\frac{p}{p_0}\right)^2 = 10^{L_p/10} \tag{16}$$

$$\begin{aligned} \left(\frac{p_{\text{total}}}{p_0}\right)^2 &= 10^{L_{p_1}/10} + 10^{L_{p_2}/10} + 10^{L_{p_3}/10} \\ &= 10^{8.6} + 10^{8.4} + 10^{8.9} \\ &= (3.982 + 2.512 + 7.944)\,10^8 \\ \left(\frac{p_{\text{total}}}{p_0}\right)^2 &= 14.438 \times 10^8 \end{aligned} \tag{17}$$

The sound pressure level at the point with all three sources running is then equal to

$$\begin{aligned} L_p\,(\text{total}) &= 10 \log\left(\frac{p_{\text{total}}}{p_0}\right)^2 \\ &= 10 \log\,(14.438 \times 10^8) \\ &= 10\,(9.16) \\ L_p\,(\text{total}) &= 91.6 \text{ dB} \end{aligned} \tag{18}$$

In general then, the procedure for adding decibels can be summarized as follows:

$$L_{\text{total}} = 10 \log\left(\sum_{i=1}^{N} 10^{L_i/10}\right) \tag{19}$$

where L can be sound power level or sound pressure level.

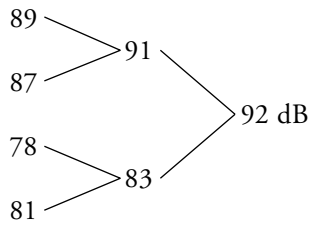
It is often adequate to use the simplified schedule shown below for adding decibels.

Difference in Decibel Values	*Add to Higher Value*
0 or 1 dB	3 db
2 or 3 dB	2 dB
4 to 9 dB	1 dB
10 dB or more	0 dB

Examples:
83 dB + 82 dB = 86 dB
83 dB + 80 dB = 85 dB
83 dB + 78 dB = 84 dB
83 dB + 73 dB = 83 dB

More than two levels can be combined using the above simplified schedule by taking the combinations in pairs.

Example 3
When measured at the same location, four noise sources have sound pressure levels of 89, 87, 78, and 81 dB, respectively. What would the sound pressure level at this location be if all four sources were running concurrently? Using the simplified method,



Using the calculated method,

$$L_p = 10 \log (10^{8.9} + 10^{8.7} + 10^{7.8} + 10^{8.1}) = 91.7 \text{ dB} \quad (20)$$

Although the simplified method is less accurate than the calculated method, the difference may not be significant. Even so, when accurate results are required, the calculated method should be used.

Loudness

Although loudness depends primarily on sound pressure, it is also affected by frequency. (Pitch is closely related to frequency.) The reason for this is that the human ear is more sensitive to high-frequency sounds than it is to low-frequency sounds.

The upper limit of frequency at which airborne sounds can be heard depends primarily on the condition of a person's hearing and on the intensity of the sound. For young adults, this upper limit is usually somewhere between 16,000 and 20,000 Hz. For most practical purposes, the actual figure is not important. It is important, however, to realize that most people lose sensitivity for the higher-frequency sounds as they grow older (presbycusis).

The complete hearing process seems to consist of a number of separate processes that, in themselves, are fairly complicated. No simple relationship exists between the physical measurement of a sound pressure level and the human perception of the sound. One pure tone may sound louder than another pure tone, even though the measured sound pressure level is the same in both cases.

Sound pressure levels, therefore, are only a part of the story and can be deceiving. The fundamental problem is that the quantities to be measured must include a person's reaction to the sound—a reaction that can be determined by such varied factors as the state of the person's health, characteristics of the sound, and the person's attitude toward the device or the person that generates the sound. In the course of time, various loudness level–rating methods have been suggested, and a number of different criteria for tolerable noise levels have been proposed.

A complete physical description of sound must include its frequency spectrum, its overall sound pressure level, and the variation of both of these quantities over time. *Loudness* is the subjective human response to sound pressure and intensity. At any given frequency, loudness varies directly as sound pressure and intensity vary, but not in a simple, straight-line manner.

The physical characteristics of a sound as measured by an instrument and the "noisiness" of a sound as a subjective characteristic may bear little relationship to one another. A sound level meter cannot distinguish between a pleasant sound and an unpleasant one. A human reaction is required to differentiate between a pleasant sound and a noise. Loudness is not merely a question of sound pressure level. A sound that has a constant sound pressure can be made to appear quieter or louder by changing its frequency.

EQUAL-LOUDNESS CONTOURS

Results of experiments designed to determine the response of the human ear to sound were reported by Fletcher and Munson in 1933. A reference tone and a test tone were presented alternately to the test subjects (young men), who were asked to adjust the level of the test tone until it sounded as loud to them as the reference tone (1,000 Hz). The results of these experiments yielded the familiar Fletcher–Munson, or equal-loudness, contours (Figure 9–6). The contours represent the sound pressure level necessary at each frequency to produce the same loudness response in the average listener. The nonlinearity of the ear's response is represented by the changing contour shapes as the sound pressure level is increased, a phenomenon that is particularly noticeable at low frequencies. The lower, dashed, curve indicates the threshold of hearing, which represents the sound pressure level necessary to trigger the sensation of hearing in the average listener. The actual threshold varies as much as ±10 dB among healthy individuals.

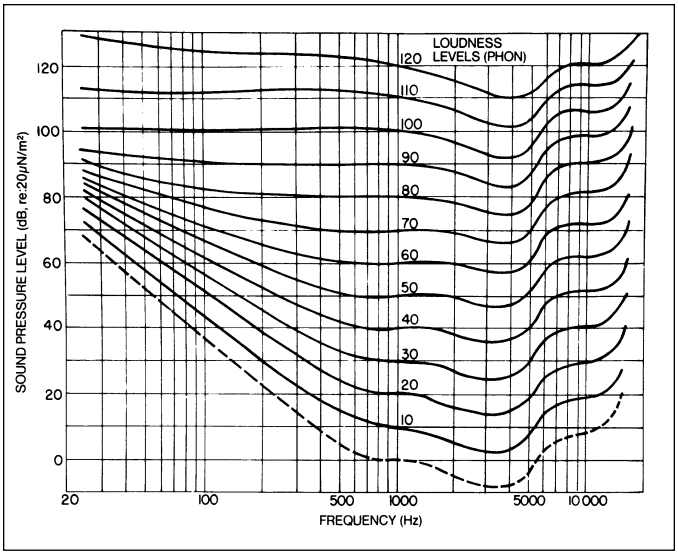


Figure 9–6. Free-field equal-loudness contours of pure tones. Because the human ear is more sensitive to the higher frequencies of sound, changing the frequency of a sound changes its relative loudness. These are also called Fletcher–Munson contours. (Adapted from the *Handbook of Noise Measurement,* 9th ed. GenRad, Inc., 1980.)

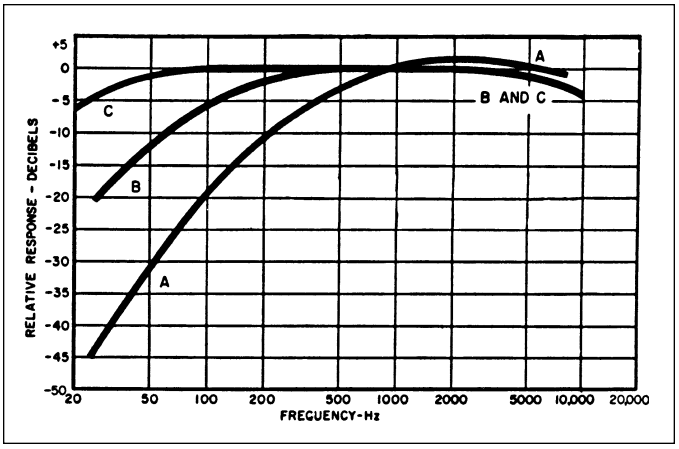

Figure 9–7. Frequency-response attenuation characteristics for the A-, B-, and C-weighting networks.

SOUND PRESSURE WEIGHTING

Electronic circuits with sensitivity that varies with frequency similar to human hearing have been developed. There are three different internationally standardized characteristics called weighting networks A, B, and C. The A-network was designed to approximate the equal-loudness curves at low sound pressure levels, the B-network was designed for medium sound pressure levels, and the C-network was designed for high levels.

The weighting networks are the sound level meter's means of responding to some frequencies more than to others. The very low frequencies are discriminated against (attenuated) quite severely by the A-network, moderately attenuated by the B-network, and hardly attenuated at all by the C-network (Figure 9–7). Therefore, if the measured sound level of a noise is much higher on C-weighting than on A-weighting, much of the noise energy is probably of low frequency.

By definition, a weighted-frequency scale is simply a series of correction factors that are applied to sound pressure levels on an energy basis as a function of frequency. Shown in Table 9–C are the corrections for the A-weighting network at each of the octave-band center frequencies commonly used in noise measurements.

Table 9–C. *Octave-Band Correction Factors of the A-Weighted Network*

Octave-Band Center Frequency (Hz)	*A-Network Correction Factor (dB)*
31.5	–39.4
63	–26.2
125	–16.1
250	–8.6
500	–3.2
1,000	0
2,000	+1.2
4,000	+1.0
8,000	–1.1
16,000	–6.6

Adapted from ANSI, 1983.

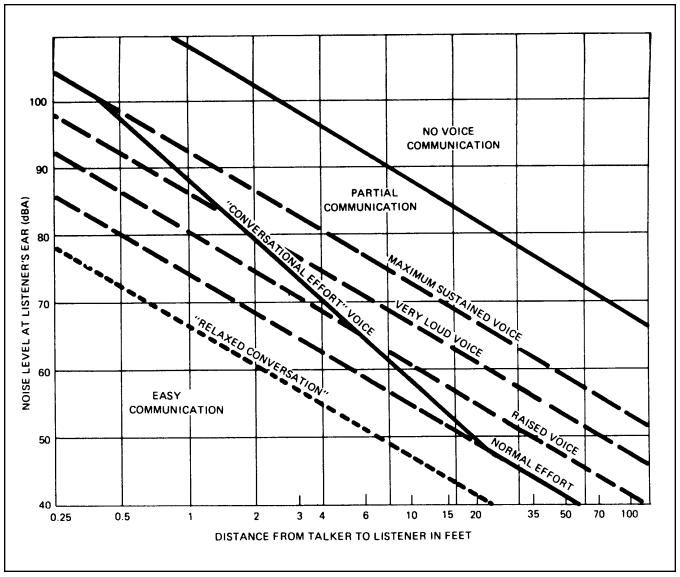

Figure 9–8. Distance at which ordinary speech can be understood (as a function of the A-weighted sound levels of the masking noise in an outdoor environment). (Reprinted from *Public Health and Welfare Criteria of Noise,* July 27, 1973, U.S. Environmental Protection Agency.)

The A-weighted sound level measurement has become popular in the assessment of overall noise hazard because it is thought to provide a rating of industrial broadband noises that indicates the injurious effects such noise has on human hearing.

As a result of its simplicity in rating the hazard to hearing, the A-weighted sound level has been adopted as the measurement for assessing noise exposure by the American Conference of Governmental Industrial Hygienists (ACGIH). The A-weighted sound level as the preferred unit of measurement was also adopted by the U.S. Department of Labor as part of its Occupational Safety and Health Standards. The A-weighted sound level has also been shown to provide reasonably good assessments of speech interference and community disturbance conditions and has been adopted by the U.S. Environmental Protection Agency (EPA) for these purposes (Figure 9–8).

OCCUPATIONAL DAMAGE-RISK CRITERIA

The purpose of damage-risk criteria is to define maximum permissible noise levels during given periods that, if not exceeded, would result in acceptable small changes in the hearing levels of exposed employees over a working lifetime. The acceptability of a particular noise level is a function of many variables.

Increasing attention is being given by regulatory agencies and industrial and labor groups to the effects of noise exposures on employees; therefore, equitable, reliable, and practical damage-risk noise criteria are needed.

A criterion is a standard, rule, or test by which a judgment can be formed. A criterion for establishing levels for damage-risk noise requires one or more standards for judgment. Damage-risk criteria can be developed once standards are selected by which the effects of occupational noise exposure on employees can be judged.

Hearing Ability

Tests for evaluating the ability to hear speech have been developed. These tests generally fall into two classes: those that measure the hearing threshold or the ability to hear very faint speech sounds and those that measure discrimination, or the ability to *understand* speech (see Chapter 4, The Ears).

Ideally, hearing impairment should be evaluated in terms of an individual's ability (or inability) to hear normal speech under everyday conditions. The ability of an individual to hear sentences and to repeat them correctly in a quiet environment is considered to be satisfactory evidence of adequate hearing ability. Hearing tests using pure tones are extensively employed to monitor the status of a person's hearing and the possible progression of a hearing loss. A person's ability to hear pure tones is related to the hearing of speech.

People who work in noisy environments should have their hearing checked periodically to determine whether the noise exposure is producing a detrimental effect on hearing. The noise-induced hearing losses that can be measured by pure-tone audiometry are the threshold shifts that constitute a departure from a specified baseline. This baseline, or normal hearing level, can be defined as the average hearing threshold of a group of young people who have no history of previous exposure to intense noise and no otological malfunction.

AMA *GUIDES*

Chapter 11.2 of the American Medical Association's (AMA) *Guides to the Evaluation of Permanent Impairment,* 5th edition (American Medical Association, copyright 2000) includes criteria for evaluating permanent impairment resulting from the principal dysfunctions of the ear. Permanent impairment is expressed in terms of impairment of the whole person.

Monaural hearing impairment is evaluated by determining hearing threshold levels for each ear at test frequencies of 500, 1,000, 2,000, and 3,000 Hz. If the average of these hearing levels is 25 dB or less, no impairment is considered to exist in the ability to hear everyday sounds under everyday listening conditions.

The AMA describes the method to convert monaural hearing impairments to a binaural hearing impairment. The binaural hearing impairment is then used to determine impairment of the whole person (see Chapter 4, The Ears).

Risk Factors

If the ear is subjected to high levels of noise for a sufficient period of time, some loss of hearing will occur. There are many factors that affect the degree and extent of hearing loss, including the following:

- ➢ The intensity of the noise (sound pressure level)
- ➢ The type of noise (frequency spectrum)
- ➢ The period of exposure each day (worker's schedule per day)
- ➢ The total work duration (years of employment)
- ➢ Individual susceptibility
- ➢ The age of the worker
- ➢ Coexisting hearing loss and ear disease
- ➢ The character of the surroundings in which the noise is produced
- ➢ The distance from the source
- ➢ The position of the ear with respect to sound waves

The first four factors are the most important, and they are called *noise exposure factors*. Thus, it is necessary to know not only the intensity of the noise, but also what type of noise it is and its duration.

Because of the complex relationship of noise and exposure time to threshold shift (reduction in hearing level) and its many possible contributory causes, the criteria designed to protect workers from hearing loss took many years to develop and establish.

The Intersociety Committee on Guidelines for Noise Exposure Control published the results of their study to

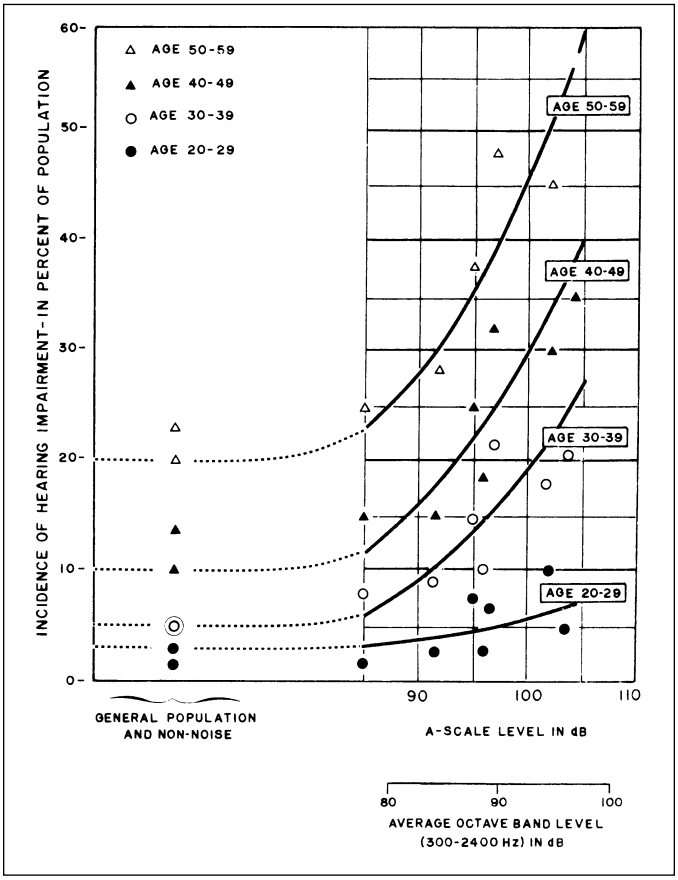

Figure 9–9. The incidence of hearing impairment in the general population and in selected populations by age group and by occupational noise exposure. (Reprinted with permission from the *American Industrial Hygiene Association Journal*.)

establish a basis for reliable noise criteria. A significant part of their report is shown graphically in Figure 9–9. The curves in the figure relate the incidence of significant hearing loss to age and the magnitude of noise exposure over a working lifetime.

Without attempting to explain the full significance of the graph, it can be stated that 20 percent of the general population between the ages of 50 and 59 experience hearing losses without having had any exposure to industrial noise, but groups of workers exposed to steady-state industrial noise over a working lifetime show a greater increase in the incidence of hearing loss.

For example, exposure to steady-state noise at 90 dB on the A-scale of the sound level meter (90 dBA) results in significant hearing losses in 27 percent of the exposed group. If the working lifetime exposure is 95 dBA, 36 percent of the group shows significant hearing loss.

Essentially, the graph in Figure 9–9 supplies industry and other interested groups with information from which the risk of developing compensable hearing loss among groups of workers exposed to noises of different magnitudes can be predicted.

Analysis of Noise Exposure

The critical factors in the analysis of noise exposure are the A-weighted sound level; the frequency composition, or spectrum, of the noise; and the duration and distribution of noise exposure during a typical workday.

It is currently believed that any exposure of the unprotected ear to sound levels above 115 dBA is hazardous and should be avoided. Exposure to sound levels below 70 dBA can be assumed to be safe and do not produce any permanent hearing loss. The majority of industrial noise exposures fall within this 45-dBA range; thus, additional information is required for evaluation of damage risk, such as the type of noise and duration of exposure.

It would be very helpful to know the predominant frequencies present and the contributions from each of the frequency bands that make up the overall level. It is currently believed that noise energy with predominant frequencies above 500 Hz has a greater potential for causing hearing loss than noise energy concentrated in the low-frequency regions. It is also believed that noises that have a sharp peak in a narrow-frequency band (such as a pure tone) present a greater hazard to hearing than noises of equal energy levels that have a continuous distribution of energy across a broad frequency range.

The incidence of noise-induced hearing loss is directly related to total exposure time. In addition, it is believed that intermittent exposures are far less damaging to the ear than are continuous exposures, even if the sound pressure levels for the intermittent exposures are considerably higher than those during continuous exposures. The rest periods between noise exposures allow the ear to recuperate.

At present, the deleterious effects of noise exposure and the energy content of the noise cannot be directly equated. For example, doubling the energy content does not produce twice the hearing loss. In general, however, the greater the total energy content of the noise, the shorter the time of exposure required to produce the same amount of hearing loss. However, the exact relation between time and energy is not known.

Another factor that should be considered in the analysis of noise exposures is the type of noise. For instance, impact noise is generated by drop hammers and punch presses, whereas steady-state noise is generated by turbines and fans. Impact noise is a sharp burst of sound; therefore, sophisticated instrumentation is necessary to determine the peak levels for this type of noise. Additional research must be done to fully define the effects of impact noise on the ear.

The total noise exposure during a person's normal working lifetime must be known to arrive at a valid judgment of how noise will affect that person's hearing. Instruments such as noise dosimeters can be used to determine the exposure pattern of a particular individual. Instruments such as sound level meters can be used to determine the noise exposure at a given instant in time (that is, during the time the test is being taken). An exposure pattern can be established using a series of such tests and the work history of the individual.

SOUND MEASURING INSTRUMENTS

A wide assortment of equipment is available for noise measurements, including sound survey meters, sound level meters, octave-band analyzers, narrowband analyzers, noise dosimeters, tape and graphic level recorders, impact sound level meters, and equipment for calibrating these instruments.

For most noise problems encountered in industry, the sound level meter and octave-band analyzer provide ample information (Figure 9–10).

Sound Level Meters

The basic instrument used to measure sound pressure variations in air is the sound level meter. This instrument contains a microphone, an amplifier with a calibrated attenuator, a set of frequency-response networks (weighting networks), and an indicating meter (Figure 9–11). The sound level meter is a sensitive electronic voltmeter that measures the electrical signal emitted from a microphone, which is ordinarily attached to the instrument. The alternating electrical signal emitted from the microphone is amplified sufficiently so that, after conversion to direct current by means of a rectifier, the signal can be displayed. An attenuator controls the overall amplification of the instrument. The response-versus-frequency characteristics of the amplified signal are controlled by the weighting networks.

Some sound level meters have a measurement range of about 40–140 dB (re: 20 μPa) without the aid of special accessory equipment. Special microphones permit measurement of lower or of considerably higher sound levels. An amplifier that can register the electrical output signal of the microphone is usually provided with the sound level meter so that it can be hooked up to other instruments for recording and analysis. The sound level meter is designed to be a device for field use and as such should be reliable, rugged, reasonably stable under battery operation, and lightweight.

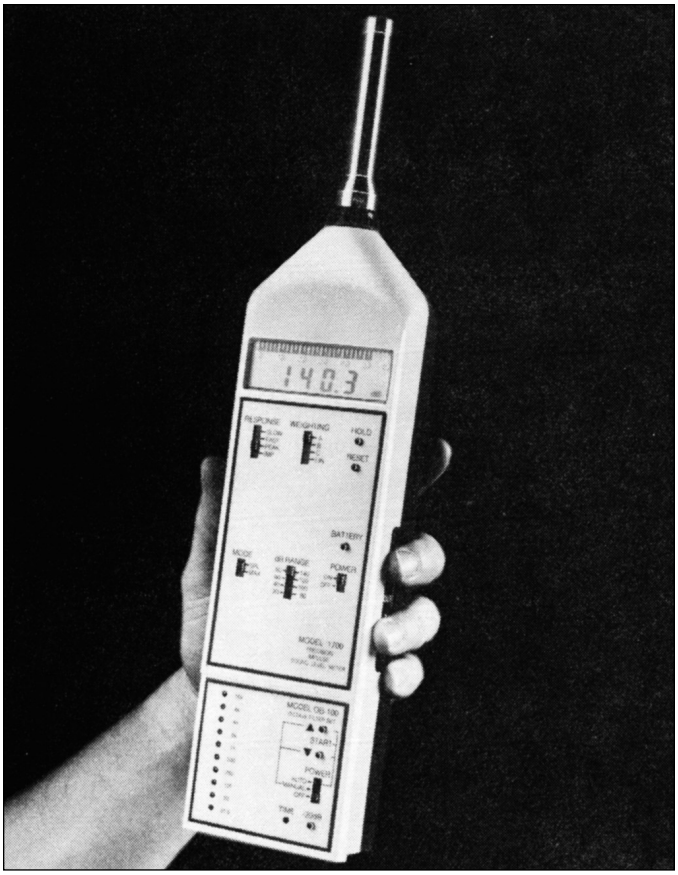

Figure 9–10. The multipurpose instrument shown here can be used as a sound level meter, octave-band analyzer, and impact/impulse noise meter. (Courtesy Quest Technologies.)

MICROPHONE

The microphone responds to sound pressure variations and produces an electrical signal that is processed by the sound level meter.

AMPLIFIER

The amplifier in a sound level meter must have a high available gain so that it can measure the low-voltage signal from a microphone in a quiet location. It should have a wide frequency range, usually on the order of 20–20,000 Hz. The range of greatest interest in most noise measurements is 50–6,000 Hz. The inherent electronic noise floor and hum level of the amplifier must be low.

ATTENUATORS

Sound level meters are used for measuring sounds that differ greatly in level. A small portion of this range is covered by the indicating meter. The rest of the range is covered by an adjustable attenuator, which is an electrical resistance network inserted into the amplifier to produce known ranges of signal level.

WEIGHTING NETWORKS

The sound level meter response at various frequencies can be controlled by electrical weighting networks. The response curves for these particular networks have been established in the American National Standards Institute's publication ANSI S1.4 1983– (R1997). C-weighting approximates a uniform response over the frequency range from 25–8,000 Hz. Changes in the electronic circuit are sometimes made to compensate for the response of particular microphones, so that the net response is uniform (flat) within the tolerance allowed by the standards. The C-weighting network is generally used when the sound level meter supplies a signal to an auxiliary instrument for a more detailed analysis. (The weighting networks are shown in Figure 9–7.) The A-weighting network is used to determine compliance with the OSHA standard.

METERING SYSTEM

After the electrical signal from the microphone is amplified and sent through the attenuators and weighting networks, the signal is used to drive a metering circuit. This metering circuit displays a value that is proportional to the electrical signal applied to it. The ANSI S1.4–1983 (R1997) standard for sound level meters specifies that the rms value of the signal should be indicated. This requirement corresponds to adding up the different components of the sound wave on an energy basis. When measuring sound, the rms value is a useful indication of the general energy content.

A running average of the rectified output of the metering circuit is displayed. The average time (or response speed) is determined by the meter ballistics and the response circuit chosen.

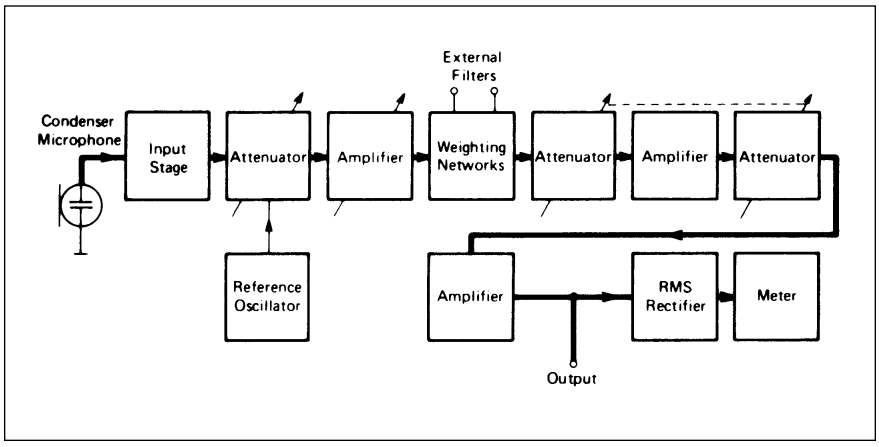

Figure 9–11. Schematic diagram of a sound level meter with auxiliary output.

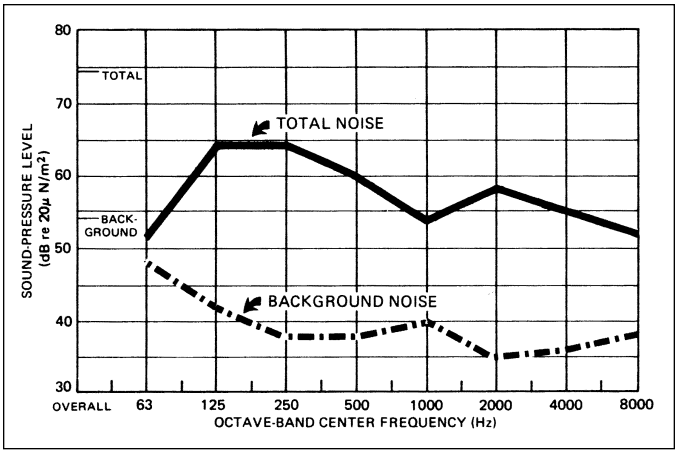

Figure 9–12. Data obtained from an octave-band analysis of a noise source, showing the total noise and the background noise levels when the noise source is not in operation.

Table 9–D. ***Octave-Band Mean Frequencies and Corresponding Band Limits ANSI S1.11–1986 (R1998)***

Lower Band Limit (Hz)	*Geometric Mean Frequency of Band (Hz)*	*Upper Band Limit (Hz)*
222	231.5	244
244	263.5	288
288	125.5	177
177	250	354
354	500	707
707	1,000	1,414
1,414	2,000	2,828
2,828	4,000	5,656
5,656	8,000	11,312

Two modes of operation—fast and slow—are provided on every sound level meter. In the fast mode, the meter responds relatively quickly to rapidly changing noise levels, whereas in the slow mode, the meter responds rather slowly. The use of each mode is best illustrated by example. If one were to measure the noise level of a passing vehicle, the fast mode would be used to obtain the maximum level. In a factory, where an average noise level is often more useful, the slow mode would be selected to reduce rapid, hard-to-read excursions. OSHA requires the use of slow response for measurements to check for compliance with its regulations.

Octave-Band Analyzers

For many industrial noise problems, it is necessary to use some type of analyzer to determine where the noise energy lies in the frequency spectrum. This is especially true if engineering control of noise problems is planned, because industrial noise is made up of various sound intensities at various frequencies (Figure 9–12).

In order to properly represent the total noise of a noise source, it is usually necessary to break the total noise down into its various frequency components—low frequency, high frequency, or middle frequency. This is necessary for two reasons: People react differently to low-frequency and high-frequency noises (for the same sound pressure level, high frequency noise is much more disturbing and is more capable of producing hearing loss than is low-frequency noise); and the engineering solutions for reducing or controlling noise are different for low-frequency and high-frequency noise (low-frequency noise is more difficult to control, in general).

It is conventional practice in acoustics to determine the frequency distribution of a noise by passing that noise through several different filters that separate the noise into 8 or 9 octaves on a frequency scale. Just as with an octave on a piano keyboard, an octave in sound analysis represents the frequency interval between a given frequency (such as 250 Hz) and twice that frequency (500 Hz).

A young, healthy ear is sensitive to sound frequency in the range from about 20 to 20,000 Hz. Most octave-band analyzing filters now cover the audio range from about 22 Hz to about 11,300 Hz in nine octave-frequency bands. These filters are identified by their geometric mean frequencies as shown in Table 9–D.

Notice that these filters are constant-percentage filters. The width of the band being utilized (bandwidth) is a fixed percentage of the frequency at which the instrument is operating. Octave-band filters have bandwidths that are 70.7 percent of the mean frequency (this is easily seen in the 1-kHz band).

For a more detailed analysis of the distribution of sound energy as a function of frequency, still narrower bands are used. The next commonly used division is a split of the octave into three parts.

Some of the mean frequencies for such a series would be, for example, 100, 125, 160, 200, 250, 315, 400, 500, 630, and 800 Hz. One-third–octave filters have bandwidths that are 23.2 percent of the mean frequency.

Still narrower band filters are available, such as one-tenth octave-band. The narrower the band for analysis, the more sharply defined the data.

The identification of pure tone components, when present, is an extremely useful diagnostic tool for locating and quieting the noise source.

Some noise sources have a well-defined frequency content. For example, the hum generated by a fan or blower is usually centered at the blade-passage frequency, which is the product of the number of blades of the fan multiplied by the speed (revolutions per second) of the fan.

The fundamental blade-passage frequency (f_B, in Hertz) of fans is given by the following equation:

$$f_B = \frac{(\text{rpm})\ (N)}{60} \tag{21}$$

where rpm = shaft rotational speed (revolutions per minute)
N = number of blades
60 = a constant to convert rpm to revolutions per second

Higher harmonics are usually present with diminished sound pressure amplitude at integral multiples of the fundamental (that is, $2f_B$, $3f_B$, . . .).

The above relation can also be used to predict the fundamental tones from blowers, gears, and so on by letting N represent the number of impeller lobes or gear teeth. For example, consider the following.

Example 4

What is the frequency of the predominant tone that would be emitted from an axial fan with four blades rotating at 6,000 rpm?

$$f_B = \frac{(\text{rpm})\ (N)}{60} = \frac{(6,000)\ (4)}{60} = 400 \text{ Hz} \qquad (22)$$

The fundamental blade-passage frequency is then 400 Hz. One would also expect additional tones at integral multiples of the predominant tone at

$f_2 = (2)(400) = 800$ Hz
$f_3 = (3)(400) = 1,200$ Hz
⋮
$f_N = (N)(400)$ Hz

The higher-frequency tones would have progressively diminished sound pressure amplitude.

Electrical transformers usually hum in frequencies that are multiples of 60 Hz. Positive-displacement pumps have a sound pressure distribution that is directly related to the pressure pulses on either the inlet or the outlet of the pump.

Noise resulting from the discharge of steam- or air-pressure relief valves has a frequency peak that is related to the pressure in the system and the diameter of the restriction preceding the discharge to the atmosphere. A peak energy content in any single octave band would provide information as to the predominant frequency of a particular noise source.

Sound level meters have evolved from relatively simple devices capable of measuring weighted sound levels and performing octave-band frequency analysis to highly sophisticated instruments that serve as the front end of a data acquisition system.

The instrument shown in Figure 9–13, for example, not only functions as a sound level meter and octave- or one- third octave-band analyzer but is also capable of measuring all the relevant parameters defined by OSHA and ANSI standards for industrial and environmental noise. The output of this instrument can be recorded, printed, or transferred to a personal computer for additional analysis or graphical presentation.

Figure 9–14. Dosimeter being worn to monitor noise exposure. (Courtesy Quest Technologies.)

Noise Dosimeters

In many work environments, it may not be adequate to measure noise exposure at a fixed location for the duration of a workshift. Some workers move about to several locations in the course of their duties or perform a variety of operations during the day and are therefore subjected to different noise levels. The practical way to measure the noise exposure in these circumstances is with a noise-exposure monitor, or dosimeter, that can be worn by the worker and that moves with the worker during the day. The noise dosimeter records the noise energy to which the worker is exposed during the workshift.

A dosimeter (Figure 9–14) includes a microphone placed in the person's hearing zone and the remainder of the instru-

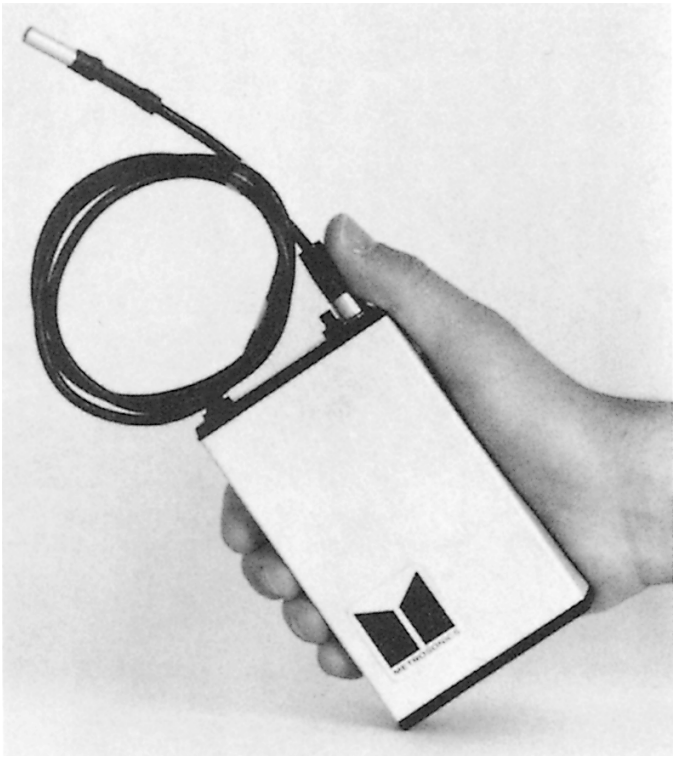

Figure 9–15. Noise dosimeter/multipurpose integrating sound level meter. (Courtesy Metrosonics, Inc.)

ment, which automatically computes the desired noise measures—most commonly the daily noise dose. This measure is used to check for compliance with the OSHA noise standard.

Dosimeters have evolved from simple devices that compute single-number exposure measures to highly sophisticated monitors that compute and store comprehensive data on the sound field encountered by the subject. The instrument shown in Figure 9–15, for example, not only functions as a noise dosimeter, but also as a multipurpose integrating sound level meter. It is also capable of producing several types of printed reports, including statistical analyses of data and graphical time history reports.

It is important to recognize the fact that dosimeters were derived directly from sound level meters. Dosimeters were developed to simplify measurement and computational procedures. In order to obtain comparable results, dosimeters must correctly duplicate the dynamic characteristics of sound level meters. Specific requirements prescribing these characteristics are set forth in the American National Standards Institute (ANSI) Standard S1.25–1991 (R1997), *Specification for Personal Noise Dosimeters.*

SOUND SURVEYS

Sound measurement falls into two broad categories: source measurement and ambient-noise measurement. Source measurements involve the collection of acoustic data for the purpose of determining the characteristics of noise radiated by a source. The source might be a single piece of equipment or a combination of equipment or systems. For example, a single electrical motor or an entire facility can be considered a noise source.

Ambient-noise measurements can be used to study a single sound level or to make a detailed analysis showing hundreds of components of a complex vibration. The number of measurements taken and the type of instruments needed depend on the information that is required. If compliance with a certain noise specification must be checked, the particular measurement required is reasonably clear. Only some guidance as to the selection of instruments and their use is needed. But if the goal is to reduce the noise produced by industrial operations in general, the situation is more complex, and careful attention to the acoustic environment is essential.

Measurement of the noise field may require using different types of sound level–measuring instruments. These measurements must be repeated as changes in noise-producing equipment or operating procedures occur.

The use of the dBA scale for preliminary noise measurement greatly simplifies the collection of sound level survey data. Detailed sound level survey and octave-band analysis data are necessary to provide sufficient information so that the proper remedial measures for noise-control procedures can be determined. Calibration checks of the instruments should be made before, during, and after the sound level survey.

Source Measurements

Source measurements frequently are made in the presence of noise created by other sources that form the background- or ambient-noise level. Although it is not always possible to make a clear distinction between source- and ambient-noise measurement, it is important to understand that source measurements describe the characteristics of a particular sound source, while ambient-noise measurements describe the characteristics of a sound field of largely unspecified or unknown sources.

A uniform, standard reporting procedure should be established to ensure that sufficient data are collected in a form suitable for subsequent analysis. To be effective, this standard reporting procedure should include detailed descriptions of the techniques of measurement position, operating conditions, instrument calibration, exposure time, amplitude patterns, and other important variables.

Several forms have been devised to record data obtained during a screening survey. Use of these forms facilitates the recording of pertinent information that will be extremely useful if more detailed studies are conducted later. An employee noise-exposure survey is conducted by measuring noise levels at each workstation that an employee occupies throughout the day or by acquiring a sufficient sampling of data at each workstation so that the exposure of an employee while at that workstation can be evaluated. Workstations that pose particular noise-exposure hazards can be readily identified by using measured sound level contours if these are obtained in adequate detail.

In many industrial situations, however, it is extremely difficult to accurately evaluate the noise exposure to which a

particular worker is subjected. This is due in part to the fact that the noise level to which the stationary worker is exposed throughout the workday fluctuates, making it difficult to evaluate compliance or noncompliance with the OSHA regulations. Another problem arises when a worker's job requires that he or she spend time in areas where the noise levels vary from very low to very high.

Because of the fluctuating nature of many industrial noise levels, it would not be accurate or meaningful to use a single sound level meter reading to estimate the daily time-weighted average (TWA) noise level.

Preliminary Noise Survey

A hearing conservation program should start with a preliminary facilitywide noise level survey using appropriate sound level–measuring equipment to locate operations or areas where workers may be exposed to hazardous noise levels.

Those conducting the survey have to decide whether to purchase sound level–measuring equipment and train personnel to use it or to contract the work to an outside firm. The extent of the noise problem, the size of the facility, and the nature of the work affect this decision. In most facilities, noise surveys are conducted by a qualified engineer, an audiologist, an industrial hygienist, or a safety and health professional.

A noise survey should be carried out at work areas where it is difficult to communicate in normal tones. A common rule of thumb is that if you have to shout to communicate at a distance of three feet, noise levels may be excessive. A noise survey should also be performed if, after being exposed to high noise levels during their workshift, workers notice that speech and other sounds are muffled for several hours or they develop ringing in the ears.

As a general guideline for conducting a noise survey, the information recorded should be sufficient to allow another individual to take the report, use the same equipment, find the various measurement locations, and, finally, reproduce the measured and/or recorded data.

The preliminary noise survey normally does not define the noise environment in depth and therefore should not be used to determine employee exposure time and other details. The preliminary noise survey simply supplies sufficient data to determine whether a potential noise problem exists and, if so, to indicate how serious it is.

Detailed Noise Survey

From the preliminary noise survey, it is relatively easy to determine specific locations that require more detailed study and attention. A detailed noise study should then be made at each of these locations to determine employees' TWA exposures.

The purposes of a detailed noise survey are the following:

- ➢ To obtain specific information on the noise levels existing at each employee's work station
- ➢ To develop guidelines for establishing engineering and/or administrative controls
- ➢ To define areas where hearing protection will be required
- ➢ To identify those work areas where audiometric testing of employees is desirable and/or required

In addition, detailed noise survey data can be used to develop engineering control policies and procedures and to determine whether specific company, state, or federal requirements have been complied with.

An effective hearing conservation program always starts with the question, "Does a noise problem exist?" The answer must not be based simply on the subjective feeling that the problem exists but on the results of a careful technical definition of the problem. Answers to the following questions must be obtained:

- ➢ How noisy is each work area?
- ➢ What equipment or process is generating the noise?
- ➢ Which employees are exposed to the noise?
- ➢ How long are they exposed?

Line supervisors can provide basic job function information concerning the duration of operation, the types of noise-producing equipment in work areas, and the percentage of time a worker spends in each of the areas. Production records can be examined, and on-site evaluation can provide information as to the extent of the noise problems.

The noise survey should be made using a general-purpose sound level meter that meets standards set by ANSI S1.4 1983 (R1997). The sound level meter should be set for A-scale slow response.

Measurements of noise exposure should be taken at approximate ear level (Figure 9–16). No worker should be exposed to steady-state or interrupted steady-state sound levels that exceed the maximum listed in the current noise stan-

Figure 9–16. Take sound level measurements near an employee's workstation.

dard. Other information should include the name of the individual making the noise survey as well as the date, location of measurement, and time the measurement was made. The serial numbers of the sound level meters and the date of calibration are also essential for compliance records.

The noise survey procedure is a three-step process.

STEP 1: AREA MEASUREMENTS

Using a sound level meter set for A-scale slow response, the regularly occurring maximum noise level and the regularly occurring minimum noise level are recorded at the center of each work area. (For measurement purposes, the size of the work area should be limited to 1,000 sq ft [93 sq m] or smaller.) If the maximum sound level in a work area does not exceed 80 dBA, it can be assumed that all employees in that area are working in an environment with an acceptable noise level. If the noise levels measured at the center of the work area fall between 80 and 92 dBA, then more information is needed.

Sound level contours (Figure 9–17) can be used during this screening survey to identify workstations that may pose particular noise-exposure hazards. Sound level contours provide a visual depiction of the degree of the noise hazard in a work area, at a particular time.

To construct a sound level contour, the work area is divided into a grid whose lines are evenly spaced at an approximate distance of 10 ft (3.05 m). A-weighted sound level measurements are recorded at each measurement position. When the observed sound levels vary significantly, then the grid spacing should be decreased. It is usually necessary to decrease the grid spacing in the proximity of dominant noise sources due to rapidly changing sound levels. The contour lines drawn in Figure 9–17 are based on 2-dBA changes in the measured sound level.

STEP 2: WORKSTATION MEASUREMENTS

To evaluate the noise exposure for people working in locations where measurements at the center of the work area range from 80–92 dBA, measurements should be made at each employee's normal workstation. If the level varies on a regular basis, both the maximum and minimum levels should be recorded. If the noise level never goes below 90 dBA, an unsatisfactory noise exposure is indicated. If the measured level is never greater than 85 dBA, the noise exposure to which the employee is subjected can be regarded as satisfactory.

STEP 3: EXPOSURE DURATION

At workstations where the regularly occurring noise varies above and below the 85-dBA level, further analysis is needed.

If an employee has varying work patterns in different work areas, it is necessary to ascertain the sound level and duration of noise exposure within each work area. A breakdown of hours worked in each area can be obtained by consulting the employee or the employee's supervisor, or by visual monitoring. A briefing/debriefing approach for a particular day's activities can also be used. This approach consists of requesting each employee to keep a general work area/time log of his or her daily activities. The employee is then debriefed at the end of the work period to ensure that sufficient information was logged. In many cases, it may be desirable for an employee to wear a noise dosimeter that records daily exposure in terms of the current OSHA requirements.

The procedure for determining an employee's daily noise-exposure rating is discussed in the section that follows.

General Classes of Noise Exposure

There are three general classes into which occupational noise exposures can be grouped: continuous noise, intermittent noise, and impact-type noise.

CONTINUOUS NOISE

Continuous noise is normally defined as broadband noise of approximately constant level and spectrum to which an employee is exposed for a period of 8 hours per day, 40 hours per week. A large number of industrial operations fit into this class of noise exposure. Most damage-risk criteria are written for this type of noise exposure because it is the easiest to define in terms of amplitude, frequency content, and duration.

The OSHA Noise Standard, 29 *CFR* 1910.95(a) and (b), establishes permissible employee noise exposures in terms of duration in hours per day at various sound levels. The standard requires that the employer reduce employee exposures

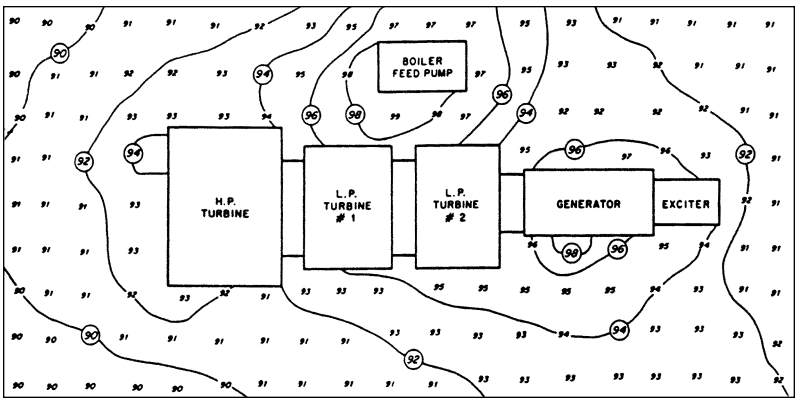

Figure 9–17. Sound level contours: operating-level turbine building. (From Di Blasi et al., 1983.)

to the allowable level by use of feasible engineering or administrative controls. The standard defines the permissible exposure level (PEL) as that noise dose that would result from a continuous 8-hour exposure to a sound level of 90 dBA. This is a dose of 100 percent. Doses for other exposures that are either continuous or fluctuating in level are computed relative to the PEL based on a 5-dBA trading relationship between noise level and exposure time (Table 9–E).

Every 5-dBA increase in noise level cuts the allowable exposure time in half. This is known as a 5-dB exchange rate.

When the daily noise exposure is composed of two or more periods of noise exposure of different levels, their combined effect should be considered, rather than the individual effect of each. If the sum of the fractions $C_1/T_1 + C_2/T_2 + \ldots + C_n/T_n$ exceeds 100 percent, the mixed exposure should be considered to exceed the limit value. C_n indicates the total time of exposure at a specified noise level, and T_n indicates the total time of exposure permitted at that level.

When employees are exposed to different noise levels during the day, the mixed exposure, E_m, must be calculated by using the following formula:

$$E_m = \frac{C_1}{T_1} + \frac{C_2}{T_2} + \frac{C_3}{T_3} + \cdots + \frac{C_n}{T_n} \qquad (23)$$

where C_n = the amount of time an employee was exposed to noise at a specific level
T_n = the amount of time the employee can be permitted to be exposed to that level

If the sum of the fractions equals or exceeds 1, the mixed exposure is considered to exceed the allowable limit value, according to the OSHA standard. Daily noise dose (D) is an expression of E_m in percentage terms. For example, $E_m = 1$ is equivalent to a noise dose of 100 percent. (Note: OSHA does not consider noise levels below 90 dBA in determining the need for engineering controls.)

Example 5
An employee is exposed to the following noise levels during the workday:
- 85 dBA for 3.75 h
- 90 dBA for 2 h
- 95 dBA for 2 h
- 110 dBA for 0.25 h

Thus, the daily noise dose is as follows:

$$D = 100\left(\frac{3.75}{\text{no limit}} \quad \text{or} \quad 0 + \frac{2}{8} + \frac{2}{4} + \frac{0.25}{0.50}\right) = 125\% \qquad (24)$$

Because the dose exceeds 100 percent, the employee received an excessive exposure during the workday.

The permissible exposures given in Table 9–E are based on the presence of continuous noise rather than intermittent or impact-type noise. By OSHA definition, "if the variations in noise level involve maxima at intervals of one second or less, it is considered to be continuous."

Table 9–E. ***OSHA Permissible Noise Exposures***

Duration Per Day (hours)	*Sound Level, Slow Response (dBA)*
8	90
6	92
4	95
3	97
2	100
1 1/2	102
1	105
1/2	110
1/4 or less	115

Note: When the daily noise exposure is composed of two or more periods of noise exposure of different leveis, their combined effect should be considered, rather than the individuai effect of each. If the sum of the fractions $C_1/T_1 + C_2/T_2 + \ldots + C_n/T_n$ exceeds 100 percent, the mixed exposure should be considered to exceed the iimit value. C_n indicates the total time of exposure at a specified noise level, and T_n indicates the total time of exposure permitted at that level.

Example 6
A drill runs for 15 seconds and is off 0.5 second between operations. This noise is rated at its "on" level for an entire eight-hour day. The noise generated by the drill would be "safe" only if the level were 90 dBA or less.

Further interpretation of the OSHA standard indicates that exposure above 115 dBA is not permissible for any length of time.

As discussed earlier, daily noise dose can be measured using a noise dosimeter. For OSHA use, the dosimeter must have a 5-dB exchange rate, 90-dBA criterion level, slow response, and either an 80-dBA or 90-dBA threshold gate for the appropriate standard to be evaluated. OSHA prescribes a 90-dBA threshold level for compliance with 29 *CFR* 1910.95 (a) and (b), which require implementation of engineering or administrative controls. An 80-dBA threshold is prescribed in 29 *CFR* 1910.95 (d) for monitoring situations for hearing conservation.

INTERMITTENT NOISE

Exposure to intermittent noise can be defined as exposure to a given broadband sound-pressure level several times during a normal working day. The inspector or facility supervisor who periodically makes trips from a relatively quiet office into noisy production areas may be subject to this type of noise.

With steady noises, it is sufficient to record the A-weighted sound level attained by the noise. With noises that are not steady, such as impulsive noises, impact noises, and the like, the temporal character of the noise requires additional specification. Both the short-term and long-term variations of the noise must be described. Nonsteady

noise-exposure measurements are most easily made using dosimeters.

IMPACT-TYPE NOISE

Impact-type noise is a sharp burst of sound, and sophisticated instrumentation is necessary to determine the peak levels for this type of noise. Noise types other than steady ones are commonly encountered. In general, sounds repeated more than once per second can be considered as steady. Impulsive or impact noise, such as that made by hammer blows or explosions, is generally less than one-half second in duration and does not repeat more often than once per second. Employees should not be exposed to impulsive or impact noise that exceeds a peak sound pressure level of 140 dB.

NOISE-CONTROL PROGRAMS

The degree of noise reduction required is determined by comparing the measured levels with acceptable noise levels. The next step is to consider various noise-control measures such as making alterations in engineering design, limiting the time of exposure, or using personal protective devices to achieve the desired level of reduction.

Every noise problem can be broken down into three parts: a source that radiates sound energy, a path along which the sound energy travels, and a receiver such as the human ear (Figure 9–18). The "system" approach to noise-problem analysis and control assists in understanding both the problem and the changes that are necessary for noise reduction. If each part of the system—source, path, and receiver—is examined in detail, the overall problem is greatly simplified. To help translate these principles into practical terms, specific examples of controlling industrial noise exposure are outlined in this section.

Source

The most desirable method of controlling a noise problem is to minimize the noise at the source. This generally means

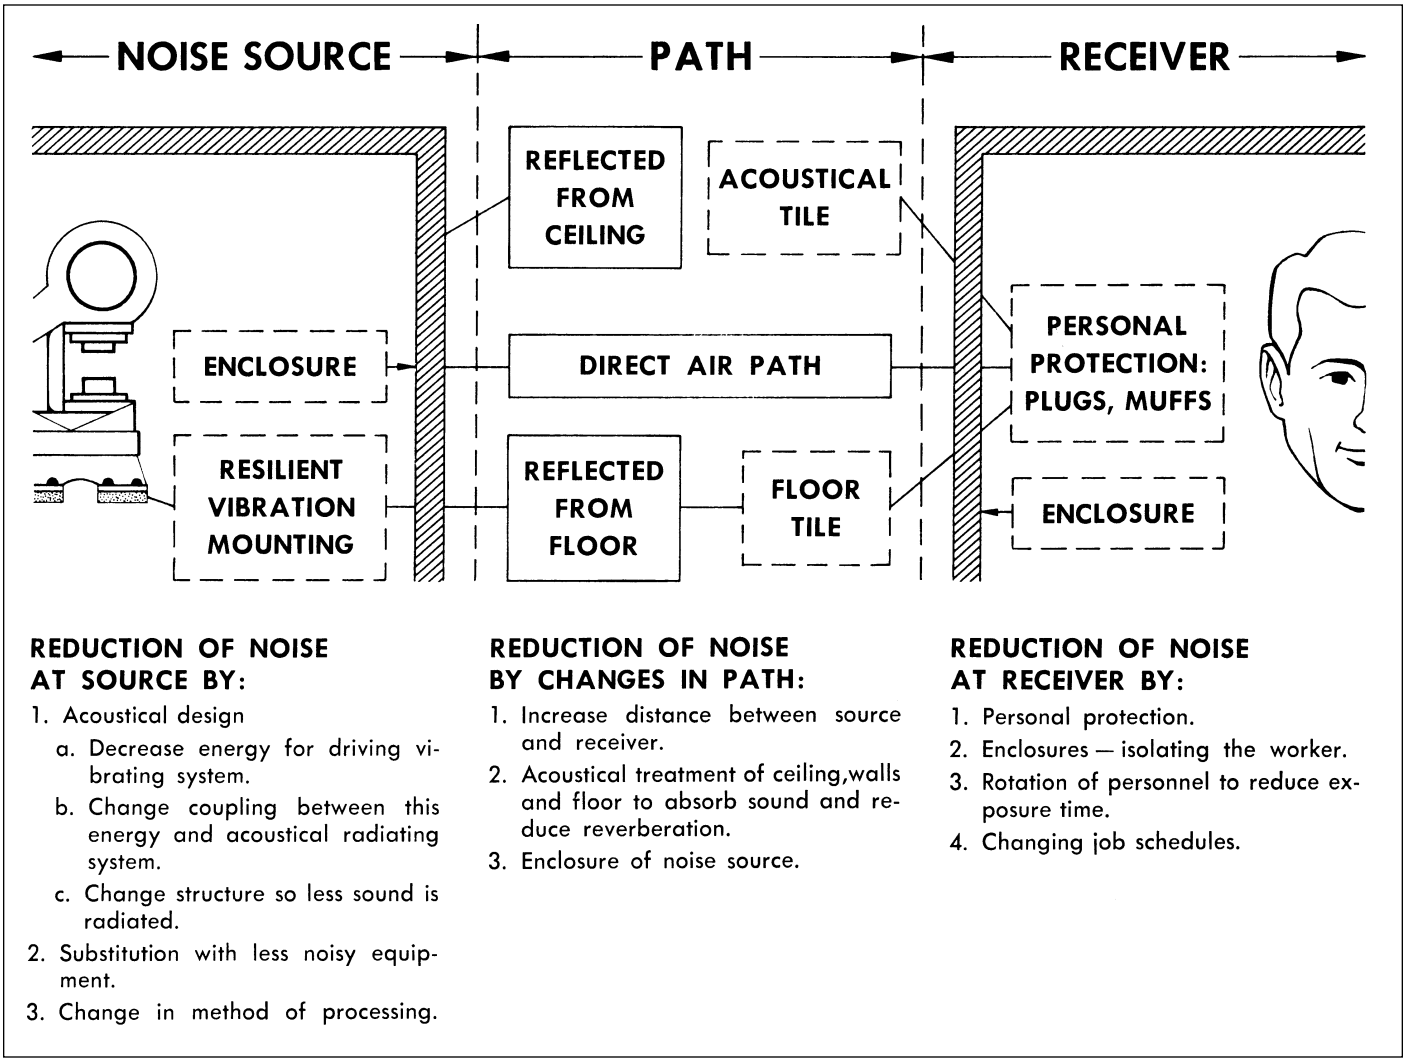

Figure 9–18. Every noise problem can be broken down into three component parts: a source that radiates sound energy, a path along which the sound energy travels, and a receiver such as the human ear.

modifying existing equipment and structures or possibly introducing noise-reduction measures at the design stage of new machinery and equipment.

Noise Path

Because the desired amount of noise reduction cannot always be achieved by control at the source, modification along the noise path and at the receiver must also be considered.

Noise reduction along the path can be accomplished in many ways: by shielding or enclosing the source, by increasing the distance between the source and the receiver, or by placing a shield between the source and the receiver. Noise can be reduced along the path by means of baffles and enclosures placed over noise-producing equipment to minimize the transmission of noise to areas occupied by employees. Use of acoustical material on walls, ceilings, and floors to absorb sound waves and to reduce reverberations can result in significant noise reduction.

Noise produced by a source travels outward in all directions. If all of the walls, the floor, and the ceiling are hard, reflecting surfaces, all the sound is reflected again and again. The sound level measured at any point in the room is the sum of the sound radiated directly by the source plus all the reflected sounds. Practically all industrial machine installations are located in such environments. These locations are known as semireverberant. Noise measured around a machine in a semireverberant location is the sum of two components: the noise radiated directly by the machine and the noise reflected from the walls, floor, and ceiling.

Close to the machine, most of the noise is radiated directly by the machine. Close to the walls, the reflected component may be predominant. Sound-absorption materials applied to the walls and ceiling can reduce the reflected noise but has no effect on the noise directly radiated by the source.

Enclosures

In many cases, the purpose of an acoustic enclosure is to prevent noise from getting inside. Soundproof booths for machine operators and audiometric testing booths for testing the hearing of employees are examples of such enclosures. More often, however, an enclosure is placed around a noise source to prevent noise from getting outside. Enclosures are normally lined with sound-absorption material to decrease internal sound pressure buildup.

Noise can best be prevented from entering or leaving an enclosure by sealing all outlets. In extreme cases, double structures can be used. Special treatment, including the use of steel and lead panels, is available to prevent noise leakage in certain cases. Gaskets around doors can also reduce noise transmission from one space to another.

Control Measures

Noise control can often be designed into equipment so that little or no compromise in the design goals is required. Noise control measures undertaken on existing equipment are usually more difficult. Engineering control of industrial noise problems requires the skill of individuals who are highly proficient in this field.

Noise-control strategies require careful objective analysis on both a practical and economic basis. Complete redesign requires that product and equipment designers consider noise level a primary product or equipment specification in the design of all new products. Full replacement of all products or equipment would eventually take place, the schedule depending on the service life of each. Many designers feel this approach minimizes the cost increases associated with noise-control measures. Existing products or equipment modifications would require manufacturers to modify or replace existing products and equipment to lower the noise levels of noisy equipment.

The existing equipment within any facility was probably selected because it was economical and efficient. However, careful acoustic design can result in quieter equipment that would even be more economical to operate than noisier equipment. Examples of noise-control measures applied at the source include the substitution of quieter machines, the use of vibration-isolation mountings, and the maximum possible reduction of the external surface areas of vibrating parts. Machines mounted directly on floors and walls can cause them to vibrate, resulting in sound radiation. Proper machine mounting can isolate the machines and reduce the transmission of vibrations to the floors and walls.

Although substitution of less noisy machines may have limited application, there are certain areas in which substitution has a potentially wider application. Examples include using "squeeze"-type equipment instead of drop hammers, welding instead of riveting, and instituting chemical cleaning of metal rather than high-speed polishing and grinding.

ENGINEERING

When starting a noise-reduction program, it is most desirable to apply engineering principles that are designed to reduce noise levels. The application of known noise-control principles can usually reduce any noise to any desired degree. However, economical considerations or operational necessities can make some applications impractical.

Engineering controls are procedures other than administrative or personal protection procedures that reduce the sound level either at the source or within the hearing zone of workers. The following are examples of engineering principles that can be applied to reduce noise levels.

1. Maintenance:
   a. replacement or adjustment of worn, loose, or unbalanced parts of machines
   b. lubrication of machine parts and use of cutting oils
   c. use of properly shaped and sharpened cutting tools
2. Substitution of machines:
   a. larger, slower machines for smaller, faster ones
   b. step dies for single-operation dies

   c. presses for hammers
   d. rotating shears for square shears
   e. hydraulic presses for mechanical presses
   f. belt drives for gears
3. Substitution of processes:
   a. compression riveting for impact riveting
   b. welding for riveting
   c. hot working for cold working
   d. pressing for rolling or forging
4. Reduction of the driving force of vibrating surfaces:
   a. reduction of the forces
   b. minimization of rotational speed
   c. isolation
5. Reduction of the response of vibrating surfaces:
   a. damping
   b. additional support
   c. increased stiffness of the material
   d. increased mass of vibrating members
   e. change in the size to change resonance frequency
6. Reduction of the sound radiation from vibrating surfaces:
   a. reduction of the radiating area
   b. reduction of the overall size
   c. perforation of the surfaces
7. Reduction of the sound transmission through solids:
   a. use of flexible mountings
   b. use of flexible sections in pipe runs
   c. use of flexible-shaft couplings
   d. use of fabric sections in ducts
   e. use of resilient flooring
8. Reduction of the sound produced by gas flow:
   a. use of intake and exhaust mufflers
   b. use of fan blades designed to reduce turbulence
   c. use of large, low-speed fans instead of smaller, high-speed fans
   d. reduction of the velocity of fluid flow (air)
   e. increase in the cross section of streams
   f. reduction of the pressure
   g. reduction of air turbulence
9. Reduction of noise by reducing its transmission through air:
   a. use of sound-absorptive material on walls and ceiling in work areas
   b. use of sound barriers and sound absorption along the transmission path
   c. complete enclosure of individual machines
   d. use of baffles
   e. confinement of high-noise machines to insulated rooms
10. Isolation of the operator by means of a relatively soundproof booth

Some of the noise-control measures described here can be executed quite inexpensively by facility personnel. Other controls require considerable expense and highly specialized technical knowledge to obtain the required results. The services of competent acoustical engineers should be contracted when planning and carrying out engineering noise-control programs.

The possibility that excessive facility noise levels exist should be considered at the planning stage. Vendors supplying machinery and equipment should be advised that specified low noise levels will be considered in the selection process. Suppliers should be asked to provide information on the noise levels of currently available equipment. The inclusion of noise specifications in purchase orders has been used successfully to obtain quiet equipment. If purchasers of industrial equipment demand quieter machines, designers will give more consideration to the problem of noise control.

It is not enough to specify that the sound pressure level of a single machine shall be 90 dBA or less at the operator's station; if another identical machine is placed nearby, the sound level produced by the two machines could be 93 dBA at the operator's station. (As mentioned earlier in this chapter, an increase of 3 dB represents a doubling of sound energy.)

To estimate the effect of a given machine on the total work environment, it is necessary to know the sound power that the machine produces. If there is no operator's work station in the machine's immediate vicinity, the sound power specifications may be sufficient; if, however, there is an operator in the near-sound field, more information is generally needed.

Objectionable noise levels that are by-products of manufacturing operations are found in almost every industry. Practical noise-control measures are not easy to develop, and few ready-made solutions are available. Unfortunately, a standard technique or procedure that can be applied to all or even most situations cannot be presented here. The same machine, process, or noise source in two different locations can present two entirely different problems that must be solved in two entirely different ways.

Noise-control techniques are now being incorporated into products during the design stage. Machine tool buyers are one group who currently specify maximum noise levels in their purchase orders. Equipment can be designed with lower noise levels, but performance tradeoffs involving weight, size, power consumption, and perhaps increased maintenance costs may be necessary. These new, quieter products will probably weigh more, be bigger and bulkier, cost more, and be more difficult and expensive to service and maintain.

To attain quieter products, the engineer must be prepared to trade off, to some degree, many of the design goals that have been achieved in response to market demands. However, lightweight, low-cost, portable machines that are easily operated and simply maintained should not be cast aside lightly, even though price increases may be inevitable. The cost/benefit relationship should be examined in each case. In addition to paying higher prices for original equipment, the user (both as a consumer and as a taxpayer) pays for increased indirect costs.

The success of a noise-reduction project usually depends on the ingenuity with which basic noise-control measures can be applied without decreasing the maximum use and accessibility of the machine or other noise source that is being quieted.

ADMINISTRATIVE CONTROLS

There are many operations in which the exposure of employees to noise can be controlled administratively; for instance, production schedules can simply be changed or jobs rotated so that individual workers' exposure times are reduced. Employees can be transferred from job locations with high noise levels to job locations with lower ones if this procedure would make their daily noise exposure acceptable.

Administrative controls also include scheduling machine operating times so as to reduce the number of workers exposed to noise. For example, if an operation is performed during only one eight-hour day per week, and the operator is overexposed on that one day, it might be possible to perform the operation in two half-days of four hours each. The employee might then not be overexposed.

Employees who are particularly susceptible to noise can be transferred and allowed to work in a less noisy area. The benefits from transferring employees can be limited, however, because personnel problems can be caused due to loss of seniority and prestige and lower productivity and pay.

Administrative controls include any administrative decision that results in lower noise exposure, such as complying with purchase agreements that specify maximum noise levels at the operator's position.

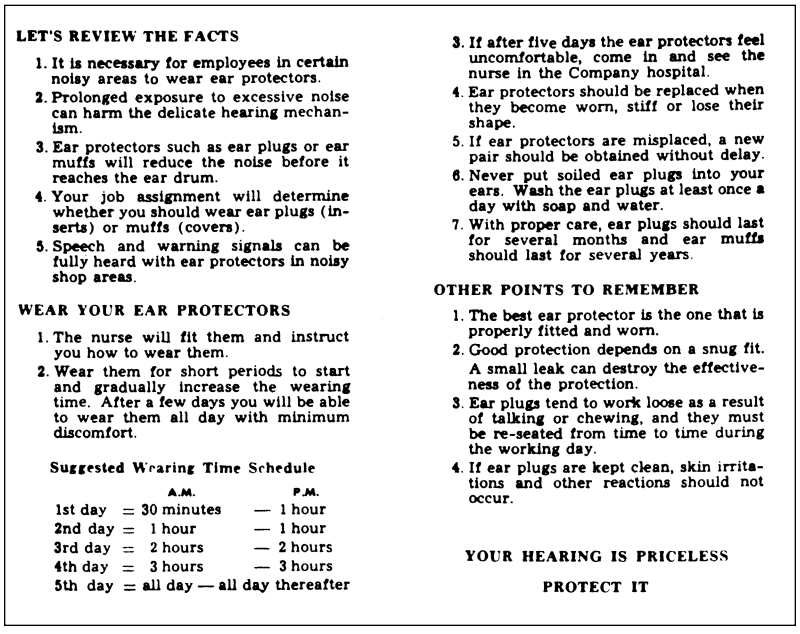
The sound level specification that is made part of a purchasing agreement must be more than just a general compliance statement such as "Must meet the requirements of the OSHA." It is important to realize that OSHA sets allowable noise limits relative to the exposure of the people involved. OSHA does not set specific standards for noise-generating equipment. The OSHA noise standard is not intended to be used as an equipment design specification and thus cannot be used as such.

PERSONAL HEARING PROTECTION

Pending the application of engineering control measures, employee exposure to noise can be reduced by the mandatory use of hearing- protective devices. Occupational noise regulations require that whenever employees are exposed to excessive noise levels, feasible administrative or engineering controls should be used to reduce those levels. When these control measures cannot be completely accomplished, or while such controls are being initiated, personnel should be protected from the effects of excessive noise levels. Such protection can, in most cases, be provided by wearing suitable hearing-protection devices. Once management has decided that hearing protectors should be worn, the success of such a program depends largely on the method of initiation used and on the proper indoctrination of supervisory personnel and workers. Supervisors should set an example by wearing their hearing protectors when they go into noisy areas.

Some companies have found it very helpful to meet with employees or their representatives to thoroughly review the contemplated protection program and reach an understanding of the various problems involved. This process includes reviewing work areas where hearing protection will be provided or required and complying with state and federal regulations that require the use of hearing-protective devices.

Hearing-protective devices. Hearing-protective devices such as earplugs and earmuffs have one serious drawback—they do nothing to reduce or eliminate the hazard. Their failure means immediate exposure to the hazard. The fact



LET'S REVIEW THE FACTS

1. It is necessary for employees in certain noisy areas to wear ear protectors.
2. Prolonged exposure to excessive noise can harm the delicate hearing mechanism.
3. Ear protectors such as ear plugs or ear muffs will reduce the noise before it reaches the ear drum.
4. Your job assignment will determine whether you should wear ear plugs (inserts) or muffs (covers).
5. Speech and warning signals can be fully heard with ear protectors in noisy shop areas.

WEAR YOUR EAR PROTECTORS

1. The nurse will fit them and instruct you how to wear them.
2. Wear them for short periods to start and gradually increase the wearing time. After a few days you will be able to wear them all day with minimum discomfort.

Suggested Wearing Time Schedule

	A.M.	P.M.
1st day	= 30 minutes	— 1 hour
2nd day	= 1 hour	— 1 hour
3rd day	= 2 hours	— 2 hours
4th day	= 3 hours	— 3 hours
5th day	= all day	— all day thereafter

3. If after five days the ear protectors feel uncomfortable, come in and see the nurse in the Company hospital.
4. Ear protectors should be replaced when they become worn, stiff or lose their shape.
5. If ear protectors are misplaced, a new pair should be obtained without delay.
6. Never put soiled ear plugs into your ears. Wash the ear plugs at least once a day with soap and water.
7. With proper care, ear plugs should last for several months and ear muffs should last for several years.

OTHER POINTS TO REMEMBER

1. The best ear protector is the one that is properly fitted and worn.
2. Good protection depends on a snug fit. A small leak can destroy the effectiveness of the protection.
3. Ear plugs tend to work loose as a result of talking or chewing, and they must be re-seated from time to time during the working day.
4. If ear plugs are kept clean, skin irritations and other reactions should not occur.

YOUR HEARING IS PRICELESS

PROTECT IT

Figure 9–19. An example of a flyer distributed to all company employees who are required to wear some form of hearing protection. The flyer highlights care and use of the protectors.

that a hearing protector can become ineffective without the knowledge of the wearer is particularly serious. Training on the purpose, benefits, proper fitting, use, and care of hearing protectors is essential to the success of the program and is required by OSHA. Distributing a flyer (Figure 9–19) highlighting the care and use of the hearing protector is also helpful.

Personal hearing-protective devices are acoustic barriers that reduce the amount of sound energy transmitted through the ear canal to receptors in the inner ear.

The sound attenuation (reduction) capability of a hearing-protective device (in decibels) is the difference in the measured hearing threshold of an observer wearing hearing protectors (test threshold) and the measured hearing threshold when the observer's ears are unprotected (reference threshold).

Inserts or muffs are hearing-protective devices that are in common use today. The insert-type protector attenuates noise by plugging the external ear canal, whereas the muff-type protector encloses the auricle of the ear to provide an acoustic seal. The effectiveness of hearing-protective devices depends on several factors that are related to the manner in which the sound energy is transmitted through or around the device. Figure 9–20 shows four pathways by which sound can reach the inner ear when hearing-protective devices are worn: seal leaks, material leaks, hearing-protective device vibration, and conduction through bone and tissue.

Seal leaks. For maximum protection, the device must form a virtually airtight seal against the ear canal or the side of the head. Inserts must accurately fit the contours of the ear canal, and muffs must accurately fit the area surrounding the external ear. Small air leaks in the seal between the hearing protector and the skin can significantly reduce the low-frequency sound attenuation or permit a greater proportion of the low-frequency sounds to pass through. As the air leak becomes larger, attenuation lessens at all frequencies.

Material leaks. Another possible transmission pathway for sound is directly through the material of the hearing-protective device. Although the hearing-protective device can attenuate or prevent the passage of most of the sound energy, some sound is still allowed to pass through.

Vibration of the hearing-protective device. Sound can also be transmitted to the inner ear when the hearing-protective device itself is set into vibration in response to exposure to external sound energy.

Because of the flexibility of the flesh in the ear canal, earplugs can vibrate in a piston-like manner within the ear canal. This limits their low-frequency attenuation. Likewise, an earmuff cannot be attached to the head in a totally rigid manner. Its cup vibrates against the head like a mass/spring system. The muff's effectiveness is governed by the flexibility of the muff cushion and the flesh surrounding the ear, as well as by the air volume entrapped under the cup.

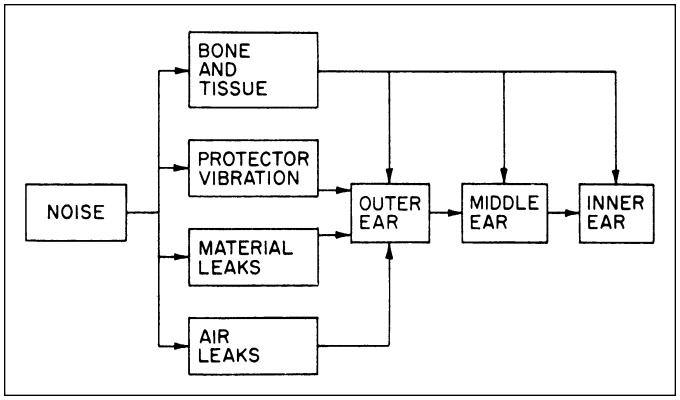


Figure 9–20. When a person is wearing a hearing protector, sound reaches the inner ear by different pathways.

Bone conduction. If the ear canal were completely closed so that no sound entered the ear by that path, some sound energy could still reach the inner ear by means of bone conduction. However, the sound reaching the inner ear by such means would be about 50 dB below the level of air-conducted sound received through the open ear canal. It is therefore obvious that no matter how the ear canal is blocked, the hearing-protective device will be bypassed by the bone-conduction pathway through the skull. A perfect hearing-protective device cannot provide more than about 50 dB of effective sound attenuation.

When a hearing-protective device is properly sized and carefully fitted and adjusted for optimum performance on a laboratory subject, air leaks are minimized, and material leaks, hearing-protective device vibration, and bone conduction are the primary sound transmission paths. In the workplace, however, this is usually not the case; sound transmission through air leaks is often the primary pathway.

All hearing protectors must be properly fitted when they are initially dispensed. Comfort, motivation, and training are also very important factors to consider if hearing protectors are to be successfully used.

CLASSES OF HEARING PROTECTION

Personal hearing-protective equipment can be divided into four classifications:

- ➢ Enclosures (entire head)
- ➢ Aural inserts, or earplugs
- ➢ Superaural protectors, or canal caps
- ➢ Circumaural protectors, or earmuffs

Enclosures. The enclosure-type hearing-protective device entirely envelops the head. A typical example is the helmet worn by an astronaut. In this case, attenuation at the ear is achieved through the acoustic properties of the helmet.

The maximum amount that a hearing protector can reduce the sound reaching the ear is from about 35 dB at 250 Hz to about 50 dB at the higher frequencies. By wearing hearing protectors and then adding a helmet that

encloses the head, an additional 10-dB reduction of sound transmitted to the ears can be achieved.

Helmets can be used to support earmuffs or earphones and cover the bony portion of the head in an attempt to reduce bone-conducted sound. Helmets are particularly well-suited for use in extremely high–noise level areas and where workers need to protect their heads from bumps or missiles. With good design and careful fitting of the seal between the edges of the helmet and the skin of the face and neck, 5–10 dB of sound attenuation can be obtained beyond that already provided by the earmuffs or earphones worn inside the helmet. This approach to protection against excessive noise is practical only in very special applications. Cost, as well as bulk, normally precludes the use of helmet-type hearing protectors in a general industrial hearing conservation program.

Aural insert protectors. Aural insert hearing-protective devices are normally called inserts or earplugs. This type of protector is generally inexpensive, but the service life is limited, ranging from single-time use to several months. Insert-type protectors or plugs are supplied in many different configurations and are made from such materials as rubber, plastics, fine glass down, foam, and wax-impregnated cotton. The pliable materials used in these aural inserts are quite soft, and there is little danger of injury resulting from accidentally forcing the plug against the tender lining of the ear canal.

It is desirable to have the employee's ears examined by qualified medical personnel before earplugs are fitted. Occasionally, the physical shape of the ear canal precludes the use of insert-type protectors. There is also the possibility that the ear canal is filled with hardened wax. If wax (cerumen) is a problem, it should be removed by qualified personnel. In some cases, the skin of the ear may be sensitive to a particular earplug material, and earplugs that do not cause an allergic response should be recommended.

Earplugs fall into three broad categories of general classification: formable, custom-molded, and premolded.

Formable earplugs (Figure 9–21) can provide good attenuation and fit any ear. Many of the formable types are designed for one-time use only, after which they are thrown away. Materials from which these disposable plugs are made include very fine glass fiber (often called Swedish wool), wax-impregnated cotton, expandable plastic, and foam.

These materials are generally rolled into a conical shape before being inserted into the ear. However, while adequate instruction must be given to emphasize the importance of a snug fit, the user must be careful not to push the material so far into the ear canal that it has to be removed by medical personnel.

One type of formable earplug is made from a plastic-like substance similar in consistency to putty. The preparation of this material requires that the individual take a quantity of it and mold or form it so that it can be inserted into the ear canal. The user should be shown the correct method of forming the material. In addition, the user must be cautioned to have clean hands when forming the material and placing it in the ear. If the hands are dirty, foreign material can get into the ear.

Custom-molded earplugs are, as the name implies, custom fit for the individual user. Generally, two or more materials (packaged separately) are mixed together to form a compound that resembles soft rubber when set. For use as a hearing-protective device, the mixture is carefully placed into the outer ear with some portion of it in the ear canal, in the manner prescribed by the manufacturer. As the material sets, it molds itself to the shape of the individual ear and external ear canal. In some cases, the materials are premixed and come in a tube from which they can be injected into the ear.

Premolded earplugs are often referred to as prefabricated, because they are usually made in large quantities in a multiple-cavity mold. The materials of construction range from soft silicone or rubber to other plastics.

There are two versions of premolded insert protector. One is known as the universal-fit type. In this type, the plug is designed to fit a wide variety of ear canal shapes and sizes. The other type of premolded protector is supplied in several different sizes to ensure a good fit (Figure 9–22). The design

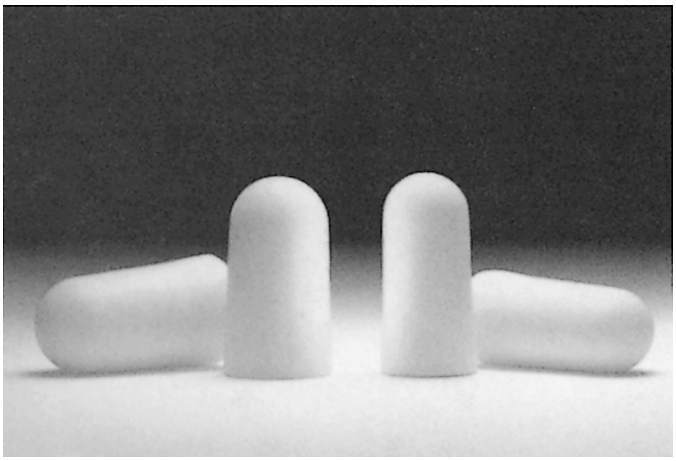

Figure 9–21. Formable earplugs. (Courtesy Cabot Safety Corp.)

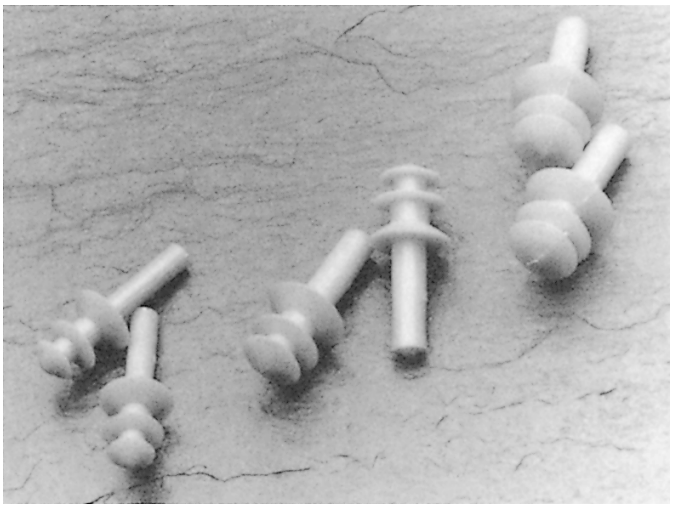

Figure 9–22. Premolded triple-flange earplugs. (Courtesy The Bilsom Group.)

of the plug is important. For example, the smooth bullet-shaped plug is very comfortable and provides adequate attenuation in straight ear canals; however, its performance falls off sharply in many irregularly shaped canals.

The use of premolded earplugs requires proper fitting by trained personnel. In many individuals, the right and left ear canals are not the same size. For this reason, properly trained personnel must prescribe the correct protector size for each ear canal. Sizing devices are available to aid in proper fitting.

The premolded type of earplug has a number of disadvantages that limit its practical acceptability. To be effective, it has to fit snugly and, for some users, this is uncomfortable. Because the plug must fit tightly and because many people have irregularly shaped ear canals, an incorrect size of plug can be selected, or the plug may not be inserted far enough, and a good fit is not obtained.

Some premolded earplugs can shrink and become hard. This is caused primarily by ear wax (present in all ear canals). The wax extracts the plasticizer from some plug materials, causing hardening and possible shrinkage of the plug. The degree of hardening and shrinkage varies from one individual user to another, depending on such factors as temperature, duration of use, and the personal hygiene of the user. Regular cleaning of the protectors with mild soap and water prolongs their useful life. To keep the plugs clean and free from contamination, most manufacturers provide a carrying case for storing the plugs when they are not in use.

Superaural protectors. Hearing-protective devices in this category (commonly known as canal caps) seal the external opening of the ear canal to achieve sound attenuation (Figure 9–23). A soft, rubberlike material is held in place by a lightweight headband. The tension of the band holds the superaural device against the external opening of the ear canal.

Circumaural protectors. Circumaural hearing-protective devices, or earmuffs, consist essentially of two cup- or dome-shaped devices that fit over the entire external ear, including the lobe, and a cushion or pad that seals against the side of the head. The ear cups are generally made of a molded rigid plastic and are lined with a cell-type foam material. The size and shape of the ear cup vary from one manufacturer to another (Figure 9–24). The cups are usually held in place by a spring-loaded suspension assembly or headband. The force applied against the head is directly related to the degree of attenuation desired. The width, circumference, and material of the earmuff cushion must be considered to maintain a proper balance of performance and comfort. To provide a good acoustic seal, the required width of the contact surface depends to a large degree on the material used in the cushion. The cup with the smallest possible circumference that can accommodate the largest ear lobes should be chosen. A slight pressure on the lobe can become painful in time, so it is very important to select a muff dome that is large enough.

The earmuffs currently on the market come with replaceable ear seals or cushions that are filled with either foam, liquid, or air—the foam-filled type is the most common. The outer covering of these seals is vinyl or a similar thermoplastic material. Human perspiration tends to extract the plasticizer from the seal material, which results in an eventual stiffening of the seals. For this reason, the seals require periodic replacement; the frequency of replacement depends on the conditions of exposure.

SELECTION OF PROTECTOR

The attenuation characteristics of a particular hearing protector must be considered before it is used for a specific applica-

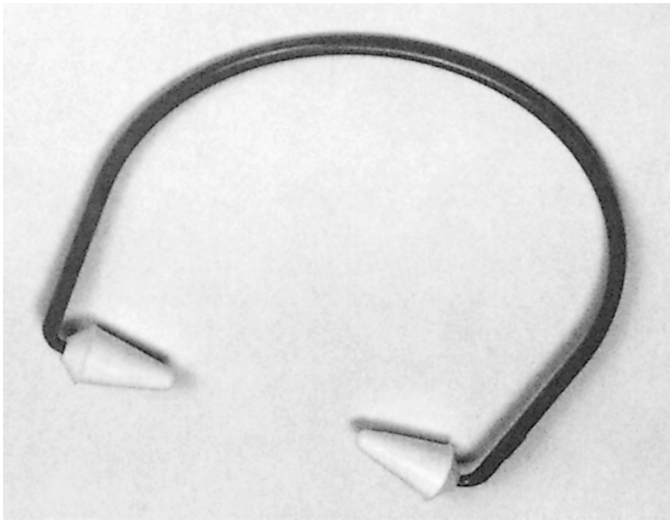

Figure 9–23. Canal caps. (Courtesy Cabot Safety Corp.)

Figure 9–24. Earmuffs. (Courtesy The Bilsom Group.)

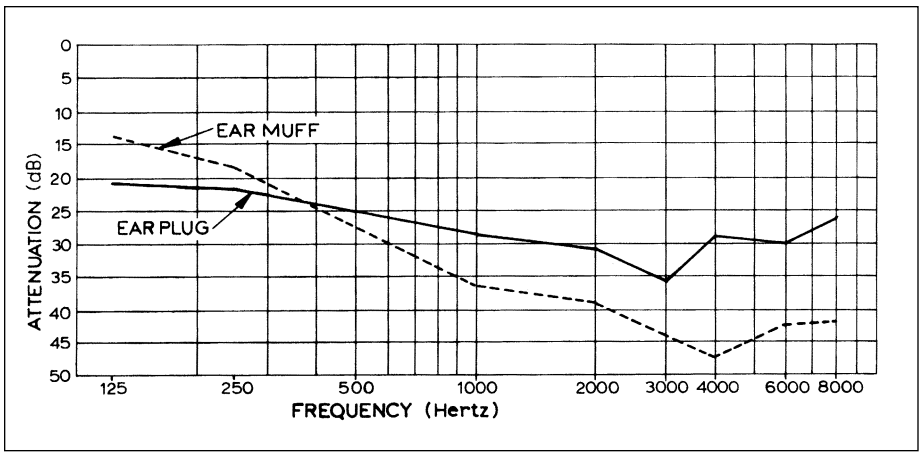

Figure 9–25. Comparison of the attenuation properties of a molded-type earplug and an earmuff protector. Note that the earplug offers greater attenuation of the lower frequencies, while the earmuff is better at the higher frequencies.

tion (Figure 9–25). As part of a well-planned hearing conservation program, characteristics of the noise levels in various areas should be known. From these data and from the attenuation information available from manufacturers, it can be determined whether a given device is suitable for the intended application. One must also consider the work area where the individual will use the hearing-protective device. For example, a large-volume earmuff would not be practical for an individual who must work in confined areas where there is very little head clearance. In such instances, a very small or flat ear cup or insert-type protector would be more practical.

When using muff-type protectors in special hazard areas (such as power-generating stations where there are electrical hazards), it may be desirable to use nonconductive suspension systems with muff-type protectors. Also, if other personal protective equipment such as safety hats or safety spectacles must be worn, the degree of hearing protection required must not be compromised. The efficiency of muff type protectors is reduced when they are worn over the frames of eye-protective devices. In these cases, the amount of reduction in noise attenuation depends on the type of glasses being worn as well as the size and shape of the individual wearer's head. When eye-protective devices are required, it is recommended that ones with cable-type temples be used, because they create the smallest possible opening between the seal and the head.

When selecting a hearing-protective device, one should also consider how often a worker is exposed to excessive noise. If exposure is relatively rare (once a day or once a week), an insert or plug device will probably satisfy the requirement. On the other hand, if the noise exposure is relatively frequent and the employee must wear the protective device for an extended period of time, the muff-type protector might be preferable. If the noise exposure is intermittent, the muff-type protector is probably more desirable, because it is somewhat more difficult to remove and reinsert earplugs.

When determining the suitability of a hearing-protective device for a given application, the manufacturer's reported test data must be examined carefully. It is necessary to correlate that information with the specific noise exposure the device is intended to control. The manufacturer should provide attenuation characteristics of the individual hearing-protective devices over a range of frequencies.

The most convenient method by which to gauge the adequacy of a hearing protector's attenuation capacity is to check its Noise Reduction Rating (NRR), a rating that was developed by the EPA (U.S. Environmental Protection Agency). According to the EPA regulation, the NRR must be printed on the hearing protector's package. The NRR can be correlated with an individual worker's noise environment to assess the adequacy of the attenuation characteristics of the particular hearing-protective device. Appendix B of 29 *CFR* 1910.95 describes methods of using the NRR to determine whether a particular hearing-protective device (HPD) provides adequate protection within a given exposure environment. It must be noted, however, that NRRs are based on data obtained under laboratory conditions using trained listeners who are fitted by professionals. Their ratings differ significantly from what is achieved in the real world. In 1998, NIOSH published *Occupational Noise Exposure, Revised Criteria.* Based on studies conducted by numerous researchers of real world NRRs achieved by 84% of wearers in 20 independent studies, they recommend lowering the manufacturer's NRRs significantly. NIOSH recommended using subject fit data based on ANSI S12.6-1997 to estimate HPD attenuation. If this is not available, they recommend that the labeled NRRs be de-rated as follows:

- ➢ Earmuffs—subtract 25 percent from the manufacturer's labeled NRR
- ➢ Formable earplugs—subtract 50 percent from the manufacturer's NRR
- ➢ All other plugs—subtract 70 percent from the manufacturer's NRR

(See Bibliography, NIOSH, 1998.)

INDUSTRIAL AUDIOMETRY

Audiometry, or the measurement of hearing, is central to industrial hearing conservation programs because all follow-up activities and program evaluations are based on such test results. Briefly, the objectives in industrial audiometry are as follows:

- ➢ Obtain a baseline audiogram that indicates an individual's hearing ability at the time of the preplacement examination.
- ➢ Provide a record of an employee's hearing acuity.
- ➢ Check the effectiveness of noise-control measures by measuring the hearing thresholds of exposed employees.
- ➢ Record significant hearing threshold shifts in exposed employees during the course of their employment.
- ➢ Comply with government regulations.

An audiometer is required to help assess an individual's hearing ability. An audiometer is an electronic instrument that converts electrical energy into sound energy in precisely variable amounts. It should meet the standards set forth in ANSI S3.6–1996, *Specifications for Audiometers*.

An audiometer consists of an oscillator, which produces pure tones at predetermined frequencies; an attenuator, which controls the intensity of the sound or tone produced; a presenter switch; and earphones, through which the person whose hearing is being tested hears the tone.

Threshold Audiometry

Threshold audiometry is used to determine an employee's auditory threshold for a given stimulus. Measurements of hearing are made to determine hearing acuity and to detect abnormal function in the ear. Before hearing can be described as abnormal, a reference point, or normal value, must be designated.

The quantity that is of interest, however, is not the sound pressure level of the normal hearing threshold, but rather the magnitude of departure from a standard reference threshold. Levels that depart from the norm can be easily detected by their divergence from the reference threshold, which shows up directly on the audiometer attenuator dial.

Hearing threshold levels are those intensities at specific frequencies at which a sound or a tone can just barely be heard. The term *air conduction* refers to the air path by which the test sounds generated at the earphones are conducted through air to stimulate the eardrum.

The record of measured hearing thresholds is called a threshold audiogram. Audiometric tests can also be recorded in the form of audiograms, on which are plotted both sound intensity (in dB) and frequency (in Hz). A sample audiogram is shown in Figure 9–26.

Who Should Be Examined

Preplacement hearing-threshold tests should be taken by all job applicants, not just those who are to work in noisy areas. This establishes a baseline hearing threshold for each employee for future comparison. Preplacement hearing tests are essential if a company is to protect itself from liability for preexisting hearing loss incurred elsewhere. If an employee is hired with hearing damage and he or she is subsequently exposed to high noise levels, the company may be liable for all the employee's hearing loss—unless it can be proved that the employee had a preexisting hearing loss when hired. In some states, the most recent employer is liable for all compensable hearing loss, regardless of past exposures.

Periodic follow-up hearing tests should be administered to persons stationed in areas where noise exposures exceed permissible levels.

The schedule for periodic follow-up hearing tests depends largely on an employee's noise exposure. Assuming that a record of the worker's hearing status was established at the time of employment or placement, the first reexamination should be made 9–12 months after placement. If no significant threshold shifts relative to the preplacement audiogram are noted, subsequent follow-up tests can be administered at yearly intervals. If the noise exposure is relatively low, the interval between follow-up tests can be increased. This decision should be based on the combination of the conditions of the exposure and the results of previous audiograms and clinical examinations.

Noise exposure is by no means the only reason for a change in an individual's audiogram. When a change in hearing status is confirmed, its cause must be determined. Improper placement of earphones and excessive ambient noise in the test room can affect audiogram results. Physiological changes as a result of the employee's age and state of health can also affect audiogram results. The individual's motivation and attitude toward the test can affect performance.

An industrial audiometric program can identify people who are experiencing hearing threshold changes that are not related to noise exposure on the job. These workers should be referred to their family physician for diagnosis and treatment. However, when threshold shifts related to noise exposure are identified, this procedure should be followed:

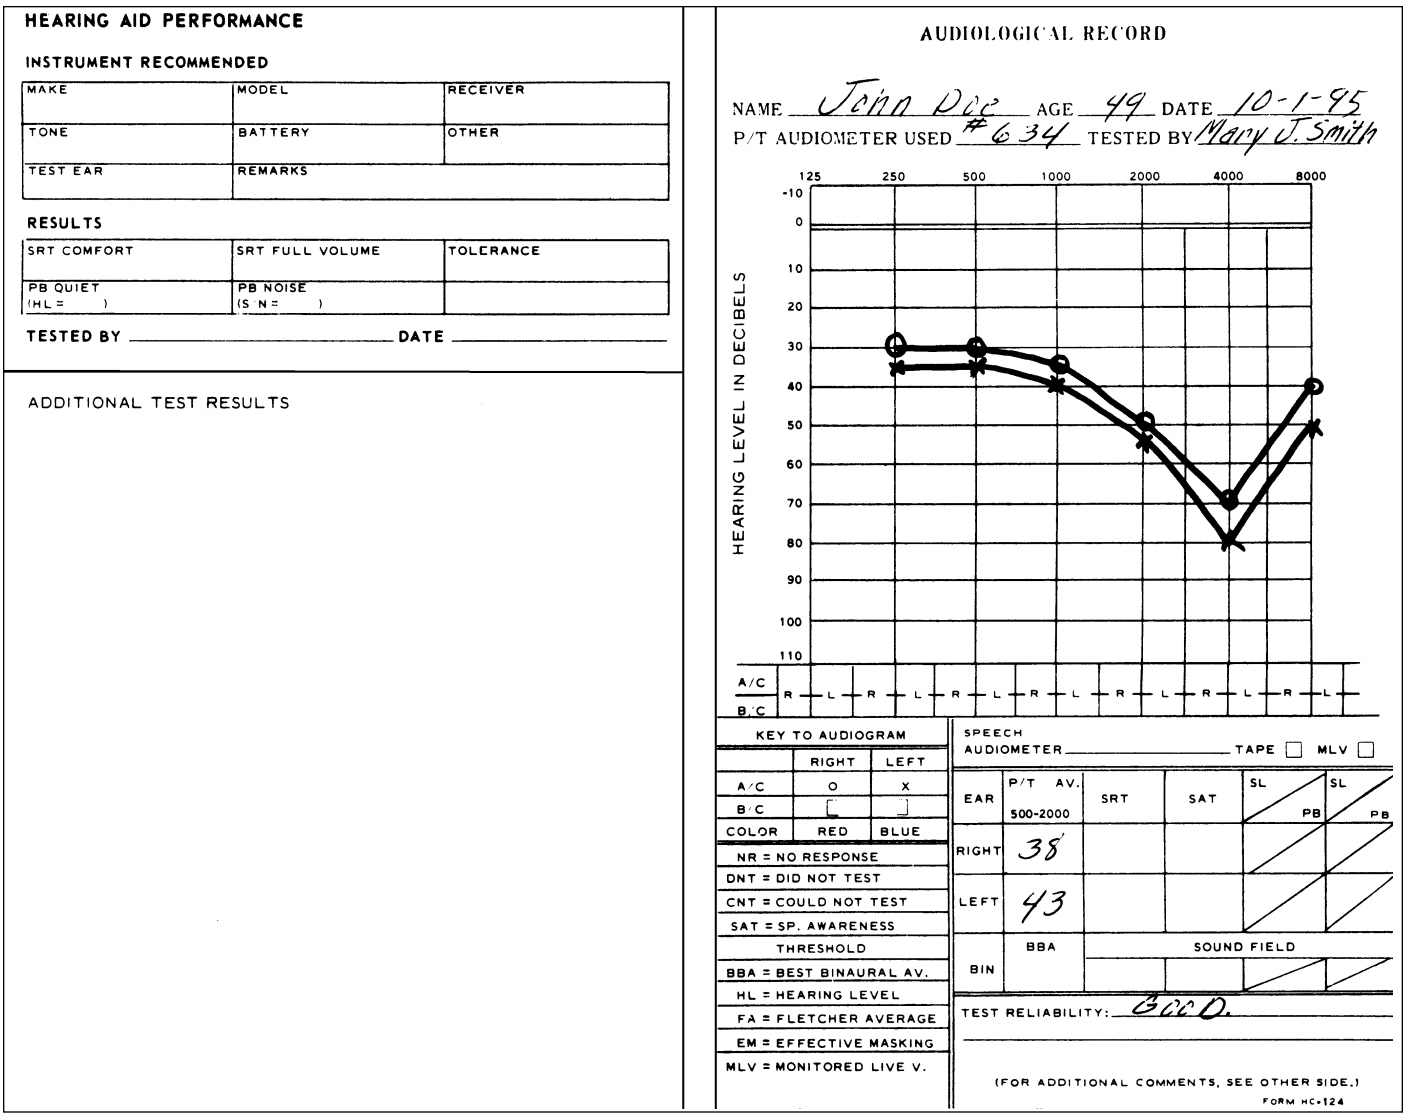
1. Check the fit of the hearing-protective device, if one is worn by the worker.
2. Repeat or initiate educational sessions to encourage the employee to wear a hearing-protective device, if it has not been worn.
3. Investigate the noise levels in the work area, particularly if a previous sound level survey failed to reveal noise hazards.

Noise exposure information, correlated with audiometric test results, is necessary to make intelligent decisions about a firm's hearing conservation program. If all hearing tests and medical opinion point to a progressive deterioration of an individual's hearing, the safety and health professional should provide and enforce the use of hearing-protection equipment and/or recommend that the individual's exposure to excessive noise be controlled.

Conclusions about the general noise environment should not be based on changes in the hearing of a single individual, because the variation in individual susceptibility to noise is broad. Conclusions can, however, be drawn from the average changes—or lack of them—in a group of employees exposed to the same noise environment.

Effective Programs

An effective industrial audiometric program should include consideration of the following components:



HEARING AID PERFORMANCE

- ➢ Medical surveillance
- ➢ Qualified personnel
- ➢ Suitable test environment
- ➢ Calibrated equipment
- ➢ Adequate record keeping

MEDICAL SURVEILLANCE

Medical surveillance is essential in a hearing-testing program so that the program can fulfill its dual purpose of detecting hearing loss and providing valid records for compensation claims. Although many smaller companies do not have a medical department, they can satisfy the general medical surveillance requirement by using part-time medical consultants.

Noise-susceptible workers are employees who suffer handicapping hearing losses more quickly than do their colleagues under equivalent noise exposures. These workers constitute the group from whom compensation claims are most likely to arise and for whom the risk of hearing damage is likely to be greatest.

During the preplacement examination, the applicant should provide a detailed history covering his or her prior occupational experience and a personal record of illnesses and injuries. For applicants who will work in noisy environments, the history should include noise exposures in previous jobs, including any in the military services. The medical phase of the history should detail frequency of earache, ear discharge, ear injury, surgery (ear or mastoid), head injury with unconsciousness, ringing in the ears, hearing loss in the immediate family, the use of drugs, and history of allergy and toxic exposures. A standard form can be created for this purpose.

QUALIFIED PERSONNEL

Audiometric tests should be administered by a qualified individual such as a specially trained nurse, an audiologist, or an occupational hearing conservationist. An occupational hearing conservationist (OHC) is an individual who has satisfactorily completed a course of training that meets, as a

minimum, the guidelines established by the Council for Accreditation in Occupational Hearing Conservation.

The duties of the OHC are to perform baseline and periodic pure-tone air-conduction threshold tests. Systematic supervision and encouragement of the OHC by the physician, audiologist, or other qualified person in charge of the audiometric program is recommended to maintain the high motivation required for proper audiometric testing. The supervision should include periodic review of the testing procedures used by the audiometric technician to make sure that they conform to established procedures.

SUITABLE TEST ENVIRONMENT

Hearing measurements must be made in a test room or booth that conforms to the requirements established by ANSI S3.1–1991 (R1999), *Maximum Permissible Ambient Noise Levels for Audiometric Test Rooms*. It must be sufficiently quiet within the enclosure so that external noises do not interfere with the employee's perception of the test sounds. This usually requires a special sound-treated enclosure (Figure 9–27).

Hearing-testing rooms should be located away from outside walls, elevators, and locations with heating and plumbing noises. If the background noise levels in the test area do not exceed the sound levels allowed by the standard, the background noise does not affect the hearing test results. The hearing test booth or room can be either a prefabricated unit or one that is built on the premises. Doors, gaskets, and other parts of the room or booth that can deteriorate, warp, or crack should be carefully inspected periodically.

Figure 9–27. Sound booth audiometric testing. (Courtesy Tremetrics Occupational Health Group.)

In addition to proper acoustical standards, the booth or room should allow for ease of access and egress and be provided with good, comfortable ventilation and lighting. The audiometric technician should be able to sit outside the room or booth but be able to see the interior of the room through a window.

To select the proper room, it is necessary to conduct a noise survey at the proposed test location. Noise levels at each test frequency should be measured and recorded using an octave-band sound level meter. The audiometric booth selected must have sufficient noise attenuation so that the background noise levels present at each test frequency are reduced and do not exceed the maximum permissible background levels listed in the current ANSI standard.

CALIBRATED EQUIPMENT

Limited-range, pure-tone audiometers must conform to the current ANSI standard listed in *Specifications for Audiometers*. Two basic types of audiometers are available: automatic recording audiometers and manually operated audiometers.

The audiometer should be subjected to a biological check each day before the instrument is used. The biological check is done by testing the hearing of a person whose hearing threshold is known and stable. The check should include the movement and bending of cords and wires, knob turning, switch actuating, and button pushing to make sure that no sounds are produced in the earphones other than the test tones.

An exhaustive electronic calibration of the audiometric test instrument should be made annually by a repair and calibration facility that has the specialized equipment and skilled technical personnel necessary for this work. A certificate of calibration should be kept with the audiometer at all times.

ADEQUATE RECORDS

The medical form used in audiometric testing programs should include all basic data related to the hearing evaluation. Hearing threshold values, noise-exposure history, and pertinent medical history should be accurately recorded each time an employee's hearing is tested. The employee should be identified by name, social security number, sex, and age. Additional information such as the date and time of the test (day of the week, time of day), conditions under which the test was performed, and the name of the examiner should also be included.

Audiometric test records for an employee should be kept for at least the duration of employment. The records could become the basis for a settlement of a hearing loss claim.

Periodic audiograms are a profile of the employee's hearing acuity. Any change from the results of previous audiograms should be investigated. One possible reason for a

hearing loss is that the employee's hearing protectors are inadequate or improperly worn.

The audiometric testing program should be both practical and feasible. In small companies, where the total number of employees to be tested is small, it would be impractical to purchase a booth and audiometer. It would be more economical to consider a mobile audiometer testing service or to refer the employees to a local, properly equipped and staffed hearing center or to a qualified physician or audiologist for an audiometric examination.

Audiometric testing is an integral part of a comprehensive hearing conservation program. The OSHA Hearing Conservation Standard discussed in the following section details specific requirements for audiometric testing and other required components of an effective hearing conservation program.

NOISE-EXPOSURE REGULATIONS

Background

The federal regulation of occupational noise exposure started with the rules issued by the Bureau of Labor Standards under the authority of the Walsh–Healey Public Contracts Act. These rules required that occupational noise exposure be reasonably controlled to minimize fatigue and the probability of accidents. The federal occupational noise-exposure regulations were originally written to apply only to contractors under the Walsh–Healey Public Contracts Act and the McNamara–O'Hara Service Contracts Act. Under the Williams–Steiger Occupational Safety and Health Act of 1970, the Bureau of Labor Standards was replaced by the Occupational Safety and Health Administration (OSHA).

The National Institute for Occupational Safety and Health (NIOSH) was established within the Department of Health and Human Services (formerly the Department of Health, Education and Welfare) by the Occupational Safety and Health Act of 1970 to conduct research and to recommend new occupational safety and health standards. The recommendations are transmitted to the Department of Labor, which is responsible for the final setting, promulgation, and enforcement of the standards.

In 1972, NIOSH provided the Department of Labor with a document called *Criteria for a Recommended Standard: Occupational Exposure to Noise*. Subsequently, the assistant secretary of labor determined that a standard advisory committee on noise should be formed. The purpose of this OSHA Advisory Committee was to obtain and evaluate additional recommendations from labor, management, government, and independent experts. The committee considered written and oral comments directed to it by interested parties. The committee then transmitted its recommendations for a revised standard to OSHA on December 20, 1973.

In 1974, OSHA published a proposed standard in the *Federal Register* that limited an employee's exposure level to 90 dBA, calculated as an eight-hour, time-weighted average (TWA). NIOSH commented on OSHA's proposed standard, stating that there was a need for reducing the eight-hour exposure level to 85 dBA. However, NIOSH was unable to recommend a specific future date after which the 85-dBA noise level should become mandatory for all industries. Sufficient data were not available to demonstrate the technological feasibility of this level.

The EPA reviewed the OSHA proposal and recommended that the limit not exceed 85 dBA. They reviewed the proposed noise standard and recommended that additional studies be undertaken to explore the efficacy of reducing the permissible level still further at some future date. The proposed revisions to the OSHA rules for occupational noise exposure were published in the *Federal Register* on October 24, 1974.

After years of collecting oral and written public testimony, which resulted in an unwieldy public record of almost 40,000 pages, OSHA promulgated revisions for the noise standard (46 *FR* 4078) in January 1981. These revisions were followed by deferrals, stays (46 *FR* 42622), further revisions, further public hearings, and a multiplicity of lawsuits, all of which culminated in the promulgation of a hearing conservation amendment (48 *FR* 9738) on March 8, 1983, with an effective date of April 7, 1983.

It was estimated by OSHA (46 *FR* 4078) that there were 2.9 million workers in American production industries who experience eight-hour noise exposures exceeding 90 dBA. An additional 2.3 million experience exposure levels in excess of 85 dBA. The Hearing Conservation Amendment (HCA) applies to all those employees with noise exposures ≥ 85 dBA except for those in oil and gas well drilling and servicing industries, which are specifically exempted. Additionally, the Amendment does not apply to those engaged in construction or agriculture, although a Construction Industry Noise Standard exists (29 *CFR* 1926.52 and 1926.101). This standard is essentially identical to paragraphs (a) and (b) of the General Industry Noise Standard.

The OSHA Noise Standard

Prior to promulgation of the HCA the existing Noise Standard (29 *CFR* 1910.95[a] and [b]) established a permissible noise-exposure level of 90 dBA for 8 hours and required the employer to reduce exposure to that level by use of feasible engineering and administrative controls. In all cases in which sound levels exceeded the permissible exposure, regardless of the use of hearing-protective devices, "a continuing, effective hearing conservation program" was required. However, the details of such a program were never mandated. Paragraphs (c) through (p) of the HCA replaced paragraph (b)(3) of 29 *CFR* 1910.95 and supplemented OSHA's definition of an "effective hearing conservation program."

Hearing Conservation Programs

An effective hearing conservation program prevents hearing impairment as a result of noise exposure on the job. In terms

of existing workers' compensation laws, an effective hearing conservation program is one that limits the amount of compensable hearing loss in the frequency range over which normal hearing is necessary for communication. It should be noted that "compensable" loss at present does not include frequencies over 4,000 Hz, although such loss impairs enjoyment of sound and may interfere with speech discrimination. In compliance with the OSHA requirements, an effective hearing conservation program must be instituted if any employee's noise exposure exceeds current limits as defined in the OSHA Noise Exposure Standard 29 *CFR* 1910.95.

All employees whose noise exposures equal or exceed an 8-hour TWA of 85 dBA must be included in a hearing conservation program comprised of five basic components: exposure monitoring, audiometric testing, hearing protection, employee training, and record keeping. Note that although the 8-hour TWA permissible exposure remains 90 dBA, a hearing conservation program becomes mandatory at an 8-hour TWA exposure of 85 dBA.

The following summary briefly discusses the required components of the hearing conservation program.

Monitoring. The HCA requires employers to monitor employee noise-exposure levels in a manner that can accurately identify employees who are exposed at or above an 8-hour TWA exposure of 85 dBA. The exposure measurement must include all noise within an 80–130-dBA range. The requirement is performance oriented and allows employers to choose the monitoring method that best suits each situation.

Employees are entitled to observe monitoring procedures, and, in addition, they must be notified of the results of exposure monitoring. However, the method used to notify employees is left to the discretion of the employer.

Employers must remonitor workers' exposures whenever changes in exposures are sufficient to require new hearing protectors or whenever employees not previously included, because they were not exposed to an 8-hour TWA of 85 dBA, are included in the program.

Instruments used for monitoring employee exposures must be calibrated to ensure that the measurements are accurate. Because calibration procedures are unique to each instrument, employers should follow the manufacturer's instructions to determine when and how extensively to calibrate.

AUDIOMETRIC TESTING

Audiometric testing not only monitors employee hearing acuity over time but also provides an opportunity for employers to educate employees about their hearing and the need to protect it. The audiometric testing program includes obtaining baseline and annual audiograms and initiating training and follow-up procedures. The audiometric testing program should indicate whether hearing loss is being prevented by the employer's hearing conservation program. Audiometric testing must be made available to all employees who have time-weighted average–exposure levels of 85 dBA. A professional (audiologist, otolaryngologist, or physician) must be responsible for the program, but need not be present when a qualified occupational hearing conservationist is actually conducting the testing. Professional responsibilities include overseeing the program and the work of the OHCs, reviewing problem audiograms, and determining whether referral is necessary. Either a professional or an OHC can conduct audiometric testing. In addition to administering audiometric tests, the tester (or the supervising professional) is also responsible for ensuring that the tests are conducted in an appropriate test environment, for seeing that the audiometer works properly, for reviewing audiograms for standard threshold shifts (as defined in the HCA), and for identifying audiograms that require further evaluation by a professional.

Audiograms. There are two types of audiograms required in the hearing conservation program: baseline and annual audiograms. The baseline audiogram is the reference audiogram against which subsequent audiograms are compared. Baseline audiograms must be provided within six months of an employee's first exposure at or above a TWA of 85 dBA. However, when employers use mobile test vans to do audiograms, they have up to one year after an employee's first exposure to workplace noise at or above a TWA of 85 dBA to obtain the baseline audiogram. Additionally, when mobile vans are used and employers are allowed to delay baseline testing for up to a year, those employees exposed to time-weighted average levels of 85 dBA or more must be issued and fitted with hearing protectors six months after their first exposure. The hearing protectors are to be worn until the baseline audiogram is obtained. Baseline audiograms taken before the effective date of the amendment are acceptable as baselines in the program if the professional supervisor determines that the audiogram is valid. The annual audiogram must be conducted within one year of the baseline. It is important to test hearing on an annual basis to identify changes in hearing acuity so that protective follow-up measures can be initiated before hearing loss progresses.

Audiogram evaluation. Annual audiograms must be routinely compared to baseline audiograms to determine whether the audiogram is accurate and whether the employee has lost hearing ability; that is, to determine whether a standard threshold shift, or STS, has occurred. An effective program depends on a uniform definition of an STS. An STS is defined in the amendment as an average shift (or loss) in either ear of 10 dB or more at the 2,000-, 3,000-, and 4,000-Hz frequencies. A method of determining an STS by computing an average was chosen because it diminishes the number of persons identified as having an STS who are later shown not to have had a significant change in hearing ability.

Example 7

An example of computing the STS is shown in Table 9–F. Considering the values for 2,000, 3,000, and 4,000 Hz, there are changes in hearing threshold of 10, 15, and 25 dB, respectively. Thus,

$$\text{STS} + \frac{(10 + 15 + 25)}{3} = \frac{50}{3} = 16.7 \text{ dB} \qquad (25)$$

Conclusion— Example 7

The STS is +16.7 dB; hearing has deteriorated; the employee must be notified in writing within 21 days; and, depending on professional discretion, the employer can elect to revise the baseline.

If an STS is identified, the employee must be fitted or refitted with adequate hearing protectors, shown how to use them, and required to wear them. In addition, employees must be notified within 21 days from the time the determination is made that their audiometric test results indicate an STS. Some employees with an STS should be referred for further testing if the professional determines that their test results are questionable or if they have an ear problem of a medical nature caused or aggravated by wearing hearing protectors. If the suspected medical problem is not thought to be related to wearing protectors, employees must merely be informed that they should see a physician. If subsequent audiometric tests show that the STS identified on a previous audiogram is not persistent, employees exposed to a TWA of less than 90 dBA can discontinue wearing hearing protectors.

A subsequent audiogram can be substituted for the original baseline audiogram if the professional supervising the program determines that the employee has experienced a persistent STS. The substituted audiogram becomes known as the revised baseline audiogram. This substitution ensures that the same shift is not repeatedly identified. The professional may also decide to revise the baseline audiogram after an improvement in hearing has occurred, which ensures that the baseline reflects actual thresholds as much as is possible. When a baseline audiogram is revised, the employer must, of course, also retain the original audiogram. To obtain valid audiograms, audiometers must be used, maintained, and calibrated according to specifications detailed in appendices C and E of the standard.

HEARING PROTECTORS

Hearing protectors must be made available to all workers exposed at or above a TWA of 85 dBA. This requirement ensures that employees have access to protectors before they experience a loss in hearing. When baseline audiograms are delayed because it is inconvenient for mobile test vans to visit the workplace more than once a year, protectors must be worn by employees for any period exceeding six months from the time they are first exposed to 8-hour average noise levels of 85 dBA or above until their baseline audiograms are obtained. The use of hearing protectors is also mandatory for employees who have experienced threshold shifts, because these workers are particularly susceptible to noise.

Table 9–F. ***Computing the Standard Threshold Shift (STS)***

Frequency (Hz)	Baseline Audiogram Threshold (dB)	Annual Audiogram Threshold (dB)	Change
500	5	5	0
1,000	5	5	0
2,000	0	10	+10
3,000	5	20	+15
4,000	10	35	+25
6,000	10	15	+5

With the help of a person who is trained in fitting hearing protectors, employees should decide which size and type protector is most suitable for their working environment. The protector selected should be comfortable to wear and offer sufficient attenuation to prevent hearing loss. Employees must be shown how to use and care for their protectors, and they must be supervised on the job to ensure that they continue to wear them correctly.

Hearing protectors must provide adequate attenuation in each employee's work environment. The employer must reevaluate the suitability of an employee's present protector whenever there is a change in working conditions that might render the hearing protector inadequate. If workplace noise levels increase, employees must be given more effective protectors. The protector must reduce the level of exposure to at least as low as 90 dBA, or to 85 dBA or below when an STS has occurred.

TRAINING

Employee training is important because when workers understand the hearing conservation program's requirements and why it is necessary to protect their hearing, they are better motivated to actively participate in the program. They are more willing to cooperate by wearing their protectors and by undergoing audiometric tests. Employees exposed to TWAs of 85 dBA and above must be trained at least annually in the following: the effects of noise; the purpose, advantages, disadvantages, and attenuation characteristics of various types of hearing protectors; the selection, fitting, and care of protectors; and the purpose and procedures of audiometric testing. Training does not have to be accomplished in one session. The program can be structured in any format, and different individuals can conduct different parts as long as the required topics are covered. For example, audiometric procedures could be discussed immediately before audiometric testing. The training requirements are such that employees must be reminded on a yearly basis that noise is hazardous to hearing, and that they can prevent damage by wearing a hearing protector, where appropriate, and by participating in audiometric testing.

Table 9–G. ***Comparison of OSHA's PEL for Noise with NIOSH/ACGIH Recommendations.***

Sound Level (dBA)	*Duration per Day (hours)*

90	8	2.5
91	7	2
94	4.6	1
95	4	47 min
97	3	30 min
100	2	15 min

Source: *Occupational Noise Exposure, Revised Criteria,* NIOSH, 1998.

RECORD KEEPING

Records of noise-exposure measurement must be kept for two years. It may be prudent, however, to keep these records for a longer time in accordance with other medical records requirements under OSHA. Records of audiometric test results must be maintained for the duration of the affected employee's employment. Audiometric test records must include the name and job classification of the employee, the date the test was performed, the examiner's name, the date of acoustic or exhaustive calibration, measurements of the background sound pressure levels in audiometric test rooms, and the employee's most recent noise-exposure measurement.

NIOSH and ACGIH Noise Exposure Guidelines

As stated above, both NIOSH and the EPA recommended to OSHA that the eight-hour TWA for noise be reduced to 85 dBA. In 1998, NIOSH issued *Occupational Noise Exposure, Revised Criteria*. In this document NIOSH revised its 1972 recommendation, going beyond attempts to conserve hearing by focusing on prevention of noise induced hearing loss. They continued to recommend an eight-hour TWA of 85 dBA. However, they recommended switching from a 5 dB exchange rate to a 3-dB exchange rate, as they believed that current scientific evidence supported this change. This 3-dB doubling rate is used by ACGIH in their TLV (see Appendix B).

NIOSH also recommended a new criterion for the definition of significant threshold shifts (STS). Instead of OSHA's definition of a STS as a 10-dB loss in either ear averaged over the frequencies of 2000, 3000, and 4000Hz, NIOSH recommended defining a STS as a 15-dB loss in either ear at any of these frequencies—500, 1,000, 2,000, 3,000, 4,000, or 6,000 Hz. This loss is as determined by two consecutive tests.

The use of Age Correction Factors, which are in the OSHA standard, Appendix F, have been dropped by NIOSH in the 1998 revised criteria. Finally, as mentioned in the previous section on NRRs, NIOSH recommended significant reductions in the NRRs of hearing protectors.

Both NIOSH and ACGIH recommend an 8-hour TWA of 85 dBA, with a 3-dB exchange rate, while OSHA's eight-hour TWA is 90 dBA with a 5-dB exchange rate. Table 9–G compares the NIOSH REL and ACGIH TLV for noise exposure with OSHA's noise standard. As the noise level increases, there are significant differences in allowable exposure between the current OSHA standard and the NIOSH/ACGIH recommendations.

SUMMARY

Because industrial noise problems are extremely complex, there is no one "standard" program that is applicable to all situations. In order to protect the hearing of employees and to avoid compensation costs, it behooves industry to consider and evaluate its noise problems and to take steps toward the establishment of effective hearing conservation procedures. The OSHA regulations require the control of noise exposures, employee protection against the effects of noise exposures, and the initiation of comprehensive and effective hearing conservation programs.

As outlined in this chapter, an effective hearing conservation program consists of the following:

- ➢ Noise measurement and analysis
- ➢ Engineering control of noise exceeding permissible levels
- ➢ Hearing protection for those employees working in areas where noise cannot be feasibly controlled
- ➢ Audiometric examinations for all employees
- ➢ Employee training
- ➢ Record keeping

The effectiveness of a hearing conservation program depends on the cooperation of employers, supervisors, employees, and others concerned. Management's responsibility in this type of program includes taking noise measurements, initiating noise-control measures, undertaking the audiometric testing of employees, providing hearing-protective equipment where it is required, enforcing the use of such protective equipment with sound policies and by example, and informing employees of the benefits to be derived from a hearing conservation program.

It is the employee's responsibility to make proper use of the protective equipment provided by management. It is also the employee's responsibility to observe any rules or regulations in the use of equipment designed to minimize noise exposure.

Detailed references to noise and its management, effects, and control can be found in a great many books and periodicals. For those companies needing assistance in establishing hearing conservation programs, consultation services are available in a number of professional areas through private consultation, insurance, and governmental groups.

1910.95—OCCUPATIONAL NOISE EXPOSURE

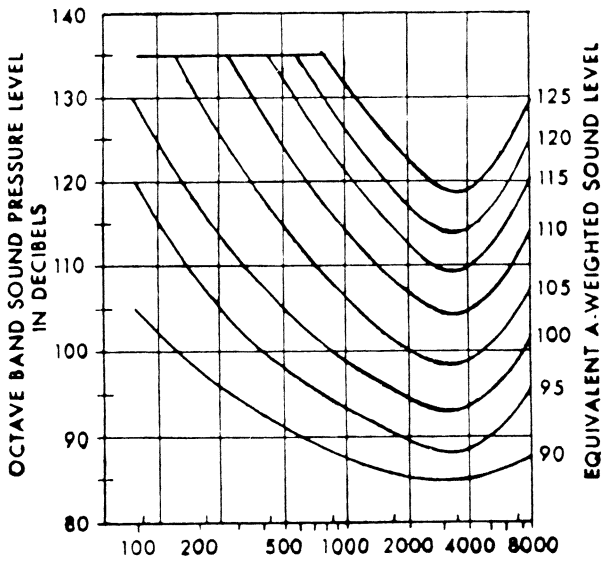
(a) Protection against the effects of noise exposure shall be provided when the sound levels exceed those shown in Table G–16 when measured on the A scale of a standard sound level meter at slow response. When noise levels are determined by octave band analysis, the equivalent A-weighted sound level may be determined as follows:

TABLE G–16—PERMISSIBLE NOISE EXPOSURES [1]

Duration per day, hours	*Sound level dBA slow response*
8	90
6	92
4	95
3	97
2	100
1½	102
1	105
½	110
¼ or less	115

[1]When the daily noise exposure is composed of two or more periods of noise exposure of different levels, their combined effect should be considered, rather than the individual effect of each. If the sum of the following fractions: $C_1/T_1 + C_2/T_2 \ldots C_n/T_n$ exceeds unity, then, the mixed exposure should be considered to exceed the limit value. C_n indicates the total time of exposure at a specified noise level, and T_n indicates the total time of exposure permitted at that level.

Figure G-9



Equivalent sound level contours. Octave band sound pressure levels may be converted to the equivalent A-weighted sound level by plotting them on this graph and noting the A-weighted sound level corresponding to the point of highest penetration into the sound level contours. This equivalent A-weighted sound level, which may differ from the actual A-weighted sound level of the noise, is used to determine exposure limits from Table G–16.

(b)

(1) When employees are subjected to sound exceeding those listed in Table G–16, feasible administrative or engineering controls shall be utilized. If such controls fail to reduce sound levels within the levels of Table G–16, personal protective equipment shall be provided and used to reduce sound levels within the levels of the table.

Exposure to impulsive or impact noise should not exceed 140 dB peak sound pressure level.

(2) If the variations in noise level involve maxima at intervals of 1 second or less, it is to be considered continuous.

(c) Hearing conservation program.

(1) The employer shall administer a continuing, effective hearing conservation program, as described in paragraphs (c) through (o) of this section, whenever employee noise exposures equal or exceed an 8-hour time-weighted average sound level (TWA) of 85 decibels measured on the A scale (slow response) or, equivalently, a dose of fifty percent. For purposes of the hearing conservation program, employee noise exposures shall be computed in accordance with Appendix A and Table G–16a, and without regard to any attenuation provided by the use of personal protective equipment.

(2) For purposes of paragraphs (c) through (n) of this section, an 8-hour time-weighted average of 85 decibels or a dose of fifty percent shall also be referred to as the action level.

(d) Monitoring.

(1) When information indicates that any employee's exposure may equal or exceed an 8-

hour time-weighted average of 85 decibels, the employer shall develop and implement a monitoring program.

(i) The sampling strategy shall be designed to identify employees for inclusion in the hearing conservation program and to enable the proper selection of hearing protectors.

(ii) Where circumstances such as high worker mobility, significant variations in sound level, or a significant component of impulse noise make area monitoring generally inappropriate, the employer shall use representative personal sampling to comply with the monitoring requirements of this paragraph unless the employer can show that area sampling produces equivalent results.

(2)

(i) All continuous, intermittent and impulsive sound levels from 80 decibels to 130 decibels shall be integrated into the noise measurements.

(ii) Instruments used to measure employee noise exposure shall be calibrated to ensure measurement accuracy.

(3) Monitoring shall be repeated whenever a change in production, process, equipment or controls increases noise exposures to the extent that:

(i) Additional employees may be exposed at or above the action level; or

(ii) The attenuation provided by hearing protectors being used by employees may be rendered inadequate to meet the requirements of paragraph (j) of this section.

(e) Employee notification. The employer shall notify each employee exposed at or above an 8-hour time-weighted average of 85 decibels of the results of the monitoring.

(f) Observation of monitoring. The employer shall provide affected employees or their representatives with an opportunity to observe any noise measurements conducted pursuant to this section.

(g) Audiometric testing program.

(1) The employer shall establish and maintain an audiometric testing program as provided in this paragraph by making audiometric testing available to all employees whose exposures equal or exceed an 8-hour time-weighted average of 85 decibels.

(2) The program shall be provided at no cost to employees.

(3) Audiometric tests shall be performed by a licensed or certified audiologist, otolaryngologist, or other physician, or by a technician who is certified by the Council of Accreditation in Occupational Hearing Conservation, or who has satisfactorily demonstrated competence in administering audiometric examinations, obtaining valid audiograms, and properly using, maintaining and checking calibration and proper functioning of the audiometers being used. A technician who operates microprocessor audiometers does not need to be certified. A technician who performs audiometric tests must be responsible to an audiologist, otolaryngologist or physician.

(4) All audiograms obtained pursuant to this section shall meet the requirements of Appendix C: *Audiometric Measuring Instruments.*

(5) Baseline audiogram.

(i) Within 6 months of an employee's first exposure at or above the action level, the employer shall establish a valid baseline audiogram against which subsequent audiograms can be compared.

(ii) **Mobile test van exception.** Where mobile test vans are used to meet the audiometric testing obligations, the employer shall obtain a valid baseline audiogram within 1 year of an employee's first exposure at or above the action level. Where baseline audiograms are obtained more than 6 months after the employee's first exposure at or above the action level, employees shall wear hearing protectors for any period exceeding six months after first exposure until the baseline audiogram is obtained.

(iii) Testing to establish a baseline audiogram shall be preceded by at least 14 hours without exposure to workplace noise. Hearing protectors may be used as a substitute for the requirement that baseline audiograms be preceded by 14 hours without exposure to workplace noise.

(iv) The employer shall notify employees of the need to avoid high levels of non-occupa-

tional noise exposure during the 14-hour period immediately preceding the audiometric examination.

(6) Annual audiogram. At least annually after obtaining the baseline audiogram, the employer shall obtain a new audiogram for each employee exposed at or above an 8-hour time-weighted average of 85 decibels.

(7) Evaluation of audiogram.

(i) Each employee's annual audiogram shall be compared to that employee's baseline audiogram to determine if the audiogram is valid and if a standard threshold shift as defined in paragraph (g)(10) of this section has occurred. This comparison may be done by a technician.

(ii) If the annual audiogram shows that an employee has suffered a standard threshold shift, the employer may obtain a retest within 30 days and consider the results of the retest as the annual audiogram.

(iii) The audiologist, otolaryngologist, or physician shall review problem audiograms and shall determine whether there is a need for further evaluation. The employer shall provide to the person performing this evaluation the following information:

(a) A copy of the requirements for hearing conservation as set forth in paragraphs (c) through (n) of this section;

(b) The baseline audiogram and most recent audiogram of the employee to be evaluated;

(c) Measurements of background sound pressure levels in the audiometric test room as required in Appendix D: Audiometric Test Rooms.

(d) Records of audiometer calibrations required by paragraph (h)(5) of this section.

(8) Follow-up procedures.

(i) If a comparison of the annual audiogram to the baseline audiogram indicates a standard threshold shift as defined in paragraph (g)(10) of this section has occurred, the employee shall be informed of this fact in writing, within 21 days of the determination.

(ii) Unless a physician determines that the standard threshold shift is not work related or aggravated by occupational noise exposure, the employer shall ensure that the following steps are taken when a standard threshold shift occurs:

(a) Employees not using hearing protectors shall be fitted with hearing protectors, trained in their use and care, and required to use them.

(b) Employees already using hearing protectors shall be refitted and retained in the use of hearing protectors and provided with hearing protectors offering greater attenuation if necessary.

(c) The employee shall be referred for a clinical audiological evaluation or an otological examination, as appropriate, if additional testing is necessary or if the employer suspects that a medical pathology of the ear is caused or aggravated by the wearing of hearing protectors.

(d) The employee is informed of the need for an otological examination if a medical pathology of the ear that is unrelated to the use of hearing protectors is suspected.

(iii) If subsequent audiometric testing of an employee whose exposure to noise is less than an 8-hour TWA of 90 decibels indicates that a standard threshold shift is not persistent, the employer:

(a) Shall inform the employee of the new audiometric interpretation; and

(b) May discontinue the required use of hearing protectors for that employee.

(9) Revised baseline. An annual audiogram may be substituted for the baseline audiogram when, in the judgment of the audiologist, otolaryngologist or physician who is evaluating the audiogram:

(i) The standard threshold shift revealed by the audiogram is persistent; or

(ii) The hearing threshold shown in the annual audiogram indicates significant improvement over the baseline audiogram.

(10) Standard threshold shift.

(i) As used in this section, a standard threshold shift is a change in hearing threshold relative to the baseline audiogram of an average of 10 dB or more at 2000, 3000, and 4000 Hz in either ear.

(ii) In determining whether a standard threshold shift has occurred, allowance may be made for the contribution of aging (presbycusis) to the change in hearing level by correcting the annual audiogram according to the procedure described in Appendix F: *Calculation and Application of Age Correction to Audiograms.*

(h) Audiometric test requirements.

(1) Audiometric tests shall be pure tone, air conduction, hearing threshold examinations, with test frequencies including as a minimum 500, 1000, 2000, 3000, 4000, and 6000 Hz. Tests at each frequency shall be taken separately for each ear.

(2) Audiometric tests shall be conducted with audiometers (including microprocessor audiometers) that meet the specifications of, and are maintained and used in accordance with, American National Standard Specification for Audiometers, S3.6-1969.

(3) Pulsed-tone and self-recording audiometers, if used, shall meet the requirements specified in Appendix C: *Audiometric Measuring Instruments.*

(4) Audiometric examinations shall be administered in a room meeting the requirements listed in Appendix D: *Audiometric Test Rooms.*

(5) Audiometer calibration.

(i) The functional operation of the audiometer shall be checked before each day's use by testing a person with known, stable hearing thresholds, and by listening to the audiometer's output to make sure that the output is free from distorted or unwanted sounds. Deviations of 10 decibels or greater require an acoustic calibration.

(ii) Audiometer calibration shall be checked acoustically at least annually in accordance with Appendix E: *Acoustic Calibration of Audiometers.* Test frequencies below 500 Hz and above 6000 Hz may be omitted from this check. Deviations of 15 decibels or greater require an exhaustive calibration.

(iii) An exhaustive calibration shall be performed at least every two years in accordance with sections 4.1.2; 4.1.3.; 4.1.4.3; 4.2; 4.4.1; 4.4.2; 4.4.3; and 4.5 of the American National Standard Specification for Audiometers, S3.6-1969. Test frequencies below 500 Hz and above 6000 Hz may be omitted from this calibration.

(i) Hearing protectors.

(1) Employers shall make hearing protectors available to all employees exposed to an 8-hour time-weighted average of 85 decibels or greater at no cost to the employees. Hearing protectors shall be replaced as necessary.

(2) Employers shall ensure that hearing protectors are worn:

(i) By an employee who is required by paragraph (b)(1) of this section to wear personal protective equipment; and

(ii) By any employee who is exposed to an 8-hour time-weighted average of 85 decibels or greater, and who:

(a) Has not yet had a baseline audiogram established pursuant to paragraph (g)(5)(ii); or

(b) Has experienced a standard threshold shift.

(3) Employees shall be given the opportunity to select their hearing protectors from a variety of suitable hearing protectors provided by the employer.

(4) The employer shall provide training in the use and care of all hearing protectors provided to employees.

(5) The employer shall ensure proper initial fitting and supervise the correct use of all hearing protectors.

(j) Hearing protector attenuation.

(1) The employer shall evaluate hearing protector attenuation for the specific noise environments in which the protector will be used. The employer shall use one of the evaluation methods described in Appendix B: *Methods for Estimating the Adequacy of Hearing Protection Attenuation.*

(2) Hearing protectors must attenuate employee exposure at least to an 8-hour time-weighted average of 90 decibels as required by paragraph (b) of this section.

(3) For employees who have experienced a standard threshold shift, hearing protectors must attenuate employee exposure to an 8-hour time-weighted average of 85 decibels or below.

(4) The adequacy of hearing protector attenuation shall be re-evaluated whenever employee noise exposures increase to the extent that the hearing protectors provided may no longer provide adequate attenuation. The employee shall provide more effective hearing protectors where necessary.

(k) Training program.

(1) The employer shall institute a training program for all employees who are exposed to noise at or above an 8-hour time-weighted average of 85 decibels, and shall ensure employee participation in such program.

(2) The training program shall be repeated annually for each employee included in the hearing conservation program. Information provided in the training program shall be updated to be consistent with changes in protective equipment and work processes.

(3) The employer shall ensure that each employee is informed of the following:

(i) The effects of noise on hearing;

(ii) The purpose of hearing protectors, the advantages, disadvantages, and attenuation of various types, and instructions on selection, fitting, use, and care; and

(iii) The purpose of audiometric testing, and an explanation of the test procedures.

(l) Access to information and training materials.

(1) The employer shall make available to affected employees or their representatives copies of this standard and shall also post a copy in the workplace.

(2) The employer shall provide to affected employees any informational materials pertaining to the standard that are supplied to the employer by the Assistant Secretary.

(3) The employer shall provide, upon request, all materials related to the employer's training and education program pertaining to this standard to the Assistant Secretary and the Director.

(m) Recordkeeping.

(1) **Exposure measurements.** The employer shall maintain an accurate record of all employee exposure measurements required by paragraph (d) of this section.

(2) **Audiometric tests.**

(i) The employer shall retain all employee audiometric test records obtained pursuant to paragraph (g) of this section:

(ii) This record shall include:

(a) Name and job classification of the employee;

(b) Date of the audiogram;

(c) The examiner's name;

(d) Date of the last acoustic or exhaustive calibration of the audiometer; and

(e) Employee's most recent noise exposure assessment.

(f) The employer shall maintain accurate records of the measurements of the background sound pressure levels in audiometric test rooms.

(3) **Record retention.** The employer shall retain records required in this paragraph (m) for at least the following periods.

(i) Noise exposure measurement records shall be retained for two years.

(ii) Audiometric test records shall be retained for the duration of the affected employee's employment.

(4) **Access to records.** All records required by this section shall be provided upon request to employees, former employees, representatives designated by the individual employee, and the Assistant Secretary. The provisions of 29 CFR 1910.20(a)-(e) and (g)-(i) apply to access to records under this section.

(5) Transfer of records. If the employer ceases to do business, the employer shall transfer to the successor employer all records required to be maintained by this section, and the successor employer shall retain them for the remainder of the period prescribed in paragraph (m)(3) of this section.

(n) Appendices.

(1) Appendices A, B, C, D, and E to this section are incorporated as part of this section and the contents of these Appendices are mandatory.

(2) Appendices F and G to this section are informational and are not intended to create any additional obligations not otherwise imposed or to detract from any existing obligations.

(o) Exemptions. Paragraphs (c) through (n) of this section shall not apply to employers engaged in oil and gas well drilling and servicing operations.

(p) Startup date. Baseline audiograms required by paragraph (g) of this section shall be completed by March 1, 1984.

APPENDIX A: NOISE EXPOSURE COMPUTATION

This Appendix is Mandatory

I. Computation of Employee Noise Exposure

(1) Noise dose is computed using Table G-16a as follows:

(i) When the sound level, L, is constant over the entire work shift, the noise dose, D, in percent, is given by: D=100 C/T where C is the total length of the work day, in hours, and T is the reference duration corresponding to the measured sound level, L, as given in Table G-16a or by the formula shown as a footnote to that table.

(ii) When the workshift noise exposure is composed of two or more periods of noise at different levels, the total noise dose over the work day is given by:
$D=100\,(C_1/T_1+C_2/T_2+\ldots+C_n/T_n)$,
where C_n indicates the total time of exposure at a specific noise level, and T_n indicates the reference duration for that level as given by Table G-16a.

(2) The eight-hour time-weighted average sound level (TWA), in decibels, may be computed from the dose, in percent, by means of the formula: $TWA=16.61\log_{10}(D/100)+90$. For an eight-hour workshift with the noise level constant over the entire shift, the TWA is equal to the measured sound level.

(3) A table relating dose and TWA is given in Section II.

TABLE G-16A

A-weighted sound level, L (decibel)	Reference duration, T (hour)
80	32
81	27.9
82	24.3
83	21.1
84	16.4
85	16
86	13.9
87	12.1
88	10.6
89	9.2
90	8
91	7.0
92	6.1
93	5.3
94	4.6
95	4
96	3.5
97	3.0
98	2.6
99	2.3
100	2
101	1.7
102	1.5
103	1.3
104	1.1
105	1
106	0.87
107	0.76
108	0.66
109	0.57
110	0.5
111	0.44
112	0.38
113	0.33
114	0.29
115	0.25
116	*0.22*
117	*0.19*
118	*0.16*
119	*0.14*
120	*0.125*
121	*0.11*
122	*0.095*
123	*0.082*
124	*0.072*
125	*0.063*
126	*0.054*
127	*0.047*
128	*0.041*
129	*0.036*
130	*0.031*

In the above table the reference duration, T, is computed by

$$T=\frac{8}{2^{(L-90)/5}}$$

where L is the measured A-weighted sound level.

II. Conversion Between "Dose" and "8-Hour Time-Weighted Average" Sound Level

Compliance with paragraphs (c)-(r) of this regulation is determined by the amount of exposure to noise in the workplace. The amount of such exposure is usually measured with an audiodosimeter which gives a readout in terms of "dose." In order to better understand the requirements of the amendment, dosimeter readings can be converted to an "8-hour time-weighted average sound level." (TWA).

In order to convert the reading of a dosimeter into TWA, see Table A-1, below. This table applies to dosimeters that are set by the manufacturer to calculate dose or percent exposure according to the relationships in Table G-16a. So, for example, a dose of 91 percent over an eight hour day results in a TWA of 89.3 dB, and, a dose of 50 percent corresponds to a TWA of 85 dB.

If the dose as read on the dosimeter is less than or greater than the values found in Table A-1, the TWA may be calculated by using the formula: $TWA = 16.61 \log_{10} (D/100) + 90$ where TWA = 8-hour time-weighted average sound level and D = accumulated dose in percent exposure.

Table A-1.—Conversion From "Percent Noise Exposure" or "Dose" to "8-Hour Time-Weighted Average Sound Level" (TWA)

APPENDIX B: METHODS FOR ESTIMATING THE ADEQUACY OF HEARING PROTECTOR ATTENUATION

This Appendix is Mandatory

For employees who have experienced a significant threshold shift, hearing protector attenuation must be sufficient to reduce employee exposure to a TWA of 85 dB. Employers must select one of the following methods by which to estimate the adequacy of hearing protector attenuation.

The most convenient method is the Noise Reduction Rating (NRR) developed by the Environmental Protection Agency (EPA). According to EPA regulation, the NRR must be shown on the hearing protector package. The NRR is then related to an individual worker's noise environment in order to assess the adequacy of the attenuation of a given hearing protector. This Appendix describes four methods of using the NRR to determine whether a particular hearing protector provides adequate protection within a given exposure environment. Selection among the four procedures is dependent upon the employer's noise measuring instruments.

Instead of using the NRR, employers may evaluate the adequacy of hearing protector attenuation by using one of the three methods developed by the National Institute for Occupational Safety and Health (NIOSH), which are described in the "List of Personal Hearing Protectors and Attenuation Data," HEW Publication No. 76-120, 1975, pages 21-37. These methods are known as NIOSH methods #1, #2 and #3. The NRR described below is a simplification of NIOSH method #2. The most complex method is NIOSH method #1, which is probably the most accurate method since it uses the largest amount of spectral information from the individual employee's noise environment. As in the case of the NRR method described below, if one of the NIOSH methods is used, the selected method must be applied to an individual's noise environment to assess the adequacy of the attenuation. Employers should be careful to take a sufficient number of measurements in order to achieve a representative sample for each time segment.

Note.—The employer must remember that calculated attenuation values reflect realistic values only to the extent that the protectors are properly fitted and worn.

When using the NRR to assess hearing protector adequacy, one of the following methods must be used:

(i) When using a dosimeter that is capable of C-weighted measurements:

(A) Obtain the employee's C-weighted dose for the entire workshift, and convert to TWA (see Appendix A, II).

(B) Subtract the NRR from the C-weighted TWA to obtain the estimated A-weighted TWA under the ear protector.

(ii) When using a dosimeter that is not capable of C-weighted measurements, the following method may be used:

(A) Convert the A-weighted dose to TWA (see Appendix A).

(B) Subtract 7 dB from the NRR.

(C) Subtract the remainder from the A-weighted TWA to obtain the estimated A-weighted TWA under the ear protector.

(iii) When using a sound level meter set to the A-weighting network:

(A) Obtain the employee's A-weighted TWA.

(B) Subtract 7 dB from the NRR, and subtract the remainder from the A-weighted TWA to obtain the estimated A-weighted TWA under the ear protector.

(iv) When using a sound level meter set on the C-weighting network:

(A) Obtain a representative sample of the C-weighted sound levels in the employee's environment.

(B) Subtract the NRR from the C-weighted average sound level to obtain the estimated A-weighted TWA under the ear protector.

(v) When using area monitoring procedures and a sound level meter set to the A-weighing network.

(A) Obtain a representative sound level for the area in question.

(B) Subtract 7 dB from the NRR and subtract the remainder from the A-weighted sound level for that area.

(vi) When using area monitoring procedures and a sound level meter set to the C-weighting network:

(A) Obtain a representative sound level for the area in question.

(B) Subtract the NRR from the C-weighted sound level for that area.

APPENDIX C: AUDIOMETRIC MEASURING INSTRUMENTS

This Appendix is Mandatory

1. In the event that pulsed-tone audiometers are used, they shall have a tone on-time of at least 200 milliseconds.

2. Self-recording audiometers shall comply with the following requirements:

(A) The chart upon which the audiogram is traced shall have lines at positions corresponding to all multiples of 10 dB hearing level within the intensity range spanned by the audiometer. The lines shall be equally spaced and shall be separated by at least ¼ inch. Additional increments are optional. The audiogram pen tracings shall not exceed 2 dB in width.

(B) It shall be possible to set the stylus manually at the 10-dB increment lines for calibration purposes.

(C) The slewing rate for the audiometer attenuator shall not be more than 6 dB/sec except that an initial slewing rate greater than 6 dB/sec is permitted at the beginning of each new test frequency, but only until the second subject response.

(D) The audiometer shall remain at each required test frequency for 30 seconds (±3 seconds). The audiogram shall be clearly marked at each change of frequency and the actual frequency change of the audiometer shall not deviate from the frequency boundaries marked on the audiogram by more than ±3 seconds.

(E) It must be possible at each test frequency to place a horizontal line segment parallel to the time axis on the audiogram, such that the audiometric tracing crosses the line segment at least six times at that test frequency. At each test frequency the threshold shall be the average of the midpoints of the tracing excursions.

APPENDIX D: AUDIOMETRIC TEST ROOMS

This Appendix is Mandatory

Rooms used for audiometric testing shall not have background sound pressure levels exceeding those in Table D-1 when measured by equipment conforming at least to the Type 2 requirements of American National Standard Specification for Sound Level Meters, S1.4-1971 (R1976), and to the Class II requirements of American National Standard Specification for Octave, Half-Octave, and Third-Octave Band Filter Sets, S1.11-1971 (R1976).

Table D-1.—Maximum Allowable Octave-Band Sound Pressure Levels for Audiometric Test Rooms

Octave-band center frequency (Hz)	500	1000	2000	4000	8000
Sound pressure level (dB)	40	40	47	57	62

APPENDIX E: ACOUSTIC CALIBRATION OF AUDIOMETERS

This Appendix is Mandatory

Audiometer calibration shall be checked acoustically, at least annually, according to the procedures described in this Appendix. The equipment necessary to perform these measurments is a sound level meter, octave-band filter set, and a National Bureau of Standards 9A coupler. In making these measurements, the accuracy of the calibrating equipment shall be sufficient to determine that the audiometer is within the tolerances permitted by American Standard Specification for Audiometers, S3.6-1969.

(1) Sound Pressure Output Check

A. Place the earphone coupler over the microphone of the sound level meter and place the earphone on the coupler.

B. Set the audiometer's hearing threshold level (HTL) dial to 70 dB.

C. Measure the sound pressure level of the tones that each test frequency from 500 Hz through 6000 Hz for each earphone.

D. At each frequency the readout on the sound level meter should correspond to the levels in Table E-1 or Table E-2, as appropriate, for the type of earphone, in the column entitled "sound level meter reading."

(2) Linearity Check

A. With the earphone in place, set the frequency to 1000 Hz and the HTL dial on the audiometer to 70 dB.

B. Measure the sound levels in the coupler at each 10-dB decrement from 70 dB to 10 dB, noting the sound level meter reading at each setting.

C. For each 10-dB decrement on the audiometer the sound level meter should indicate a corresponding 10 dB decrease.

D. This measurement may be made electrically with a voltmeter connected to the earphone terminals.

(3) Tolerances

When any of the measured sound levels deviate from the levels in Table E-1 or Table E-2 by ±3 dB at any test frequency between 500 and 3000 Hz, 4 dB at 4000 Hz, or 5 dB at 6000 Hz, an exhaustive calibration is advised. An exhaustive calibration is required if the deviations are greater than 10 dB at any test frequency.

Table E-1.—Reference Threshold Levels for Telephonics—TDH-39 Earphones

Frequency, Hz	Reference threshold level for TDH-39 earphones, dB	Sound level meter reading, dB
500	11.5	81.5
1000	7	77
2000	9	79
3000	10	80
4000	9.5	79.5
6000	15.5	85.5

Table E-2.—Reference Threshold Levels for Telephonics—TDH-49 Earphones

Frequency, Hz	Reference threshold level for TDH-49 earphones, dB	Sound level meter reading, dB
500	13.5	83.5
1000	7.5	77.5
2000	11	81.0
3000	9.5	79.5
4000	10.5	80.5
6000	13.5	83.5

APPENDIX F: CALCULATIONS AND APPLICATION OF AGE CORRECTIONS TO AUDIOGRAMS

This Appendix is Non-Mandatory

In determining whether a standard threshold shift has occurred, allowance may be made for the contribution of aging to the change in hearing level by adjusting the most recent audiogram. If the employer chooses to adjust the audiogram, the employer shall follow the procedure described below. This procedure and the age correction tables were developed by the National Institute for Occupational Safety and Health in the criteria document entitled "Criteria for a Recommended Standard ... Occpational Exposure to Noise," ((HSM)-11001).

For each audiometric test frequency;

(I) Determine from Tables F-1 or F-2 the age correction values for the employee by:

(A) Finding the age at which the most recent audiogram was taken and recording the corresponding values of age corrections at 1000 Hz through 6000 Hz;

(B) Finding the age at which the baseline audiogram was taken and recording the corresponding values of age corrections at 1000 Hz through 6000 Hz.

(II) Subtract the values found in step (i)(A) from the value found in step (i)(B).

(III) The differences calculated in step (ii) represented that portion of the change in hearing that may be due to aging.

Example: Employee is a 32-year-old male. The audiometric history for his right ear is shown in decibels below.

	Audiometric test frequency (Hz)				
Employee's age	1000	2000	3000	4000	6000
26	10	5	5	10	5
*27	0	0	0	5	5
28	0	0	0	10	5
29	5	0	5	15	5
30	0	5	10	20	10
31	5	10	20	15	15
*32	5	10	10	25	20

The audiogram at age 27 is considered the baseline since it shows the best hearing threshold levels. Asterisks have been used to identify the baseline and most recent audiogram. A threshold shift of 20 dB exists at 4000 Hz between the audiograms taken at ages 27 and 32.

(The threshold shift is computed by subtracting the hearing threshold at age 27, which was 5, from the hearing threshold at age 32, which is 25). A retest audiogram has confirmed this shift. The contribution of aging to this change in hearing may be estimated in the following manner:

Go to Table F-1 and find the age correction values (in dB) for 4000 Hz at age 27 and age 32.

	Frequency (Hz)				
	1000	2000	3000	4000	6000
Age 32	6	5	7	10	14
Age 27	5	4	6	7	11
Difference	1	1	1	3	3

The difference represents the amount of hearing loss that may be attributed to aging in the time period between the baseline audiogram and the most recent audiogram. In this example, the difference at 4000 Hz is 3 dB. This value is subtracted from the hearing level at 4000 Hz, which in the most recent audiogram is 25, yielding 22 after adjustment. Then the hearing threshold in the baseline audiogram at 4000 Hz (5) is subtracted from the adjusted annual audiogram hearing threshold at 4000 Hz (22). Thus the age-corrected threshold shift would be 17 dB (as opposed to a threshold shift of 20 dB without age correction).

Table F-1.—Age Correction Values In Decibels For Males

APPENDIX G: MONITORING NOISE LEVELS NON-MANDATORY INFORMATIONAL APPENDIX

This appendix provides information to help employers comply with the noise monitoring obligations that are part of the hearing conservation amendment.

What is the purpose of noise monitoring?

This revised amendment requires that employees be placed in a hearing conservation program if they are exposed to average noise levels of 85 dB or greater during an 8 hour workday. In order to determine if exposures are at or above this level, it may be necessary to measure or monitor the actual noise levels in the workplace and to estimate the noise exposure or "dose" received by employees during the workday.

When is it necessary to implement a noise monitoring program?

It is not necessary for every employer to measure workplace noise. Noise monitoring or measuring must be conducted only when exposures are at or above 85 dB. Factors which suggest that noise exposures in the workplace may be at this level include employee complaints about the loudness of noise, indications that employees are losing their hearing,

or noisy conditions which make normal conversation difficult. The employer should also consider any information available regarding noise emitted from specific machines. In addition, actual workplace noise measurements can suggest whether or not a monitoring program should be initiated.

How is noise measured?

Basically, there are two different instruments to measure noise exposures: the sound level meter and the dosimeter. A sound level meter is a device that measures the intensity of sound at a given moment. Since sound level meters provide a measure of sound intensity at only one point in time, it is generally necessary to take a number of measurements at different times during the day to estimate noise exposure over a workday. If noise levels fluctuate, the amount of time noise remains at each of the various measured levels must be determined.

To estimate employee noise exposures with a sound level meter it is also generally necessary to take several measurements at different locations within the workplace. After appropriate sound level meter readings are obtained, people sometimes draw "maps" of the sound levels within different areas of the workplace. By using a sound level "map" and information on employee locations throughout the day, estimates of individual exposure levels can be developed. This measurement method is generally referred to as *area* noise monitoring.

A dosimeter is like a sound level meter except that it stores sound level measurements and integrates these measurements over time, providing an average noise exposure reading for a given period of time, such as an 8-hour workday. With a dosimeter, a microphone is attached to the employee's clothing and the exposure measurement is simply read at the end of the desired time period. A reader may be used to read-out the dosimeter's measurements. Since the dosimeter is worn by the employee, it measures noise levels in those locations in which the employee travels. A sound level meter can also be positioned within the immediate vicinity of the exposed worker to obtain an individual exposure estimate. Such procedures are generally referred to as *personal* noise monitoring.

Area monitoring can be used to estimate noise exposure when the noise levels are relatively constant and employees are not mobile. In workplaces where employees move about in different areas or where the noise intensity tends to fluctuate over time, noise exposure is generally more accurately estimated by the personal monitoring approach.

In situations where personal monitoring is appropriate, proper positioning of the microphone is necessary to obtain accurate measurements. With a dosimeter, the microphone is generally located on the shoulder and remains in that position for the entire workday. With a sound level meter, the microphone is stationed near the employee's head, and the instrument is usually held by an individual who follows the employee as he or she moves about.

Manufacturer's instructions, contained in dosimeter and sound level meter operating manuals, should be followed for calibration and maintenance. To ensure accurate results, it is considered good professional practice to calibrate instruments before and after each use.

How often is it necessary to monitor noise levels?

The amendment requires that when there are significant changes in machinery or production processes that may result in increased noise levels, remonitoring must be conducted to determine whether additional employees need to be included in the hearing conservation program. Many companies choose to remonitor periodically (once every year or two) to ensure that all exposed employees are included in their hearing conservation programs.

Where can equipment and technical advice be obtained?

Noise monitoring equipment may be either purchased or rented. Sound level meters cost about $500 to $1,000, while dosimeters range in price from about $750 to $1,500. Smaller companies may find it more economical to rent equipment rather than to purchase it. Names of equipment suppliers may be found in the telephone book (Yellow Pages) under headings such as: "Safety Equipment," "Industrial Hygiene," or "Engineers-Acoustical." In addition to providing information on obtaining noise monitoring equipment, many companies and individuals included under such listings can provide professional advice on how to conduct a valid noise monitoring program. Some audiological testing firms and industrial hygiene firms also provide noise monitoring services. Universities with audiology, industrial hygiene, or acoustical engineering departments may also provide information or may be able to help employers meet their obligations under this amendment.

Free, on-site assistance may be obtained from OSHA-supported state and private consultation organizations. These safety and health consultative entities generally give priority to the needs of small businesses. See the attached directory for a listing of organizations to contact for aid.

APPENDIX H: AVAILABILITY OF REFERENCED DOCUMENTS

Paragraphs (c) through (o) of 29 CFR 1910.95 and the accompanying appendices contain provisions which incorporate publications by reference. Generally, the publications provide criteria for instruments to be used in monitoring and audiometric testing. These criteria are intended to be mandatory when so indicated in the applicable paragraphs of Section 1910.95 and appendices.

It should be noted that OSHA does not require that employers purchase a copy of the referenced publications. Employers, however, may desire to obtain a copy of the referenced publications for their own information.

The designation of the paragraph of the standard in which the referenced publications appear, the titles of the publications, and the availability of the publication are as follows:

Paragraph designation	Referenced publication	Available from—
Appendix B	"List of Personal Hearing Protectors and Attenuation Data," HEW Pub. No. 76-120, 1975, NTIS-PB267461.	National Technical Information Service, Port Royal Road, Springfield, VA 22161.
Appendix D	"Specification for Sound Level Meters," S1.4-1971 (R1976).	American National Standards Institute, Inc., 1430 Broadway, New York, NY 10018.
§1910.95(k)(2), appendix E	"Specifications for Audiometers," S3.6-1969.	American National Standards Institute, Inc., 1430 Broadway, New York, NY 10018.
Appendix D	"Specification for Octave, Half-Octave and Third-Octave Band Filter Sets," S1.11-1971 (R1976).	Back Numbers Department, Dept. STD, American Institute of Physics, 333 E. 45 St., New York, NY 10017; American National Standards Institute, Inc., 1430 Broadway, New York, NY 10018.

The referenced publications (or a microfiche of the publications) are available for review at many universities and public libraries throughout the country. These publications may also be examined at the OSHA Technical Data Center, Room N2439, United States Department of Labor, 200 Constitution Avenue, NW., Washington, D.C. 20210, (202) 523-9700 or at any OSHA Regional Office (see telephone directories under United States Government—Labor Department).

APPENDIX I: DEFINITIONS

These definitions apply to the following terms as used in paragraphs (c) through (n) of 29 CFR 1910.95.

Action level—An 8-hour time-weighted average of 85 decibels measured on the A-scale, slow response, or equivalently, a dose of fifty percent.

Audiogram—A chart, graph, or table resulting from an audiometric test showing an individual's hearing threshold levels as a function of frequency.

Audiologist—A professional, specializing in the study and rehabilitation of hearing, who is certified by the American Speech-Language-Hearing Association or licensed by a state board of examiners.

Baseline audiogram—The audiogram against which future audiograms are compared.

Criterion sound level—A sound level of 90 decibels.

Decibel (dB)—Unit of measurement of sound level.

Hertz (Hz)—Unit of measurement of frequency, numerically equal to cycles per second.

Medical pathology—A disorder or disease. For purposes of this regulation, a condition or disease affecting the ear, which should be treated by a physician specialist.

Noise dose—The ratio, expressed as a percentage, of (1) the time integral, over a stated time or event, of the 0.6 power of the measured SLOW exponential time-averaged, squared A-weighted sound pressure and (2) the product of the criterion duration (8 hours) and the 0.6 power of the squared sound pressure corresponding to the criterion sound level (90 dB).

Noise dosimeter—An instrument that integrates a function of sound pressure over a period of time in such a manner that it directly indicates a noise dose.

Otolaryngologist—A physician specializing in diagnosis and treatment of disorders of the ear, nose and throat.

Representative exposure—Measurements of an employee's noise dose or 8-hour time-weighted average sound level that the employers deem to be representative of the exposures of other employees in the workplace.

Sound level—Ten times the common logarithm of the ratio of the square of the measured A-weighted sound pressure to the square of the standard reference pressure of 20 micropascals. Unit: decibels (dB). For use with this regulation, SLOW time response, in accordance with ANSI S1.4-1971 (R1976), is required.

South level meter—An instrument for the measurement of sound level.

Time-weighted average sound level—That sound level, which if constant over an 8-hour exposure, would result in the same noise dose as is measured.

Chapter 10

Ionizing Radiation

by C. Lyle Cheever, MS, MBA

This chapter presents the basic concepts of ionizing radiation and safe handling of radioactive materials to provide the framework within which the safety of ionizing radiation conditions can be evaluated. The chapter is directed to health and safety professionals who need a basic understanding of radiation safety. Health and safety professionals should also know where to find consultation and technical help on specific radiation problems. The control of ionizing radiation exposures requires special training in health physics, and professionals qualified in health physics should be obtained for this work. Radiation safety should be part of an organization's total health and safety program. The introduction of radiation devices or radioactive materials entails radiation safety reviews, engineering studies, and facility modifications. It may be necessary to alter traffic patterns of personnel and mobile equipment to minimize the spread of radioactive materials in the event of an accident.

The health and safety professional should have general knowledge of the nature of radiation, the detection of radiation, permissible exposure limits (PELs), biological effects of radiation, monitoring techniques, procedures, and control measures. Facility personnel need to be properly advised of radiation hazards and safe procedures. The health and safety professional should ensure that health physicists review or oversee radiation installations to ensure compliance with federal, state, and local regulations and company policies. Medical and emergency plans must be in place.

Effective accident prevention techniques are required for the control of radiation exposures to personnel. Radiation hazards can in some cases be controlled with common safety measures. In other cases, health physicists must provide expert guidance. Some radiation control operations entail extraordinarily expensive facilities and equipment. The organization and the health and safety professional must see that the proper actions are taken.

Basic information on the characteristics of radiation, standards for exposure limitation, safety factors, and control measures

are presented here. As an aid to further study, consult the Bibliography at the end of this chapter. Also, visit the websites of the Health Physics Society (www.health-physics.com) and the National Safety Council (www.nsc.org) to access a wealth of information on ionizing radiation protection.

IONIZING RADIATION TERMS

In order to discuss intelligently the health and safety aspects of ionizing radiation, an understanding of some basic terminology is necessary. Brief definitions of some important terms are given. In the text, English units of radiation exposure are listed first, followed by the SI (metric) units in parentheses. Figure 10–1 illustrates the process of radioactive disintegration.

Activity The number of nuclear disintegrations occurring in a given quantity of material per unit of time.

Alpha-particle (alpha-radiation, α) An alpha-particle is made up of two neutrons and two protons that give it a unit charge of +2. It is emitted from the nucleus of a radioactive atom and causes high-density ionization. Alpha-particles transfer their energy in a very short distance and are readily stopped by a piece of paper or the top, dead layer of the skin. Alpha-radioactivity is therefore primarily an internal radiation hazard.

Annihilation The process by which a negative electron and a positive electron, or positron, combine and disappear. The process results in the emission of electromagnetic radiation.

Annual limit on intake (ALI) The activity of a radionuclide that, taken into the body over the course of one year,

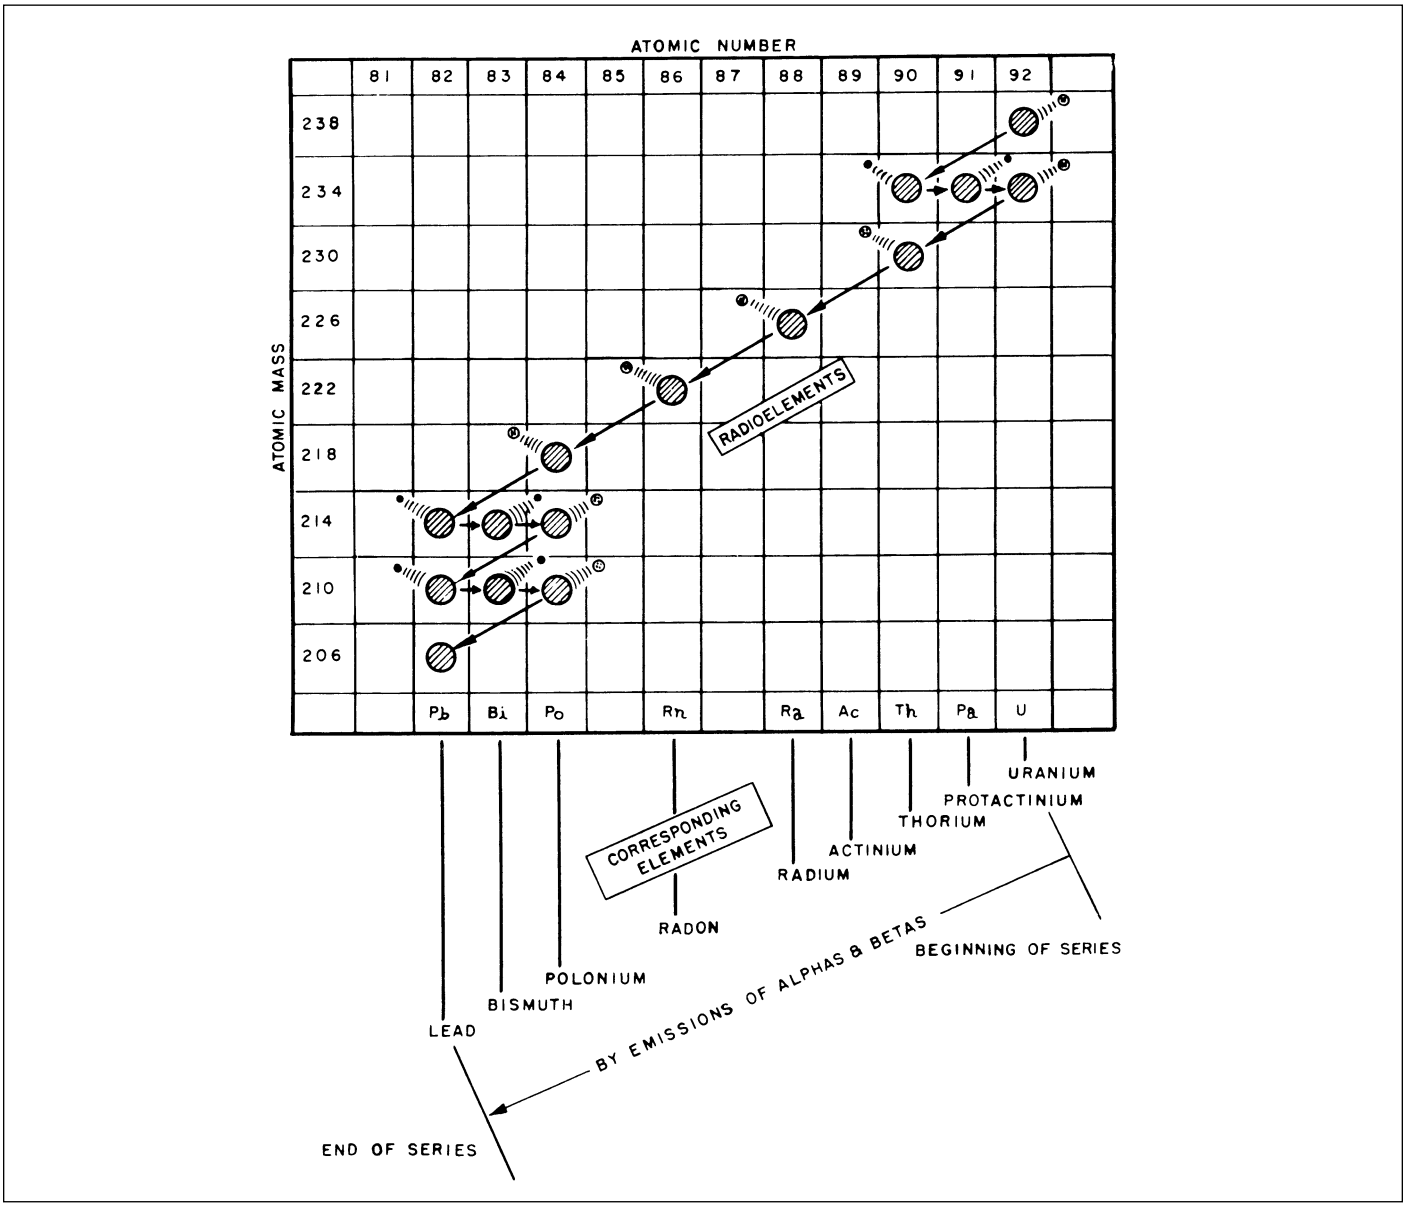

Figure 10–1. The radioactive disintegration scheme of uranium-238 by emissions of alpha- and beta-particles. (Reprinted with permission from *Atomic Radiation,* RCA Service Co., Inc., 1957.)

constitutes a committed effective dose-equivalent equal to the annual occupational effective dose-equivalent limit. This is based on Reference Man.

Atomic number The number of protons (positively charged particles) in the nucleus of an atom. Each element has a different atomic number. The atomic number of hydrogen is 1, that of oxygen 8, iron 26, lead 82, and uranium 92. The atomic number is also called the charge number.

Atomic weight The atomic weight is approximately the sum of the number of protons and neutrons in the nucleus of an atom. This sum is also called the mass number. The atomic weight of oxygen, for example, is approximately 16; most oxygen atoms contain 8 protons and 8 neutrons.

Background radiation The radiation coming from sources other than the radioactive material to be measured. Background radiation is primarily a result of cosmic rays, which constantly bombard the earth from outer space. It also comes from such sources as soil and building materials. Background radiation may vary somewhat depending on location.

Becquerel (Bq) One disintegration per second (dps). This unit is used in measuring the rate of radioactive disintegration. There are 3.7×10^{10} becquerels per curie of radioactivity.

Beta-particle (beta-radiation, β) Beta-particles are small, electrically charged particles emitted from the nucleus of radioactive atoms. They are identical to electrons and have a negative electrical charge of 1. Beta-particles are emitted with various kinetic energies. They pose an internal exposure hazard and are often penetrating enough to cause skin burns.

Bremsstrahlung The electromagnetic radiation associated with the deceleration of charged particles. The term can also be applied to electromagnetic radiation produced by acceleration of charged particles.

Compton effect The glancing collision of a gamma-photon with an orbital electron. The gamma-photon gives up part of its energy to the electron, ejecting the electron from its orbit.

Controlled area A specified area in which exposure of personnel to radiation or radioactive material is controlled. Controlled areas should be under the supervision of a person who has knowledge of and responsibility for applying the appropriate radiation protection practices.

Counter A device for counting nuclear disintegrations, thereby measuring the amount of radioactivity. The electronic signal announcing disintegration is called a count.

Curie (Ci) A measure of the rate at which a radioactive material emits particles. One curie corresponds to 3.7×10^{10} becquerels (disintegrations per second).

Derived air concentration (DAC) The Annual Limit on Intake (ALI) of a radionuclide divided by the volume of air inhaled by Reference Man in a working year (units, Bq/m^3).

Disintegration When a radioactive atom disintegrates, it emits a particle from its nucleus. What remains is a different element. For example, when an atom of polonium 210 disintegrates, it ejects an alpha-particle and changes to a lead 206 atom by this process. When an atom of bismuth 210 disintegrates, it changes to an atom of polonium 210 by beta-particle emission (see Figure 10–1).

Dose A general term denoting the quantity of radiation or energy absorbed by a specified mass. For special purposes, its meaning should be specified, as in *absorbed dose*.

Dosimeter (dose meter) An instrument used to determine the radiation dose a person has received.

Electron A minute atomic particle possessing the smallest possible amount of negative electric charge (–1). Orbital electrons rotate around the nucleus of an atom. Electrons have only about 1/1,820 the mass of protons or neutrons.

Electron volt (eV) A small unit of energy—the amount of energy that an electron gains when it is acted upon by one volt. Radioactive materials emit radiation in energies of up to several million electron volts, or MeV. Gamma-ray energies from radioisotopes range up to 4 MeV or higher. Some are emitted at relatively low energies and are correspondingly less hazardous.

Element All atoms of a given element contain the same number of protons and therefore have the same atomic number. Various isotopes of an element result from a change in the number of neutrons in the nucleus. However, the electrical charge and chemical properties of the various isotopes of an element are identical.

Film badge A piece of masked photographic film worn as a badge for personal monitoring of radiation exposure. It is darkened by penetrating radiation, and radiation exposure can be checked by developing and interpreting the film. The type of masking depends on the type of radiation to be measured.

Gamma-rays (Gamma-radiation, γ) A class of electromagnetic photons emitted from the nuclei of radioactive atoms. Gamma-rays are highly penetrating and present an external radiation exposure hazard.

Gray (Gy) Unit of absorbed radiation dose equal to one joule of absorbed energy per kilogram of matter. 1 Gray = 100 rad.

ICRP International Commission on Radiological Protection and Measurements.

Half-life A means of classifying the rate of decay of radioisotopes according to the time it takes them to lose half their strength (intensity). Half-lives range from fractions of a second to billions of years. Cobalt-60, for example, has a half-life of 5.3 years.

Half-value layer The thickness of a specified substance that, when introduced into the path of a given beam of radiation, reduces the value of the radiation quantity by one-half. It is sometimes expressed in terms of mass per unit area.

Ion An atom or molecule that carries either a positive or negative electrical charge.

Ionizing radiation Electromagnetic or particulate radiation capable of producing ions, directly or indirectly, by interaction with matter. In biological systems, such radiation

must have a photon energy greater than 10 eV. This excludes most of the ultraviolet bands and all longer wavelengths.

Ionization chamber A basic counting device to measure radioactivity.

Isotope These are nuclei that have the same atomic number. Isotopes of a given element contain the same number of protons but a different number of neutrons. For example, the isotope uranium-238 contains 92 protons and 146 neutrons whereas U-235 contains 92 protons and 143 neutrons. Thus the atomic weight, or mass, of U-238 is 3 higher than that of U-235.

Moderator A material used to slow neutrons; it is used, for example, in reactors. Slow neutrons are particularly effective in causing fission. Neutrons are slowed down when they collide with atoms of light elements such as hydrogen, deuterium, and carbon—three common moderators.

Molecule The smallest unit of a compound or element as it exists in nature. A water molecule consists of two hydrogen atoms combined with one oxygen atom, hence the well-known formula H_2O. The element oxygen exists in the form of diatomic molecules, O_2.

NCRP National Council on Radiation Protection and Measurements.

Neutron An atomic particle. The neutron weighs about the same as the proton. As its name implies, the neutron has no electrical charge. Neutrons make effective atomic projectiles for the bombardment of nuclei. Neutrons can also present unique external exposure hazards to personnel.

NRC Nuclear Regulatory Commission.

Nucleus The inner core of an atom. The nucleus consists of neutrons and protons tightly bound together.

Pair production The conversion of a gamma-ray into a pair of particles—an electron and a positron. This is an example of direct conversion of energy into matter, and is quantified by Einstein's famous formula: $E = Mc^2$; energy = mass x velocity of light (squared).

Photoelectric effect Occurs when an electron is ejected from the orbit of an atom by a photon that imparts all of its energy to the electron.

Photon A class, or quantum, of electromagnetic radiation, such as x-rays, gamma-rays, visible light, and radio waves.

Plutonium A human-made heavy element that undergoes fission under the impact of neutrons. It is a useful fuel in nuclear reactors. Plutonium can be produced by the capture of slow neutrons in uranium. It is a highly hazardous alpha-emitter.

Proton An elementary particle found in an atom's nucleus. Its positive charge of +1 is opposite that of the electron.

Quality factor (Q) A function of the linear collision stopping power (L ∞) in water at the point of interest and with a specified energy dependence. It weights the absorbed dose for the biological effectiveness of the charged particles producing the absorbed dose.

Radioactivity The emission of very fast atomic particles or rays by nuclei. Some elements are naturally radioactive; others become radioactive after bombardment with neutrons or other particles. The three major forms of radioactivity are alpha (α), beta (β), and gamma (γ), named for the first three letters of the Greek alphabet.

Radioisotope A radioactive isotope of an element. A radioisotope can be produced by placing material in a nuclear reactor and bombarding it with neutrons. Many fission products are radioisotopes. Radioisotopes are sometimes used as tracers or as energy sources for chemical processing, food pasteurization, and nuclear batteries.

Radium One of the earliest-known naturally radioactive elements. Radium is far more radioactive than uranium and is found in the same ores. It is a highly hazardous alpha-emitter.

Roentgen (R) The amount of x- or gamma-radiation that produces ionization resulting in one electrostatic unit of charge in one cubic centimeter of dry air at standard conditions.

Roentgen absorbed dose (rad) The mean energy per unit of mass imparted by ionizing radiation in a mass. One rad is 100 ergs absorbed per gram. 1 rad = 0.01 Gray.

Roentgen equivalent man (rem) A unit of absorbed dose (in rad) times a quality factor that is used to express the relative biological effect of the particular radiation as compared to gamma-radiation. Personnel exposure limits are often expressed in rem.

Scintillation counter A radiation-counting device that registers the tiny flashes of light (scintillations) that particles produce when they strike certain crystals or liquids.

Shielding A barrier that protects workers from harmful radiations released by radioactive materials. Lead bricks, dense concrete, water, and earth are examples of materials used for shielding.

Sievert (Sv) Unit of absorbed radiation dose (in Gy) times the quality factor of the radiation as compared to gamma-radiation. It is equal to the Gray times the quality factor and is equivalent to 100 rem.

Strontium-90 An isotope of strontium having a mass number of 90. Strontium-90 is an important fission product. It has a half-life of 25 years and is a highly hazardous beta-emitter.

Tracer A radioisotope that is mixed with a stable material. Radioisotopes enable scientists to trace chemical and physical changes in materials. Tracers are widely used in science, industry, and agriculture. For example, when radioactive phosphorus is mixed with a chemical fertilizer, the uptake of radioactive phosphorus from fertilized soil can be measured in the plants as they grow, thereby also indicating the rate of uptake of the fertilizer.

Tritium Often called hydrogen-3. Tritium is an extra-heavy hydrogen whose nucleus contains two neutrons and one proton. It is radioactive as a beta-emitter.

Uranium A heavy metal, the two principal natural isotopes of which are U-238 and U-235. U-235 has the only readily fissionable nucleus that occurs in appreciable quantities in nature, hence its importance as a nuclear reactor fuel. Only one part in 140 of natural uranium is U-235.

X ray Highly penetrating electromagnetic radiation similar to the gamma-ray. X rays are produced by electron bombardment of target materials. They are commonly used to produce shadow pictures (roentgenograms) of dense portions of objects.

TYPES OF IONIZING RADIATION

Radiation is a form of energy. Familiar forms of radiation energy include light (a form of radiation we can see) and infrared (a form of radiation we can feel as heat). Radio and television waves are forms of radiation that we can neither see nor feel. The relationship between the various categories of electromagnetic radiation is shown in Figure 10–2.

Gamma-rays and x rays overlap and occupy a common range in the electromagnetic spectrum. X-radiation is produced in the orbiting electron portion of the atom or from free electrons, whereas gamma-radiation is produced in the nucleus. X rays generally are machine produced and gamma-rays are emitted spontaneously from radioactive materials.

All matter is composed of atoms, each of which has two basic parts: a heavy core, or nucleus, containing positively charged particles called protons and neutral particles called neutrons; and relatively lightweight, negatively charged particles called electrons, which spin around the nuclear core (Figure 10–3). Neutrons and protons were once considered basic particles. However, they have been found to be composed of even smaller particles.

Ionization is an energy transfer process that changes the normal electrical balance in an atom. If a normal atom (electrically neutral) were to lose one of its orbiting electrons (one negative charge), the atom would no longer be neutral. It would have more positive charges than negative charges, making it a positive ion. Electrons thus removed are called free electrons. If the free electron then attaches to another atom, that atom would become a negative ion. The positive and negative ions thus produced are known as an ion pair.

The term *nuclear radiation* describes all forms of radiation energy that originate in the nucleus of a radioactive atom. In addition to gamma-rays, fast-moving particles are sometimes emitted from radioactive atoms.

Some materials are naturally radioactive; others can be made radioactive in a nuclear reactor or accelerator. Some nonradioactive atoms can be converted to radioactive atoms when an extra neutron is captured by a nucleus. The resulting radioactive atom is unstable because of the extra energy that the neutron added to the nucleus. The excited, or radioactive, atoms get rid of their excess energy and return to a stable state by emitting subatomic particles and gamma-rays from the nucleus. The most important of these particles are alpha-particles, beta-particles, and neutrons.

The hazardous properties of radioactive materials are usually thought of in terms of nuclear radiation. All types of radiation share the common properties of being absorbed and transferring energy to the absorbing body.

The most commonly encountered types of ionizing radiation are alpha-, beta-, and neutron particles and x- or gamma-electromagnetic radiation. Other types of ionizing radiation are encountered in specialized facilities.

Alpha-Particles

Alpha-particles originate in the nuclei of radioactive atoms during the process of disintegration. These particles consist of a cluster of 2 protons and 2 neutrons (giving a mass number of 4, which is structurally the same as the nucleus of a helium atom). Alpha-particle emission changes an atom to one having an atomic number lowered by 2 and an atomic mass lowered by 4. Uranium-238 changes to thorium-234 by emission of an alpha particle. Alpha-particles, on slowing down, combine with electrons from the material through which they are passing, and thus become helium atoms.

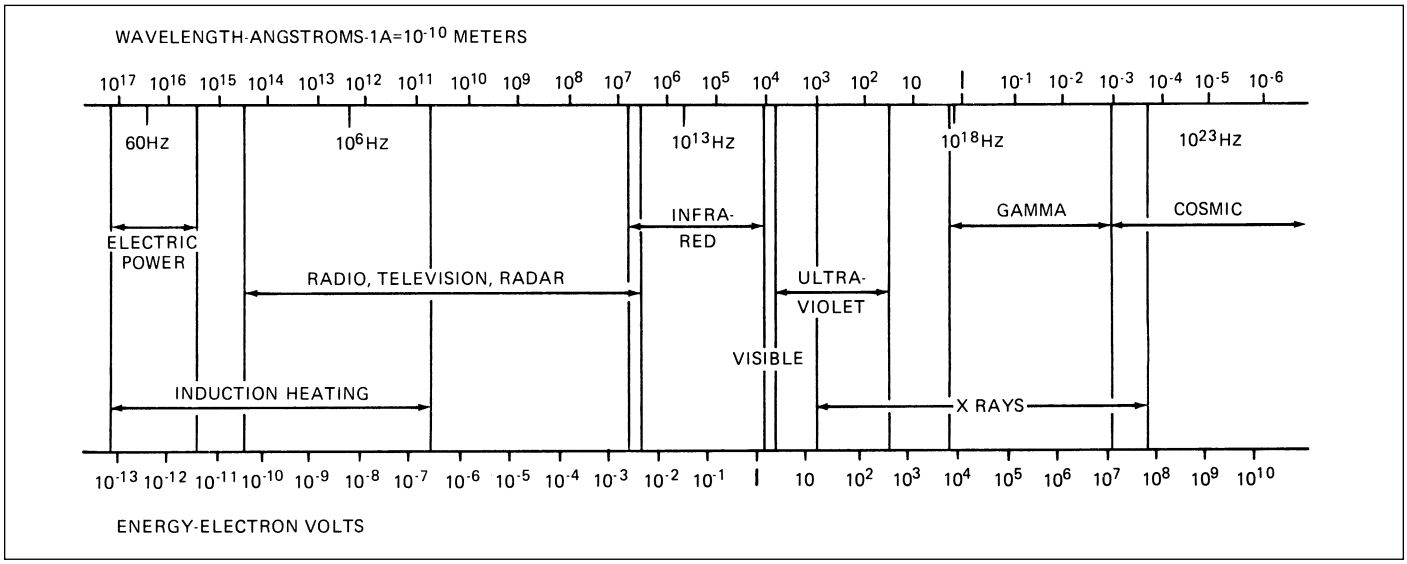

Figure 10–2. Electromagnetic spectrum illustrates energy and wavelength of the various categories of electromagnetic radiation.

The mass and electrical charge characterize the hazardous properties of alpha-particles. They have a positive charge of 2 units and interact electrically with human tissues and other matter. Alpha-particles range in energy to over 7 MeV. Because of their large mass and the dense ionization along their path through a material, they travel only a short distance. Their range is at most about 4 in. (10 cm) in air. They are stopped by the dead, outer layer of the skin, a film of water, a sheet of paper, or other paper-thin material (Figure 10–4).

To detect alpha-particles with a radiation survey meter, the instrument probe must be held close to the source, and the window on the probe must be very thin and designed specifically for alpha-detection.

Alpha-particles are produced by elements with high atomic numbers (Figure 10–1). Alpha-emitters are hazardous when taken into the body. Because they are chemically similar to calcium in their action within the body, some alpha-emitters are absorbed into the bones, where they remain for long periods of time. As they disintegrate, they emit alpha-particles, which can damage tissue. Other alpha-emitters are not bone seekers but concentrate in body organs such as the kidney, liver, lungs, and spleen.

If the alpha-emitting material is kept outside the body, little damage results because generally alpha-particles cannot penetrate the outermost, dead layer of skin. Care is needed to avoid inhalation or ingestion of alpha-radioactive materials and to avoid puncture wounds by items contaminated with alpha radioactivity. Alpha-emitters are considered to be only internal radiation hazards.

Beta-Particles

Beta-particles are electrically charged particles ejected from the nuclei of radioactive atoms during disintegration. They generally have a negative electrical charge of 1 unit and the same mass as an electron. Negative beta-particle emission causes the disintegrating atom to change into an element of a higher atomic number. Thus, strontium-90 changes to yttrium-90 on disintegration with ejection of a beta-particle (electron) from a neutron in the nucleus. The atomic number of the atom (the number of protons in the nucleus) is changed from 38 to 39 by the beta-particle emission from a neutron, causing it to gain a proton. (A neutron, by emitting a beta-particle, becomes a proton.)

Particles similar to beta-particles, with the same mass as electrons but with a positive unit charge, are called positrons, which can also be ejected from nuclei by disintegration. A proton from which a positron is emitted subsequently becomes a neutron, and the atomic number of the atom is reduced by 1. However, positrons are readily annihilated by combination with electrons, yielding gamma-radiation.

Beta-particles do not penetrate to the depth that x rays or gamma-radiation of similar energy do (Figure 10–4). Their maximum range in wood is about 1.5 in. (4 cm), and they can penetrate the human body to a depth of 0.1–0.5 in. (0.2–1.3 cm).

Skin burns result from extremely high doses of beta-radiation, because it requires only about 70 keV (1 keV = 0.001 MeV) of energy for a beta-particle to penetrate the dead, outer layer of skin. Beta-emitters are internal radiation hazards when taken into the body.

Beta-particles have a broad distribution of energies ranging from near zero up to the maximum value specific for the particular radionuclide. The maximum range in air of the beta-particles emitted from one radionuclide may be 6 in. (15 cm), and the maximum range of emissions from another radionuclide may be 60 ft (18 m). The higher-energy beta-particles penetrate farther, transfer more energy, and cause more damage.

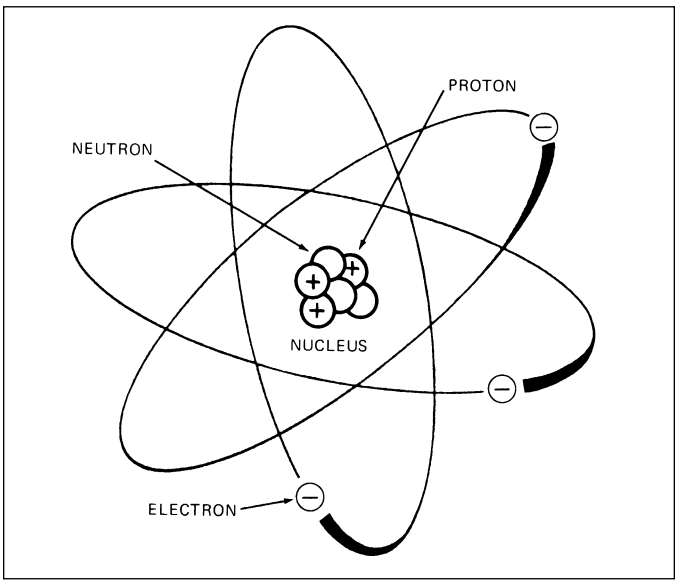

Figure 10–3. Basic model of the atom. The atom illustrated here is lithium-6.

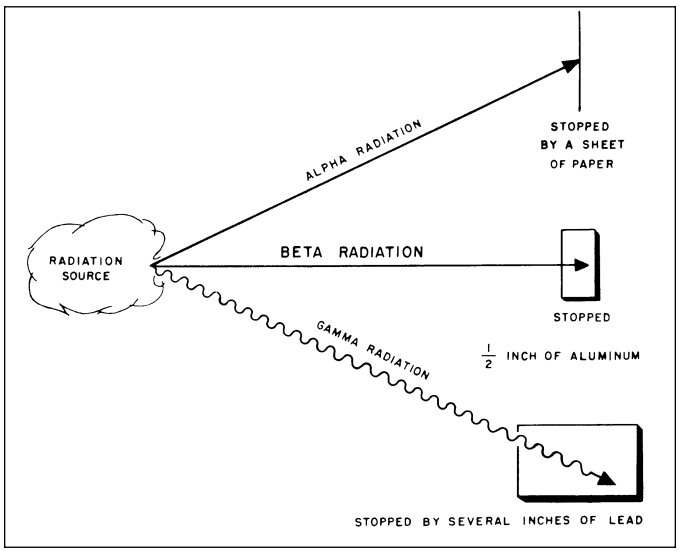

Figure 10–4. Relative penetrating power of alpha-, beta-, and gamma-radiation. (Reprinted with permission from *Atomic Radiation,* RCA Service Co., Inc., 1957.)

Beta-particles, or high-energy electrons, are emitted from a wide range of light and heavy radioactive elements. Beta-particles are much smaller than alpha-particles, and some have a velocity approaching the velocity of light. The energy level of beta-particles can be 4 MeV or higher. The energy range of beta-particles is similar to that of gamma-rays.

Beta-particles have an electrical charge of 1 unit, which tends to limit their penetration range somewhat, but penetration is greater than that of the doubly charged alpha-particles. Beta-particles are relatively more hazardous externally than alpha-particles because their penetration power is greater.

When a beta-particle is slowed down or stopped, secondary x-radiation, known as bremsstrahlung, may be produced.

Light metals such as aluminum are preferred for shielding from beta-particles because light metals produce less bremsstrahlung radiation. Plexiglas™ is another shielding material that is effective against such radionuclides as P-32. Common beta-radiations have ranges of less than 30 ft (9 m) in air. Depending on their energy, they can be stopped by the walls of a room or by a sheet of aluminum 0.5 in. (1.3 cm) thick.

Neutrons

Neutrons are not encountered as commonly as alpha- and beta-particles. The neutron particle, as its name implies, has no electrical charge. Neutrons exist within the nuclei of all atoms except those of the lightest isotope of hydrogen.

Neutrons are released on disintegration of certain radioactive materials (the fissionable isotopes). They have long or short ranges in air depending on their kinetic energy, which in turn depends on the method by which a particular neutron was produced. Furthermore, their range depends on the characteristics of the material through which they pass, the way the atoms of that material interact with the neutrons, and the kind of collisions that occur. In human tissue, the average depth of penetration of neutrons varies from about 0.25 in. (0.6 cm) to several inches (centimeters), depending on the neutrons' energy.

Very high-energy neutrons collide with atoms of the material through which they are passing, often breaking these nuclei into high-energy fragments. The neutron itself is unstable and emits a beta-particle as it decays to a proton. Interaction with the atoms of the material through which neutrons pass is the main way neutrons are removed from a beam.

Absorption of neutrons results when neutrons are deflected by, or collide with, nuclei. They collide repeatedly, which slows them down. The loss of energy by neutrons that suffer such collisions leads to an increased probability of absorption by a nucleus. This absorption process is called neutron capture.

In the human body, most of the captures that occur take place in hydrogen or nitrogen atoms. The result is that the nucleus of the atom is in an excited state. That is, an excess of energy is available. An atom can exist in this state only for a short period of time and returns to the ground (unexcited) state by releasing the excess energy. In the process, a proton, gamma-ray, beta-particle, or alpha-particle is emitted, depending on what type of atom captures the neutron. Because it is these secondary emissions that produce damage in tissue, the task of determining the neutron dose is difficult. The health hazard that neutrons present arises from the fact that they cause the release of secondary radiation.

Human exposure to neutrons occurs around reactors, accelerators, and sources designed to produce neutrons. Determination of the extent of damage from neutron exposures must be made by highly skilled people using specialized equipment. The amount of harm caused by a dose is dependent not only on the number of neutrons absorbed but also on their energy distribution.

X-Radiation

X-radiation is commonly thought of as electromagnetic radiation produced by an x-ray machine. When high-speed electrons are suddenly slowed down when they strike a target, they lose energy in the form of x-radiation. In an x-ray machine, the voltage across the electrodes of the vacuum tube determines the energy of the electrons, which principally determines the wavelength and penetrating quality of the resulting x rays.

The character of x-radiation is also affected by the target material inside the x-ray tube. That is, the wavelength of a portion of the x-radiation is affected by the kind of material composing the target. Because the electrons strike and interact at various speeds, the x-ray beam has a variety of wavelengths and energies. The energy of an x ray is inversely proportional to its wavelength; the more energy an x ray possesses, the shorter its wavelength.

The extent of penetration of x rays depends on wavelength and the material being irradiated. The x rays of short wavelength are called hard, and they penetrate several centimeters of steel. The x rays of long, or soft, wavelengths are less penetrating. The power to penetrate through matter is called the *quality*. *Intensity* is the energy flux density. The physical properties of a beam of x or gamma-rays are often summarized by the two concepts of intensity and quality.

The range of penetration can be expressed in terms of *half-value layer*. This is the thickness of material necessary to reduce the incident radiation by one-half. The half-value layers for x-radiation range up to several centimeters of concrete (Table 10–A).

Gamma-Radiation

Gamma-radiation is similar to x-radiation in that it is also electromagnetic and ionizing. In fact, it is identical to x-radiation except for its source being the nucleus of an atom. X-radiation is electromagnetic radiation that originates outside the nucleus.

Table 10–A. ***Half-Value Layer for Five Shielding Materials***

Material	*Cobalt-60*	*Cesium-137*
Lead	1.24 cm	0.64 cm
Copper	2.10 cm	1.65 cm
Iron	2.21 cm	1.73 cm
Zinc	2.67 cm	2.06 cm
Concrete	6.60 cm	5.33 cm

Note: 1 cm= 0.394 in.

Radioactive materials, by definition, spontaneously emit one or more characteristic radiations, possibly including gamma-radiation. The radiation comes from an excited or unstable nucleus of an atom.

A gamma-ray emitted by a given radionuclide has a fixed energy specific to that radionuclide (Table 10–B). Gamma-rays from various radionuclides cover a wide range of wavelengths, or energies. They present an external exposure problem because of their deep penetration. The half-value layer of shielding for 1.0 MeV gamma- or x-radiation is slightly more than 0.5 in. (1.3 cm) of steel.

Radioactive Decay Calculations

Radioactive materials decay—that is, they give off alpha-particles, beta-particles, and photon energy and lose a portion of their radioactivity with a characteristic half-life. The half-life can be brief, for example, 55 seconds for R-220; a matter of days, such as 8 days for I-131; or many years, such as 4.51 billion years for U-238. The amount of radioactivity remaining after a given period of time is calculated as follows:

Equation 1

$$A = A_0\, e^{\left(-0.693\ \frac{t}{T_{1/2}}\right)} = \frac{A_0}{e^{\left(0.693\frac{t}{T_{1/2}}\right)}}$$

where A = radioactivity remaining after time t
A_0 = radioactivity at a given original time
e = base of natural logarithms (2.718)
t = elapsed time
$T_{1/2}$ = half-life of the radionuclide

Note that radioactivity and time units must be consistent: If is given in curies (Ci), then A should also be in curies. If $T_{1/2}$ is given in years, then t must also be in years.

Example

What radioactivity would remain from 1 Ci (curie) of Co-60 (5.24 years half-life) after a 20-year period?

Solution

Equation 2

$$A = \frac{1\text{ Ci}}{e^{\left(\frac{0.693\ [20y]}{5.24y}\right)}} = \frac{1\text{ Ci}}{e^{(2.645)}} = \frac{1\text{ Ci}}{14.08} = 0.071\text{ Ci}$$

The amount of radioactivity remaining from 1 Ci of cobalt-60 after 20 years is 0.071 Ci (71 mCi).

Note that in some instances radioactive decay results in another radioisotope, and there is a decay chain of radioisotopes before a nonradioactive (stable) isotope is formed (see Figure 10–1). The published tables of radioisotopes should be checked to determine the decay chains.

BIOLOGICAL EFFECTS OF RADIATION

The human body can apparently tolerate a certain amount of exposure to ionizing radiation without its overall functions being impaired as a result. We are continuously exposed to ionizing radiation from natural sources such as cosmic radiation from outer space and from radioactive materials in the earth and materials around us and in us. This "background radiation" is part of our normal environment; we have evolved under its effects and are continuously exposed to it. The average annual dose from background radiation varies across the country, but it is commonly around 300 mR/y.

One fundamental property of ionizing radiation is that when it passes into or through a material, it transfers energy by the ionization process. The intensity of radiation to which a material is subjected is known as the radiation field. The term *dose* is generally used to express a measure of radiation that a body or other material absorbs when exposed to a radiation field.

If the incoming and outgoing energies are almost identical in nature and amount, then little energy is transferred and the dose is small.

External radiation sources, which are located outside of the body, present an entirely different set of conditions than radionuclides that have entered the body. Once inside the body, radionuclides are absorbed, metabolized, and distributed throughout the tissues and organs according to their chemical properties. Their effects on organs or tissues depend on the type and energy of the radiation and their residence time within the body.

The effects of irradiation on living systems are studied by looking for effects on the living cells, for changes in biochemical reactions, for evidence of production of disease, and for changes in life or normal growth patterns (Figures 10–5 and 10–6).

Interpretation of such findings is not simple. Extensive research in this field continues to be conducted in many laboratories.

The effect of ionizing radiation on living tissue is generally assumed to be almost entirely due to the ionization process, which destroys the capacity of reproduction or division in some cells and causes mutation in others (Figure 10–6). The human body is a complex chemical machine that constantly produces new cells to replace those that have died or been damaged. The body has a tremendous capability for repairing cell damage. Therefore, our survival depends on our ability to keep cell damage within the body's repair capabilities.

Table 10–B. *Isotopes Commonly Available, Listed by Increasing Half-Life*

Half-Life	Element and Symbol	Atomic Number	Mass Number	Gamma-Radiation Energy (MeV)
88 days	Sulfur (S)	16	35	none
115 days	Tantalum (Ta)	73	182	0, 0.68, .10, .15, .22, 1.12, 1.19, 1.22

3.1×10^5 years	Chlorine (Cl)	17	36	none

(Reprinted from *Radiological Health Handbook,* revised ed., January 1970. U.S Dept. of Health & Human Services, Rockville, MD.)

Ionization strips electrons from atoms and breaks their chemical bonds with other atoms. A simple molecule such as that of water recombines after ionization. This, however, is not the case in a complicated living cell. Here, ionization can result in many possible atomic recombinations. The rupture of a few bonds in the elaborate structure of the molecules of the living cell can have profound effects.

Types of Injuries

We started to learn about the effects of radiation on humans in 1895, when Wilhelm Roentgen discovered the x ray. Radiation from uranium was discovered by Antoine-Henri Becquerel in 1896. Alpha- and beta-particles and gamma-rays were identified shortly thereafter, and the neutron was discovered in 1930. Injurious effects of radiation were experienced by these early workers.

There are two points of view for consideration of the injurious effects of ionizing radiation: the somatic effects (injury to individuals) and the genetic effects, which are passed on to future generations.

The degree of injury inflicted on an individual by radiation exposure depends on such factors as the total dose, the rate at which the dose is received, the kind of radiation, and the body part receiving it.

Tissues such as the bone marrow, where blood cells are produced, the lining of the digestive tract, and some cells of the skin are more sensitive to radiation than those of bone, muscle, and nerve.

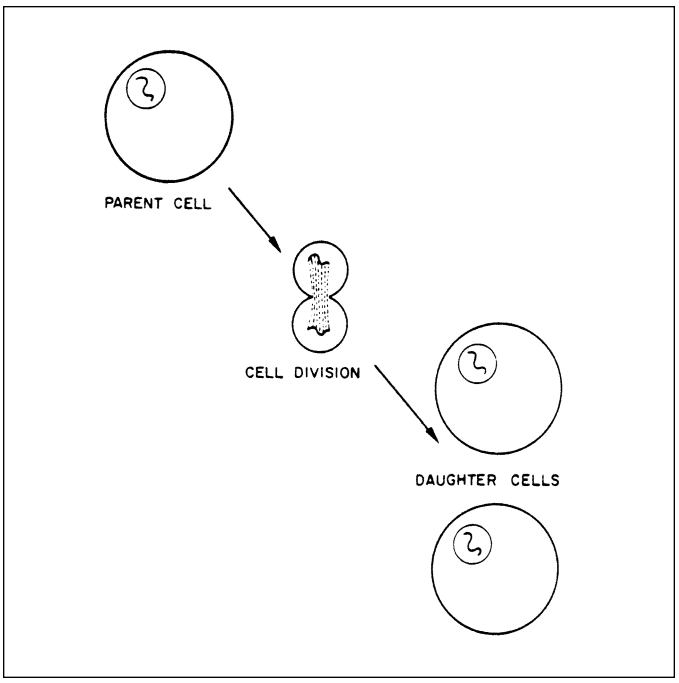

Figure 10–5. Normal cell division. (Reprinted with permission from *Atomic Radiation,* RCA Service Co., Inc., 1957.)

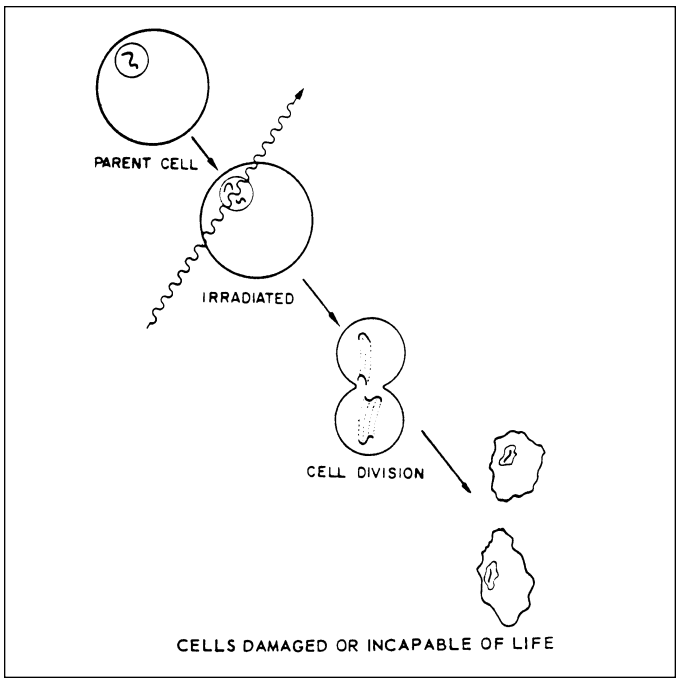

Figure 10–6. Damage or death of cells after division of irradiated parent cell. (Reprinted with permission from *Atomic Radiation,* RCA Service Co., Inc., 1957.)

In general, if the total amount of radiation is received slowly over a long period of time, a larger dose is required to produce the same degree of damage than if the same total is received over a short period. If the rate at which the dose is received is low enough, the body recovery processes are able to keep abreast of the slight damage.

Some relatively small doses have no effect if given only once but will shorten life span and produce abnormalities if continued long enough. The time between exposure and the first signs of radiation damage is called the latent period. The larger the dose, the shorter the latent period.

The various tissues and organs of the body are not affected equally by equal irradiation. Their responses vary considerably. For radiation protection purposes, it is essential that the dose to the most sensitive organs be given primary consideration.

Over the years, allowable radiation levels have been consistently reduced, as researchers have obtained more information on the effects of radiation exposure and as judgments involving acceptable risks have become more conservative. As radiation was applied to humans for healing purposes, effects such as skin redness, dermatitis, and skin cancer were noted, as were hair loss and eye inflammation. It was found that the incidence of cancer and certain blood diseases was higher among radiologists than would be expected for a chance distribution in the population studied.

The pool of health experience data was obtained from the following sources:

- ➢ Early radiation workers
- ➢ Medical personnel who routinely administered radiation for diagnostic and therapeutic purposes
- ➢ Patients who were treated with radiation
- ➢ A group of workers who painted dials with luminous paints containing radium
- ➢ Studies of Japanese atomic bomb survivors

With data collected from these sources, it became apparent that exposure to ionizing radiation was associated with a higher than normal incidence of certain diseases such as skin, lung, and other cancers; of bone damage; and of cataracts. There was also some evidence of life shortening.

Geneticists consider the population as a whole rather than particular individuals. Their concern is the effect of radiation on future generations. Radiation damage to human reproductive materials can be transmitted to succeeding generations.

Genetic damage is sometimes caused by disease or toxic chemicals as well as by ionizing radiation. Birth defects are usually the result of defective genes, but it is not possible at this time to determine what caused the damage to a given defective gene.

Relating Dosage to Damage

Extensive work has been done in an attempt to relate radiation dose to resulting damage. Researchers have done a great deal of laboratory work with various biological systems (both plants and animals) in order to learn more about the conditions of irradiation, the effects it produces, and the relative effectiveness of the kinds and energies of radiation.

These studies provide the basis for determining maximum permissible levels of exposure. The maximum permissible levels denote the maximum radiation dose that can

be tolerated with little chance of later development of adverse effects. The BEIR V report from the National Academy of Sciences listed in the Bibliography at the end of the chapter gives information on biological effects of ionizing radiation.

STANDARDS AND GUIDES

Maximum permissible levels of external and internal radiation have been published by the National Council on Radiation Protection and Measurements (NCRP), with exposure limits as shown in Table 10–C. The Nuclear Regulatory Commission establishes "Permissible Doses, Levels, and Concentrations" in *10 CFR 20*. (See Bibliography at the end of the chapter.)

Guides for maximum permissible external exposure to ionizing radiation have also been published by the International Commission on Radiological Protection and Measurements (ICRP). The 2000 Threshold Limit Value® is identical to the ICRP exposure guides. (See Appendix B for the TLV.)

Levels far below the maximum exposure limits recommended by the Federal Radiation Council can generally be achieved with no substantial inconvenience. The accepted practice is to keep radiation exposure as low as reasonably achievable (ALARA). Present limiting values are given separately for protection against different types of effects on health and apply to the sum of doses from external and internal sources of radiation. For cancer and genetic effects, the limiting value is specified in terms of a derived quantity called the effective dose equivalent. The effective dose equivalent received in any year by an adult worker should not exceed 5 rem (0.05 Sv). For other health effects, the limiting values are specified in terms of the dose equivalent to specific organs and tissues. (See *Recommendations for the Safe Use and Regulation of Radiation Sources in Industry, Medicine, Research and Teaching,* ICRP Report 102, 1990.)

Occupational dose equivalents to individuals under the age of 18 should be limited to educational and training purposes and should be less than 0.1 rem per year (1 mSv per year) (NCRP).

There is disagreement on the magnitude, extent, and cause of effects, if any, at exposures below the guide levels. Much of this discussion centers on theory, rather than on measured cause and demonstrated effect in human beings.

Because of the sensitivity of the fetus to radiation damage, the NCRP has recommended an occupational monthly equivalent dose limit of 50 mrem (0.5 mSv) to fetuses (excluding medical and natural background radiation) once pregnancy is known. The reason for the lower limit of exposure is that rapidly dividing cells are more susceptible to radiation damage than are mature cells. Women of childbearing age who may be exposed to

Table 10–C. *NCRP Recommendations on Limits for Exposure to Ionizing Radiation (Excluding Medical Exposures)*

A. Occupational exposure		
1. Effective dose limits		
a. Annual	5 rem	50 mSv
b. Cumulative	1 rem × age	10 mSv × age
2. Equivalent dose annual limits for tissues and organs		
a. Lens of eye	15 rem	150 mSv
b. Skin, hands, and feet	50 rem	500 mSv
B. Guidance for emergency occupational exposure* (see Section 14 of NCRP report 116)		
C. Public exposure (annual)		
1. Effective dose limit, continuous or frequent exposure*	100 mrem	1 mSv
2. Effective dose limit, infrequent exposure*	500 mrem	5 mSv
3. Equivalent dose limits for tissues and organs		
a. Lens of eye	1.5 rem	15 mSv
b. Skin, hands, and feet	5 rem	50 mSv
4. Remedial action for natural sources:		
a. Effective dose (excluding radon)	>500 mrem	>5 mSv
b. Exposure to radon decay products		>7 x 10^{-3} Jh m^{-3}
D. Education and training exposures (annual)*		
1. Effective dose limit	100 mrem	1 mSv
2. Equivalent dose limit for tissues and organs		
a. Lens of eye	1.5 rem	15 mSv
b. Skin, hands, and feet	5 rem	50 mSv
E. Embryo/fetus exposures (monthly)*		
1. Equivalent dose limit	50 mrem	0.5 mSv
F. Negligible individual dose (annual)*	1 mrem	0.01 mSv

Note: Recommendations on WR and WT are in tables 4.2 and 5.1 of NCRP report 116.

* Sum of external and internal exposures but excluding doses from natural sources.

(From NCRP Report No. 116, Limitation of Exposure to Ionizing Radiation, 1993, with English units added for comparison to metric units.)

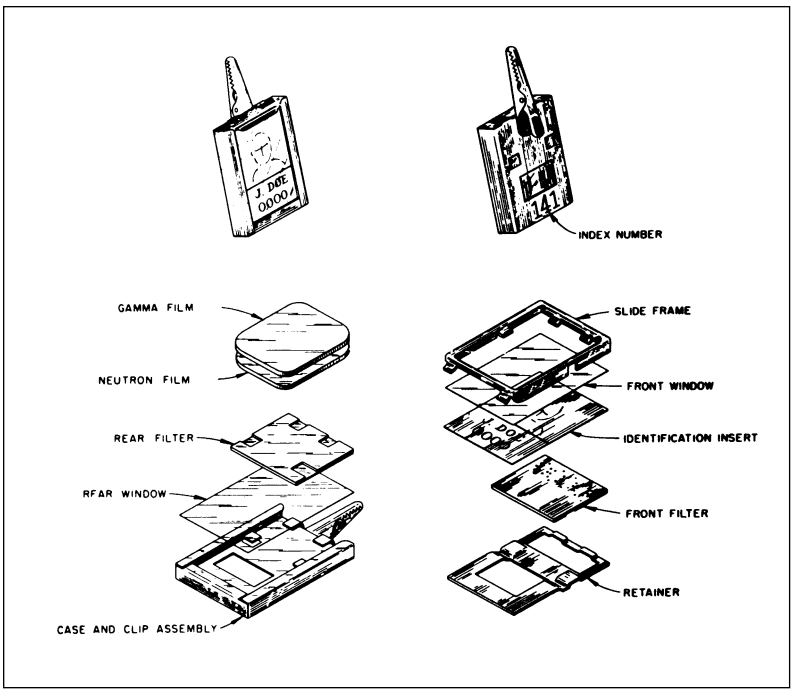

Figure 10–7. Exploded view of radiation film badge. Upper left is front view; upper right is back view.

radiation should be informed of the need to protect the fetus from excessive or unnecessary radiation exposure. In the event that occupational exposure exceeds PELs, action should be taken to reduce the exposures to within the guidelines. If this is not practicable, it is necessary to transfer the female worker out of the radiation exposure area for the duration of the pregnancy.

In summary, radiation dose limits established by any official organization or government body that has authority with respect to the user should be considered upper limits; the objective should be to keep exposure as low as reasonably achievable.

The NCRP recommends a whole-body dose limit of 5 rem per year (50 mSv) for occupational exposure. Cumulative exposure is not to exceed 1 rem (0.01 Sv) multiplied by the individual's age in years.

For further explanation of radiation protection standards and guides, refer to the Bibliography at the end of this chapter.

MONITORING INSTRUMENTS

There are a variety of detectors and readout devices used for monitoring and measuring radiation. None is universally applicable, and selection of the most appropriate detector or detectors for each radiation measurement (or type of measurement) is a matter of great importance.

Radiation monitoring involves the routine or special measurement of radiation fields in the vicinity of a radiation source, measurement of surface contamination, and measurement of airborne radioactivity. Such monitoring procedures are sometimes called radiation surveys.

Film Badges

The film badge, worn on the outer clothing, is an example of a personal radiation monitor for gamma-, x-, and high-energy beta-radiation. It consists of a small piece of photographic film wrapped in an opaque cover and supported with a metal backing. It can be pinned to the clothing or worn as a ring. Radiation interacts with the silver atoms in the photographic film to affect (expose) the film the same way that light rays do. The badge is removed at regular intervals and the film developed. The amount of darkening of a film is then compared to a control film, that was not exposed to radiation during the same time period, to determine the amount of radiation exposure. Figure 10–7 shows a typical film-badge arrangement for monitoring personnel; the film badge provides a permanent record of dosage.

Thermoluminescence Detectors

Thermoluminescence detectors (TLDs) have come into widespread use for radiation exposure monitoring for gamma-, x-, and beta-radiation. These dosimeters can be worn by the person as body badges or finger rings. Most commonly they are small chips of lithium fluoride. A major advantage of the TLDs is that for x- and gamma-radiation, they essentially require no energy source to operate in exposure from 20 keV up. The ionizing radiation energy absorbed by the TLD displaces electrons on it from their ground state (valence state). The electrons are trapped in a metastable state but can be returned to the ground state by heating. When electrons return to the ground state, light is emitted. A TLD readout instrument is used for precise control of heating the chip and measuring the light that is then emitted from it. The amount of light released is related to the absorbed radiation dose and, in turn, to the radiation exposure of the individual. Because the stored energy is released on readout, the readings cannot be repeated. It is therefore common practice to include two or more chips in

Figure 10–8. A health physics technician wearing a thermoluminescence detector attached to a neck strap and an electronic alarming dosimeter on his right shirt pocket.

a dosimeter. Figure 10–8 shows a health physics technician wearing a TLD dosimeter attached to a neck strap. Neck straps are available with friction connectors and quick release clips for safe and efficient use.

Pocket Dosimeters

The pocket dosimeter is a direct-reading portable unit shaped like a pen with a pocket clip. It is generally used to measure x- and gamma-radiation (although it may respond to beta-radiation).

A dosimeter consists of a quartz fiber, a scale, a lens to observe the movement of the fiber across the scale, and an ionization chamber. The fiber is charged electrostatically until it reaches zero on the scale. When the dosimeter is exposed to radiation, some of the air atoms in the chamber become ionized. This allows the static electricity charge to leak from the quartz fiber in direct relationship to the amount of radiation present. As the charge leaks away, the fiber deflects to some new position on the scale that indicates the amount of radiation exposure.

The main advantage of the pocket dosimeter is that it allows the individual to determine the radiation dose while working with radiation, rather than waiting until after periodic processing of a film badge or thermoluminescent dosimeter.

Electronic Alarm Dosimeters

Personal electronic alarm dosimeters are used to monitor the presence of x- and gamma-radiation. These units, usually Geiger–Mueller tubes, have an automatic audible alarm if significant exposure rates are encountered. They can also be set to alarm at a preset total integrated exposure. With a reader, they can provide a digital readout of exposure. They are compact and lightweight to allow for wearing them on clothing, similar to a pager. See Figure 10–8 showing a health physics technician wearing an electronic alarming dosimeter on his right shirt pocket.

Ionization Chambers

Radiation can be measured very conveniently and accurately by measuring the ionization in a small volume of air. If two plates or electrodes with an electrical potential between them are placed in a container filled with air, an ionization chamber is formed. If the ionization chamber is exposed to a beam of radiation, a current flows in the circuit because the electrons that are knocked out of the air atoms by the radiation are attracted by the positive electrode. In other words, ionized air becomes conductive (Figure 10–9).

The ionization chamber measures ionization directly and is energy independent. These units can measure gamma-, x-, beta-, and, if the window is thin enough, alpha-radiation. It is a very useful and popular tool for radiation safety work. Use of an ionization chamber instrument for gamma-radiation measurements is illustrated in Figures 10–10 and 10–11.

Geiger–Mueller Counters

A Geiger–Mueller counter is used for beta-, gamma-, and x-radiation survey measurements because it is capable of detecting very small amounts of radiation. It is especially sensitive to beta-radiation. It uses an ionization chamber but it is filled with a special gas and has a greater voltage supplied between its electrodes. It only takes a very small number of

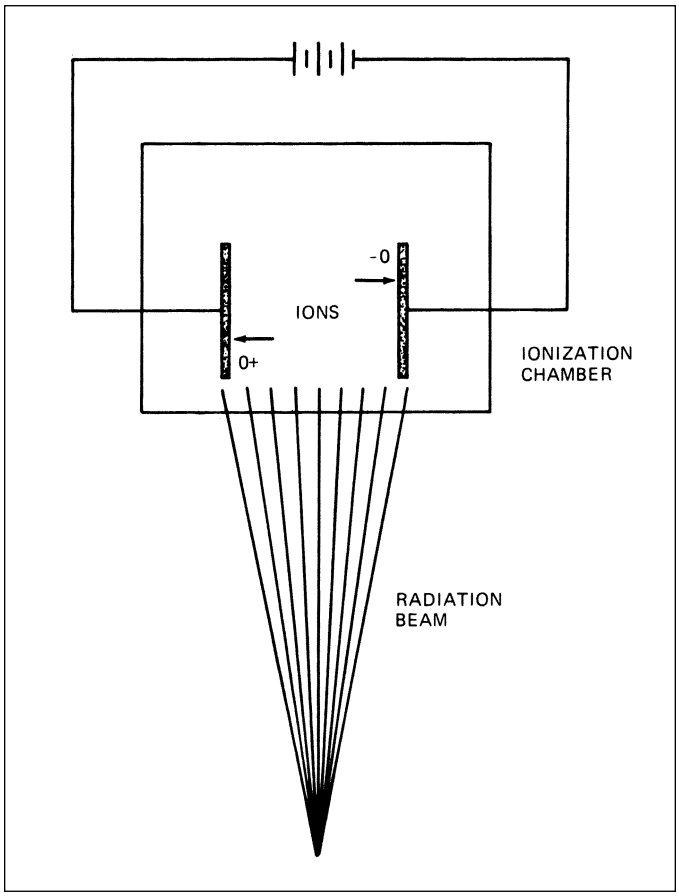

Figure 10–9. Diagram of an ionization chamber.

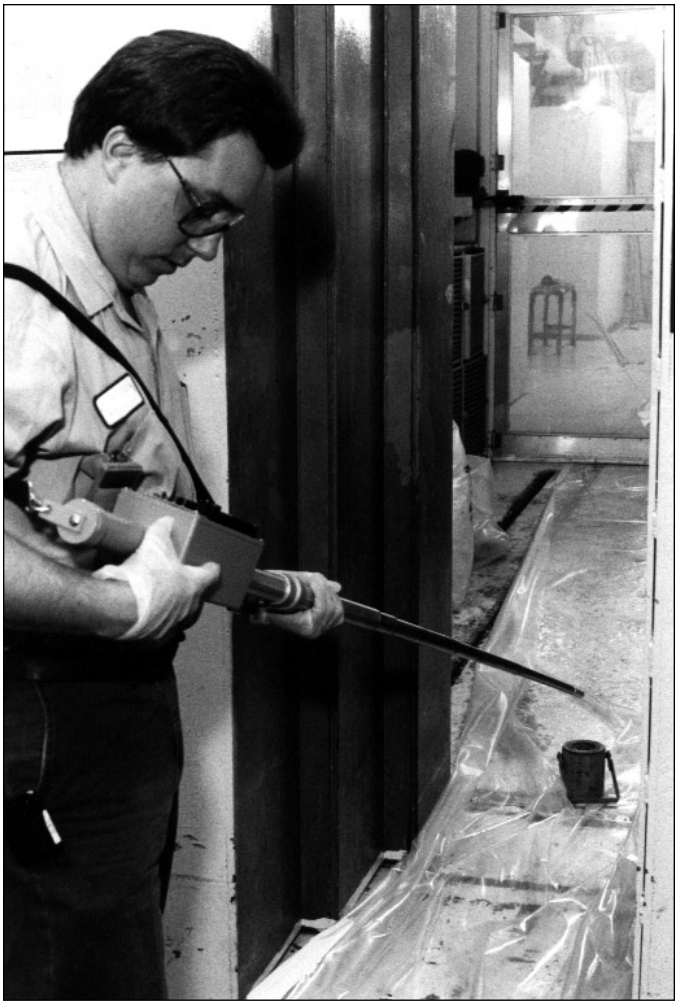

Figure 10–10. Health physics technician using telescopic high-range ion chamber survey instrument. (Note the thermoluminescent dosimetry badge on shirt pocket and electronic alarm dosimeter on trouser pocket.)

Figure 10–11. Health physics technician taking exposure rate readings with an ion chamber survey instrument.

ions to put it into discharge. Electrons are freed by the initial ionization process, and they acquire enough extra energy from the applied voltage to create more ions. This instrument does not give a uniform response for different radiation energy levels and is accurate only for the type of radiation energy for which it is calibrated. A radiation survey with a Geiger–Mueller counter is shown in Figure 10–12.

Other Monitoring Instruments

Scintillator types of radiation-monitoring instruments are designed to measure light flashes created by the interaction of ionizing radiation and scintillator materials. This type of survey instrument, which is useful for sensitive measurements of alpha- and beta-gamma–radiation, is shown in Figure 10–13.

Calibration

Usually, the calibration of radiation meters is a laboratory procedure that should be carried out by qualified experts. Under certain circumstances, however, it is possible and permissible to calibrate meters by comparing a radiation-measuring instrument with a standard radiation source of known output.

Figure 10–12. Use of a Geiger–Mueller counter. (Courtesy Argonne National Laboratory.)

Consult up-to-date manuals and become familiar with regulations concerning the use and calibration of radiation-monitoring devices.

BASIC SAFETY FACTORS

For external radiation exposure hazards, the basic protection measures are associated with time, distance, and shielding.

Time

The longer the exposure, the greater the chance for radiation injury. Because there is a direct relationship between exposure dose and duration of exposure, reducing the exposure time by one-half reduces the dose received by one-half.

A common practice is to reduce the exposure time and thus the exposure. From the knowledge of the dose rate in a given location and the maximum dose that is acceptable for the time period under consideration, the maximum acceptable exposure time can be calculated. If the exposure rate is 2.5 mrem/h (0.025 mSv/h), 40 hours results in 100 mrem (1 mSv) exposure. If the exposure rate is 10 times higher, then the time must be reduced to one-tenth (to 4 h) for the same dose (Figure 10–14).

In practice, the dose received in accomplishing a task can be spread over several employees so that no one person's exposure exceeds the guidance levels. Only the minimum necessary exposure should be planned for a work task. Exposure rate is measured with one of several types of instruments. Direct-reading dosimeters are available, as are those that emit alarm sounds at a preset exposure rate and at an accumulated exposure setting.

Distance

The inverse square law can be applied to determine the change in external penetrating radiation exposure with change in distance from a radiation source. Figure 10–15 indicates that by doubling the distance from the source of radiation the exposure would be decreased to $(1/2)^2$, or one-fourth, of the original amount. By increasing the distance from 2 to 20 m, the exposure would be decreased to $(2/20)^2$, or one percent, of the original amount. While the inverse square law can be used as an approximation, it should be recognized that it applies only to a point source in free space where there is no scattering of radiation. In practical applications, the radiation source may not be equivalent to a point source, and surrounding surfaces may reflect some radiation so that free space does not apply. However, in most instances, the approximation is adequate.

Maintaining a safe distance is especially critical for employees who must work near inadequately shielded sources of radiation. This applies to both portable and nonportable source types (Table 10–D).

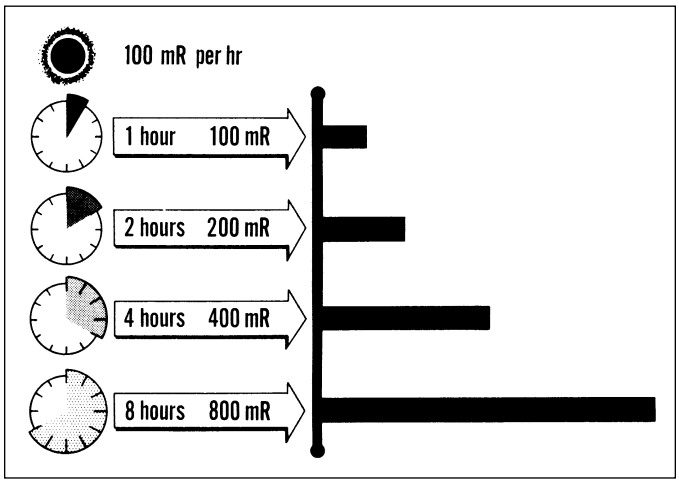

Figure 10–14. The effect of time on radiation exposure is easy to understand. An individual in an area where the radiation level from penetrating x- or gamma-radiations is 100 mrem/h would get 100 mrem in an hour. After two hours, the exposure would be 200 mrem, and so on. (Reprinted from U.S. Nuclear Regulatory Commission, *Living with Radiation—Fundamentals*.)

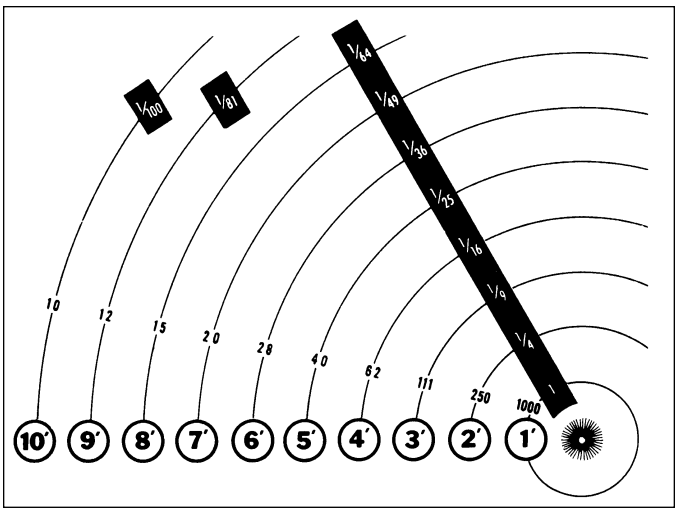

Figure 10–15. The effect of distance on radiation exposure follows the inverse square law—the intensity of radiation falls off by the square of the distance from the source. If we had a point source of radiation giving off 1,000 units of penetrating external radiation at 1 ft (or any other unit of distance), we would receive only one-fourth as much, or $(1/2)^2$, if we double our distance. If we triple our distance, we reduce the dose to one-ninth, or $(1/3)^2$. (Reprinted with permission from *Safe Handling of Radioisotopes in Industrial Radiography,* Picker X-Ray Corp., 1962.)

In such cases, a radiation survey should be made with an appropriate survey meter by a qualified health and safety professional to establish minimum safe distances that workers must abide by.

Work involving penetrating types of radiation should be performed where permanent barriers and shielding protect workers from harmful exposure. However, it is possible that certain operations cannot be performed without some exposure of employees. In these cases, all unnecessary exposure to radiation should be avoided, for example, by barring workers, including technicians, from active areas during exposure time such as during use of x-ray equipment.

A safe distance is the distance nonoperating workers must maintain from the radiation source in order to receive no more exposure than that specified in the NCRP *Radiation Protection Guides,* even if personnel were to remain at that distance continually. The distances specified for a given job do not necessarily remain constant if the radiation source in use is modified.

Hazardous areas indicated by the protection survey must be barricaded or roped off to form a restricted section that cannot be entered by nonoperating workers or bystanders. Large signs bearing the standard radiation symbol with proper wording should be posted (Figure 10–16). Standard colors are magenta on yellow.

Table 10–D. ***Gamma-Emitters and Radiation Levels at Various Distances from the Source***

Isotope	*0.3m*	*0.6m*	*1.2m*	*2.4m*	*3.0m*
Cobalt-60	14.5	3.6	0.9	0.23	0.145
Radium-226	9.0	2.3	0.6	0.14	0.09
Cesium-137	4.2	1.1	0.26	0.07	0.042
Iridium-192	5.9	1.5	0.4	0.09	0.059
Thulium-170	0.027	0.007	0.002	0.0004	0.00027

Note: Distances given in meters; 3.28 ft = 1 m.

(Reprinted form *Safe Handling of Radioisotopes in Industrial Radiography,* Picker X-Ray Corp., 1962.)

Shielding

Shielding is commonly used to protect against radiation from radioactive sources. The more mass that is placed between a source and a person, the less radiation the person will receive (Figure 10–17). For a high-density material such as lead, the barrier thickness required for a given attenuation of x- or gamma-radiation is less than it is for a less dense material such as concrete (Table 10–E).

Shielding from neutrons requires a different approach than does shielding from x- or gamma-radiation. Neutrons transfer energy to, and are stopped most effectively by, light nuclei (hydrogen atoms are the most effective). Therefore, water or other materials rich in hydrogen content are used as shields for neutrons. Carbon atoms such as in graphite are also often applied for neutron shielding.

Shielding can take many forms. These include cladding on radioactive material, containers with heavy walls and cov-

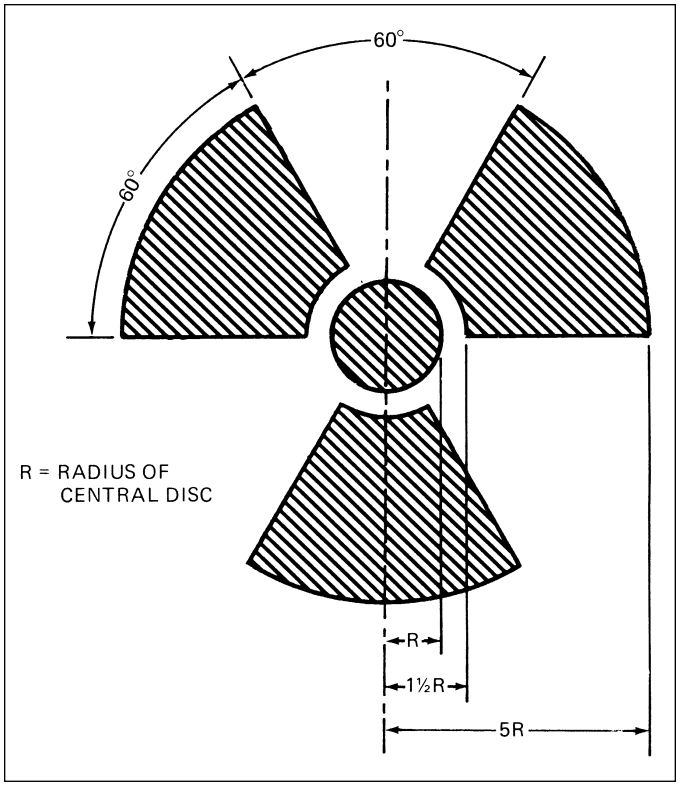

Figure 10–16. Standard symbol for radiation warning signs. (Courtesy American National Standards Institute.)

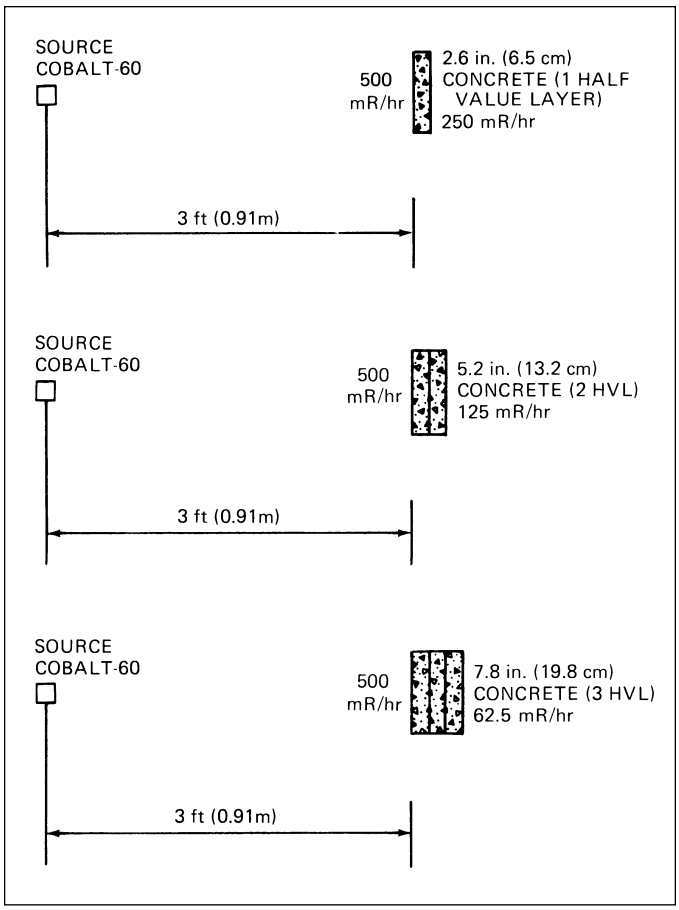

Figure 10–17. Illustration shows attenuation of cobalt-60 gamma-radiation by half-value layers of concrete.

ers for radioactive sources, cells with thick, high-density–concrete walls having viewing windows filled with high-density transparent liquid for remote handling of high-level gamma-emitters, and a deep layer of water for shielding against gamma-radiation from spent nuclear reactor fuel. Shielding calculations are often highly technical and require the services of an expert in this area.

Tables of half-value layers are given in radiation handbooks, and typical values for two radioactive materials, cobalt-60 and cesium-137, are given in Table 10–A.

Table 10–A states that 2.6 in. (6.6 cm) thickness of concrete can reduce the gamma-radiation coming from any cobalt-60 source to a factor of 1/2. If the gamma-emitter is cesium-137, then the half-value layer for concrete becomes 2.1 in. (5.3 cm). The gamma-radiation from cesium-137 is lower in energy (not as many MeVs) than the gamma-radiation from cobalt-60. Figure 10–17 illustrates how additional mass reduces radiation levels. The example used is a cobalt-60 source that gives a meter reading of 0.5 roentgen per hour (5 mGy/hr) at a distance of 3 ft (0.91 m).

A formula used for gamma-emitters is

Equation 3

$$\text{R/hr at 1 ft} = (6)(Ci)(E)(f)$$

This relationship states that the number of roentgens (R) per hour measured at a distance of 1 ft (0.3 m) from a source is approximately equal to six times the curie strength (Ci) of the source times the energy (E) of the gamma-radiation in MeV times the fractional yield (f) of the gamma-radiation per disintegration. It cannot be used for estimating beta-radiation levels.

Given the name of the radioactive source and its quantity (or activity) in curies, the value for its energy in MeVs can be obtained from handbooks. For example, Table 10–B gives the energy of radiation from several radioactive isotopes. The fractional yield (f) of the gamma-radiation per disintegration can be found in the *Handbook of Health Physics and Radiological Health* (see Bibliography).

Two cautions are required for proper application of this formula:

➢ Some radioactive materials such as cobalt-60 emit more than one gamma, each with different energies. The sum of the energy of the total emissions must be used. This information can be found in handbooks.

Table 10–E. ***Approximate Tenth- and Half-Value Thicknesses for Shielding Radiographic Sources***

Radiographic Source	Tenth- and Half-Value Thicknesses (cm)					
	Lead		Iron		Concrete	
	1/10	1/2	1/10	1/2	1/10	1/2
(Cobalt) Co-60	4.11	1.24	7.36	2.21	22.9	6.90
(Radium) Ra-226	4.70	1.42	7.70	2.31	24.4	7.37
(Cesium) Cs-137	2.13	0.64	5.72	1.73	15.7	4.83
(Iridium) Ir-192	1.63	0.48	*	*	15.7	4.83

* = No data.

Notes: This thicknesses for tenth- and half-value layers provide shielding protection from the scattered radiation resulting from deflection of the primary gamma-rays within the shield as well as protection from primary radiation from the source. The tenth-value layers were determined from the reduction factor v shield thickness curves. The tenth-value thicknesses were taken as one-third the thickness of shielding material necessary to give a reduction factor of 1,000. The half-value thickness is equal to the tenth-value thickness divided by 3.32.

1 cm = 0.394 in.

Density of concrete assumed to be 2.35g/cm^3 (147 lb/ft^3).

(Reprinted from the Nuclear Regulatory Commission Publication U-2967.)

➢ Terms must be consistent. If the source activity is given in millicuries or microcuries, it should be converted to curies. If millicuries are used in the source term, then the answer is in milliroentgens.

EXAMPLES/APPLICATIONS:
Example calculations for expected radiation levels are as follows:

Example
What radiation reading would be expected at a distance of 1 ft from an unshielded 100-millicurie cobalt-60 source?

Equation 4

$$\text{R/hr at 1 ft} = (6)(Ci)(E)(f)$$

where Ci = 100 millicuries (0.1 curie)
E = 1.2 MeV + 1.3 MeV (from handbook tables)
f = 1 (from handbook tables)
h = hour
R = Roentgen

Solution
Equation 5
R/h at 1 ft = 6(0.1) (1.2 + 1.3) (1) = 1.5 R/h (15mGy/h)

Example
What radiation reading would be expected at a distance of 1 ft from an unshielded 1-millicurie cesium-137 source?

Solution
Equation 6

$$\text{R/h at 1 ft} = 6(0.001)\ (0.66)\ (0.9) = 0.0036$$

which is 3.6 milliroentgens per hour (36mGy/h) at 1 ft (0.3 m).

The preceding examples illustrate the use of the formula in calculating dose rates and show how the application of the formula can assist in the interpretation of fractional amounts of curies.

The fact that a one-millicurie source of cesium-137 is used does not quantify the exposure problem. However, by calculating the exposure rate of 3.6 milliroentgens per hour at one foot, and then applying the distance rule of decreasing radiation (one divided by the distance squared— the inverse square rule) it becomes apparent that 4 ft (1.2 m) away from the source the radiation level would be $3.6/(4)^2$ = 0.22 mR/h (2.2µGy/h), which is very low.

Table 10–D lists a number of gamma-emitters and their radiation levels measured at various distances from a one-curie source. The numbers were obtained by using the previous formula and then applying the inverse square law for distances of other than one foot.

Knowledge of existing radiation levels at various distances from various radioactive sources facilitates use of control procedures to ensure that cumulative doses do not exceed the maximum permissible dose (MPD).

Example
As a final example of how control calculations can be used, assume that a 0.5-curie cobalt-60 source is involved in a fire. The radiation meters have been damaged and there is reason to believe that the source container is not functioning as an effective shield. Until someone with a good meter can conduct a survey and determine how severe the problem is, at what distance should the area be fenced off?

Solution
First, calculate R/h at 1 ft for a 0.5-curie cobalt-60 source.

Equation 7

$$\text{R/h at 1 ft} = 6(0.5)(2.5)(1) = 7.5 \text{ or } 7{,}500 \text{ milliroentgen per hour at one foot}$$

Second, at a control level of 40 milliroentgens per week (0.4 mSv per week) for a 40-hour week, the dose rate per hour should not exceed 40 mR/40 h or 1.0 mR/h (10mGy/h).

Third, use the inverse square law as follows:

Equation 8

$$x \text{ ft} = \left(\frac{\text{mrem/h at 1 ft}}{1.0 \text{ mrem/h}}\right)^{0.5}$$

$$= \sqrt{\frac{7{,}500 \text{ mrem/h at 1 ft}}{1 \text{ mrem/h at control ft.}}}$$

The distance in feet to place the barricade equals the square root of the quotient (milliroentgen per hour at one foot divided by 1.0 milliroentgen per hour). Thus,

Equation 9

$$x \text{ ft} = \left(\frac{7{,}500}{1.0}\right)^{0.5} = 86.6 \text{ ft}$$

Workers should not be allowed within 86.6 ft (26.2 m) of the source location. The warning signs and rope barrier or other access barrier should be placed not nearer than 86.6 feet from the radiation source. (All examples assume that exposures are occupational to workers with accurately maintained radiation exposure records.)

Calculations can be useful for planning purposes and subsequently actual radiation levels will need to be monitored.

CONTROL PROGRAMS

A radiation health and safety program should establish safe working procedures, detect and measure radiation, make surveys, be concerned with decontamination and disposal, laboratory and other special services, and record keeping.

Ionizing radiation cannot be felt, seen, heard, tasted, or smelled. However, radioactive isotopes can be measured and identified with instruments, and therefore can be adequately controlled.

A basic concept in radiation protection practice is the establishment of a controlled area. Areas where radiation dose rates are excessive can be guarded during exposure times by suitable methods such as the erection of barriers and warning signs (Figure 10–15), stationing of attendants to keep personnel out of restricted localities, and, in extreme cases, complete closing off of the areas. Safe exposure times and safe practices can be established through measurement and control and by learning from past experience.

Work with radiation can and should be so planned and managed that radiation exposures of employees and the general public are kept to a minimum. Controls are needed to prevent the release of radioactive materials that would result in exposures above guide levels.

Potential avenues of exposure to the public are contaminated air or water, waste materials, or employees unknowingly leaving the place of work with contamination on their persons, clothing, or shoes. Use of a hand-and-shoe monitor is shown in Figure 10–18.

Sources of Radiation

One must always consider the amount and kind of radiation sources used in a contemplated operation. Suitable radiation safety operating conditions can then be designed. Special circumstances can greatly affect the safety requirements.

Table 10–F lists a number of radioactive materials according to their toxicity. Table 10–G classifies the laboratory or work area required for radioactive materials of differing toxicity.

Radionuclides are often used because measurements of their radiation can disclose useful information. One example is the employment of radioactive sources to effect quantitative or dimensional control of industrial materials. For example, radionuclides can measure fluid-flow rates or thickness of semifinished or finished products.

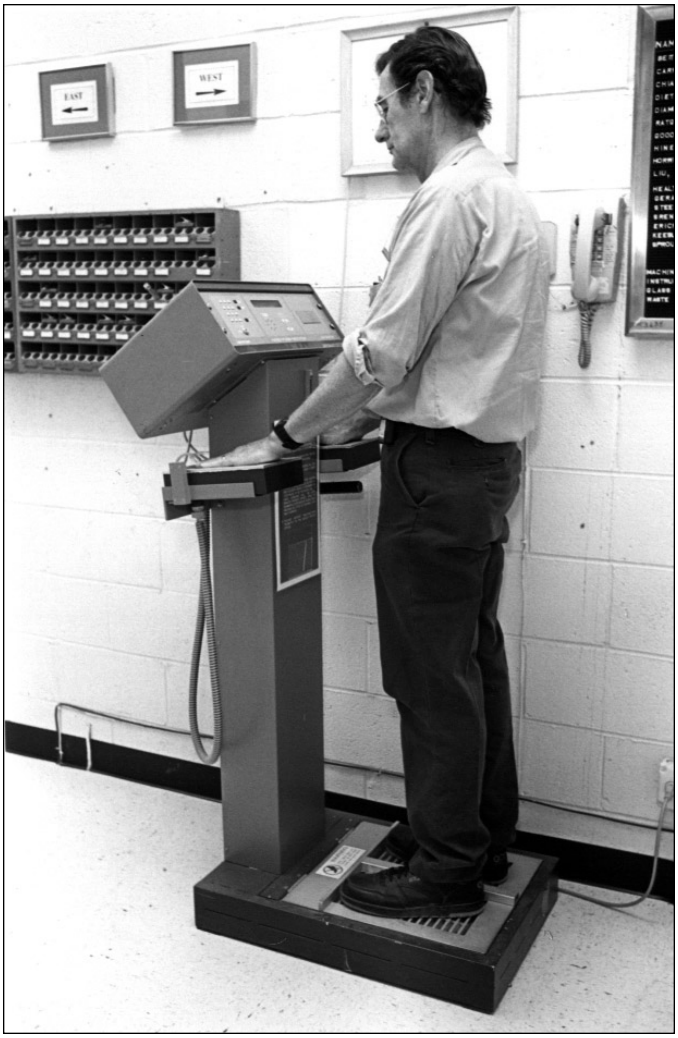

Figure 10–18. Use of a hand-and-shoe monitor for final radiological checkout.

SEALED SOURCES

Sealed sources with widely varying amounts of radioactivity are available. A high-intensity source may require so much

Table 10–F. *Classification of Isotopes According to Relative Radiotoxicity per Unit Activity*

The isotopes in each class are listed in order of increasing atomic number	
CLASS 1 (very high toxicity)	Sr-90 + Y-90, *Pb-210 + Bi-210 (RaD + E), Po-210, At-211, Ra-226 + percent * daughter products, Ac-227, *U-233, Pu-239, *Am-241, Cm-242
CLASS 2 (high toxicity)	Ca-45, *Fe-59, Sr-89, Y-91, Ru-106 + *Rh-106, *I-131, Ba-140 + La-140, Ce-144 + *Pr-144, Sm-151, *Eu-154; *Tm-170, Th-234 + *Pa-234, natural uranium
CLASS 3 moderate toxicity)	*Na-22, *Na-24, P-32, S-35, Cl-36, *K-42, *Sc-46, Sc-47, *Sc-48, *V-48, *Mn-52, *Mn-54, *Mn-56, Fe-55, *Co-58, *Co-60, Ni-59, *Cu-64, *Zn-65, *Ga 72, *As-74, *As-76, *Br-82, *Rb-86, *Zr-95 - *Nb-95, *Mo-99, Tc-98, *Rh 105, Pd-103 - Rh-103, *Ag-105, Ag-11, Cd-109, *Ag-109, *Sn-113, *Te-127, *Te-129, *I-132, Cs-137, *Ba-137, *La-140, Pr-143, Pm-147, *Ho-166, *Lu-177, *Ta-182, *W-181, *Re-183,*Ir-190, *Ir-192, Pt-191, *Pt-193, *Au-198, *Au-199, Tl-200, Tl-202, Tl-204, *Pb-203
CLASS 4 (Slight toxicity)	H-3, *Be-7, C-14, F-18, *Cr-51, Ge-71, *Tl-201

Note: The isotopes in each class are listed in order of increasing atomic number.

*Gamma-emitters.

Table 10–G. ***Laboratory or Work Area Required for Isotopes of Increasing Radiotoxicity***

		Type of Laboratory or Work Area Required		
Radiotoxicity of Isotopes	*Minimum significant quantity*	*Type C Good Chemical Laboratory*	*Type B Radioisotope Laboratory*	*Type A High-Level Laboratory*
Very high	0.1 μCi	10 μCi or less	10 μCi–10 mCi	10 mCi or more
High	1.0 μCi	100 μCi or less	100 μCi–100 mCi	100 mCi or more
Moderate	10 μCi	1 mCi or less	1 mCi–1 Ci	1 Ci or more
Slight	100 μCi	10 mCi or less	10 mCi–10 Ci	10 Ci or more

Procedure	*Modifying factor*
Storage (stock solutions)	X 100
Very simple wet operations	X 10
Normal chemical operations	X 1
Complex wet operations with risk of spills	X 0.1
Simple dry operations	X 0.1
Dry and dusty operations	X 0.01

Note: Modifying factors should be applied to the quantities shown in the last three columns, according to the complexity of the procedures to be followed. Factors are suggested only because due regard must be paid to the circumstances affecting individual cases.
(Reprinted from *Safe Handling of Radionuclides*, Safety Series No. 1, Atomic Energy Agency, Vienna.)

shielding that it is not considered portable. Shielding, control devices, and procedures should be designed by someone experienced in such work. Keeping external exposures to personnel under control can be accomplished with the aid of alarms, interlocks, strict control of access, and thorough monitoring.

Sources of low intensity should only require keeping track of their presence and condition.

Sources of intermediate intensity are more troublesome. They are portable and in some cases require so little shielding that they can easily be moved by hand. Persons operating a portable source must consistently follow the necessary precautions, including the use of dosimeters to measure their own exposure. They must operate the source so that other persons are not accidentally irradiated.

Some sealed sources are subject to breakage and spillage, and even welded seals have been known to fail. The hazard can be severe, and great care should be taken in handling sealed sources. Even if no known accident has occurred, such sources should be tested for leaks by a standardized procedure at scheduled intervals by an experienced technician.

RADIATION-PRODUCING MACHINES

For many years, radiation-producing machines have been in use, and proper operation of x-ray machines has been described in many publications. Remote actuation and shielding are common ways to control personnel exposures. If an accelerator is used, radiation safety personnel with special training or experience are required to ensure proper installation and operation. (See Bibliography, NCRP Report 88.)

Portable x-ray units present many of the same kinds of radiation safety problems as nonportable sources of corresponding intensity. Special problems related to the portability and lack of stationary shields must also be considered.

RADIOISOTOPES

Use of radioisotopes in the laboratory encompasses a wide range of hazards. The degree of hazards depends on the quantities and types of radioisotopes used as well as the kinds of operations to be performed.

Radioisotopes must be considered individually when hazards are being analyzed because their effect on human health varies with the type of radiation emitted, the process or work being conducted, and the safety practices being employed by those conducting the work. No general statements can be made until specific information is gathered and analyzed. Controls and procedures should be established by a health physicist.

Table 10–F groups various radioisotopes according to their relative radiotoxicity per unit activity in accordance with the International Atomic Energy Agency's (IAEA) publication, *Safe Handling of Radionuclides*. The IAEA explains the hazard classification for unsealed radioactive sources as follows:

> *Hazards arising out of the handling of unsealed sources depend on factors such as the types of compounds in which these isotopes appear, the specific activity, the volatility, the complexity of the procedures involved, and of the relative doses of radiation to the critical organs and tissues, if an accident should occur that gives rise to skin penetration, inhalation, or ingestion.*

Broad classifications for the radiotoxicity of various isotopes and their significant amounts are given in Tables 10–F and 10–G.

Spent fuel elements from a nuclear power reactor can contain on the order of a million curies, depending on the length of time they have been irradiated in the reactor and the interval of time between their removal from the reactor and measurement of their radioactivity. Shielding is required for handling, storage, and shipment of spent fuel materials and other high-level gamma-radiation sources. The use of manipulators, shielding cells, and shielding windows for remote work is shown in Figures 10–19 and 10–20. This illustrates confinement and shielding for high-level gamma-radioactivity. The photographs show the use of an in-cell remote camera and external video screen in Figure 10–19 and the remote use of strippable decontamination paint in Figure 10–20.

RADIOACTIVE METALS

Radioactive metals vary greatly in degree of hazard. Some have such low radiation rates that they can safely be held in the hand (if they are solids that are not flaking or dusting). A piece of normal uranium or an alloy of this material, for example, can be safely handled without personal protection for a few hours per week. It is good practice, nevertheless, to wear gloves when handling such materials, because metals (like uranium) can oxidize and develop a flaky surface. Use of metal cladding or a paint-type surface coating may be necessary to avoid loose contamination. Respiratory protection may also be needed.

Certain radioactive metals have such high surface dose rates that they must be handled only with remote control devices. If a solid radioactive metal has a loose contaminating layer of radioactivity on its surface, it must be handled in a ventilated enclosure equipped with a high-efficiency exhaust filter. In each case, the radiation level of the particular material and its composition must be known before safe handling practices can be determined.

Instrument measurement of the dose rate from the material help determine the control measures needed. Exposure time, distance, and shielding are the basic control measures. Confinement and other means to avoid intake of radioactive material constitute other important control measures. Review of processes and handling history, visual inspections, and smear and air sampling are useful when determining the probability of contamination incidents and the necessary control measures.

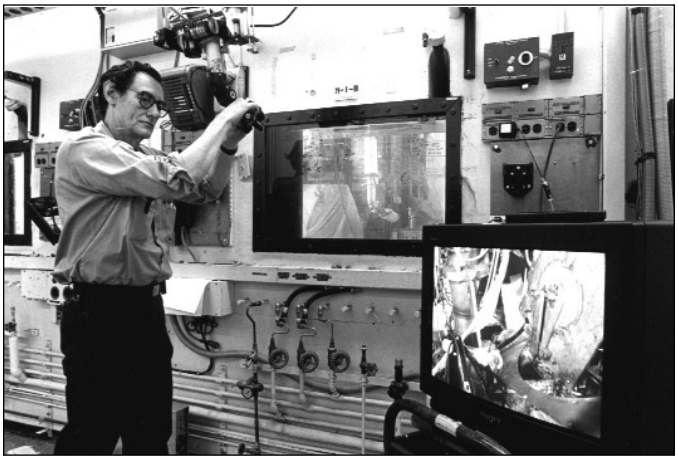

Figure 10–19. Use of a remote camera and external video screen for viewing areas in a hot cell.

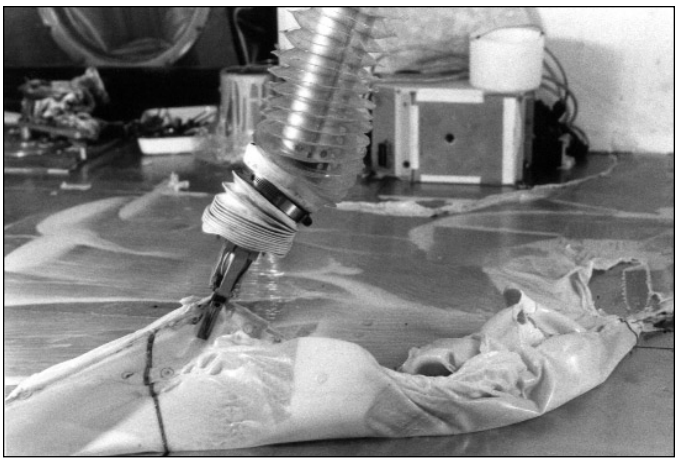

Figure 10–20. Remote removal of strippable decontamination paint in a hot cell.

Uranium metal will burn under certain conditions and, along with some alloys used in chemical operations, poses a chemical explosion hazard. Casting of uranium metal must be done in a vacuum. It is necessary to use an inert gas, rather than air, to break the vacuum. Wastes and scraps must be carefully handled from the time they are generated until they are ultimately disposed of, not only for reasons of safety, but also because of their monetary value.

Cutting of uranium with abrasive cutoff wheels requires special local exhaust ventilation. Because chips, turnings, and finely divided uranium burn spontaneously under some conditions, it is advisable to convert uranium into oxide daily, as the scrap is accumulated. Uranium-contaminated waste requires packaging that meets U.S. Department of Transportation and disposal site criteria.

CRITICALITY

Criticality is the fissioning, or breaking apart, of nuclei, with emission of neutrons at a rate faster than neutrons are absorbed or lost from the system. It results in a highly hazardous instantaneous burst of neutrons with associated high-level gamma-radiation. Whenever the presence of fissionable radioactive materials such as uranium-235 and plutonium-239 necessitates criticality controls, an expert in this area of radiation safety must be involved.

A number of fatalities have resulted from criticality incidents, and even personnel at considerable distances from the source can receive severe radiation exposure. Stringent controls over amounts and movement of fissionable materials are necessary. Immediate local sensing of a critical incident and audible alarms to trigger quick evacuation are other precautions employed to protect against this hazard.

PLUTONIUM

Plutonium is a highly hazardous alpha-emitter that must be handled under rigidly controlled conditions. Enclosures, some of which are called glove boxes or dry boxes (Figure 10–21), must be carefully designed and are relatively expensive. Glove boxes must be maintained at a negative pressure, and may necessitate an inert atmosphere such as argon or nitrogen to avoid fires. Plutonium is pyrophoric under certain conditions. Plutonium-239 is fissionable and presents a criticality control problem when sufficient amounts are present (>300 grams).

Glove-box exhaust gas is usually filtered by two or more high-efficiency particulate air (HEPA) filters in series. Emergency power for exhaust ventilation and alarms for loss of negative pressure in the boxes are system safety features.

Because glove-box gloves can develop pinholes, cracks, tears, or punctures, workers wear another pair of protective gloves when using them. Workers should monitor their gloved hands periodically and monitor and remove protective clothing when leaving the work area.

Operational Factors

Ascertain the required level of radiation protection and evaluate the problems that might arise by analyzing the radiation work in terms of the following factors:

- ➢ Area involved (in square feet or meters), and number of rooms and buildings.
- ➢ Number of employees exposed to radiation and in what locations.
- ➢ Chemical and physical states of the radioactive material and the nature of its use.
- ➢ Incidents that might occur and their possible locations.
- ➢ Nonradiation hazards involved.
- ➢ Nature of the probable radiation exposure or release of radioactive material:

  Controlled, or supervised, release (as in a disposal operation)

  Accidental release or exposure that cannot be sensed by radiation-detection instruments

  Violent release of dust, droplets, gases, or vapors through fire, increase in temperature, or explosion

  Spread of contamination as the result of its adherence to other material or through spillage
- ➢ Inherent danger of the material because of its internal or external effect on humans. This danger depends on the isotopic and chemical forms of the material (Bibliography, NCRP Report 22).
- ➢ Probability of detection of hazardous situation by routine surveys or monitoring.
- ➢ Knowledge of current conditions is essential to determine the acceptability of the risks involved.
- ➢ Possible effects of accidents on operations, such as interruption of production, loss of occupancy of space, loss of equipment, and cost of cleanup.

Employee Exposure Potential

The industrial accidents that can produce radioactive contamination are usually no more difficult to prevent than the more common types of industrial accidents, but there is an added, compelling reason to control them—the danger of intake of radioactive materials by personnel.

Monitors for detecting radioactive contamination of personnel are shown in Figures 10–13 and 10–18. It is impor-

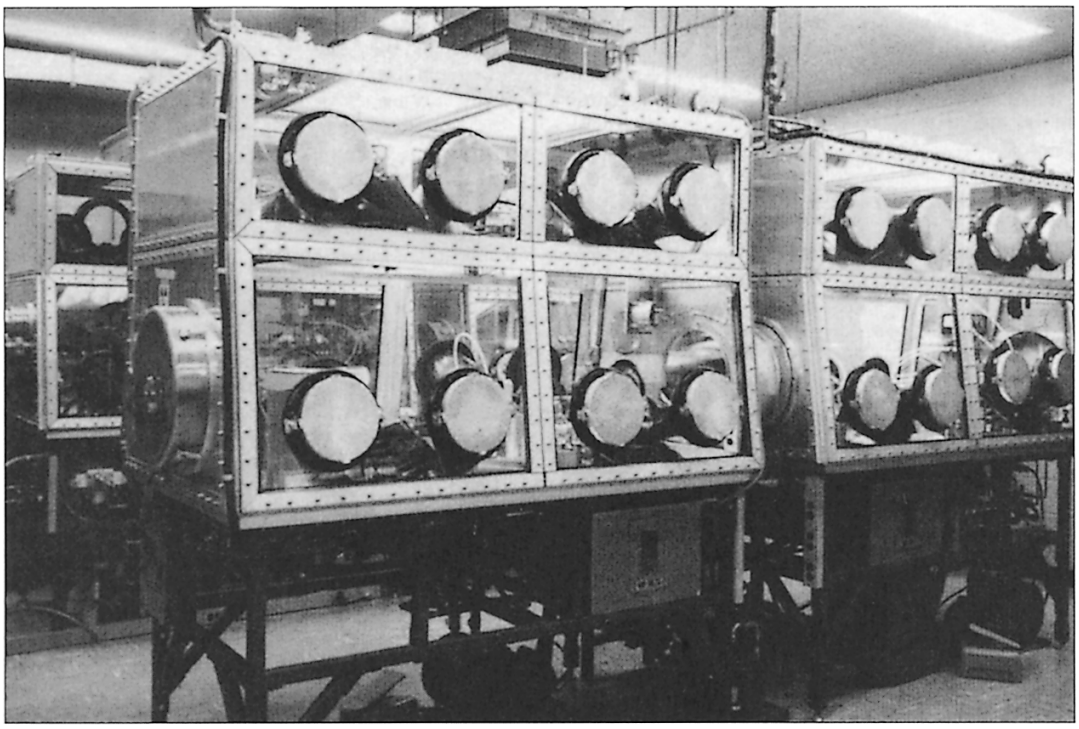

Figure 10–21. A glove box type of hood permits rigid control of conditions when radioactive metals are worked. (Courtesy Argonne National Laboratory.)

tant that the appropriate monitoring instruments be available and properly maintained and calibrated.

EXTERNAL HAZARDS

Under ordinary operating conditions, and barring accidents, the level of exposure to external radiation can be determined through use of continuously monitoring instruments or dosimeters, or from previous measurements of radiation fields for identical operations. The problem is then reduced to limiting the rate of exposure or the length of exposure time. Instrument measurement of the exposure indicates what advantage can be obtained by installing additional shielding or by having personnel work farther from the source of radiation.

Under emergency conditions with high-exposure levels, it is advisable to rotate personnel so as to prevent exposure of any one individual above guide levels. Emergency exposure levels for extreme conditions have been published in NCRP Report No. 116, *Limitation of Exposure to Ionizing Radiation*. These are essentially once-in-a-lifetime allowances for handling an extremely serious situation.

Occasionally, an unexpectedly high reading appears on a personal dosimeter. While the reading may be invalid for any one of a number of reasons, an investigation should be conducted to determine whether or not the reading was valid and what should be done to prevent recurrences.

INTERNAL HAZARDS

Inhalation is the most frequent route of entry of radioactive material into the body. Routine air sampling can detect the concentration, and a constant air-monitoring system can be designed to sound an alarm if hazardous levels are detected. Also, employees are likely to recognize conditions that in the past have resulted in exposure, and can act promptly to minimize exposure.

In the event that a spill of radioactive material is detected by immediate recognition, hand and foot monitoring, or through air or room surface monitoring, prompt action is essential. If there is a potential inhalation hazard, personnel should evacuate to the nearest safe location. Further movement of workers should be restricted until a monitoring survey can be done to determine the extent of radioactive contamination. Quick arrangements should be made to restrict exit from and entry into the building, wing, or laboratory until there is a determination that radioactivity has not and will not be tracked or carried out to other areas. Corridors should be roped off or posted to control movement until monitoring of personnel, surface, and air shows that contamination is controlled.

It is important to isolate and clean up a spill as soon as possible. Personnel who conduct the monitoring and cleanup should wear appropriate protective equipment and clothing. The incident can be resolved as soon as there is assurance that the potential hazards have been controlled.

A less common route by which radioactive material enters the body is through broken skin, and in rare cases this can be more serious than entry through the lungs. When radioactive materials gain entry through a minute cut or abrasion, they enter the bloodstream and are then dispersed throughout the body. The result can be serious if there is a high concentration of the radioisotope at the skin break. If the workers have been appropriately educated, the injured person will be aware of the possible danger and can request a radiation survey of the wound area.

By and large, absorption through intact skin is not a significant route of entry. Tritiated water vapor is one of the exceptions; it is absorbed rapidly through unbroken skin. It is important to scrub up immediately when significant skin contamination occurs. This minimizes the possibility of entry through inhalation, ingestion, or a subsequent skin break and prevents the spread of the radioactive material.

Analysis of the radionuclide content of body fluids and excreta and whole-body counting are important for after-the-fact detection of intake of radioactivity. When the presence of radionuclides within the body is detected or an accidental intake of radionuclides becomes known, steps should be taken to determine the cause and prevent recurrence. This serves as a backup to environmental monitoring.

Records

Some diseases that are caused by exposure to radiation or radioactive materials occur after many years of exposure. Retention of suitable records relating to exposures and working conditions is desirable and is usually required.

SUMMARY

It is impossible to discuss all of the important aspects of radiation safety in a fundamentals manual such as this. Nevertheless, health and safety professionals will have a good background for further study and assistance in radiation safety if they do the following:

- ➢ Recognize that ionizing radiation control requires the expertise of qualified health physics personnel.
- ➢ Treat radiation and radioactive materials with respect because of the recognized potential hazards.
- ➢ Recognize the two distinct types of exposure hazards involved: external and internal.
- ➢ Learn about the various types of ionizing radiation.
- ➢ Know that calibrated monitoring instruments appropriate for the specific type of ionizing radiation must be used for measurements.
- ➢ Recognize the importance of basic exposure control measures including time, distance, and shielding.
- ➢ Know that control guidelines and exposure limits must be followed.

Chapter 11

Nonionizing Radiation

by Gordon Miller, CIH
revised by Michael Yost, PhD

Radar was one of the scientific wonders to emerge from World War II, but there is controversy over whether it is safe. Microwaves are finding more and more uses as portable communications change from luxury to necessity. There is a radar in a box in most kitchens and no food products supplier can ignore the need to package food so it is microwavable. Lasers were a scientific wonder of the 1960s, but now laser CDs have displaced phonograph disks and most offices have at least one laser printer. One hallmark of technological change is the increasing use of the electromagnetic spectrum, and it is certain that new uses of electromagnetic energy will be found after this edition is published. Perhaps the scientific controversy regarding the safety of power line fields will be at least partially resolved before this chapter is revised for the next edition. This chapter presents the basic principles of electromagnetic fields and radiation and how to protect people from the hazards associated with this energy.

ELECTRIC AND MAGNETIC FIELDS

Electric Fields

Atoms are divided into a central part, the *nucleus,* and *electrons* that orbit around the nucleus. The *protons* in the nucleus carry what is arbitrarily called a *positive charge* and the *electrons* orbiting about the nucleus carry what is called a *negative charge*. Negative charges attract positive charges, negative charges repel other negative charges, and positive charges repel other positive charges. These parts are able to exert a force on other distant objects; they create a force field. This field is an electric field, often visualized as lines of force that originate at a positively charged object and end at a negatively charged object, as shown in Figure 11–1. The charge state (positive or negative) is the *polarity*. The force exerted by a charged object on another charged object at a distance depends on the amount of charge in the objects, the

polarity of the charges in the objects, and the distance between them. *Force* is directly proportional to the amount of charge and decreases as the distance between charged objects increases according to an inverse square relationship. If some level of *electric force* exists at a given distance, the electric force is one quarter as great at twice the distance, one ninth as much at three times the distance, and so on. Any charged object creates an electric field whether it is stationary or in motion.

The electric force is very powerful. Opposite charges attract and meet to cancel each other out. For example, the protons in the nuclei of atoms attract an identical number of electrons so the atom is neutral. Electrical imbalances are rare, so a much weaker force created by all matter—gravity—dominates. An object carrying an electric charge is an *ion.* An *ion* can be an atom carrying too few or too many electrons or a bigger object, such as a dust particle, with a deficit or surplus of electrons.

Magnetic Fields

A *moving* electric charge creates yet another field: *magnetism.* Imagine electric charges are moving in some direction, such as through a wire. The amount of charge flowing past a given point is the current. *Magnetic fields* exist in a direction perpendicular to the direction of the current flow. The orientation of the field is such that the north-seeking end of a compass needle points as shown in Figure 11–2a. Magnetic field polarities are given as north and south, and magnetic fields are usually visualized as lines of force that start at the north pole of a magnet and come back around, land on the south pole of the magnet, and complete a circuit by going through the body of the magnet until they reemerge at the north pole. Thus, magnetic fields don't radiate out into space as electric field lines do; they return to the other pole, as shown in Figure 11–2b. The north pole of a magnet points to the north pole of the Earth.

A magnetic field exerts a force on moving electrically charged particles in a direction perpendicular to the field. The force is proportional to the amount of moving charge (the current flow) and the distance between the system carrying that current and a charged object.

When a magnetic field changes, in time it causes nonmoving charges to move or induces a current flow in objects that conduct electricity, including the human body. The human body is mostly made of salt water, a good conductor filled with ions. Thus, a person in a changing magnetic field experiences current flow in loops oriented perpendicular to the direction of the magnetic field, as shown in Figure 11–3.

People are usually unaware of this current flow, but it is always happening because they are immersed in magnetic fields that change with time (time-varying fields) arising from the transmission and use of alternating current (AC) electricity. The polarity and strength of the current keeps alternating between positive and negative, so it is called alternating cur-

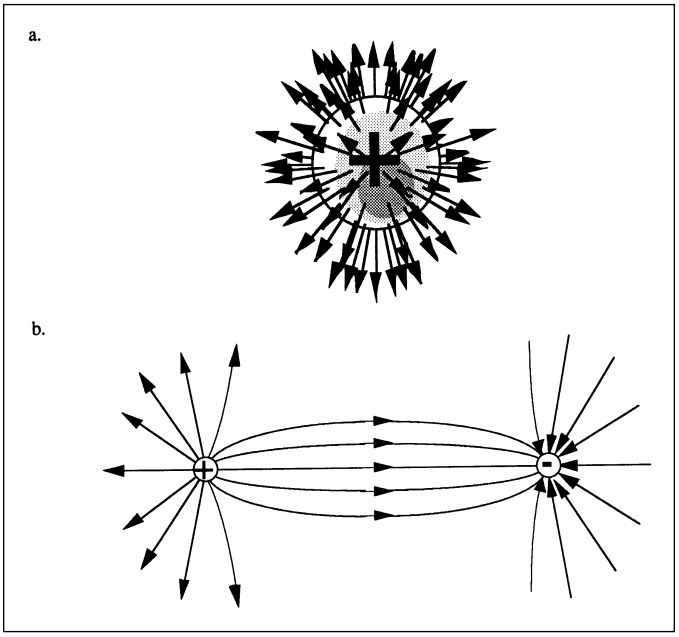

Figure 11–1. Depictions of an electric field. a. Electric field lines originating at a positively charged object and extending out equally in all directions. b. Electric field lines leaving a positively charged object and landing on a negatively charged object. If the objects had the same charge, the field lines would push away from each other.

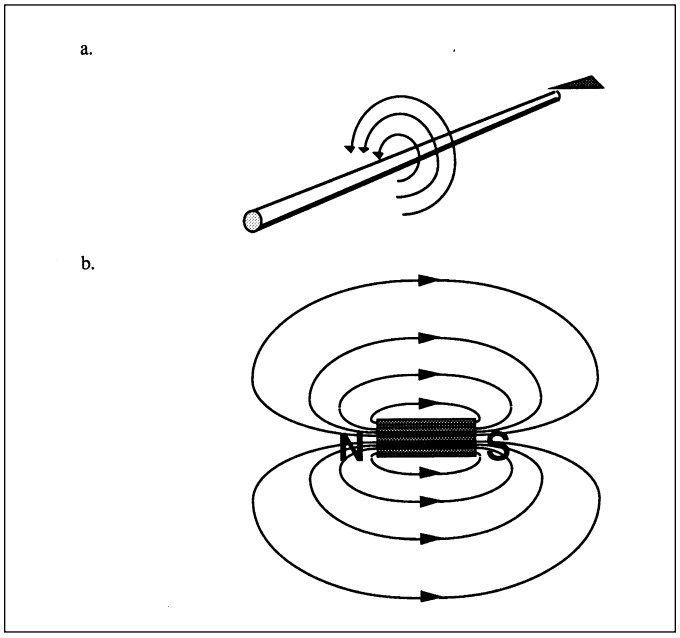

Figure 11–2. Depictions of a magnetic field. a. Magnetic field created by current flow. In this figure, current flows from negative to positive, as shown by the arrow pointing right at the upper end of the wire. The north-pointing needle of a compass will point in the direction of the smaller arrows around the wire. b. Fields around a common bar magnet. Fields form loops that are assumed to start at the north pole, come around to land at the south pole, and move through the magnet. The current flow that creates the field of a permanent magnet is the movement of electrons around atoms.

rent. In the United States and Canada, polarity changes occur 60 times a second (50 times a second elsewhere).

The history of AC power is worth describing because it underlies concerns about power line fields and introduces the basic law of electrical engineering: Ohm's law. Resistance describes the proportionality between the current flow in a conductor, and the potential difference (voltage) across the conductor. Electric current flows from one pole of a source to the other pole, through the source, and back out again for further rounds in the pathway or circuit. The current is measured in units of amperes (A, amps). A useful mechanical analogy is that of the closed-circuit water pump in an aquarium. The pump requires a source of energy to give the water pressure to keep moving because there is resistance to flow in the system. Electrical circuits also have resistance to flow. The unit of electrical resistance (R) is the ohm (Ω) and the unit of pressure or potential that keeps the current flowing is the volt (V). The power (P) is the product of voltage times current, in units of watts. According to Ohm's law, volts equals amps times ohms ($V = I \times R$).

The power loss dissipated in an electrical circuit due to resistance is proportional to the square of the current. Electrical engineers in the early twentieth century faced a problem figuring out how to transmit electric power to distant points. The answer is to keep changing the polarity of the current and use the resulting changes in magnetic fields to induce another current to flow. The device that does this is the transformer, which swaps current for voltage and vice versa. A utility generates current at a voltage of, say, 20,000 V at a power plant, and sends the current to a transformer, which steps up the voltage to create a much smaller current that is transmitted over large distances with low resistance losses. The transmitted current then passes through a sequence of other transformers that step down the voltage in exchange for higher currents and is finally distributed to users at a modest 115 volt potential, as shown in Figure 11–4. Thus electric power is transmitted as a high voltage at a low current, and distributed to customers at a relatively low voltage but larger current. Transmission line voltages range from 69,000 V up to 765,000 V, and the intermediate distribution voltages created by the step-down transformers range from 4,000 to 35,000 V. AC current makes long-distance electrical power systems practical; otherwise, resistance losses would become intolerable.

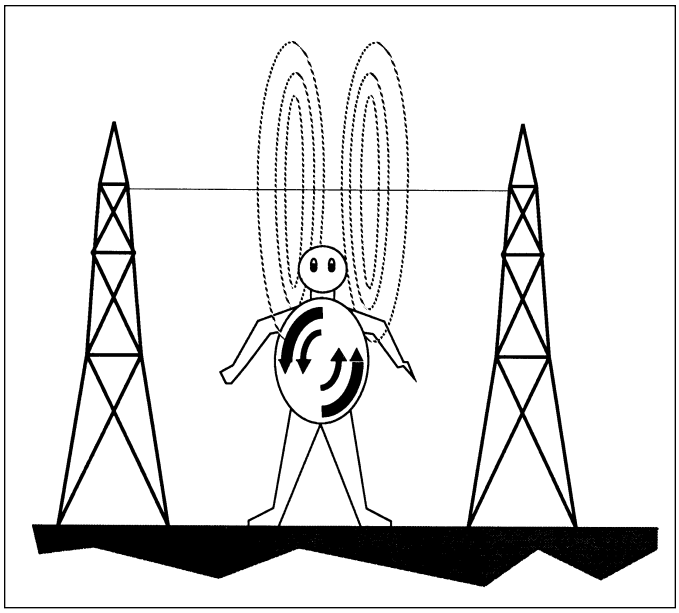

Figure 11–3. Interaction of an AC magnetic field with a person. The field will induce a flow of current at a right angle to the direction of the field. The field radiates out from the line overhead, as shown by dotted lines, but changes direction as the line current changes polarity. The current induced in the body also changes direction. The magnitude of the current is proportional to the radius of the loop it is traveling in, so magnetic fields would be of greatest concern in big organs that are electrically active, such as the brain and heart. (Adapted from Nair, Morgan, and Florig, 1989.)

ELECTROMAGNETIC RADIATION

So far, we have discussed electric and magnetic fields as single entities. There is a common phenomenon where the two exist together: *electromagnetic radiation.*

Electric and magnetic fields change polarities as the fields pass by any given location in space, as shown in Figure 11–5. The number of times the fields change polarity and return to the beginning polarity in a given time is the frequency. The frequency (ν) is usually specified in full cycles of polarity reversals and returns that occur in one second. If the electric field is zero at a given moment and starts climbing to a peak positive value, it will peak, fall back through zero, reach a maximum negative value, and climb back to zero. This is a full cycle. If this happened once in a second, then the frequency would be one cycle per second. If it happens one thousand times a second, then the frequency is one thousand cycles per second. One cycle per second is also called 1 hertz (Hz), after Heinrich Hertz, who discovered radio waves. One cycle per second equals 1 Hz, 1,000 cycles per second equals 1,000 Hz or, using proper metric prefixes, 1 kilohertz (kHz). See Table 11–A for a list of metric prefixes.

Not only do the fields change polarity and strength, but they are rigidly bound together. If the electric field is pointing in some direction, then the magnetic field must move in a direction perpendicular to the electric field, and the wave must travel in yet another direction perpendicular to the other two, as shown in Figure 11–5. Note how the shape of the fields is similar to that of waves on the ocean. They can be drawn by plotting the trigonometric sine or cosine functions and are often called sine waves.

In air and a vacuum, the speed of electromagnetic radiation is 299,792,458 m/s, or about 186,000 mi/s. The speed of light is often rounded off to 300,000,000 m/s. An important way of expressing frequency is the distance the wave travels through one cycle, or the wavelength (λ). The amount of time elapsed

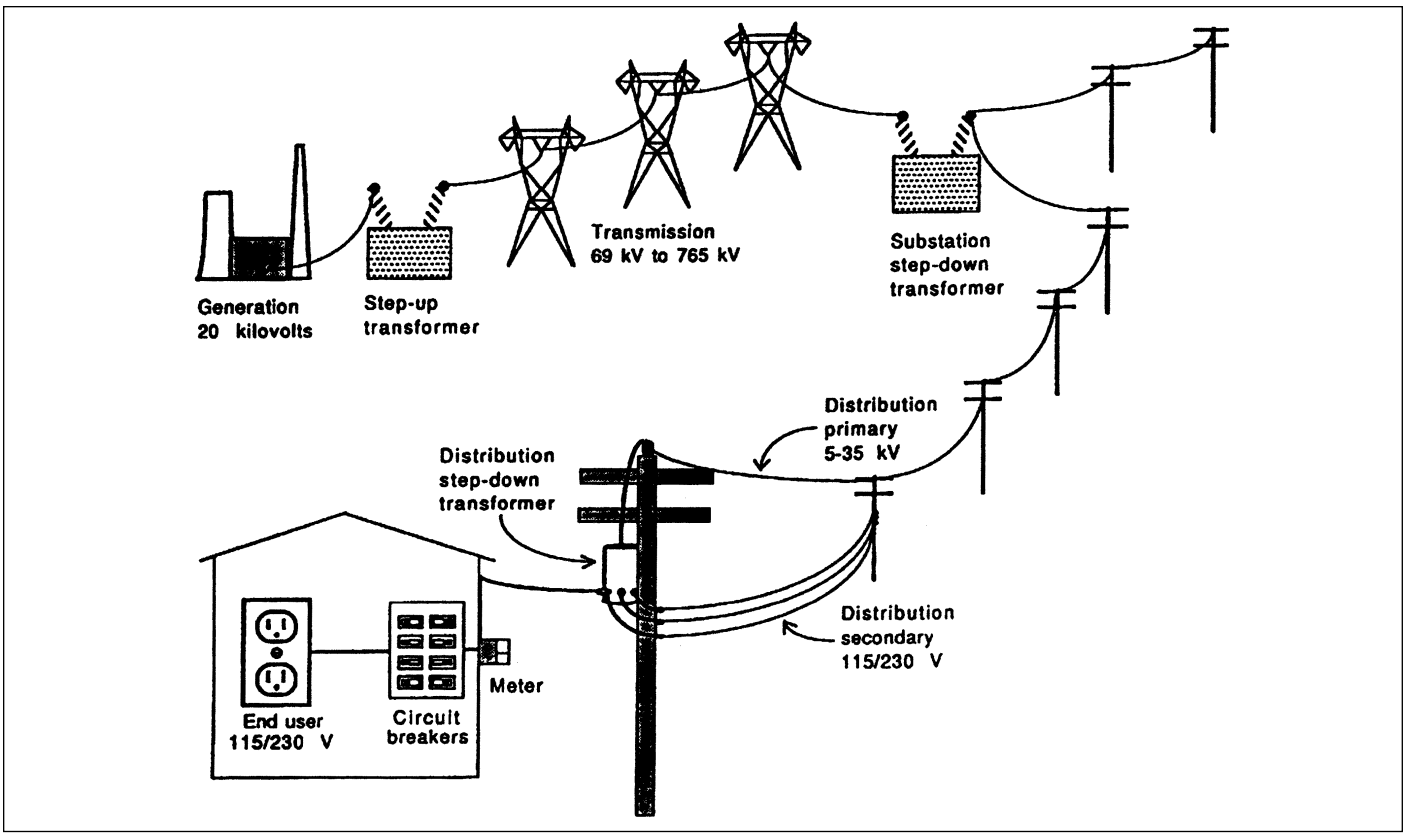

Figure 11–4. Electrical transmission and distribution. Transformers are used at several points, first to step up the voltage and reduce the current so the electricity can be transmitted over large distances with minimal resistance losses, then stepped down to lower voltages at higher current levels before final distribution. Transmission lines are designed to operate with little variation in current, but distribution systems are designed to take broad ranges of current flows. The voltages are fixed at each step and currents vary. (From Nair, Morgan, and Florig, 1989.)

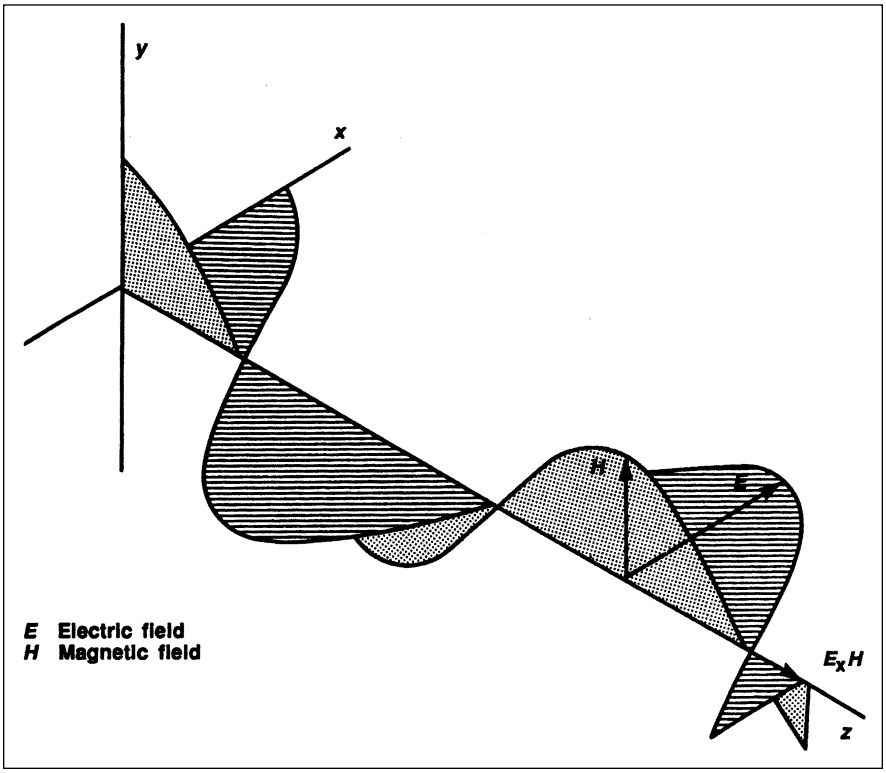

Figure 11–5. The components of electromagnetic radiation. Note that the electric field (E) is oriented in one direction (shown by line-filled curves) whereas the magnetic field (H) (shown by dot-filled curves) is perpendicular to the electric field and the direction of travel is perpendicular to the other two. The number of times that the fields change from a given strength and polarity to the opposite polarity and back to the starting strength and polarity in a second is the frequency. Polarization (not to be confused with polarity or charge state) is the direction of the electric field in relation to the surface of the earth. If the earth were below this page, then this wave would be horizontally polarized. If the electric field were turned 90 degrees (vibrating perpendicularly to the earth's surface), then it would be vertically polarized. The electric field can be caused to change direction constantly; it is circularly polarized if it points in all directions equally, or elliptically polarized if it points more in one direction than another.

Table 11–A. ***Metric Prefixes***

Prefix	*Abbreviation*	*Definition*	*Scientific Notation*	*Common Uses in Nonionizing Radiation*
Atto	a	pentillionth	10^{-18}	—
Femto	f	quadrillionth	10^{-15}	—
Pico	p	trillionth	10^{-12}	Picometer (ionizing radiation wavelengths)
Nano	n	billionth	10^{-9}	Nanometer (UV, visible, and IR-A wavelengths)
Micro	μ	millionth	10^{-6}	Micrometer (IR-B, IR-C wavelengths), microjoule (energy level), microwatt (power level)
Milli	m	thousandth	10^{-3}	Millimeter (microwave or IR-C wavelength), milliwatt (power level)
Centi	c	hundredth	10^{-2}	Centimeter (microwave wavelength)
Kilo	k	thousand	10^{3}	Kilohertz (radiofrequencies), kilometers (wavelengths of radiofrequency and extremely low-frequency radiation), kilowatt (power level)
Mega	M	million	10^{6}	Megahertz (higher microwave frequencies), megawatt (power level), megajoule (energy level)
Giga	G	billion	10^{9}	Gigahertz (higher microwave frequencies), gigawatt (power level)
Tera	T	trillion	10^{12}	Terahertz (IR and visible frequencies)

Exa	E	pentillion	10^{18}	Exahertz (ionizing radiation frequency)

during one cycle is called the period, which is calculated by dividing 1 by the frequency, in Hz. The frequency times the wavelength must equal the speed of light, so as frequency increases, wavelength decreases. Wavelength can be calculated by dividing the speed of light, 300,000,000 m/s, by the frequency. Thus, radiation with a frequency of 300,000,000 Hz has a wavelength of 1 m; 60 Hz radiation, if encountered, would have a wavelength of 5,000,000 m (about 3,100 mi).

Electromagnetic Spectrum

The electromagnetic spectrum is summarized in Table 11–B. Note the immense variation in frequencies. A gamma-ray might have a frequency of about 3,000,000,000,000,000,000,000 Hz (300 EHz, wavelength about 0.1 pm), a helium-neon laser pointer has a frequency of about 474,400,000,000,000 Hz (about 474 THz, wavelength 0.632 μm), a microwave oven has a frequency of 2,450,000,000 Hz (2.45 GHz, wavelength 12.2 cm), a well-known New York AM radio station broadcasts at 710,000 Hz (wave length 422 m), and the U.S. Navy's submarine communications system operates at 76 Hz (wavelength about 3,945 km). This is an immense span of frequencies. Frequency is extremely important because the energy of a parcel of electromagnetic radiation, or photon, is directly proportional to its frequency. The electromagnetic spectrum is divided into four parts in this chapter: Subradiofrequency ranges from 0 to 3 kHz, radiofrequency/microwave (RF/ MW) ranges from 3 kHz to 300 GHz, optical radiation ranges from 300 GHz to 3×10^{15} Hz, and ionizing radiation exists at higher frequencies. This chapter covers all of the electromagnetic spectrum except ionizing radiation, which is covered in Chapter 10.

The strength of the magnetic field and the strength of the electric field are related to one another. The ratio of the two is set, in accordance with Ohm's law, by the resistance of the medium in which the radiation is traveling. In air and a vacuum, the resistance is 377 ohms.

The two fields together transmit power through an area of space that can be expressed in watts of power passing through an area of space or striking a given surface area. It is customary to adjust the units to milliwatts of power per cm^2 of area. Radiofrequency and microwave specialists call this power *density;* laser and optical specialists call it *irradiance*. These different terms have the same units and same meaning.

Because power losses are proportional to current, today we use AC electricity. This results from the second basic relationship of electrical engineering: Power (P), in watts, equals current (I), in amps, times resistance (R), in ohms. Recall Ohm's law, which states that volts equals amps times ohms. Combining these two relationships gives the relationship watts equals amps times amps times ohms, or $P = I^2 \times R$. Given that the resistance of air and space is 377 Ω, the relationships given in Table 11–C are widely used by people who do field surveys of radiofrequency and microwave radiation.

WHEN ARE FIELDS IMPORTANT AND WHEN IS RADIATION IMPORTANT?

This question is important in the radiofrequency and microwave portion of the spectrum for two reasons:

- ➢ The strengths of the fields in radiation are rigidly related to each other so only one field must be measured (usually the electric field). Both the electric and magnetic field must be measured where radiation does not exist.
- ➢ Radiation obeys the inverse square law unless the source happens to be a laser, so a field strength measurement at one location can be used to calculate field strengths at other distances in the same direction from the source.

Table 11–B. *Two Views of the Electromagnetic Spectrum*

Frequency (Hz)		*Name*	*Wavelength (m)*	*1 (other units)*	*Photon Energy (eV)*	*Type*

Table 11–C. ***Relationships Between Electric Field Strength, Magnetic Field Strength, and Power Density (Irradiance) for Electromagnetic Radiation***

$S_m = E^2/3{,}770$
$S_m = 37.7\ H^2$
$E^2 = 3{,}770\ S_m$
$E = (3{,}770\ S_m)^{1/2}$
$H^2 = S_m/37.7$
$H = (S_m/37.7)^{1/2}$
S_m = Power density in units of mW/cm
E^2 = Electric field strength^2 (V^2/m^2)
E = Electric field strength (V/m)
H^2 = Magnetic field strength^2 (A^2/m^2)
H = Magnetic field strength (A/m)

Separate fields are commonly found at lower frequencies (longer wavelengths). Radiation is commonly found at higher frequencies (shorter wavelengths). As a rule, separate fields are found within one to a few wavelengths of a source. Light has wavelengths ranging between 400 and 760 nm, so light is always found as radiation. A 60-Hz wave has a wavelength of 3,100 miles, so it follows that fields, rather than radiation, are found around power lines. Electrical engineers refer to separate fields as near fields (because they are found close to sources) and to places where radiation is found as far fields. Near fields are divided into *reactive* near fields, which are electric fields created by the voltages and magnetic fields created by current flows in the source, and *radiating* near fields, where electric and magnetic fields combine to form radiation that travels away from the source. The relationship between electric and magnetic field strengths in both near fields is not rigid, so both fields must be measured separately. Electrical engineers have formulas and rules for calculating the distance from specific antennas where far fields exist. It is customarily assumed that separate fields exist when the wavelength is more than about 1 m (frequency of 300 MHz) and that radiation exists at shorter wavelengths or higher frequencies. As a result, *separate electric and magnetic field surveys are needed for frequencies of 300 MHz and less.*

Parts of an Electromagnetic Device

Any electromagnetic device, whether it is a microwave antenna, junkyard magnet, or laser, can be visualized as having three parts: a source, a transmission path, and a receiver. A laser scanner in a CD player has a laser embedded in the device, optics to transmit the energy to the disk, and a sensor to receive the reflected energy. A 27.12 MHz plasma etcher has an energy source, a cable to transfer the energy, and a chamber where the energy is deposited to do work; these are often all located in one cabinet. A surveyor always needs to be aware of these parts and their locations. Particular attention should be paid to the transmission path, which could pass through open air, an enclosed passage such as a microwave waveguide that could leak at joints or connections, or a fiber-optic cable that could be cut or broken.

SUBRADIOFREQUENCY FIELDS: 0–3,000 HZ

Because the distance where radiation is dominant is about one wavelength, fields, rather than radiation, are considered in this section. The wavelength of the highest frequency in this section, 3 kHz, is 100,000 m, or about 61 mi. Static fields do not produce radiation. As shown in Table 11–D, the subradiofrequency portion of the spectrum includes the extremely low frequency (ELF) band, which includes AC fields and radiation up to 300 Hz, and the voice frequency band, which includes frequencies from 300 to 3,000 Hz. Power lines use 50 or 60 Hz currents, which create fields at these frequencies; these frequencies are often called power frequencies.

Field Strengths

Electric fields can be measured by inserting a displacement sensor, a pair of flat conductive plates, into the field and measuring the electric potential between the plates. The electric field lines land on one plate and create voltage that drives a current through the meter to the other plate, where the field lines continue as shown in Figure 11–6. The electric field can be calculated by dividing the voltage between the two plates by the distance between the plates. If a 1-kV potential were found to exist and the plates were 1 m apart, then the electric field strength would be 1 kV/m; if the plates were 0.5 m apart and the potential were 1 kV, then the electric field strength would be 2 kV/m. Instruments like this are widely used for measuring electric fields at frequencies ranging up to 100 kHz.

Magnetic fields are often measured with loops of conducting wire, as shown in Figure 11–7. The lines of magnetic field passing through the loop induce current flow. The field can be calculated by measuring the amperes of induced current and dividing that by the circumference of the loop. The common unit of magnetic field strength in the United States was the gauss (G), but it is being replaced by an SI unit, the tesla (T): 1 T = 10,000 G, 1 mT = 10 G, and 1 μT = 10 mG. One G ≅ 80 A of induced current per meter of circumference of conducting loop (A/m).

How Do Fields Interact with the Body?

The body is a conductor of electricity, but it does not have well-known magnetic structures. (At the time this chapter was prepared, research suggested that microscopic magnetic structures exist in the human brain.) We have seen that electric charge imbalances are balanced as quickly as possible. Imagine you were below a high-voltage electric transmission line, as shown in Figure 11–8, and the line's polarity was positive. Your body would develop a corresponding negative charge because the positive charge above would attract any movable negative charge toward it. These charges would come from your body and from the infinite pool of charges

Table 11–D. ***Uses of Radiofrequency and Subradiofrequency Fields***

0 Hz	DC					

you were standing on, the ground. The electric field lines would originate at the power line and land on your body. As the polarity reversed, the charge in your body would subside and reverse; the rush of negative charges into your body would be replaced by an exodus of negative charges, so you would take on a positive charge as the line overhead became negatively charged. The electric field lines are perpendicular to the conducting surface they end at or leave. The result of this perpendicularity phenomenon is that a person in an electric field created by a source above the person, such as a power line, distorts field lines in from nearby space so they land perpendicular to the head. As a result, the electric field around the head becomes highly concentrated and intense. At other regions of space, the electric field lines are spread further apart, lowering the field intensity. If this person was holding an electric field meter at waist height, the surveyor's body would largely shield it and the reading would be falsely low. The reading also could be falsely increased if the surveyor was the tallest object in the area and the field source was above the surveyor.

Magnetic fields are easier to measure, because the human body does not perturb the magnetic field as it perturbs the electric field. We are filled with conductive brine, so a magnetic field that changes with time induces loop-shaped current flows in a direction perpendicular to the field, as shown in Figure 11–3. The strength of the induced current is proportional to the strength of the magnetic field and the radius of the loop in which the current is flowing. The current at the center of the loop is zero and reaches a maximum level at the rim of the loop.

BIOLOGICAL EFFECTS AND STANDARDS FOR STEADY (DC) ELECTRIC FIELDS

Steady fields are created with charges and currents that do not change polarity or strength with time. Steady electric fields are not a significant area of concern today; in fact, no instrument is marketed that is intended for use in safety surveys for DC fields (although there are instruments that can be adapted for exposure surveys). The adverse effects identified by the Non-Ionizing Radiation Committee of the Inter-

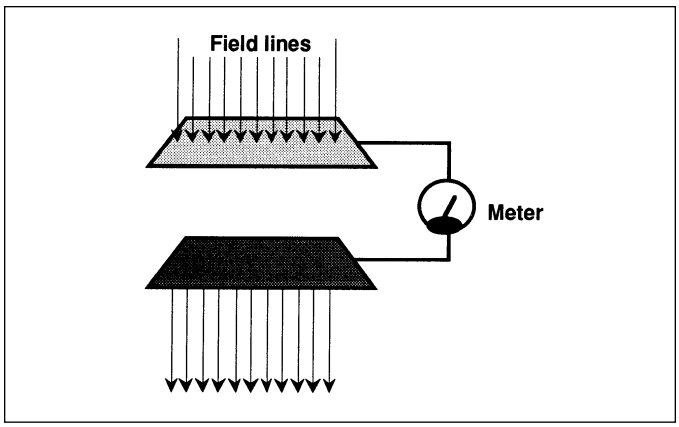

Figure 11–6. Displacement (split-plate) electric sensor used for AC field instruments in extremely low-frequency through medium-frequency regions (>0 Hz–3 MHz). Note that field lines impinge on the upper plate, drive a current through the meter, and reemerge at the other plate. The field strength is the voltage difference between the two plates divided by the distance (V/m).

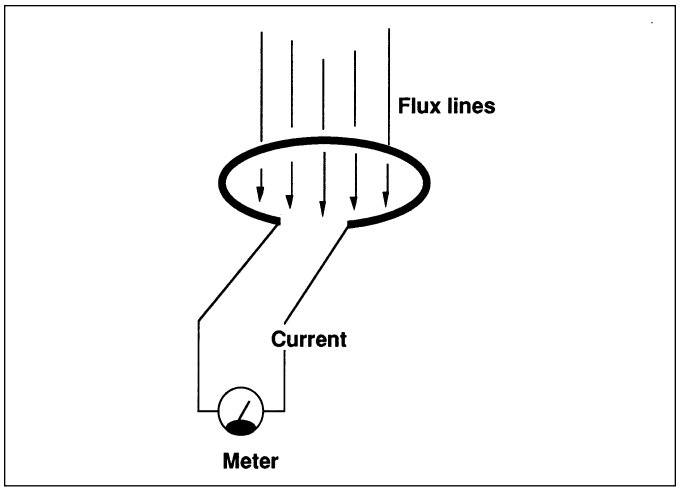

Figure 11–7. Most AC magnetic field survey instruments use looped conductors. The changing magnetic field induces a flow of current in the loop. The unit of field measurement is the amperes of current induced to flow through a specified distance of loop (A/m). The induced current is proportional to the sine of the angle between the loop and field. If the loop is parallel to the field, the sine of 0° is 0 and no current is induced to flow. If the loop is perpendicular to the field, as shown, the sine of 90° is 1, so the loop will give a maximum response. Thus, measurements made with one loop are highly directional. Rotating a loop like this in a magnetic field produces a sinusoidally changing current.

national Radiation Protection Association (now the International Commission for Non-Ionizing Radiation Protection, or ICNIRP) are as follows:

- ➢ Irritating sparks could occur at electric field strengths of 5 kV/m or more.
- ➢ Painful sparks could occur at electric field strengths of 15 kV/m.

The 2001 Threshold Limit Value (TLV®) for DC electric fields from 0 Hz to 100 Hz is 25 kV/m as a ceiling limit (a limit that should not be exceeded for any length of time).

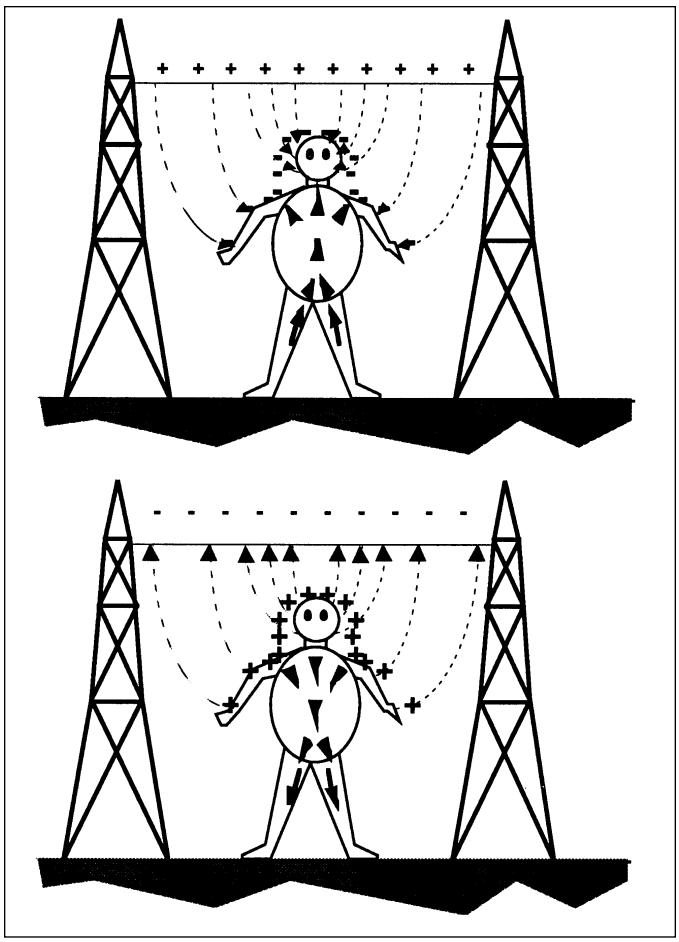

Figure 11–8. Induction of current by an external magnetic field. a. The overhead transmission line has a positive voltage. The electric force (dashed lines) induces negative charges to accumulate in the person's body. The negative charges enter the body as a flow of electrical current from the ground. This happens 60 times a second. b. 1/120 of a second later, the line's charge is negative, inducing a positive charge in the body created by a flow of electrical current into the ground. Radiofrequency fields can create similar current flows, but at higher frequencies. (Adapted from Nair, Morgan, and Florig, 1989.)

The field strengths in the TLV are the field levels present in air away from the surfaces of conductors (where spark discharges and contact currents pose significant hazards). It applies to both partial-body and whole-body exposures.

BIOLOGICAL EFFECTS AND EXPOSURE STANDARDS FOR STATIC MAGNETIC FIELDS

Magnetic effects are caused by charges in motion or changes in magnetic fields. The static fields from permanent magnets or superconducting magnets do not change with time, so any interaction would need to occur where charges are in motion. Blood is briny material, so magnetic field effects can be expected in the circulatory system where charges are in motion. The effect can be seen on an electrocardiogram

(ECG) made while an animal is in a static magnetic field. The entire output of the heart is pumped into the aorta at high speed. This flow induces a magnetohydrodynamic (MHD) voltage that appears on the ECG at the same time as the T wave of the heart. The added MHD voltage makes the T wave look bigger. The bigger the magnetic field, the bigger the T wave; when the magnetic field is shut off, the T wave reverts to normal.

Based on this effect, the current TLV® is 60 millitesla (mT), or 600 G, which is based on limiting the average MHD voltage to 1 mV. It is an 8-hour time-weighted average (TWA) criterion. The peak exposure is set at 2 T, based on medical imaging exposure limits. The International Commission for Non-Ionizing Radiation Protection announced guidelines for static magnetic fields in the January 1994 issue of *Health Physics* that retain the 2 T peak exposure limit but raise the TWA exposure limit to 200 mT (2,000 G). This change accounts for MHD voltage and is based on human experience and on the results of lifetime exposure studies involving mice exposed to 1 T, which demonstrated no effects. Humans exposed to 4 T fields are reported to experience symptoms such as nausea, metallic taste in the mouth, dizziness, and, when the head is moved, magnetic phosphenes.

Another effect is worth noting. Rotating the earth's magnetic field, which is usually about 0.5 G, disrupts the circadian rhythms of test animals and fluctuations in body function that are associated with time of day, such as hormone levels and body temperature. This is related to our sense of time, which is perceived as jet lag. This effect occurs if the animal is unaware of the day–night cycles around it, but even 9 T fields did not break the sense of time of animals aware of light–dark cycles. People who work in strong magnetic fields should avoid unusual shift work that causes them to lose track of day–night cycles.

Other Safety Concerns of Static Magnetic Fields

Before leaving static magnetic fields, it is necessary to consider two related issues: the effects on medical electronic devices and classic safety concerns. Artificial cardiac pacemakers work by amplifying the electrical activity of the natural pacemaker tissues of the heart. The electrical output of the pacemaker changes as the electrical activity of the heart's pacemaker tissue changes. Artificial cardiac pacemakers can be fooled by ambient electric and magnetic fields, including very strong AC fields. When this happens, they could amplify the AC fields instead of boosting the activity of the natural pacemaker, and the heart, now trying to work at 60 Hz, would not circulate blood. Pacemakers have built-in protective circuits that sense malfunctions and cause the pacemaker to send impulses to the heart at a fixed rate. The wearer tests these circuits in a cardiologist's office (or at home while in telephone/telemetry contact with a cardiologist) by changing the setting of a reed switch in the artificial pacemaker so it fires at the fixed rate. A permanent magnet held over the pacemaker is used to reset the reed switch. Thus, strong static fields could cause this reed switch setting to inadvertently change in places where no medical supervision is available. Magnetic fields stronger than 0.31 mT (3.1 G) could reset some very susceptible pacemakers, so a pacemaker safety criterion of 0.5 mT (5 G) has been set; this criterion may be revised to 0.3 mT in the near future.

Magnetic fields exert forces on objects that can be magnetized. The degree to which material can be magnetized depends on its permeability. Aluminum, stainless steel, plastics, and organisms are not permeable. Soft iron, steel, and various transition metal alloys (such as those of nickel and cobalt) are permeable. Tools and some medical implants are made of permeable alloys so they can move in a strong magnetic field. The force of such a field is proportional to the strength of and gradient of the field (the rate at which that field changes intensity through some part of space). A steel wrench in a perfectly uniform super-strong magnetic field would not move because there is no gradient, but it would move as it was taken from the strong field through a weak field. The force is also proportional to the object's permeability and volume. A nonpermeable stainless steel wrench would not move even in a strong and rapidly changing field. Thus, tool and compressed gas cylinder controls, and limits on workers with metal prosthetic implants, are needed. The simplest test devised to locate hazardous locations is to tie a washer or other small permeable object to a string and tie off the other end to a belt loop and watch for places where the washer is pulled out by magnetic fields. Stainless steel, widely used in prosthetic implants, is normally nonpermeable but can be made permeable where it is machined. The ICNIRP advises that mechanical hazards due to flying tools and movement of metallic medical implants become a potential hazard when fields are as low as 3 mT (30 G). The ICNIRP also advises that magnetic media, such as the magnetic stripes on the backs of credit cards and diskettes, can be erased by fields above 1 mT (10 G).

BIOLOGICAL EFFECTS AND EXPOSURE STANDARDS FOR TIME-VARYING SUBRADIOFREQUENCY FIELDS

Time-varying fields have emerged as an area of concern because of widespread fear that they may lead to cancer. The initial concern arose as a result of epidemiological studies. These studies are not discussed further here because they are sufficiently diverse in their findings as to leave reasonable doubt. A large body of research results from in vivo and in vitro experiments has accumulated about the possible biological effects of such fields, but much of it is contradictory. The Bioelectromagnetics Society issued a primer on biophysics and exposure systems to assist researchers in 1993. The National Institute of Environmental Health Sciences (NIEHS) conducted a comprehensive review of the literature on health effects, and found limited evidence of any concern.

It is now generally, but not universally, accepted that power line fields can influence cell membranes. This effect is observable as an increase in the rate at which calcium ions are moved from the inside of a cell through the cell membrane to the outside. The possible effects of these interactions are potentially far-reaching and include promotion of tumor growth, but adverse effects have not been demonstrated in replicated experiments at the time this chapter was written.

It is also generally accepted that power line fields affect circadian rhythms much as static fields do. Recent research suggests that the prolonged exposures do not exert this effect; rather, the rapid changes that occur when the field is turned on and off exerts the effect. Circadian rhythm is controlled by the pineal gland, located in the center of the brain. The pineal receives electrical impulses from the eyes via the suprachiasmatic nucleus, located where the optic nerves cross. The pineal secretes melatonin at night. It has been speculated that altered pineal function could reduce the ability of the immune system to eliminate infections or tumors, but this has not been proven at the time this chapter was written.

Before setting science-based exposure standards, it is necessary to demonstrate a mechanism by which the fields exert their effects on living tissue. The one well-established mechanism of interaction is based on current flow through tissue, which can cause stimulation of nerves and muscles, and tissue heating. Many possible alternative mechanisms have been proposed, but none have been proven. This uncertainty about mechanisms is important because some of the proposed mechanisms do not involve either of the classic dose-response models. It is possible that moderate field intensities are hazardous whereas stronger or weaker fields are not hazardous. Regulations have assumed that less is safer, so the possibility of windowed effects is something regulators have not seen before.

The standards that do exist are based on the known effects of currents induced in the body. According to *WHO Environmental Health Criterion 69, Magnetic Fields,* the following associations can be drawn between induced currents and reported biological effects:

Induced Current Density (mA/m^2)	*Effect*
<1	None established
1–10	Minor biological effects
1–10	Magnetophosphenes, possible nervous system effects, enhancement of bone fracture healing
1–10	Changes in CNS excitability, stimulation thresholds, possible health hazards
>1,000	Extra systoles, possible ventricular fibrillation, definite health hazards

Health regulations fall into two broad categories: exposure criteria, which specify how much a person can be exposed to, and emission criteria, which describe how much can be released into or be present in the environment near a source. Both types of regulations exist for nonionizing radiation. The ICNIRP has issued general public and occupational exposure criteria based on induced current flow considerations, as shown in Table 11–E.

The American Conference of Governmental Industrial Hygienists (ACGIH) also issued TLV® exposure criteria for workers, based on avoiding induced currents that are stronger than those that already exist in the body due to the normal functioning of nerves and muscles. A number of states have established emission criteria for power transmission lines by specifying maximum fields that can exist along the edges of the right of way occupied by a power transmission line. These tend to be around 20 μT (200 mG) for magnetic fields and 1 kV/m for electric fields.

The clamor for action has prompted researchers and regulators to develop a number of ideas. Two are worth noting. The first, prudent avoidance, relies on reducing magnetic fields when possible by means that do not involve great expense, similar to the As Low As Reasonably Achievable (ALARA) concept applied to reducing ionizing radiation exposures. The second, 2 mG, is an averaged exposure level used to define high average exposure scenarios in epidemiological studies. It may not define the field strengths that might actually cause harmful effects; such levels could be much higher. Thus, caution is advisable when deciding whether to apply the prudent avoidance or 2 mG approaches in the absence of definitive scientific data.

Before leaving biological effects, it is necessary to return to the subject of pacemakers. The ICNIRP advises that power frequency AC fields could interfere with normal pacemaker function at field strengths of 2 kV/m and 1 G. This is because such fields create potentials that the pacemaker could confuse with the heart's natural electrical activity, which has a similar ELF frequency. The ACGIH advises that pacemakers could be influenced by 1 kV/m electric fields and 1 G magnetic fields. There is no generally accepted guidance about how to address this potential hazard.

MEASURING SUBRADIOFREQUENCY FIELDS

Electric fields are measured using variations of the displacement sensor described earlier. The surveyor must stand away from the detector when measuring electric fields because the surveyor's body will shield the detector and create a falsely low measurement. Thus, these instruments come with long nonconductive handles so they can be held as far from the operator's body as possible. One vendor supplies a long pole, one supplies a long handle and instructs the surveyor to hold the detector as far away as possible and to use a fiber-optic readout, and a third uses an electrician's hot stick. The sensors of these instruments resemble paddles or clamshells, with a nonconducting seam separating the shell halves. These instruments are directional; that is, they do not respond equally to fields coming from all directions. These instruments must be

Table 11–E. ***Exposure Criteria for DC and Subradiofrequency Fields***

				Exposure Criterion	
Frequency	*Exposure Group*	*Exposure Duration*	*Exposed Part of Body*	*Electric (kV/m)*	*Magnetic (mT)*
Static	Occupational	8-hr shift	Trunk		200*
Static	Occupational	<8-hr shift	Limbs		5,000
Static	Occupational	Ceiling	All		2,000
60 Hz	Public	24-hr day	All	5	0.1 (80 A/m)†
60 Hz	Public	<24-hr**	All	10	1 (800 A/m)†
1 Hz–300 Hz††	Occupational	Ceiling‡	All		60/f (600/f G)‡
1 Hz–300 Hz††	Occupational	Ceiling‡	Extremities		300/f (3,000/f G)‡‡
DC to 100 Hz	Occupational	Ceiling‡	All	25	
100 Hz–4,000 Hz§	Occupational	Ceiling‡	All	2,500/f‡‡	

* Time-weighted average.
** Peak allowed for times below 24 h as long as the average exposure during an 8-h shift does not exceed 5 kV/m or 0.1 mT (1 G).
† 1 mT = 10 G ≅ 800 A/m.
†† ACGIH considers frequencies <30 kHz to be subradiofrequencies, but their standard matches the 163 A/m standard of ANSI/IEEE C95.1-1991 at a frequency of 294 Hz, which ACGIH rounds up to 300 Hz. ACGIH advises that pacemakers can malfunction at field strengths of 0.1 mT (1G), but only at 50 and 60 Hz.
‡ Maximum exposure allowed for any time period.
‡‡ Frequency in Hz.
§ ACGIH considers frequencies <30 kHz to be subradiofrequencies, but their standard matches the 614 V/m standard of ANSI/IEEE C95.1-1991 at 4,071 Hz, which ACGIH rounds down to 4,000 Hz. ACGIH advises that pacemakers can malfunction at field strengths of 1 kV/m, but only at 50 and 60 Hz.

held so that the electric field is perpendicular to the paddle or to the seam between the clam shells. The reading reaches a peak level when the sensor is aligned properly.

Magnetic fields are measured with loops. The induced current can be boosted by increasing the number of wire turns in the loop or by putting a core of permeable material in the loop. Loops are highly directional. The current induced in a loop reaches a peak value when the loop opening is perpendicular to the flux lines of a magnetic field and does not respond when the opening is parallel to the lines of flux. The response is proportional to the sine of the angle between the loop opening and the flux lines. (The sine of 0° is 0, the sine of 90° is 1, and sine values cannot be higher than 1.)

When using a single-loop detector, it is necessary either to know how the field is oriented (from a knowledgeable person or other reliable source) or to measure the field with the detector pointed in one direction, then in another perpendicular direction, and finally in a third direction perpendicular to the other two. The center of the detector must be the same for these three measurements. The field is estimated by taking the squares of each measurement, adding the squares, and by taking the square root of the sum of the squares. This calculation is easily done using a spreadsheet.

A word of caution about loops: An instrument using a loop or coil sensor will display the average magnetic field in the area surrounded by the loop; magnetic fields at specific points in the loop may be different.

Another method of magnetic field measurement relies on the Hall effect. An object with a current flowing through it in a magnetic field will develop a voltage in a direction perpendicular to the magnetic field, which can be measured. Hall effect sensors are less sensitive than loops, but are used for DC field surveys where concern begins at a few G, whereas AC field concerns begin at 1 mG or less. Hall effect instruments also read super-strong tesla strength fields. Hall effect probes come in axial response and transverse response types. Transverse response probes are handled just like the single- axis loops just mentioned; peak response occurs when the field is perpendicular to the flat side of the tip of the sensor blade. Axial probes are aligned to give peak response when the field is parallel to the long axis of the probe, so the measurement protocols mentioned earlier must be modified to account for the fact that the peak response occurs when the field is parallel with, rather than perpendicular to, the probe. A personal dosimeter is now available that has three mutually orthogonal Hall effect sensors for isotropic response.

Loops are often ganged together in mutually orthogonal arrays of three loops so that the detector does not operate in a directional manner; such an instrument is shown in Figure 11–9.

Magnetic field survey instruments using orthogonal triple-loop detector arrays are now available for all frequencies of interest. Orthogonal loops (or Hall effect sensors) confer isotropic response; that is, the response is about equal for all probe orientations in the field and the sensor is largely nondirectional.

Field loggers, often called dosimeters, are available for ELF magnetic field measurements. The EMDEX loggers for ELF fields were developed for the Electric Power Research Institute and closely resemble modern audio dosimeters in the kind of data they provide. They use mutually orthogonal loop sensors (for time-varying fields). The EMDEX loggers read out through a computer to provide a minute-by-minute summary of exposures in all three axes plus the overall field. Several vendors offer wheeled harnesses for EMDEX loggers, which can be used to precisely map locations when the logger is used to log field strengths at various points in a measurement area.

CONTROLS AND SHIELDING

Stopping electric fields is easy. Imagine that a person is standing below a power transmission line. If a sheet of conductive material were placed between the person and the source and that conductor were grounded, induced charges would flow between the conductor and the earth. As a result, the field lines would begin at the conductor above the person, induce current flow in the sheet through the ground, and not reach down to the person. The material can be solid, but mesh will do as long as the opening of the mesh is smaller than about 1/4 wavelength. This means that chicken wire will block a 60 Hz electric field. Operational shields must be grounded in accordance with electrical safety codes. A practical result of the ease of blocking electric fields for surveyors is that the electric fields in most structures are created by appliances inside the structure, even if a high-voltage transmission line passes overhead.

Shields used to block magnetic fields are different from other forms of shielding, which work by stopping an agent with a barrier. Magnetic fields are controlled using permeable alloy that confines the magnetic flux lines and diverts them. Recall that magnetic fields exist as circuits; they do not reach out into space as electric field lines and radiation do. Magnetic shielding can be made using high nickel alloys called mu metal or soft iron. Forming mu metal into complex shapes is expensive and mu metal is easily damaged. Magnetic field shielding alloys are less permeable at low field strengths than at high field strengths, so they work best at high field strengths. Such shielding is best applied near the field source, whenever practical. Materials that work at lower magnetic field strengths could become commercially available in the future. Another approach is to use nonpermeable metals such as copper or aluminum to produce eddy currents that cancel out the original magnetic field.

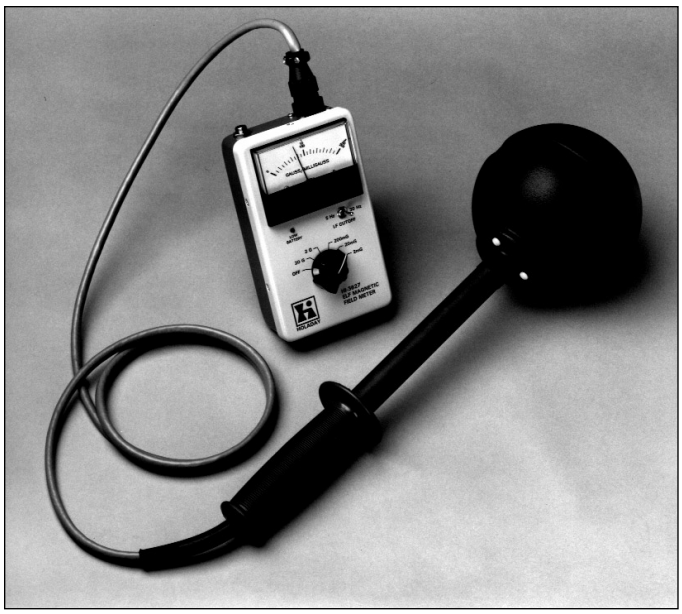

Figure 11–9. Loops are often ganged together in mutually orthogonal arrays of three loops. (Courtesy Holaday Industries, Inc.)

Exposures of people to magnetic fields is routinely but unintentionally reduced by canceling fields, as in appliance cords with closely spaced conductors. If a current flows in one direction through a conductor, say from the power outlet in a wall to an appliance, and back in the opposite direction through the conductor next to the first one, each conductor creates a magnetic field, but the orientations of the fields are opposite and the fields nearly cancel each other out. The closer the two conductors are, the more cancellation occurs. Overhead power lines use widely spaced conductors to avoid arcing, so relatively little cancellation occurs compared with underground power lines, where the insulated conductors are close together. This is why magnetic fields around underground lines are lower than those of overhead lines. Soil has no shielding value for magnetic fields although, as a conductor, it does block electric fields.

Field cancellation technology is being increasingly used for AC fields. Some low-field video display terminals (VDTs) use it in the form of additional field coils next to the coils that steer the electron beam to create a canceling field. Utilities can rewire transmission lines to obtain more cancellation. One utility company has developed a technique for creating canceling fields around transmission lines. Field cancellation may also prove useful in households where poorly wired appliances are leaking currents to the ground. The current leaving a house through the ground often does not enter where the current entered the house, so it cannot cancel the magnetic fields created by the incoming current. A house with leaking appliances can have two magnetic hot spots: one where the service enters the house and the other by the ground carrying the leakage current, as shown in Figure 11–10. Any changes made to household wiring to reduce magnetic field exposure must comply with electrical safety codes. It may be necessary to change electrical safety codes if 60 Hz magnetic fields prove to be hazardous.

RADIOFREQUENCY/MICROWAVE RADIATION AND FIELDS (RF/MW)

This portion of the electromagnetic spectrum covers a huge range of frequencies, from 3 kHz to 300 GHz or wavelengths ranging from 100 km to just 1 mm. Recall the earlier section about when fields are important and when radiation is important. Some RF/MW scenarios involve fields and others involve radiation. It is generally agreed that radiation is likely to be found at frequencies above 300 MHz (wavelength = 1 m) whereas fields are likely to be found at lower frequencies. The practical consequence of this is that two surveys, one for electric fields and the other for magnetic fields, are required at lower frequencies but only one survey is needed at higher frequencies.

See Table 11–D for a summary of divisions and uses of the RF/MW portion of the spectrum, which includes very low frequency or VLF (3–30 kHz), low frequency or LF (30–300 kHz), medium frequency or MF (300 kHz–3 MHz), high

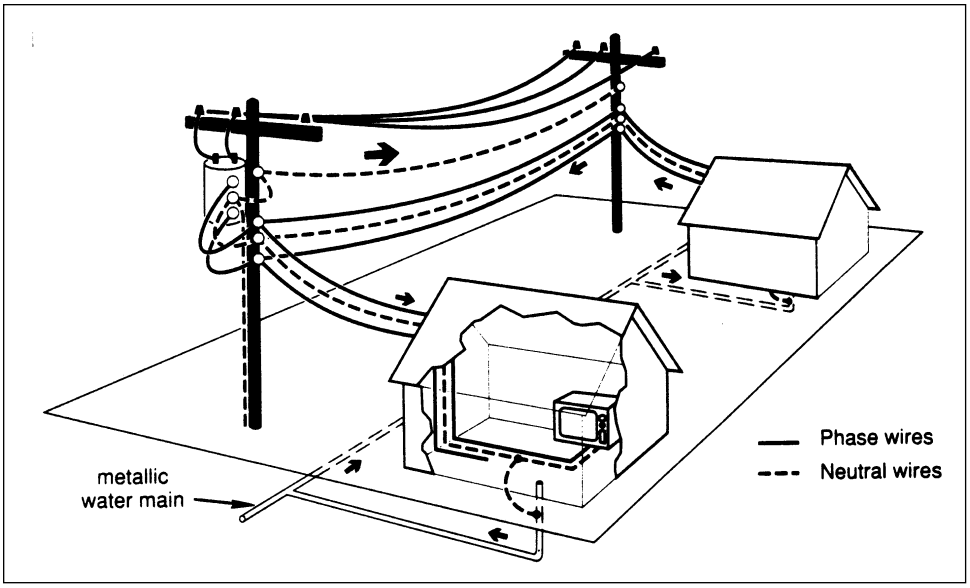

Figure 11–10. Current can leave a house next to where it came in, in which case there is good field cancellation. If an appliance is poorly grounded, however, some current leaves through the ground and returns to the utility by flowing through the earth. The current flow into the house is not balanced and canceled by the return current, so the magnetic fields are higher at the unbalanced supply wires and where the current flows into the ground. The phase wires bring the current in and the neutral wires return it. (Reprinted from Electric Power Research Institute, *Electric and Magnetic Field Fundamentals—An EMF Effects Resource Paper.*)

frequency or HF (3–30 MHz), very high frequency or VHF (30–300 MHz), ultrahigh frequency or UHF (300 MHz–3 GHz), super high frequency or SHF (3–30 GHz), and extremely high frequency or EHF (30–300 GHz). Microwaves are the portion of the radiofrequency spectrum ranging from 300 MHz to 300 GHz; strictly speaking, the radiofrequencies extend from 3 kHz to 300 GHz.

Industrial, Scientific, and Medical Bands and Frequency Nomenclature

A band is a part of the entire electromagnetic spectrum. Safety and health specialists often find equipment working in the industrial, scientific, and medical (ISM) bands, which anyone can freely use because no licensing is required. The most popular ISM band is the 2.45 GHz band used by microwave ovens. Electrical engineers often use the traditional band designations originally used for radars and military electronics in World War II. Thus, you may hear or read about a Ka band police radar speed gun that works at 24.15 or 35 GHz. These designations were not user-friendly; the modern designation system uses letters of the alphabet, in ascending order, to describe increasing frequencies. For example, the MiG-25 radar operates in the J band, which is somewhere between 10 and 20 GHz. Table 11–D lists the ISM bands and the traditional and new band designations.

Interactions of Radiation and Matter

The interactions of radiation and matter can be described in terms of how much energy in the radiation is lost to the matter it strikes, as shown in Figure 11–11. If all of the energy in the radiation is lost to the matter, it is absorbed. If some energy, but not all, passes from a chunk of matter, then the radiation is scattered because the remaining, less energetic radiation often leaves in a different direction. If none of the energy is lost, then the radiation was transmitted. Electrical engineers call objects such as radio broadcast towers and radar sets emitters rather than transmitters. Finally, radiation does not pass from one medium to another when the electrical properties are too dissimilar. When this occurs, the radiation is reflected back into the medium it came from. Reflection is the basis of radar; controlling reflections from mirrors and other shiny objects is a major concern in laser safety.

RF/MW that is absorbed or scattered can impart energy to living matter by induction of current flow, which in turn encounters resistive parts of tissues such as cell membranes, or by interactions between the electric field and charged portions of water or organic molecules such as proteins. Electrically charged portions of molecules can be caused to vibrate and ions of metals dissolved in water can be caused to move in response to the electric fields. In both cases, the energy finally appears as heat.

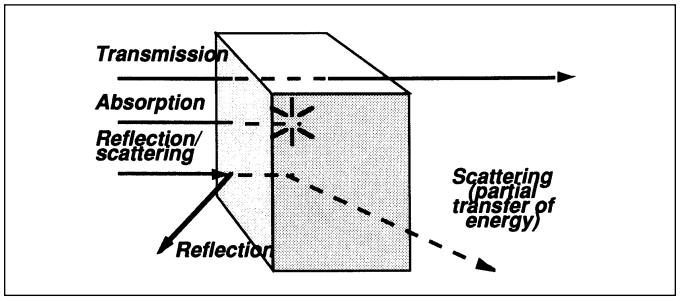

Figure 11–11. Electromagnetic energy can be completely absorbed by matter (absorption), pass through without any interaction (transmission), lose some of its energy (scattering), or not enter at all (reflection). Reflection occurs when the electrical properties of the material the radiation comes from and those of the material it strikes are too different. Radar works when electromagnetic radiation in air, a fair insulator, strikes metal, a superb conductor.

BIOLOGICAL EFFECTS AND EXPOSURE STANDARDS FOR RADIOFREQUENCY FIELDS

The status of biophysics research in the radiofrequencies is somewhat more certain that it is for the subradiofrequencies. More research is needed to answer concerns about the safety of radiofrequency energy used by devices such as VDTs (which use ELF fields in the 60 Hz range and VLF fields in the 20–30 kHz range), cellular phones (which work around 840 MHz), wireless office technology (which uses the 915 MHz ISM band), and police radars (which have used 10, 24.15, and now 35 GHz). A great deal of research has been conducted and more is under way. The research has been sufficient to develop generally accepted safety standards. Radiofrequency and microwave energy causes a wide variety of biological effects (summarized in Table 11–F), especially if exposures are intense enough to cause significant heating. The health significance of doses that are not sufficient to cause measurable heating (athermal effects) is uncertain.

Table 11–F. ***Biological Effects Reported for Radiofrequency and Microwave Radiation***

Target Organ/ Overall Effect	*Effect*	*Exposure*
Eyes (animals and humans)	Cataracts	Hours at 120 mW/cm^2
	Keratitis	40 mW/cm^2
Behavioral (animals only)	Various test changes	≥1.1 W/kg
	Behavioral thermoregulation	≥1.1 W/kg
Endocrine (animals only)	Corticosteroid and thyroid increases	>8.3 W/kg
Immune (animals only)	B and T cell activity changes	≥1.4 W/kg
Neurological (animals only)	Tests of blood/brain barrier contradictory	
Mutations	Not found in replicated studies to date	
Cancer	Not found in humans or animals to date	
Reproduction	Temporary male sterility	5.6 W/kg
	Testicular changes	≥15 W/kg
	Leutenizing hormone changes	>2 W/kg
Teratology (animals only)	Malformed offspring	≥31 W/kg
Thermoacoustic/ inner ear (pulsed only)	Observed in radar operators in WWII as perceived clicking sound while in beam	
	Possible cause of neurological effects observed in test animals	0.6 W/kg

Dosimetry

It is not enough in radiofrequency biophysics research to state that rats were exposed to 10 mW/cm^2 of 2.45 GHz continuous wave radiation and certain effects were observed. Researchers must address physics problems that determine how the power density in the rats' ambient environment turns into power deposited in the rats' tissues. The issues to be addressed are the size of the organism compared with the wavelength of the radiation, the polarization of the radiation (how the electric field is aligned to the earth's surface) as compared with the orientation of the exposed organism, and the interaction of exposed tissues with the radiation or fields. The response of tissue to radiation and fields is determined by the electrical properties of the tissue. The discipline that addresses this concern is RF/MW dosimetry.

The dose rate (rate at which energy is transferred to tissue) is called the *specific absorption rate* (SAR), expressed in watts of power deposited per kilogram of tissue (W/kg). The term for the quantity of energy transferred to tissue is specific absorption (SA), expressed in joules of energy per kilogram (J/kg) of tissue. Note that energy is equal to power times time. Power is expressed in watts and 1 watt times 1 second equals 1 joule of energy. One kilowatt hour of energy use equals 3,600 s × 1,000 W, or 3.6 million J. Joules are used in exposure standards for pulsed laser energy.

An organism acts as an antenna. An object absorbs the most radiation energy if it is about 40 percent of the wavelength and not well-grounded or when it is about 20 percent of the wavelength and well-grounded. Thus, the resonant frequency for a rat is much higher than for a human. Present regulations assume that peak absorption, or resonance, occurs at frequencies of 30–300 MHz. At lower frequencies (<30 MHz), absorption diminishes in proportion to the square of the frequency so the object absorbs 25 percent as much radiation at 50 percent of the frequency and 1 percent as much radiation at 10 percent of the frequency. At higher frequencies (>300 MHz), absorption also falls off for a while and then flattens out at about 8 percent of that at the resonant peak. This is illustrated in Figure 11–12.

Another significant factor is polarization. Radiofrequency radiation is absorbed most when the electric field is parallel to the long axis of the organism and is absorbed least when the magnetic field is parallel to the long axis of the organism, as shown in Figure 11–13. Rats typically best absorb horizontally polarized radiation whereas upright humans best absorb vertically polarized radiation. Some absorption occurs within "H" (magnetic field).

Dosimetry can be done by measurement or mathematically. Measurement dosimetry was hampered by using common thermocouples, which include a pair of conducting wires trailing from the object being tested. The wires interact with the electric fields so only one temperature measurement could be made even in a human-sized object. Fiber-optic devices are now available so several concurrent temperature measurements can be made in one animal. Another way of

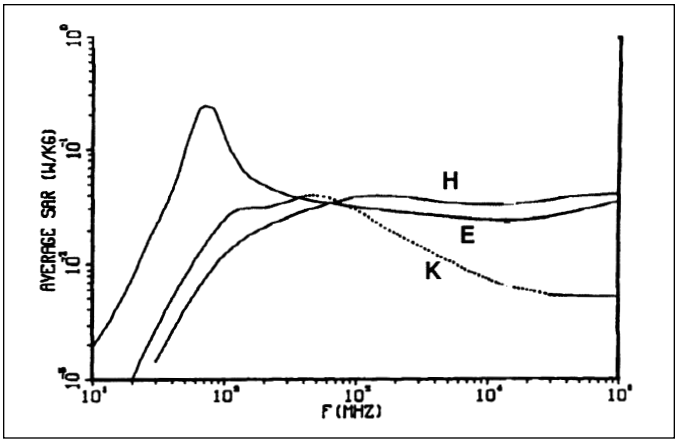

Figure 11–12. Specific absorption rates (SAR) for humans as a function of frequency. The letters *E*, *H*, and *K* show that the radiation is aligned so the electric field axis points along the long axis of the organism (vertically polarized), the magnetic field points along the long axis of the organism, and the radiation travels through the long axis of the organism. *E* = electric field, *H* = magnetic field, and *K* = direction of travel. Note that there are three major regions. In the *subresonant region,* the body does not function well as an antenna. Absorption drops in an inverse square relationship to wavelength. In the *resonant region*, the body is a good antenna that maximizes absorption. In the *superresonant region* (6–300 GHz), the body no longer acts as a good antenna and absorption levels off at about 10 percent of peak absorption. Quasi-optical focusing occurs from 6 to 15 GHz and skin absorption predominates at >15 GHz (penetration <1 cm).

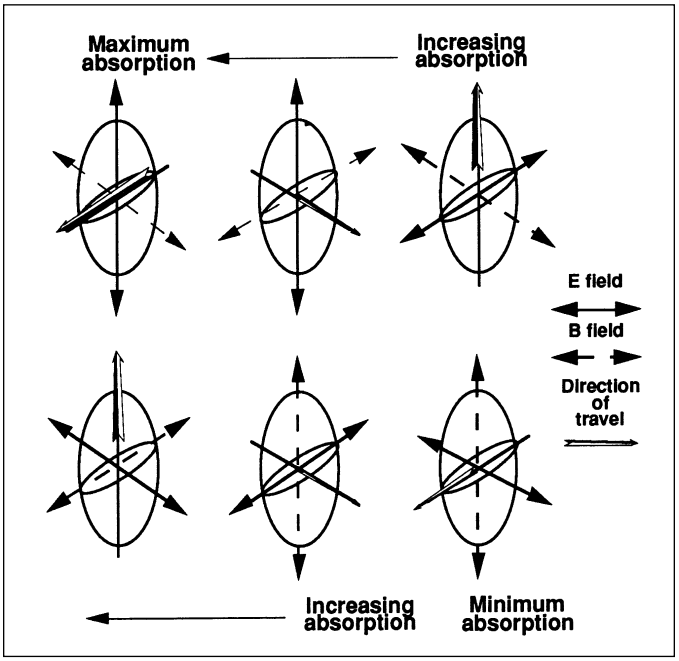

Figure 11–13. An elongated object (prolate spheroid) absorbs the most energy when the electric field is parallel to its long axis and the least energy when the magnetic field is parallel to its long axis.

making dosimetric measurements is to sacrifice animals and cut the remains in two longitudinal halves. The halves are joined, irradiated at intense levels, separated, and the temperature change is measured using an infrared device. The irradiation takes place in the same place as the irradiation of live animals, but at higher levels to produce more easily measured heating.

Mathematical dosimetry is also progressing. Early efforts were limited by computer capacity and by the need to use immense amounts of computer memory. Newer mathematical models make more efficient use of computer memory and supercomputers offer adequate capacity to do complex, tedious calculations. The original models used to develop the relationships just described between wavelength and polarization and the size and orientation of the organism simply estimated the average whole body SAR. Newer models estimate the SAR for specific organs and parts of the body. This will make it easier to interpret the results of future animal experiments. The University of Utah pioneered the development of mathematical dosimetry with funding from the U.S. Air Force School of Aerospace Medicine and published a series of dosimetry handbooks.

The leading dosimetric standard in the United States today is 0.4 W/kg as a whole body average. This objective is based on heat avoidance behavior of animals at an SAR of 4 W/kg, divided by a safety factor of 10. Higher local SARs are permitted (8 W/kg for specific parts of the trunk and nonextremity parts of the body and up to 20 W/kg at the extremities).

Target Organs

A variety of effects are known to occur at SARs above 4 W/kg, but the target organs are the eyes and testes, based on limits of circulation and heat dissipation at these two organ systems. It is assumed that the thermal equilibrium time for these target organs could be as brief as 6 min, so the standards specify exposure limits that apply for 6-min time intervals (until the frequency rises above 15 GHz, where the time interval gradually drops to 10 seconds). The only proven adverse effects for humans, regardless of SAR, are eye cataracts, facial burns, and electric shocks and burns. Cataracts occur in animals at power densities above 120 mW/cm^2 if the exposures last for hours, but only minutes of exposure are needed at 350 mW/cm^2. Electric shocks and strong current flows through the ankles have occurred in humans and are important at frequencies below 100 MHz. Other effects have been demonstrated in animals, such as teratogenic effects in animals subjected to intense SARs and neurochemical and eye effects in animals exposed to pulsed radiofrequency and microwave radiation, but these effects have not been duplicated in humans.

Standard-Setting Rationale

We can now see that the radiofrequency portion of the electromagnetic spectrum can be divided into three major parts,

as shown in Figure 11–14. At lower frequencies, current flow considerations dominate. The goal of the standard is to prevent burns caused by radiofrequency electric current (at frequencies of a few MHz and below) and excessive ankle heating caused by the surge of electricity to and from the ground through the feet (from a few MHz through the resonant frequencies). There was no convenient way to measure contact current until about 1991. Regulators approached the problem by limiting the ambient field strengths allowed to strengths that were equivalent to 100 mW/cm^2 if the fields existed as electromagnetic radiation. The risk of electrical burns caused by touching an object energized by radiofrequency fields and the risk of significant ankle heating are covered by current flow criteria.

At the resonant frequencies, where our bodies act as good antennas, controlling SAR becomes the main concern and remains a serious concern at higher frequencies until skin absorption becomes dominant. For regulatory purposes, the resonant portion of the spectrum ranges from 3 MHz (for electric fields) or 100 kHz (for magnetic fields) to 3 GHz and is most restrictive at frequencies ranging from 30 to 300 MHz, wavelengths where an adult or child functions as a good antenna.

At higher frequencies (above 3 GHz) skin absorption predominates and mathematical modeling reveals that absorption is about 8 percent of absorption at the resonant peak. Above about 6 GHz, most of the radiation is absorbed in the skin and outer tissue layers; at frequencies above 15 GHz, most radiation is absorbed in the first centimeter of tissue. The properties of microwaves become similar to those of infrared (IR) radiation and thermal damage to the skin becomes a major concern.

The regulatory community also had examined the question of how magnetic fields should be regulated in near-field scenarios. Magnetic fields passing through conductors induce current loops, as discussed in the ELF section of this chapter. Based on this and calculations of the current density induced by magnetic fields, it was agreed that magnetic fields would be subject to relatively lenient regulations.

Separate criteria were set for the general public and for occupational exposures. All earlier versions of the Institute of Electrical and Electronic Engineers' C95.1 standard, *American National Standard Safety Levels with Respect to Human Exposure to Radio Frequency Electromagnetic Fields*, did not differentiate between occupational and nonoccupational exposures. For frequencies from 1.34 MHz to 15 GHz, nonoccupational standards are generally five times more restrictive than occupational standards. The Institute of Electrical and Electronic Engineers (IEEE) replaced the general public and occupational standards approach used for chemicals with an uncontrolled access versus controlled access approach, which allowed higher exposures for those who knew they were being exposed and could be provided with hazard awareness information, warnings, and training.

The standards are presented in Tables 11–G, 11–H, and 11–I. These are whole-body average exposures that are calculated based on measurements made at 20-cm vertical intervals beginning at the floor and reaching to the head at distances of 20 cm or more from radiating or energized objects.

Averaging Time and Pulsed Fields

Industrial hygienists are used to thinking in terms of 8-h time-weighted averages or 15-min intervals for short-term exposure limits. Radiofrequency standards rely on another interval, the thermal equilibrium of the target organs (the

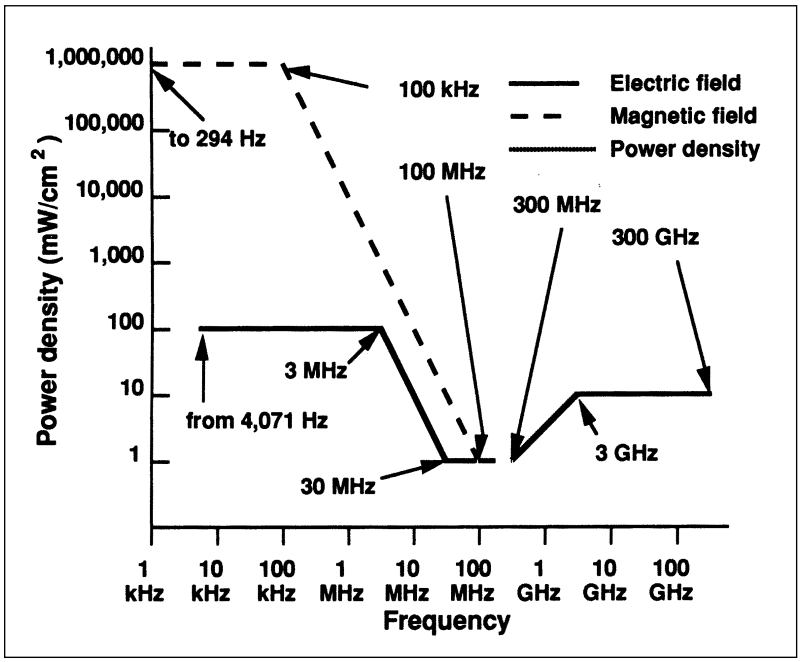

Figure 11–14. The inverse of the absorption curves shown in Figure 11–12. These are the C95.1 standards, which are most stringent in the frequencies where absorption is at its peak and level off at higher frequencies. The leveling off at lower frequencies reflects the risk of RF electric burns caused by contact with conductors immersed in strong fields. The *subresonant region* (<3 MHz) is the region in which current flow considerations are most important. In the *resonant region* (3 MHz–6 GHz), current flow and SAR are both important considerations where current is ≤100 MHz. Absorption falls off in proportion to the square of the frequency between 3 MHz and 30 MHz. Standards are most stringent between 30 MHz and 300 MHz. Between 300 MHz and 3 GHz, absorption falls off linearly as frequency increases. The *superresonant region* ranges from 3 GHz to 300 GHz. (From ANSI/IEEE C95.1-1991, 1992.)

0.003–1	$2,000f_m$	$1,000f_m$	$1,000f_m$
0.1–100	200	100	100

* The exposure values in terms of electric and magnetic field strength are obtained by spatially averaging values over an area equivalent to the vertical cross-section of the human body (projected area).
** f_m = frequency in MHz.
† ANSI/IEEE C95.1-1991 covers frequencies between 3 kHz and 300 GHz; at 294 Hz and 4,071 Hz, C95.1 magnetic and electric field standards match the subradio-frequency TLVs.
†† These plane-wave equivalent power density values, though not appropriate for near-field conditions, are commonly used as a convenient comparison with maximum permissible exposures at higher frequencies and are displayed on some instruments.
(From ANSI/IEEE C95.1-1991, 1992.)

eyes and testes), which is assumed to be 6 min. Thus, time-averaging calculations can be made much as they are for chemicals, but the exposures must not exceed the C95.1 limit over a 6-min interval rather than an 8-h shift. Put another way, a person can be exposed to twice the limit for 3 min if no other radiation exposures occur for the other 3 min. The averaging interval for uncontrolled exposure situations is 30 min for frequencies ranging between 3 MHz and 3 GHz. IR exposures at the end facing microwave radiation are set at 10 mW/cm^2 for 10 s, so the averaging time changes from 6 min to 10 s for frequencies between 15 and 300 GHz.

The idea of limiting above-average exposures so the 6-min time-weighted average is below the standard has limits. Much as the chemical TLV® committee has attempted to address the topic of brief but intense exposures above a TLV, the C95.1 committee considered pulsed electromagnetic radiation and fields. Pulsed fields are common and recent military devices that simulate the pulses from nuclear weapons stimulated public concern about pulsed electromagnetic fields. As with chemical exposures, a simple TWA allows for extremely intense exposures if they are brief enough. Thus, an exposure to a 360-ns pulse could be a billion times more than the C95.1 limit if there were no other exposures for 6 min. The resolution has been to limit electric fields to 100 kV/m and to ensure that the power density does not exceed that given by the following formula:

$$\frac{(\text{cw limit of table 7 or 8} \times \text{average time of Table 11–F or 11–G in secs})}{(5 \times \text{pulse width in secs})} \quad (1)$$

The Europeans, led by Finland, are in the process of adopting pulsed field standards. The proposed standard sets limits on electric fields induced in the body by external pulses. Application of this standard entails resolving how pulses behave when they enter tissue and calculating the induced fields that result. Further developments in regulations for exposures to pulsed fields and radiation can be expected.

Regulatory Considerations

The standard paperback volume of Title 29 *Code of Federal Regulations* (*CFR*), Part 1910, the OSHA general industry regulations, includes the original 1970 radiofrequency/microwave exposure standard, 29 *CFR* 1910.97. This standard, based on ANSI C95.1-1966, is obsolete. The original regulation was struck down by the Occupational Safety and Health Review Commission in 1981, but the *UAW, Brock v. General Dynamics Land Systems Division* decision allows OSHA to apply state-of-the-art standards developed by others when OSHA has no standard of its own. IEEE adopted a revision of C95.1 in 1992 as IEEE C95.1-1991 and the American National Standards Insti-

0.003–0.1	$900f_m$	$450f_m$	$450f_m$
0.1–100	90	45	45

* The exposure values in terms of electric and magnetic field strength are obtained by spatially averaging values over an area equivalent to the vertical cross-section of the human body (projected area).
** f_m = frequency in MHz.
† These plane-wave equivalent power density values, though not appropriate for near-field conditions, are commonly used as a convenient comparison with maximum permissible exposures at higher frequencies and are displayed on some instruments.
(From ANSI/IEEE C95.1-1991, 1992.)

tute (ANSI) adopted the 1991 revision in 1992. Hence, OSHA can enforce ANSI/IEEE C95.1-1991, so the reader should become acquainted with this standard (Figure 11–15).

MEASURING RADIOFREQUENCY RADIATION AND FIELDS

Recall that fields rather than radiation are presumed to exist at frequencies below 300 MHz so two surveys, one for electric fields and the other for magnetic fields, are needed. Only one survey is needed for frequencies above 300 MHz.

Electric fields at frequencies above 100 kHz are measured using small dipole antennas. The electric field induces a current in the dipole, which is connected to a diode. A diode is the electrical equivalent of a one-way valve so the induced current is allowed to leave the detector and goes to an amplifier. The amplified current drives a display. Alternatively, the electric field induces current flow and heating in an array of thermocouples and the change of resistance caused by heat-

ing is measured to drive the display. Dipoles and diodes can be used at lower frequencies (below about 100 kHz), but displacement sensors are also used.

Most dipole/diode field survey instruments gang three sensors together so they are mutually orthogonal (perpendicular to each other) to provide an isotropic response (a response that is about equal regardless of how the sensor is aligned in the field), as shown in Figure 11–16. Microwave oven survey instruments have two dipole/diode sensors that are perpendicular to each other. The lack of the third sensor makes them directional and they must be held so the probe handle is perpendicular to the surface being measured. When measuring electric fields using a single detector, it is often apparent where the field source is located so alignment of the detector is simple. A displacement sensor is oriented so that its flat surface faces the source; such an instrument is shown in Figure 11–17. Most instruments used for radiofrequency measurements below 300 MHz have displays marked to read in V/m. Instruments operating in the microwave region can be marked to read out in V^2/m^2 or mW/cm^2; microwave power density meters usually measure the electric field intensity and convert it to power density at the display.

Magnetic fields below 300 MHz are measured with single loops or triple mutually orthogonal loops. Single loops are highly directional, so the surveyor must follow the protocol outlined earlier in the section, measuring "Subradiofrequency Fields." Triple orthogonal loops are isotropic, so probe orientation is not critical.

Radiofrequency field and radiation measurements should be made where the worker would normally be, but without the person present, so reflections and induced fields do not create falsely high results. (This is similar to noise measurements, which are best done where the ears would normally be, but while the operator is away.) Either the sensor is held

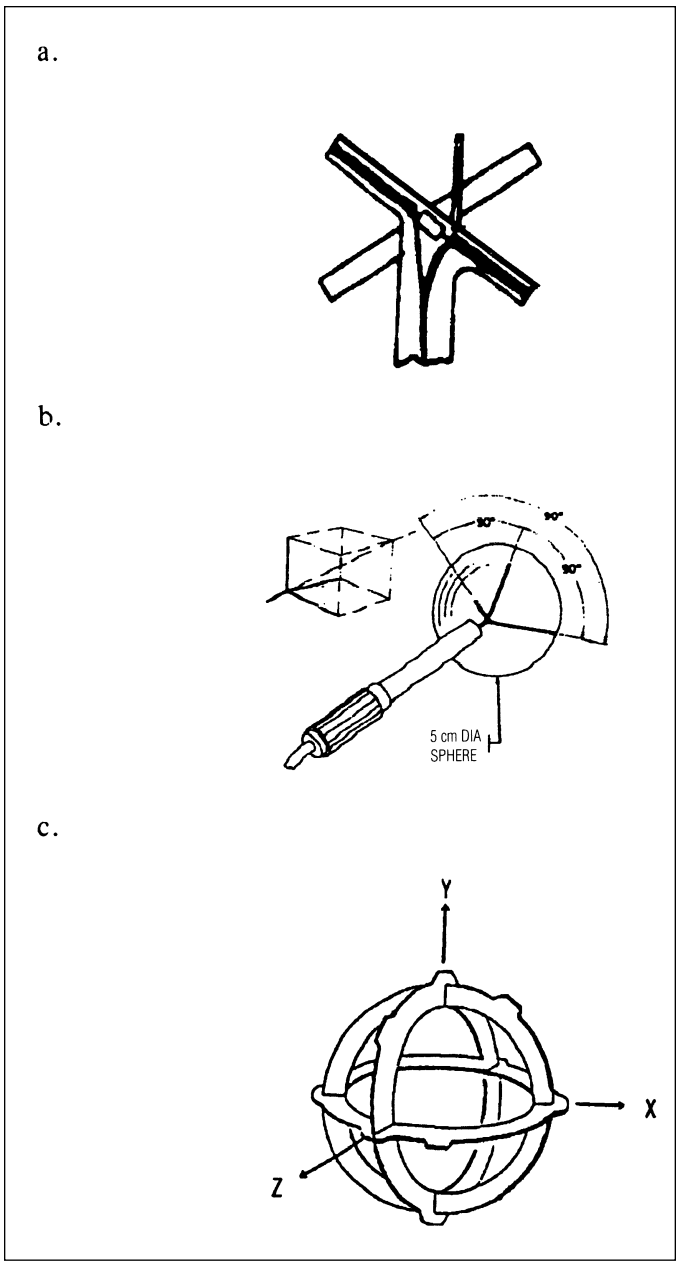

Figure 11–16. Isotropic (nondirectional) antenna arrays. a. Mutually orthogonal dipoles respond to electric fields (Holaday Industries HI 3102 probe). b. Mutually perpendicular array of thermocouples (Loral/Narda 8621 series probes). c. Mutually perpendicular magnetic field loops.

just above floor level and raised up through the body position at 8-in. (20-cm) vertical intervals and the result recorded for each point, or the probe is steadily moved through the body positions using an instrument with an add-on module that averages the readings. The sensor must be kept 20 cm or one sensor dimension (whichever is greater) from energized objects. At this time, measurements must be made at the locations of the eyes and testes. Exposures above the standard and their locations must also be recorded. Excursions up to 20 times the standard are allowed

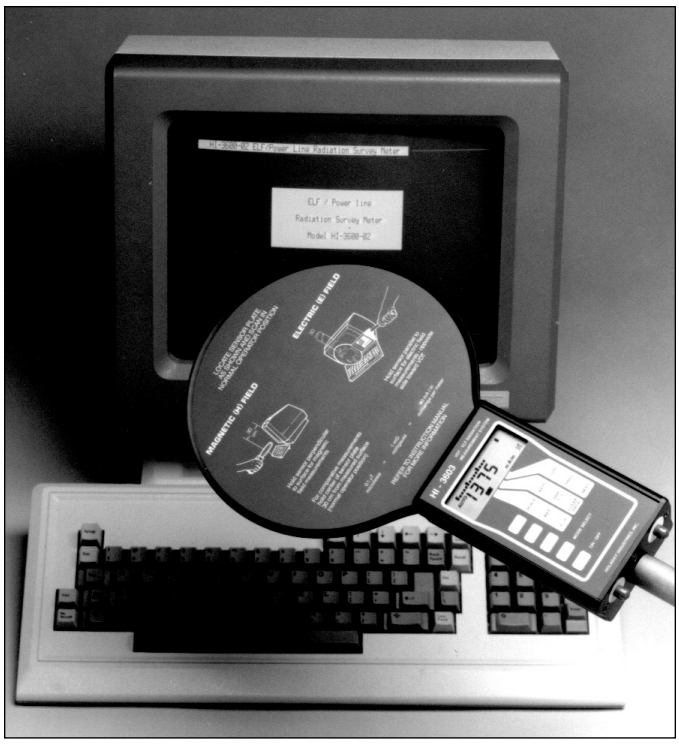

Figure 11–17. A displacement sensor is oriented so that its flat surface faces the source. (Courtesy Holaday Industries, Inc.)

at the extremities (hands and feet) and excursions up to 8 times the standards are allowed elsewhere (except at the locations of the eyes and testes).

Contact and induced current meters are now available. The contact current meter has electrodes that are pressed against an object that may be electrically charged due to ambient RF fields, as well as a cable and built-in ammeter. Induced current meters look like bathroom scales and are meant for people to stand on. The induced current flows through the instrument and drives an AC ammeter before going to ground. One manufacturer sells a cylindrical antenna that electrically simulates an upright human and can be placed on an induced current meter. Soon, an instrument that measures current flow through the ankle with a cuff-shaped coil will be available. At this time, ANSI/IEEE C95.1-1991 specifies that current flows are to be averaged over a 1-s time interval.

VIDEO DISPLAY TERMINALS AND MICROWAVE OVENS

Video Display Terminals

These are given their own section because they operate in both the ELF and VLF portions of the spectrum. A video display terminal (VDT) includes a cathode ray tube (CRT) very similar to the picture tube in a TV set. The CRT has an electron source or electron gun at the back and uses a high-voltage electric field to accelerate a beam of electrons from the gun to the screen and impart enough energy to the beam to cause phosphors on the inside of the screen to glow. The beam is steered to specific parts of the screen by a pair of fields created by magnets in a yoke near the back of the CRT. One magnetic field is aligned vertically the other horizontally. Remember that magnetic fields act at right angles. The vertical magnetic field moves the beam left and right while the horizontal field moves it up and down. The image on the screen contains about 500 lines (this varies with manufacturer) and it is refreshed or replaced with a brand-new image about 60 times a second (which also varies with manufacturer) to avoid flicker. Thus, the magnetic field that deflects the beam vertically has a frequency of about 60 Hz. The field that deflects the beam horizontally has a frequency of 60 images per second times the number of lines in the image (about 500), for about 30,000 Hz. The horizontal scanning field is generated by the "flyback" transformer. Most VDTs work at frequencies below 30,000 Hz, whereas a commercial TV image has 525 lines refreshed only 30 times a second, for a flyback frequency of 15.75 kHz. See Figure 11–18 for a depiction of the fields around a VDT or TV.

If you watched how the field strength of most VDTs changed with time, you would not see the familiar sine (ocean) wave. You would see the field slowly change as the beam was dragged from the left of the screen to the right, then abruptly change to the starting value so the beam could be swept across the next line (the beam itself is actually shut off during this abrupt reversal). The result is called a sawtooth waveform. The refresh field also has a sawtooth shape, but at a lower frequency.

Thus, a survey of VDTs is more complex than many other surveys. The electric and magnetic fields at two frequencies

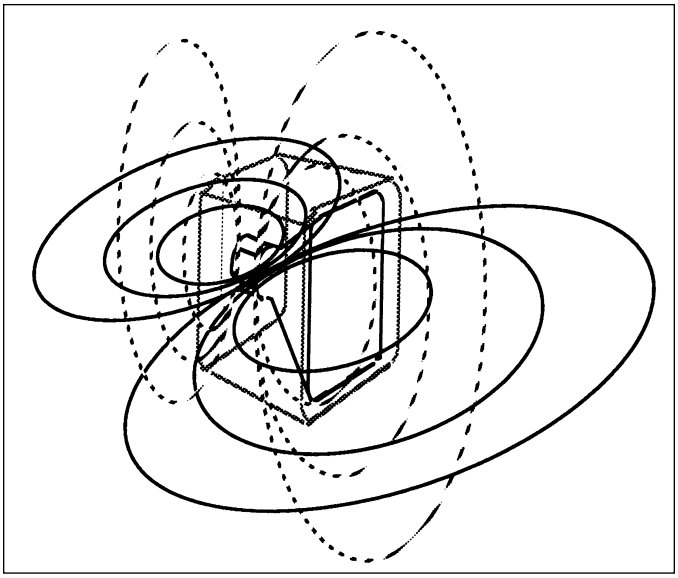

Figure 11–18. VDTs create two magnetic fields. The vertically aligned flyback field moves the beam horizontally at a frequency of 20,000–30,000 Hz. The horizontally aligned refresh field moves the beam from top to bottom at a frequency of about 60 Hz.

can be assessed. One manufacturer has developed a family of meters using paddle-shaped displacement electric field and single-loop magnetic field sensors for this application. A worker's electric field exposure is assessed by placing the sensor squarely over his or her chest so the electric field lines land on the sensor. Of course, the surveyor must stand away during electric field measurements (a fiber-optic remote readout is provided), but the surveyor can be near the VDT during magnetic field surveys.

The Swedish MPR or Swedish Board for Technical Accreditation (SWEDAC) standards are emission standards rather than exposure standards, and are summarized below:

ELF electric field	25 V/m
ELF magnetic field	2.5 mG
Electric field	2.5 V/m
Magnetic field	0.25 mG

The Swedish standard is given in two Swedish Board for Technical Accreditation publications cited in the Bibliography. It is a convenience standard; that is, it is based on what is attainable rather than on an estimate of what constitutes a safe exposure. SWEDAC wrote:

> *Knowledge of the biological effects of weak low-frequency magnetic fields is limited. The debate on this that occurred in Sweden during 1986 and 1987 resulted in the publishing of guidelines of acceptable values of fields from VDUs [video display units]. These guidelines were not based on biological effects, but rather on what was technically possible. The results obtained from the first three years of voluntary testing show that it is possible to obtain VDUs that give rise to only low magnetic field intensities without significantly degrading other performance requirements. It has also been found that, for good-quality VDUs, there does not appear to be any correlation between the magnetic field and the important visual ergonomic characteristics.*

SWEDAC specifies conducting a series of measurements at 50 cm in a laboratory with a controlled electromagnetic environment. Any field measurement made to assess approximate compliance with SWEDAC must be made at 50 cm rather than at the 30 cm customary in the United States. TCO, the Swedish Confederation of Professional Employees, has developed guidelines for VDT electromagnetic emissions and ergonomics. The TCO emission criteria are somewhat stricter than MPR's. TCO has established an office in Chicago to support distribution of its guidelines, which have been translated into English.

Microwave Ovens

Microwave ovens use the 2.45 GHz ISM band. Power is supplied by a magnetron tube and routed to the cooking chamber via a waveguide. The radiation leaving the waveguide passes over a rotor (or rotating waveguide) set in motion by moving air. The rotor is shaped to reflect the radiation around the cooking chamber to obtain a somewhat even distribution of energy. This caused concern when microwave ovens first appeared because the radiation leaking from an oven was amplitude-modulated by the rotor and could be picked up by cardiac pacemakers of that era. The pacemakers could amplify the leaking radiation rather than the heart's own electrical activity, with serious consequences for the user. Since that time, pacemaker manufacturers have added capacitors and protective circuits to block out extraneous fields and most pacemakers are now tested against electric fields equivalent to 10 mW/cm^2, the ANSI C95.1-1966 exposure standard in effect when microwave ovens first appeared. The present emission standard for microwave ovens, 21 *CFR* 1930.10, from the Food and Drug Administration, allows new ovens to leak no more than 1 mW/cm^2 when measured at 5 cm and old ovens to leak no more than 5 mW/cm^2 when measured at 5 cm (microwave oven survey meters have Styrofoam spacer cones to guarantee this 5-cm separation).

Excessive leakage from a microwave oven could occur if the oven was mechanically damaged, so oven users should check the condition of the door, door jamb, vision screen, and interlock when they use an oven and have damaged ovens repaired or replaced. Annual surveys are not warranted.

RF/MW CONTROLS

RF/MW shielding is relatively simple and can be installed using relatively inexpensive materials. Lead is not needed. The most effective form of shielding is applied at the source as an enclosure. Absorbing foams, porous polyurethane foam filled with carbon in a manner that causes the arriving radiation to pass through gradually lowering impedance, can be used. Electromagnetic radiation does not pass from one medium to another if the difference in electrical conductivities is large; it is simply reflected from the object. Air is a fairly good insulator, whereas metals are good conductors, so devices such as radar work by causing radiation arriving from air to strike and be reflected by metal. The foam manufacturer makes the impedance change gradually so the radiation is not reflected from the absorber. This can be done by forming the foam into pyramid shapes so the arriving radiation passes the tips and travels towards the bases of the pyramids. The impedance gradually drops as the radiation encounters less air and more carbon. The arriving radiation eases into the foam and induces a flow of electric current in the foam. Graphite is a poor conductor, so the current induced by the radiation is dissipated as heat. The foam manufacturer can also make the carbon content of the foam increase from nothing at the outside of the foam to a maximum level at the base of the foam. Then the foam can be sold as flat sheet because pyramids are not needed.

Metal screens or sheets also can be used for shielding or enclosures. The key concept is that the mesh openings be no more than 1/4 wavelength in dimension. Metal screens and sheets must be electrically bonded to each other where they join and the whole assembly grounded; otherwise, fields can pass through the gaps. A Faraday cage is a grounded enclosure made of continuously bonded conductors. An object inside is protected from electric fields and radiation on the outside. The doors and door jambs of Faraday cages are lined with resilient alloy strips that make contact when the door is shut so the door is bonded to the jamb and the rest of the cage.

Waveguides and coaxial cables are used to transfer power and act as enclosures. Waveguides are open metallic conduits with flanged ends. The flanged ends allow waveguides to be fastened to other waveguides, sources, or receivers. Waveguides must be snugly attached or leakage will occur. Similarly, coaxial cables can be bent and fail. Leakage can occur where they fail.

Copper tape is most commonly used in electrical engineering. It is used to patch leak points in enclosures or in runs of waveguide. Very-high–power devices have been successfully enclosed in wooden boxes lined on the inside with well-joined copper sheets and absorbing foam and finished outside with copper tape at the seams.

Distance is very effective in far fields, due to the inverse square law, and also can be used in near fields. Examples of using distance as a control include enclosing a source in a barricade to keep people away from the source or using long-handled tools to manipulate objects immersed in strong radiation fields.

Time limitations are possible, based on a 6-min averaging time, but often are not practical. Another control, the sign found in the OSHA nonionizing radiation standard, became obsolete in 1992; the symbol shown in Figure 11–15 should be used instead of the aluminum, black, and red diamond found in the old OSHA standard. The magenta and yellow trefoil associated with ionizing radiation should never be used!

OPTICAL RADIATION AND LASERS

CIE Bands

Optical radiation includes infrared/visible and ultraviolet radiation. Optical radiation is manipulated with nonconductive optics (with the exception of mirrors, which use metal to reflect the radiation). It is customary to describe optical radiation by wavelength rather than frequency. Nomenclature has been developed by the Commission Internationale d'Eclairage (CIE), or International Lighting Commission. The band designations for infrared and ultraviolet radiation begin at the border of each band starting with visible radiation (wavelength of 400–750 nm) and extend each way from the visible band:

CIE Band	*Wavelength*	*Non-CIE Nomenclature*
Microwaves	>1 mm	
IR-C	3 μm–1 mm	Far IR: 25 μm–1 mm
IR-B	1.4 μm–3 μm	Intermediate IR: 2500 nm–25 μm
IR-A	760–1400 nm	Near IR: 760–2500 nm
Visible	400–760 nm	
UV-A	315–400 nm	Near UV, black light
UV-B	280–315 nm	Middle UV, actinic UV
UV-C	100–280 nm	Far UV, actinic UV, Vacuum UV: <200 nm
x rays	<4 nm	

Note that the ANSI standard for laser safety, Z136.1-1993, uses the non-CIE terms *near*, *intermediate*, and *far* to define IR bands.

BIOLOGICAL EFFECTS AND EXPOSURE STANDARDS FOR OPTICAL RADIATION

Biological effects of optical radiation result from thermal and photochemical mechanisms. (The scientific controversy and uncertainty that plague efforts to protect people from microwave, RF, and ELF do not apply to optical radiation.) Thermal effects are dominant in the IR portion of the spectrum, photochemical effects dominate in the UV, thermal effects are more important at the red end of the visible spectrum, and photochemical effects are dominant at the blue end of the visible spectrum. The target organs are the eyes and skin. Visible and IR-A radiation, 400–1400 nm, is particularly hazardous to the eye because it is transmitted through the cornea, is focused by the lens, and strikes the retina. The potential for retinal damage is great because the radiation can be highly concentrated by focusing.

The Eye

The exterior of the eye is protected by a transparent layer that contains living tissue, the cornea. The cornea is wetted by continual blinking of the eyelids when they are open. The vitreous humor, a sac of watery material, lies inside the cornea. The cornea and vitreous humor form the anterior portion of the eye, which is divided from the posterior region by the iris, which is opaque and pigmented. The iris can absorb energy and be heated by radiation. The iris contains muscles that adjust the size of the central opening, the pupil, to control the amount of light passing into the rest of the eye. Behind the iris lies the lens, a flexible mass that is made thicker or thinner by the ciliary muscles to provide the sharpest possible image on the retina. It transmits visible and IR-A radiation, but other bands of IR and UV are absorbed here or at the cornea. Light passes through the aqueous humor and strikes the retina, where photosensitive cells convert the energy of light to electrical signals that are fed to the vision centers of the brain and the pineal. There are two types of photoreceptor cells in the retina: rods, which work in a broad range of lighting conditions but cannot differen-

tiate between wavelengths (see colors), and cones, which perceive colors in brightly lit conditions. Rods cover the entire retina, but cones cover only the macula, a small area in the back of the retina. The fovea, a small pit rich in cones and essentially rod-free, is located in the center of the macula directly opposite the center of the iris, which makes color vision particularly vulnerable to overexposures to visible and IR-A radiation. When the lens is removed surgically, creating an aphakic condition, then UV-A that normally is blocked by the lens also passes through and evokes a retinal response. The rods lie on a bed of highly pigmented tissue, the retinal pigmented epithelium (RPE); whereas the rods are essentially transparent and do not absorb light, the underlying RPE can absorb light, become hot, and damage the rods. (See Chapter 5, The Eyes, for anatomical illustrations of the human eye.)

The target portions of the eye are summarized below:

CIE Band	*Wavelengths*	*Primary Visual Hazard*	*Other Visual Hazards*
IR-C	1 mm–3.0 μm	Corneal burns	
IR-B	3 μm–1.4 μm	Corneal burns	
IR-A	760–1400 nm	Retinal burns	Cataracts of lens (glassblowers' cataracts)
Visible	400–760 nm	Retinal burns	Night and color vision impairment (chronic exposures to intense sunlight)
UV-A	315–400 nm	Cataracts of lens	
UV-B	280–315 nm	Corneal injuries (welder's flash)	Cataracts of lens (at longer wavelengths of UV-B band)
UV-C	100–280 nm	Corneal injuries (welder's flash)	

See Figure 11–19 for a summary of the CIE bands and target organs of optical radiation.

The blood circulating through the choroid below the retina is an important defense mechanism. The capillaries in the choroid have larger diameters than typical capillaries elsewhere, but the oxygen demand of the living retinal and other eye tissues is modest; this capillary net is a vast liquid cooling system that extracts heat from the retina. This defense can be overwhelmed by an extremely brief but intense pulse of light into the retina providing energy above the rate at which the heat can be extracted by blood flow. Pulsed lasers are particularly hazardous; they can deposit energy so rapidly that the water in the retinal tissue flashes to a boil and "explodes," causing local tissue damage. If the same amount of energy is deposited in a shorter time period in briefer pulses, more damage is created by the shorter pulses because less heat dissipation can occur. This thermoacoustic mechanism of damage was unknown until the laser was invented. Alternatively, large quantities of light can be hazardous when deposited over larger areas of the retina; this is why it is unsafe to look at the sun through a telescope. The choroid circulation can remove the heat of glimpsing at the sun for a brief period because the image of the sun on the retina is so small that only a small part of the retina is strongly illuminated. A telescope makes the retinal image much larger and the brightness that was limited to just a small retinal area now strikes a much larger area. This can overwhelm the heat-removing capacity of choroid circulation. Visible radiation can cause retinal injuries or burns because it is transmitted and focused. If the resulting lesion, or scotoma, damages some portion of most of the retina, very little visual impairment will result, but if the scotoma occurs in the macula, serious visual impairment results.

Another defense is afforded by aversion reflex actions such as blinking or looking away from bright light. Excessively bright light prompts these responses, which end exposure in about 1/4 s; this is enough to provide protection from injuries due to sunlight and most artificial light sources other than lasers. One reason why lasers are hazardous is because they can deposit damaging amounts of energy into the eye well before the aversion reflex ends the exposure.

The Skin

See Chapter 3, The Skin and Occupational Dermatoses, for anatomical illustrations of the skin. The outermost layer of skin, the epidermis, contains a single sheet of cells at its base, consisting of keratinocytes (cells that divide and move outward) and melanocytes (cells that form dark granules of melanin pigment that are transferred to the keratinocytes). The keratinocytes divide and are pushed outward by newer cells being created by the basal cells. As they move outward they flatten, develop pigment granules, and finally die. Thus, the dividing and moving keratinocytes carry pigment with them. This pigment absorbs UV and prevents the generation of excessive levels of vitamin D and UV injuries to the dermal and subcutaneous tissues below. The inner layer of living cells is called the stratum malphigii; the outermost layer of dead cells the stratum corneum.

IR and visible light skin injuries are confined to thermal burns. About 2/3 mW/cm^2 irradiance produces a feeling of warmth. UV also causes skin effects through photochemical mechanisms. Sunbathers now use sunscreen lotions to allow UV-A to reach the skin and stimulate melanin production by the melanocytes, but absorb UV-B before it can reach the skin. UV-B and UV-C produce two undesirable effects: the skin toughening evident among desert dwellers and skin cancer. (Outdoor exposures do not include UV-C because it is absorbed by oxygen in the atmosphere to produce ozone.) Research now shows that UV-A can also cause skin cancer. Thermal and photochemical damage mechanisms again dominate. The most common skin effect is erythema, or reddening, which is commonly called sunburn. UV penetrates to the living cells of the dermis and causes damage, which is

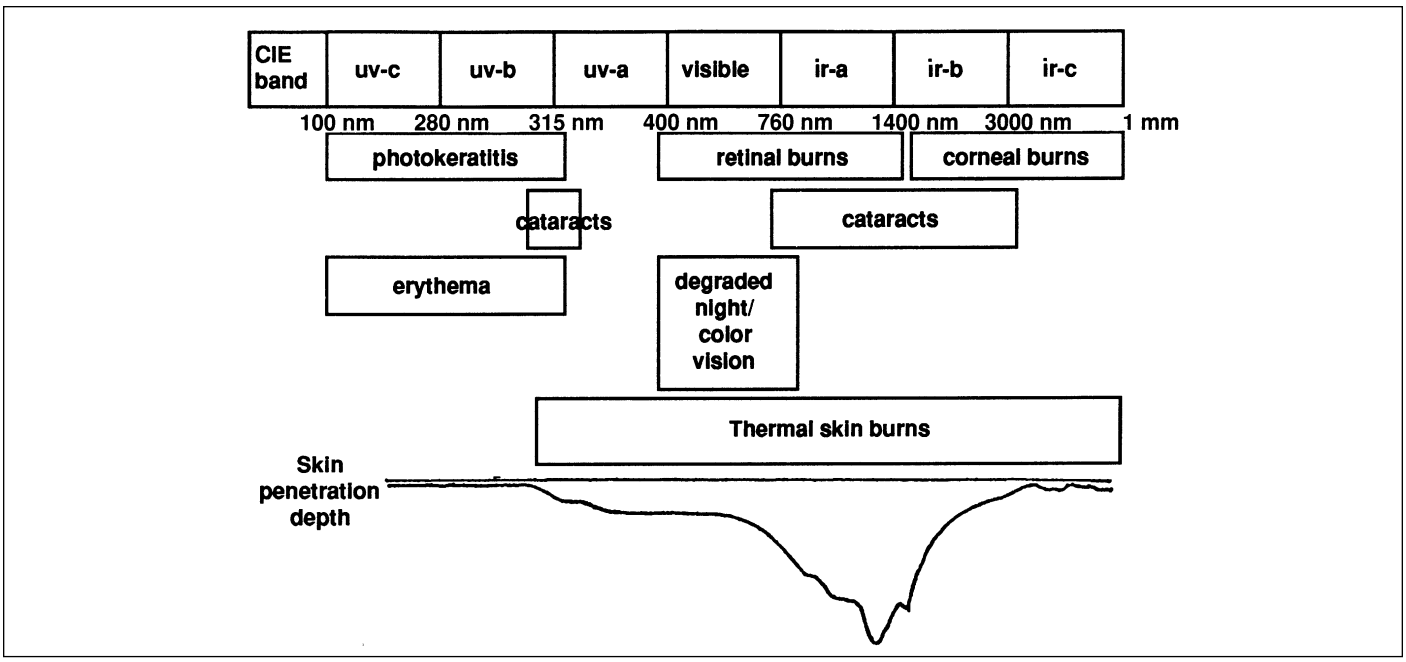

Figure 11–19. A summary of the CIE bands and target organs for the various types of radiation. (From Sliney & Wolbarsht, 1985.)

repaired. Blood supply to the skin is increased as part of the repair process, causing the reddening. Repeated exposure to UV, particularly UV-B, causes the skin to thicken and harden. This is why people who live in sunny areas can develop leathery skin.

The exposure standards that address UV and far IR exposure to the skin are about the same as the standards addressing eye exposures, but the standards for visible and near IR skin exposure are much more lenient than those for eye exposure because of the possibility of retinal damage caused by focusing.

Standards

It is necessary to digress into mathematics here. Optical radiation and laser safety standards use *radians* rather than degrees as a measure of angle. The length of an arc (segment of a circle) created (subtended) by a given angle is equal to the radius of the circle times the size of the angle in radians. Put another way, the size of a source that is emitting radiation or a surface that is reflecting radiation is equal to the distance between the source or surface and the viewer times the angle in radians. The customary symbol for the angle is alpha (α). The use of radian units is shown in Figure 11–20. For comparison purposes, half a circle, 180°, is π (about 3.1416) radians and a full circle, 360°, contains 2π (about 6.2832) radians. Another angular measure is also used to describe portions of the surface of a sphere: the *steradian*. Radians and degrees cover familiar two-dimensional circles and arcs, but the steradian unit applies to three-dimensional situations such as areas that are reflecting or generating radiation. The size of an area on the surface of a sphere is equal to the solid angle subtended by that area times the radius of the sphere. A sphere subtends a solid angle of 4π steradians. Put another way, the size of an illuminated or radiating area is equal to the square of the distance between the area and the observer times the solid angle, in steradians.

The principal standards for nonlaser optical radiation are found in the back of the TLV® booklets issued annually by the ACGIH. ACGIH groups visible radiation with IR radiation and addresses UV separately. These TLVs are fundamentally identical in concept to the more familiar noise

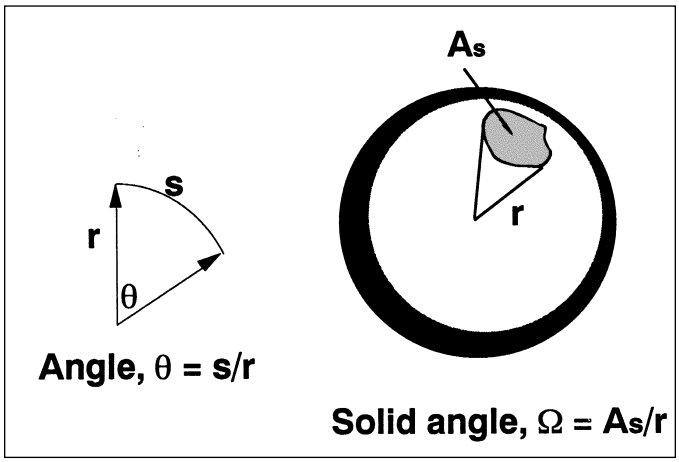

Figure 11–20. An angle in radians can be calculated by dividing its arc by the radius. A solid angle can be calculated in steradians by dividing the area subtended by the solid angle by the radius squared. In optical safety applications, the arc is the long dimension of an illuminated or luminous area. The area for a solid angle calculation is the illuminated or luminous area. In both cases, the radius is the distance between the illuminated or luminous area and an observer.

standard in that they use spectral effectiveness factors to account for the difference in damage caused by energy of different wavelengths (much as the A-weighting curve does for noise exposures) and they trade exposure intensity off against permissible exposure time. Instruments are now on the market that have wavelength response characteristics that approximate the spectral effectiveness curves of the TLV®s; such an instrument is shown in Figure 11–21.

The TLV for visible/IR radiation has two basic elements: one for situations where visible radiation is present and a much simpler standard that applies when only IR is present. The visible standards must account for both photochemical injuries at the blue end and thermal injuries at the red end and IR. The thermal injury standard covers wavelengths from 400 to 1,400 nm and balances ambient irradiances multiplied by the appropriate spectral effectiveness factors (listed in a table that shows that the maximum thermal hazard exists almost at the UV end, wavelength = 435 and 440 nm) against the angle being viewed and the exposure time. Thus, stronger exposures to more hazardous wavelengths from bigger sources warrant shorter permissible exposures. The TLV also specifies making a second comparison to account for blue light photochemical hazards of visible radiation, wavelengths from 400 to 700 nm. A table of spectral effectiveness factors is given for red light and blue light injury. Stronger exposures of more hazardous wavelengths from bigger sources (sources covering larger solid angles) are balanced against permissible exposure duration. Special spectral effectiveness factors are required for those who have had their lenses removed (aphakes); these require assessments down to 305 nm (through all of UV-A and just into the high wavelength end of UV-B).

The IR TLV does not extend to wavelengths >1.4 μm; one must consult LIA/ANSI laser safety standard Z136.1 for guidance about wavelengths between 1.4 μm and 1 mm. The Z136 standard can be applied to nonlaser sources at wavelengths above 1.4 μm because the concern about retinal focusing does not exist above 1.4 μm so eye and skin hazards are the same for laser and nonlaser sources.

Two formulas are given for situations such as heat lamps where IR is not accompanied by visible radiation. One formula addresses corneal hazards from 770 nm to 3 μm by limiting exposure times if irradiances exceed those allowed for viewing intervals greater than 1,000 seconds (10 mW/cm^2). The other addresses retinal hazards from 770 to 1400 nm.

The TLV for UV uses similar logic and relies on a combined eye and skin hazard weighting curve so only one set of measurements is needed. The combined curve shows maximum potency at 270 nm. Neither the skin nor the eye hazard curve peaks at 270 nm, but the combined curve does. Instruments have been developed in which the sensor *response* approximates the combined UV spectral effectiveness curve.

Figure 11–21. Instruments are now on the market that have wavelength response characteristics that approximate the spectral effectiveness curves of the TLVs. (Courtesy International Light, Inc.)

Controls for Nonlaser Sources

It is necessary to discuss optical density before proceeding to controls. *Optical density* (OD) is the base-10 logarithm of the ratio of the intensity of the radiation leaving the filter divided by the intensity of the radiation entering the filter (the attenuation provided by the filter). If a filter absorbs all but 1 percent, or 1/100, of the radiation entering it, then the OD is the logarithm of 100, or 2. If a (1-kW) laser beam strikes a filter and only 1 mW is transmitted through the filter, then the filter reduced the beam intensity by a factor of 1,000,000 and its OD is 6.

A variation of optical density, *shade number*, has been used in ANSI Z49.1 to describe welders' eye protection for several decades. The shade number is 1 plus the product of 7/3 multiplied by the optical density of the filter.

Baffles and sight barriers are common engineering controls for optical radiation, particularly for welding areas. A number of vendors sell absorbing plastic panels that allow observers to see welders without being exposed to hazards from arcs.

Table 11–J. ***Guide for Welding Shade Numbers***

Process	*Electrode Size in 1/32 in. (mm) or Process Description*	*Arc Current (A)*	*Minimum Protective Shade***	*Suggested Shade (Comfort)**
Shielded metal arc	<3 (2.5)	<60	7	—
	3–5 (2.5–4)	60–160	8	10
	5–8 (4–6.4)	160–250	10	12
	>8 (6.4)	250–550	11	14
Gas metal arc or flux covered arc		<60	7	—
		60–160	10	11
		160–250	10	12
		250–550	10	14
Gas tungsten arc		<50	8	10
		50–150	8	12
		150–500	10	14
Air carbon	Light	<500	10	12
Arc cutting	Heavy	500–1,000	11	14
Plasma arc welding		<20	6	6–8
		20–100	8	10
		100–400	10	12
		400–800	11	14
Plasma arc cutting	Light†	<300	8	9
	Medium†	300–400	9	12
	Heavy†	400–800	10	14
Torch brazing				3** or 4
Torch soldering				2
Carbon arc welding				14
		Plate thickness in. (mm)		
Gas welding	Light	<1/8 (<3.2)		4** or 5
	Medium	1/8-1/2 (3.2–12.7)		5** or 6
	Heavy	>1/2 (>12.7)		6** or 8
Oxygen cutting	Light	<1 (<25)		3** or 4
	Medium	1-6 (25–150)		4** or 5
	Heavy	>6 (>150)		5** or 6

* Start with a shade too dark to see the weld zone. Then go to a lighter shade that gives a sufficient view of the weld zone without going below the minimum. In oxyfuel gas welding or cutting, where the torch produces a harsh yellow light, use a filter lens that absorbs the yellow or sodium line in the visible radiation.
** This is listed as the minimum protective shade in the OSHA General Industry Standard for Eye and Face Protection, 29 *CFR* 1910.133 of April 6, 1994.
† These values apply where the arc can be seen clearly. Experience has shown that lighter filters can be used when the arc is hidden by the workpiece.
(From AWS/ANSI Z49.1-1988.)

A wide variety of personal protective equipment is now available for nonlaser optical radiation hazards. Some points of interest follow:

- ➢ The shade numbers for welding eyewear are summarized in Table 11–J. They are excerpted from ANSI Z49.1-1988, which OSHA incorporated in the 1994 revisions of 29 *CFR* Subpart I, personal protective equipment standards.
- ➢ Common glass does not offer complete protection against UV-A, although it is very effective against UV-B and UV-C. Tinted eyewear is often effective against UV-A. Eyewear vendors will send transmission curves for their products that can be used to select UV-A protective eyewear for applications that do not involve intense exposures to UV-A.
- ➢ The use of photochemically darkened lenses should be avoided because the lenses can darken fairly rapidly in response to sunlight, but become paler slowly. One can enter a building or drive into a tunnel and experience impairment of vision by such glasses, particularly immediately after entry, until the tinting adjusts to the reduced light levels.
- ➢ Special lenses are available for nonlaser light and IR sources such as glass blowing and steel making.
- ➢ OSHA standard 29 *CFR* 1910.133 requires eye and face protectors to be distinctly marked to facilitate identification of the manufacturer and to meet ANSI Z87.1-1989 impact criteria. OSHA standard 29 *CFR* 1910.133 also requires that protective eyewear for users with prescriptions either have the prescription built in or be worn over prescription lenses without disturbing the prescription lenses. Several eyewear vendors now offer clip-on adapters so prescription lenses can be worn behind eyewear that filters optical radiation.

LASER

Laser is an acronym for *light amplification by stimulated emission of radiation.* Its original derivation has been obscured by

years of common use. The original lasers followed microwave devices called masers (the *m* stands for *microwave*) and were called optical masers. Masers and lasers work by pumping the electrons in a suitable material, the lasing medium, with strong energy and directing some of that energy out in the form of a beam of radiation. To do this, most lasers include the parts shown in Figure 11–22: a source of pumping energy such as a flash lamp or electrodes embedded in a gas-filled tube, a lasing medium that emits radiation when pumped, and a resonant cavity that is a multiple of the product radiation's wavelength and is formed by placing a mirror at each end of the lasing material. The pumping energy strikes electrons of atoms in the lasing medium, which quickly lose the pumping energy as radiation. Some of the radiation produced hits electrons in other pumped atoms in the lasing medium and makes them yield their stored energy as more radiation. The radiation reaches one end of the cavity and is reflected off of a mirror back into the lasing medium, where it strikes more electrons in other pumped atoms and causes them to yield their energy until it strikes a mirror at the opposite end of the cavity, where the process begins again. The radiation surges back and forth along the cavity, gaining strength until it emerges from one end (with a partially reflective mirror) as a beam with parallel sides.

Laser radiation has unique properties. It is monochromatic, which means that it is made of one or a few wavelengths of radiation, determined by the lasing material. It is coherent; that is, the waves are matched to one another as soldiers in a column are matched to one another. It is also bright. It can have very high irradiance and be focused to deposit intense energy on small surfaces. Coherent radiation can be very sharply focused whereas common noncoherent radiation cannot. The parallel-sided and coherent nature of the product radiation means that the beam does not spread as rapidly as radiation from other sources. Thus, a laser beam keeps its strength over long distances. Visible and IR-A laser beams can be focused to create extremely intense exposures on the retina that deliver up to 300,000 times as much power or energy per unit area on the retina as on the outside of the eye. This is why laser safety standards are much stricter in this band than at other bands and why laser standards are stricter than standards for noncoherent sources in this band.

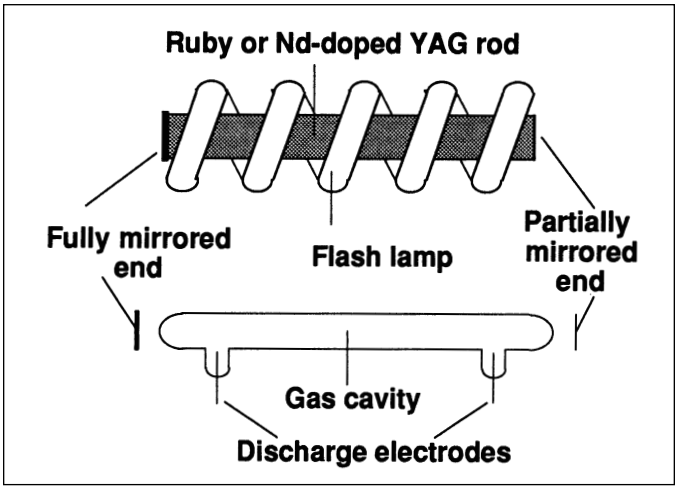

Figure 11–22. Parts of two types of lasers: solid state and gas. The top drawing is a solid-state laser, the bottom a gas laser. Both lasers fit in protective housings that include cooling equipment for high-power lasers and a beam-blocking device for Class 4 lasers. Power supplies and control panels are usually located elsewhere; the power supply and cooling cables leading to the laser enclosure give a rough indication of the laser's power.

Lasers can be operated in two major modes, much like other radiation sources: pulsed and continuous wave (CW). Exposure standards and laser outputs for pulsed and relatively brief exposures are expressed in J/cm^2 of lit area; exposure standards and outputs for continuous wave lasers are expressed in W/cm^2 of lit area.

All forms of matter are used as lasing media. The first lasers used ruby rods; the pumping energy came from high-intensity flash lamps. Yttrium aluminum garnets treated with neodymium (Nd-doped YAG) followed for IR-A lasers. Helium-neon (He-Ne) lasers, essentially neon lamps filled with helium-neon mixtures surrounded by mirrors to create an appropriate resonant cavity, are very common. Similar lamps filled with krypton, argon, or carbon dioxide gas are also in common use. Carbon dioxide lasers produce 10.6 μm beams in the IR-C band; the other lasing media just mentioned produce mostly visible wavelengths, as shown in Tables 11–K and 11–L. Organic dyes are used because the output wavelength can be precisely adjusted at the discretion of the user, unlike other media, which have fixed product wavelengths. Solid-state diodes made from selectively blended compounds of gallium arsenide can be used to produce radiation in the IR-A band and diode lasers are now used in supermarket bar code scanners and lecture hall pointers. Diode lasers producing dangerous outputs can be smaller than a fingertip. Excimer lasers use ionized halogen atoms in inert gases to emit UV radiation.

Energy sources usually use electricity to fire flash lamps or energize electrodes in a gas cavity, but other forms of pumping energy can be used. The energy released by the combustion of deuterium and fluorine is harnessed in gas dynamic lasers, rocket engine-like devices that exhaust in one direction and produce an IR beam in a perpendicular direction. Dye lasers use light from a flash lamp or from another laser for pumping.

Biological Damage Mechanisms of Lasers

Laser beams produce biological damage by the two mechanisms mentioned earlier (thermal burns and photochemical injuries) and visible and IR-A lasers produce retinal damage by a third mechanism unique to lasers. The highly focused beam generates a steam bubble near the retina that pops,

Table 11–K. *Common Continuous Wave Laser and Division into Classes by Accessible Emission Limits**

Lasing Medium	*Output Wavelength (nm)*	*Class 1 (W)*	*Class 2 (W)*	*Class 3b (W)*	*Class 4 (W)*
UV-B and C					
Argon	275	$\leq 9.6 \times 10^{-9}$ for 8 h	—	>Class I and <0.5	>0.5
UV-A					
Helium-cadmium	325				
Argon	351 and 363	$\leq 3.2 \times 10^{-6}$	—	>Class I and <0.5	>0.5
Krypton	350.7 and 356.4

Far IR					
Indium gallium arsenic phosphide	1.550 μm				
Holmium	2.10 μm				
Erbium	2.94 μm				
Hydrogen fluoride	2.6–3 μm	$\leq 9.6 \times 10^{-3}$			
Helium-neon	3.39 μm only		—	>Class I and <0.5	>0.5
Carbon monoxide	5.00–5.50 μm				
Carbon dioxide	10.6 μm				
Water vapor	118	$\leq 9.5 \times 10^{-2}$			
Hydrogen cyanide	337				

* Assumes no mechanical or electrical design incorporated into laser system to present exposures from lasting 8 hours; otherwise, the Class 1 AEL could be larger than tabulated.
(From LIA/ANSI Z136.1-1993.)

sending shock waves into the retinal tissue that produce thermoacoustic tissue damage. Briefer pulses are more hazardous than longer pulses of equal energy content because the heat does not dissipate as much during a shorter pulse. Q- switching is a method of reducing the pulse duration of a laser. Q-switched pulses can last tenths of microseconds whereas the original unswitched beams can last milliseconds. Thus, joule for joule, Q-switched pulses are more hazardous than non-Q-switched pulses. The bursting bubble can damage blood vessels and blood is toxic to nerve tissue, so the degree of lasting impairment caused by thermoacoustic injury is a matter of luck determined by what part of the retina was struck and whether blood reached nerve tissue.

It is important to note that coherent visible and IR-A radiation with wavelengths of 400–1,400 nm can be focused into an ultra-small (diffraction-limited) spot at the back of the retina. The brightness of the radiation striking the retina can be as much as 300,000 times stronger than that entering the eye. Thus, visible and IR-A lasers are particularly hazardous to the eye. This explains why laser exposure standards are so strict.

Standards

The dominant standard for laser safety in the United States is the Laser Institute of America's LIA/ANSI Z136.1 standard, *American National Standard for Safe Use of Lasers*, last revised in 1993. Regulations for commercial laser products promulgated by the Center for Devices and Radiological Health (CDRH) of the Food and Drug Administration, 21 *CFR* Part 1040, are important for commercial laser devices.

The ANSI standard addresses facility and program elements as well as laser safety features. The 21 *CFR* 1040

Table 11–L. *Common Single-Pulsed Lasers and Division into Classes by Accessible Emission Limits*

Lasing Medium	*Output Wavelength (nm)*	*Pulse Duration*	*Class 1 (J)*	*Class 3b (J)*	*Class 4 (W)*
UV					
Argon fluoride excimer	193	20 ns	$\leq 1.9 \times 10^{-6}$		
Krypton fluoride excimer	248	20 ns	$\leq 1.9 \times 10^{-6}$		
Xenon chloride excimer	308	20 ns	$\leq 4.3 \times 10^{-6}$	>Class 1, but <0.125	>0.125
Nitrogen	337	10 ns	$\leq 3.6 \times 10^{-6}$		
Xenon fluoride excimer	351	20 ns	$\leq 4.3 \times 10^{-6}$		
Visible					
Rhodamine 6G dye	450–650	1 μs	$\leq 0.2 \times 10^{-6}$	>Class 1, but <0.03 C_A*	
Copper vapor	510 and 578	25 ns	$\leq 2 \times 10^{-7}$

** Q-switched.
(From LIA/ANSI Z136.1-1993.)

addresses product safety features. Both standards were early uses of the hazard control class type of regulation. Control class regulations require assigning a classification that reflects the severity of the hazard. For lasers, the principal parameters that describe the anticipated hazard severity are wavelength and output power or energy.

Other measures of anticipated severity are pulse duration and the size of extended sources such as groups of diode lasers or the reflection of a spread laser beam from a surface. The LIA/ANSI and CDRH standards specify precautions based on the anticipated hazard of the accessible beam by setting accessible emission limits (AELs) for the amount of laser energy people could encounter from each class of laser. Precautions can be relaxed when the beam is thoroughly enclosed or reduced in power before it can enter a place where people could be exposed to it; this gives laser equipment suppliers a strong incentive to apply effective engineering controls. Precautions become more stringent in a series of defined steps (Classes) as the output of the laser increases from Class 1 (so low-powered as to be intrinsically safe) through Class 4 (very dangerous).

Classifications for several lasers are given in Tables 11–K and 11–L. Extremely weak beams are deemed nonhazardous (Class 1) and no precautions are needed. Low-power visible beams that could be hazardous if viewed for prolonged periods (Class 2 and 2a) warrant limited precautions. Class 2a visible lasers are those that could cause excessive exposures if the beam was viewed for 1,000 s or more; Class 2 lasers are visible light lasers that could produce excessive exposures if viewed for more than the 0.25-s response time of the aversion reflexes. Class 3 moderate-power lasers warrant more precautions and include moderately high-powered visible lasers and moderately powered invisible UV and IR lasers. Class 3 lasers are subdivided into Class 3a and 3b; Class 3a includes lasers that could be hazardous only if stared at or viewed through an optical device such as a telescope. All other Class 3 lasers are Class 3b and are presumed to have beams powerful enough to harm the eye during incidental exposure without an optical instrument. Class 4 high-power lasers warrant rigorous precautions because the beam can harm the skin and eyes and even diffuse reflections could be harmful. The precautions specified by LIA/ANSI Z136.1-1993 for each class are summarized in Table 11–M.

The use of hazard control classes reduces the need for measurements to determine personnel exposures and puts reliance on being able to estimate exposures by calculations.

LIA/ANSI Z136.1-1993 also sets maximum permissible exposures (MPEs) for lasers, as listed in Tables 11–N, 11–O, and 11–P. The MPEs are directly equivalent to OSHA PELs for chemicals or the MPEs for radiofrequency/microwave radiation set by ANSI/IEEE C95.1-1991. Adjustment factors are applied to calculate MPEs for extended sources,

based on the size of the angle subtended by that source in radian units. The AELs used to define laser classes are equal to the MPEs for the maximum allowable viewing time listed in the standard for visible and IR-A lasers, multiplied by the limiting aperture (typically the size of the pupil opening, which can range from 1 to 7 mm, as defined in the standard [see Table 11–P]). The MPEs for wavelengths above 1,400 nm are the only available guidance for nonlaser IR sources emitted at frequencies above 1,400 nm. Limiting aperture dimensions depend on wavelength and the expected duration of an exposure.

LIA/ANSI Z136.1-1993 uses different averaging times depending on the wavelength of the radiation involved. The averaging time for UV exposures is the duration of the expo-

(From LIA/ANSI Z136.1-1993.)

sure throughout a shift, similar to the averaging time for chemicals. The standard actually is based on accumulating a dose of UV energy rather than measuring or calculating the average exposure. The averaging time for visible exposures is 0.25 s, the operating time of aversion reflexes. The averaging time for IR exposures is 10 s.

This standard also gives protocols for evaluating repetitively pulsed exposures that are used when the pulse repetition rate exceeds one pulse per second. Pulses that occur less frequently than once per second are addressed by the standards shown in Table 11–Q. Computer applications are available to do routine laser safety calculations, but the user should know how to do the calculations on paper before beginning to routinely use the application and verify that the application works for the pulsing and wavelength scenarios of interest by comparing computer results to the results of paper calculations.

Pulsed laser exposure criteria are complicated and hard to apply. LIA/ANSI Z136.1-1993 specifies that the exposure interval for visible lasers is 0.25 s (it defines visible as ranging between 400 and 700 nm rather than 760 nm) whereas the exposure interval for IR lasers is 10 s. These exposure durations are applied concurrently in two procedures for determining MPEs and AELs for pulsed lasers, per paragraph 8.2.2 of the standard. People working with pulsed lasers need to understand this part of the standard completely, but a full discussion of paragraph 8.2.2 is beyond the scope of this chapter.

Controls

Engineering and administrative controls and personal protective equipment are used for lasers and optical radiation. The main engineering control for lasers is enclosure, often in the form of interlocked rooms and protective housings. Interlocked laser beam enclosures can range from plastic panels on a framework for research setups to sturdy metal boxes with person- or vehicle-sized access doors for IR laser cutting tools. Laser beams can be routed over or below walkways using mirrors and, possibly, elevated enclosures or tunnels. LIA/ANSI Z136.1-1993 calls for fail-safe interlocks, such as double interlocks connected in series, on access panels of enclosures of Class 3b or 4 laser beams. The interlocks either shut off the electrical power to the laser or drop a shutter into the beam at or within the housing of the laser itself. An important extension of interlocks is the remote interlock connection, which allows additional interlocks, including those located remotely, to trigger a shutdown of electric power to a laser or drop a shutter or filter into the beam. Remote interlocks can make up safety chains for laser systems covering large areas and include emergency panic button shutoffs.

Viewing portals, viewing screens, and optical instruments must be connected to interlocks or reduce beam intensity to acceptable levels for Class 4 lasers. LIA/ANSI Z136.1-1993 recognizes the use of fasteners requiring special tools as providing equivalent safety to interlocks for access panels. It is convenient to add room status lights (green for safe to enter, yellow for possibly unsafe to enter, and red for unsafe to enter) to the laser interlock system and to install a loudspeaker and buzzer near the room status lights so visitors can

Table 11–P. *Correction Factors for Intrabeam Viewing MPEs of Table 11–N and Table 11–O*

Correction Factor		Definition	Wavelength (μm)
C_A	=	1	0.400–0.700
C_A	=	$10^{2(\lambda-0.700)}$	0.700–1.050
C_A	=	5	1.050–1.400
C_B	=	1	0.400–0.550
C_B	=	$10^{15(\lambda-0.550)}$	0.550–0.700
C_C	=	1	1.050–1.150
C_C	=	$10^{18(\lambda-1.150)}$	1.150–1.200
C_C	=	8	1.200–1.400
C_E	=	1 (if the subtended angle, α, is α_{min})	0.4–1.4
C_E	=	α/α_{min} if the subtended angle is between α_{min} and 100 mradians	0.4–1.4
C_E	=	$\alpha/(100\ \alpha_{min})$ if the subtended angle is > 100 mradians	0.4-–1.4
T_1	=	$10 \circ 10^{20(\lambda-0.550)}$	0.550–0.700

α_{min} = 1.5 milliradians when $t \leq 0.7$s; $\alpha_{min} = 2\ t^{3/4}$ milliradians when 0.7 s < t < 10 s; α_{min} = 11 milliradians when $t \geq 10$ s.
(From LIA/ANSI Z136.1-1993.)

* This exposure duration normally would not be used for hazard evaluation.
** Area in cm^2 is used to calculate AELs.
(From LIA/ANSI Z136.1-1993.)

talk to the room occupants during laser operations. These boxes were developed and are used extensively at Lawrence Livermore National Laboratory, and are also commercially available.

A simple control, especially useful for lasers located in places where unauthorized people could find them, is a key-in-lock control, which makes it very unlikely that the laser could be inadvertently operated by unauthorized people. Of course, the operator must remove the key and take it when the laser is turned off.

Engineering controls are effective when a laser system is set up, but not while it is being set up or during maintenance. Thus, special caution, including heavy reliance on administrative controls and special warning signs, is needed during setup and maintenance. A recent review of laser accidents shows that 37.2 percent of laser accidents occurred during alignment. Techniques for reducing hazards during alignment include using low-powered alignment lasers. The alignment laser beam is brought into the path of the main laser beam and system adjustments are made using the less dangerous alignment beam; the accessible main laser beam power can also be reduced for setup or alignment, if practical. Alternatively, special laser alignment eyewear that blocks most of the light can be used during alignment after steps have been taken to ensure that the main beam cannot enter the eyes. ANSI Z136.1 specifies special warning signs to be used during setup. A variety of aids are available to make alignment easier even with protective eyewear:

- ➢ An IR disc that is mounted in an optical-component holder.
- ➢ IR or UV cards that glow with visible light when struck by an IR or UV laser beam.
- ➢ IR viewers that make the place where the beam strikes a surface show as a visible dot.
- ➢ Strong white paper or colored paper that fluoresces in different wavelengths (colors) when struck by a visible laser beam. The fluorescent radiation can pass through the lenses of laser safety eyewear intended for the laser wavelength. Some experimentation is needed to find which papers work.

Specular (mirror-like) reflections are more hazardous than diffuse reflections because virtually all of the beam's power is retained, as shown in Figure 11–23, and safety precautions always include eliminating all unnecessary specular reflectors. Most optical instrument manufacturers mount their products on shiny posts, but the posts are cylindrical, so a reflected beam will still be spread out. LIA/ANSI Z136.1-1993 includes formulae for calculating reflections from rounded mirrors. Painted walls and stipple-finished tools can easily be specular reflectors for CO_2 laser beams because the surface roughness that causes the diffuse reflections we see is smaller than 10.6 μm so the surface acts as if it is slick and causes specular reflections at 10.6 μm.

Administrative controls are used during setup and maintenance. Z136.1-1993 calls for calculating the nominal hazard zone (NHZ), where people could be exposed to laser beam levels above the MPEs, and excluding people from the NHZ by barriers, signs, flashing beacons, and the diligence of personnel authorized to be inside the NHZ. Warning signs should follow international conventions, applied in the United States through the ANSI Z535 series of standards; these specify colors, warning words, standard symbols, and

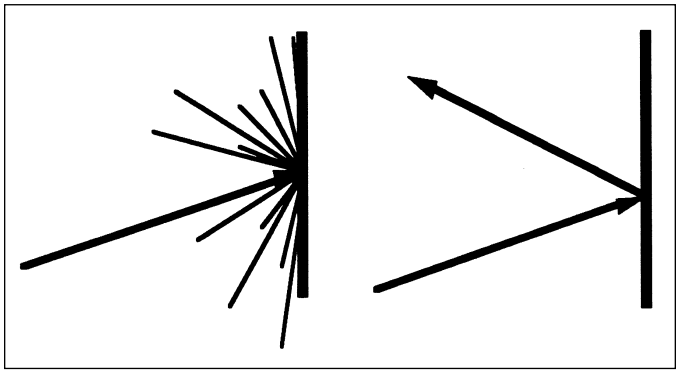

Figure 11–23. Diffuse reflections (left) dissipate the energy of incident radiation, so the reflection is not as bright as the incident radiation because it is scattered in many directions. Specular reflections (right) are much more dangerous because the beam bounces in only one direction, retaining most of its original intensity and hazard.

warning sign layout. The laser warning symbol is the familiar sunburst. The word *CAUTION* is used on signs and labels for Class 2 and 3a lasers and laser systems that do not exceed the appropriate MPE. The word *DANGER* must be used for other Class 3a lasers and all Class 3b and 4 lasers. Existing laser-safety signs and labels are grandfathered in by Z136.1-1993. The signs must specify essential precautions above the tail of the sunburst (shown in Figure 11–24) and describe the properties of the laser and the laser class below the center of the tail and the lower–right-hand corner of the sign, respectively.

Medical surveillance and training programs are required for users of Class 3b and 4 lasers. The laser safety program must include the following:

- ➢ A laser safety officer and, if the number and diversity of laser operations warrants, a laser safety committee
- ➢ Education of authorized personnel
- ➢ Application of the controls specified in the standard
- ➢ Accident reporting and investigation and action plans to prevent recurrence of incidents
- ➢ Medical surveillance as specified in the standard

Laser protective goggles must show the manufacturer, wavelengths they work against, and optical density, and must meet the provisions of the latest edition of ANSI Z87.1 for safety eyewear. As with all personal protective equipment, it is necessary to select laser eyewear of appropriate optical density for the type (wavelengths) of radiation encountered and the severity of exposure. Color coding is recommended for multilaser environments and eyewear manufacturers offer color-coded frames. Laser-protective eyewear usually includes glass or plastic lenses. In general, glass lenses are heavier, but offer more resistance to direct strikes by laser beams and often let through more light. As a rule, glass is often used when the average power of a laser exceeds about 100 mW.

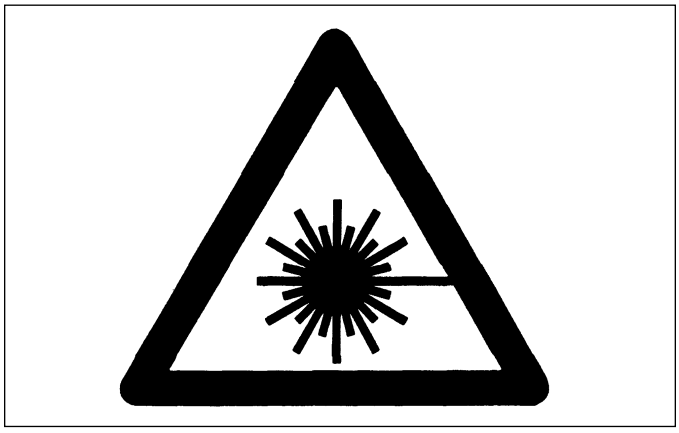

Figure 11–24. The internationally recognized sunburst laser warning icon. ANSI Z535 standards eliminate the tradition of using special colors for specific hazard warnings, but ANSI Z136.1-1993 makes limited use of a red symbol for *DANGER* signs. Symbols and narrative text now appear in black and colors are used to indicate degree of hazard (yellow and black for *CAUTION*, orange and black for *WARNING*, and red, black, and white for *DANGER*). The long tail symbolizes how laser beams retain their power over long distances. The same symbol, but without the tail, was proposed for intense nonlaser sources of optical radiation, but it is not widely used.

Laser Pointers

Laser pointers are now available at retail office supply stores. The first laser pointers were helium-neon (He-Ne) lasers emitting at 632 nm (red). But they were delicate because of the glass envelope of the He-Ne laser. Diode lasers rapidly replaced He-Ne lasers because they are more rugged and allow for compact, pen-sized pointers. Unfortunately, the early diodes emitted at 670 nm, where the visual response of the eye is much poorer than it is at 632 nm. This difficulty was overcome by raising the laser output from somewhere below one mW to a few mW. Although the visual response of the eye is exquisitely wavelength-sensitive, the vulnerability of the eye to thermal injury is not. The old He-Ne pointers were Class 2 lasers; the original diode pointers were Class 3a. The original He-Ne pointers bore a caution label; the diode laser pointers bear danger labels. Stories of cavalier use of laser pointers at lectures are common and these lasers are accessible to children. Fortunately, diode pointers emitting at 635 nm are now on the market and even shorter wavelength pointers can be expected as solid state laser technology advances. The new Class 2 laser diode pointers are both more brilliant and safer.

Safety officers should:

- ➢ Warn employees about the hazard of misusing diode laser pointers—they could cause injury if someone stares into the beam for a prolonged period.
- ➢ Replace Class 3a 670-nm pointers with Class 2 635-nm pointers.

Safety officers working for retailers should advise management to market only Class 2 laser pointers. The possibility that a child could misuse a Class 3a pointer cannot be overlooked.

Nonbeam Hazards of Lasers

The two greatest hazards of lasers, other than laser weapons, are electricity and fire. Electrocution from high-voltage power supplies and capacitor banks is a real hazard and can kill while most laser beam exposures cause some loss of vision at worst. A draft NFPA standard for laser fire protection advises that a continuous wave laser radiation creating an irradiance above beam irradiances <2 W/cm^2 is an ignition hazard. The beam could ignite flammable substances such as paper and solvents, so flammable materials must be kept out of Class 4 and some focused Class 3 laser areas. One partial exception is plastic walls of enclosures that glow where they are struck by visible or strong invisible laser beams while the area is occupied; fire-resistant plastics should be used for these applications. Objects that could be struck by laser beams must be selected to avoid toxic pyrolysis products; for

X = listed precaution.
— = not a listed precaution.
L = limited precaution class (good chemical lab practice, assigned to dyes known to be neither highly toxic nor mutagenic/carcinogenic).
M = moderate precaution (dyes known to be highly toxic or to have unknown toxic, mutagenic, or carcinogenic properties).
S = strict precaution (mutagenic materials, treated with same precautions as carcinogens).

example, some polyurethanes and epoxies produce hydrogen cyanide when they burn. Dye lasers are particular fire hazards because most use solutions of dye in an alcohol, dimethyl sulfoxide (DMSO), or some other flammable or combustible solvent. The dye solution may be located close to pumping energy sources such as flash lamps, which can add the energy needed to ignite the solvent.

Some lasers use flash lamps to supply pumping energy. Flash lamps can explode if dropped, struck, or improperly handled, posing a laceration hazard.

Laser beams can pyrolyze organic materials, and investigators who have looked at the pyrolysis products report finding polycyclic aromatic hydrocarbons (PAHs), the carcinogenic substances found in chimney soot. Thus, pyrolysis products must be controlled both in the air and as deposits on surfaces. For example, Kwan (1990) found that epoxy-reinforced graphite composite materials emit a variety of PAHs when cut by CO_2 lasers. It is also now known that viable organisms can be found in the plumes created when lasers are used to cut tissue.

Many laser dyes were brought to the market with essentially no toxicology screening and often come from chemical families that include mutagens or highly toxic materials. Mosovsky and Miller, 1986, working with Avila, Felton, and Lewis, found that a number of laser dyes are mutagenic; the chemistries of these dyes are such that a positive mutagenicity finding is cause for concern that the material may be a carcinogen. The original dye recipes used DMSO solvent, which carries other materials through the skin. However, most butyl and some neoprene and nitrile gloves are effective for blocking DMSO. DMSO can increase absorption through the skin of the dye, which may be toxic or mutagenic; it also contains sulfur, which makes disposal by incineration difficult. Dioxane, a potential carcinogen that also forms explosive peroxides if left in contact with air for prolonged time periods, should be avoided as a solvent. Chlorinated solvents are costlier to dispose of than glycols or alcohols because it is difficult to send chlorinated solvents to incinerators. Precautions for laser dyes developed at Lawrence Livermore National Laboratory are summarized in Tables 11–R and 11–S. A variation on this theme is found in the recipe for Q-switching dyes. Dye-filled cells can be used for Q-switching. Some Q-switching dyes use ethylene dichloride, a potential carcinogen, as the solvent.

Excimer lasers use halogen mixtures such as 5 percent or less of fluorine or hydrogen chloride in inert gas. These mixtures are toxic, but fortunately the corrosiveness of the halogens is moderated by dilution in inert gases. Care is still needed in selecting corrosion-resistant materials, and consideration must be given to venting these gases during cavity refilling and emergencies. Passivation procedures, which use small quantities of the reactive gas to lay down a nonreactive deposit on surfaces that will later be exposed to larger flows of that gas, must be used to prepare piping for halogen gas service and avoid serious piping failures. Gas-handling equipment that is corrosion-resistant, highly automated, and designed to maximize safety and convenience is now very common in the semiconductor industry. Excimer laser users

can obtain information about this technology from gas suppliers affiliated with gas-handling equipment manufacturers.

Other forms of radiation, such as flash lamp radiation, electromagnetic fields from power supplies, and x rays from high-voltage devices, can also be hazardous. It may be necessary to provide additional shielding or implement additional controls for these fields and other forms of radiation. Radiation from flash lamps, which can contain 100–1,000 times the energy of the laser beam, could be a hazard during setup and maintenance.

Hazardous materials can be found in optical components (such as heavy metals in detectors), components of lasers (such as beryllia heat sinks of electronic parts), or miscellaneous applications (such as coolants). Thus, an industrial hygiene review of laser maintenance procedures is warranted.

Other Regulatory Concerns with Lasers

OSHA has promulgated construction safety standard 29 *CFR* 1926.54 for the use of lasers in tasks such as alignment, although general industry uses of lasers are covered by ANSI Z136.1-1993 through the *UAW, Brock v. General Dynamics Land Systems Division* decision because OSHA general industry standards do not address lasers. The use of laser protective eyewear is covered by the eye and face protection standard, 29 *CFR* 1910.132. The OSHA construction standard specifies that those who could be exposed to direct or reflected light above 5 mW must be provided with laser eye protection and that only mechanical or electronic devices may be used to guide the alignment of a laser. The standard also sets exposure criteria summarized below:

Direct staring limit	1 $\mu W/cm^2$
Incidental observing limit	1 mW/cm^2
Diffused reflected light	2.5 W/cm^2

The LIA/ANSI Z136 committee has also issued standards Z136.2 and Z136.3 for use of lasers in fiber-optic communications systems and medical applications, respectively. The Z136.3 standard addresses the same concerns as the Z136.1 standard, but allows for greater flexibility and use of administrative controls.

The Center for Devices and Radiological Health (CDRH) of the Food and Drug Administration sets standards for commercial laser products that specify the types of safety devices that must be installed for commercial equipment using lasers. The CDRH also uses control classes based on AELs that are defined in their standard for laser devices (21 *CFR*, part 1040). CDRH specifies using interlocks, beam stops/shutters, and key-in-lock controls. CDRH also has very explicit requirements for audible and visible alarms to announce when a laser is functioning and, for Class 4, when a laser is about to function. The CDRH regulations also include an incident reporting procedure.

MEASURING OPTICAL RADIATION

Two types of detectors are widely used: thermal and quantum. Thermal detectors are fundamentally no different from globe thermometers used in heat stress studies. They consist of a sensor embedded in an object that is dark-colored to absorb IR radiation, warm up, and produce a measurable response in the detector. Relatively small, lightweight objects are desirable for thermal sensors because they change temperature rapidly, leading to faster response times (but still not fast enough to measure pulsed lasers). A variant of the thermal detector is the pyroelectric detector, which measures the rate of temperature change in crystals. This is much faster than a conventional thermal detector and, with some caution, these can be used for repetitively pulsed lasers. Thermal detectors are best for IR measurements. The heat-absorbing coatings vary in how well they absorb IR, so one should obtain information about the absorption properties of the coating before buying a thermal sensor. Another note of caution is that these detectors respond to temperature changes, so changing the room thermostat can produce a response in the instrument.

Quantum detectors emit electrons in response to being struck by radiation and are best suited for use in the UV, visible, and IR-A bands (up to 1,100 nm). These can be very fast. The detectors are often made of alloys such as cesium telluride, lead telluride, or lead selenide and the responses of the detectors to radiation of differing wavelengths are different. A buyer should check with the instrument vendor about the suitability of a detector for the radiation of interest. Note that no procedure exists for field verification of the ODs of laser eyewear.

LIGHTING

Insufficient light causes accidents and reduces work performance. One needs adequate lighting to see hazards in the workplace and to read information such as text and dials. Most lighting concerns are quantitative, but some qualitative concerns may also arise such as contrast, reflections, and color.

The Illumination Engineering Society (IES) advises that 20 footcandles of illuminance are needed for tasks requiring sustained seeing. This is also one aspect of nonionizing radiation covered by various OSHA regulations, as summarized in Table 11–T. IES/ANSI RP-7-1991 specifies the following illuminance levels for safety in normal conditions (where light will not ruin a process or pose a safety hazard):

	Illuminance Level (footcandles)	
Degree of Hazard	*Low Activity Level*	*High Activity Level*
Slight Hazard	0.5	2
High Hazard (obstacle in path)	1	5

Illuminance is similar to irradiance and power density, but the levels of light of various wavelengths are weighted in terms of their impact on the functioning of the cone cells of the retina, which are involved in color and detailed vision. The units of illuminance are the lux and the footcandle; 1 lux = 10 footcandles. The dominant quantitative standards for indus-

Table 11–S. ***Laser Dye and Solvent Control Classes in Use at Lawrence Livermore National Laboratory***

Materials/Synonyms	*Control Class*	*Comments*
BBQ	M	Nonmutagenic, unknown toxicity
Benzyl alcohol	L	Moderate toxicity, low vapor pressure
Carbazine 720	M	Nonmutagenic, unknown toxicity
Coumarin 1/460	M	Nonmutagenic, moderately toxic
Coumarin 2/45	M	Nonmutagenic, unknown toxicity
Coumarin 30/515	S	Mutagenic, unknown toxicity
Coumarin 102/480	S	Strong mutagen, unknown toxicity
Coumarin 120/440	M	Nonmutagenic, unknown toxicity
Coumarin 314/504	M	Nonmutagenic, unknown toxicity
Coumarin 420	M	Nonmutagenic, unknown toxicity
Coumarin 481	M	Nonmutagenic, unknown toxicity
Coumarin 498	M	Unknown mutagenicity, unknown toxicity
Coumarin 500	S	Mutagenic, unknown toxicity
Coumarin 535	S	Mutagenic, unknown toxicity
Coumarin 540A	M	Nonmutagenic, unknown toxicity
Cresyl violet 670	S	Very strong mutagen, unknown toxicity
1,3,5,7-Cyclooctatetrene (COT)	M	Unknown mutagenicity, unknown toxicity
DCM	S	Very strong mutagen, unknown toxicity
p,p'-diaminoquaterphenyl	M	Nonmutagenic, unknown toxicity
p,p'-diaminoterphenyl	S	Mutagenic, unknown toxicity
Dioxane	M	Moderate toxicity
DMSO	M	Moderate toxicity
DODCI	M	Unknown mutagenicity, unknown toxicity
DQOCI	M	Unknown mutagenicity, unknown toxicity
DPS	M	Doubtful bacterial mutagen, unknown toxicity
Ethylene dichloride (1,2 dichloroethane)	M	Suspected carcinogen; avoid inhalation of vapors
Ethyl alcohol	L	Low toxicity
Ethylene glycol	M	Moderate toxicity, low vapor pressure
Fluorescein 548	M	Unknown mutagenicity, unknown toxicity
IR-26	M	Unknown mutagenicity, unknown toxicity
IR-125	M	Unknown mutagenicity, unknown toxicity
IR-132	M	Unknown mutagenicity, unknown toxicity
IR-140	M	Unknown mutagenicity, unknown toxicity
IR-144	M	Unknown mutagenicity, unknown toxicity
Kiton Red 620	L	Nonmutagenic, practically nontoxic
Kodak Q-Switch #2	M	Unknown mutagenicity, unknown toxicity
Kodak Q-Switch #5	M	Unknown mutagenicity, unknown toxicity
LD-390	M	Unknown mutagenicity, unknown toxicity
LD-490	S	Mutagenic, unknown toxicity
LD-688	S	Mutagenic, unknown toxicity
LD-700	M	Nonmutagenic, unknown toxicity
LDS-698	S	Mutagenic, unknown toxicity
LDS-722	S	Strong mutagen, unknown toxicity
LDS-750	M	Unknown mutagenicity, unknown toxicity
LDS-751	M	Unknown mutagenicity, unknown toxicity
LDS-820	M	Unknown mutagenicity, unknown toxicity
LDS-867	M	Unknown mutagenicity, unknown toxicity
9-Methylanthracene	S	Mutagenic, unknown toxicity

Table 11–S. ***Laser Dye and Solvent Control Classes in Use at Lawrence Livermore National Laboratory (Continued)***

Materials/Synonyms	*Control Class*	*Comments*
Methyl alcohol	L	Moderate toxicity
Bis-MSB	M	Nonmutagenic, unknown toxicity
Nile Blue 690	S	Commercial grade is strongly mutagenic; purified dye is not. Unknown toxicity.
Oxazine 720	M	Nonmutagenic, unknown toxicity
Rhodamine 6G/590	M	Moderately toxic. National Toxicology Program tests did not demonstrate strong carcinogenicity. Commercial-grade dye has been found to induce injection-site tumors.
Rhodamine 110/560	S	Weak mutagen, unknown toxicity
Rhodamine 610/B	M	Nonmutagenic, moderately toxic
Rhodamine 640	M	Nonmutagenic, unknown toxicity
Sulforhodamine	M	Unknown mutagenicity, unknown toxicity
Stilbene 420/3	L	Nonmutagenic, practically nontoxic
N,N,N',N'-tetraethyldiaminoquaterphenyl	M	Nonmutagenic, unknown toxicity
N,N,N',N'-tetraethyldiaminoterphenyl	S	Strong mutagen, unknown toxicity

L = limited control class; M = moderate control class; S = strict control class. Precautions to be followed for the L class are given in Table 11–R. Dye/solvent mixtures with less than 1 percent dye must be handled as appropriate to the solvent, with the exception that strict-class requirements for container and equipment labeling and spill cleanup must be followed when strict-class dyes are used. When using dye/solvent mixtures with more than 1 percent dye, follow the precautions for the component in the strictest control class.

The appropriate mutagen potency of the dye in the standard Ames *Salmonella* assay is as follows: weak mutagen = <100 revertants/mg; mutagenic = 100–1,000 revertants/mg; strong mutagen = 1,000–10,000 revertants/mg; very strong mutagen = ≥10,000 mutagens/mg. The Ames test is a reliable predictor of whether a compound is a carcinogen in mammals, but it does not predict the potency of the carcinogen. Thus, a weak Ames mutagen could be a strong carcinogen. Ames test data are used because animal testing is more costly and has not been done on most dyes.

trial lighting in the United States are IES/ANSI RP-1-1982 and RP-7-1991, which address office and industrial lighting, respectively. These standards replace the historical telephone-directory-style list of tasks and listed lighting levels with a procedure in which workplaces, work force, and tasks are analyzed for type of task, age, reflectance of room surfaces, and (in some cases) whether the seeing task is unimportant, important, or critical. Important aspects of any seeing task are object size (the bigger it is, the easier it is to see), contrast, time available to do the seeing job, and luminance. RP-7 notes that luminance is often the only factor that can be controlled. Illuminances are specified in ranges for nine categories (A through I); ranges of three levels of illuminance are specified for each category. The analyst reviews the other factors to determine whether to select from the low, middle, or high end of the illuminance range for each category. The categories and specified illuminances are listed in Table 11–U; the work force and environmental/task factors are summarized in Table 11–V.

Common qualitative concerns include glare (particularly off of VDT screens), contrast, and color. Glare, either reflected or direct, is still a major concern. Reflected glare is usually a specular reflection of a sunlit window or lamp off of a screen or other shiny surface that partially obscures or veils the scene at the reflection. Direct glare is a relatively bright object, such as an unshaded window, in an otherwise dark area that prevents the eyes from adapting to the dark area. Reflected glare can be controlled by locating the screen or other surface of interest so it does not reflect the images of windows or lamps.

A screen can be angled so it does not reflect the images of lamps or windows into the user's eyes. In some cases, visors or partitions can be used to block light from lamps or windows. Another option is to place a textured surface above the object that breaks up specular reflections while allowing the light from the object below it to pass through. Dimpled plastic is often used.

RP-7 devotes an entire Annex to the subject of glare. RP-7 also gives guidance for lighting contrast, listed in Table 11–W. A gradation of contrasts is sought between the task and its immediate and more remote visual surroundings. In essence, strong lighting can exist in an area of moderate lighting, which can be surrounded by a dimly lit or unlit expanse, but darkness should not immediately surround brightness. An example of harsh contrast is a lit desk in a poorly lit warehouse. The lamp at the desk should be supplemented by area lighting to avoid contrast problems. People look away from their visual tasks from time to time, so the person at this desk would probably not wish to stay there because the visual contrast between the desk and its visual surroundings is too great for comfort.

Nonlaser lighting adheres to the inverse square law. This means that lights must be placed close to areas being lit if the lighting is needed to perform a task. Sometimes, this cannot be done by area lighting alone. A warehouse may need area lights placed above the heights of shelves and forklift trucks, so supplemental lighting, provided by floor or desk lamps, may be needed at desks located in the warehouse. The limits of supplemental lighting include harsh contrast, already

Table 11–T. *Summary of OSHA Regulations Concerning General Lighting*

Regulation	*Summary*	
1910.179(c)(4): Cranes	Cab lighting shall be adequate.	
1910.303(g)(1)(v): Electrical work areas	Illumination shall be provided.	
1910.303(h)(3)(ii): Lighting maintenance	Adequate illumination shall be provided.	
1910.333(c)(4): Electrical work practices	Spaces containing energized parts shall be illuminated; work shall not be performed in and people shall not reach into unlit spaces.	
1910.38(q): Exits	Exit signs shall be lit by a reliable light source >5 footcandles.	
1910.120: Hazardous waste site operations	Quantitative specifications: Area	Illumination (footcandles)
	General work areas	5
	Excavation and waste areas, loading platforms, refueling, and field maintenance areas.	3
	Indoors: warehouses, corridors, hallways, and exit ways.	5
	Tunnels, shafts, and general underground work areas. (Exception: ≥10 footcandles is required at tunnel and shaft heading during drilling, mucking, and scaling. MSHA-approved cap lights acceptable for use in the tunnel heading).	5
	General shops (mechanical and electrical equipment rooms, active storerooms, barracks or living quarters, locker or dressing rooms, dining areas, indoor toilets, and workrooms).	10
	First-aid stations, infirmaries, and offices.	30
1910.142(g): Labor camps	Each habitable room shall have at least one ceiling light fixture and a floor or wall outlet. Laundry rooms, toilets, and rooms where people congregate shall contain a ceiling or wall fixture. Toilets and storage rooms shall be lit at ≥20 footcandles 30 in. above the floor. Other rooms, including kitchens and living quarters, shall be lit ≥30 footcandles 30 in. above the floor.	
1910.219(c)(5)(iii): Power transmission equipment in basements	Lighting shall conform to ANSI A11.1-1970.	
1910.68(b)(6)(iii): Manlifts	Lighting ≥5 footcandles shall be provided at each landing when lift is operating.	
1910.68(b)(14): Manlifts	Lighting ≥1 footcandles shall be provided in runs when lift is operating.	
1910.178(h): Industrial trucks	Supplemental lighting shall be provided where lighting is ≤2 lumens/ft^2.	
1910.261(b)(7): Pulp and paper mills	Emergency lighting shall be provided where operators must stay during emergencies, in passageways, stairways, and aisles used for emergency exit, and at first-aid and medical facilities.	
1910.261(c)(10): Pulp and paper mills	Loading/unloading areas shall be lit in accordance with ANSI A11.1-1970.	
1910.266(e)(15): Pulpwood logging	Lighting shall be provided for night work if needed.	
1910.265(c)(5)(iii): Sawmills	Stairway shall be adequately illuminated.	
1910.265(c)(9): Sawmills	Work areas shall be provided with adequate illumination.	
1910.265(c)(23)(iii): Sawmills	Fuel houses and bins shall have adequate exits and lighting.	
1910.268: Telecommunications	Adequate lighting shall be provided.	
1926.56: Construction	Areas not covered by the following table shall be illuminated in accordance with ANSI A11.1-1970.	
	Quantitative specifications: Area	Illumination (footcandles)
	General construction area lighting	5
	General construction areas, concrete placement, excavation and waste areas, access ways, active storage areas, loading platforms, refueling, and field maintenance areas.	3
	Indoors: warehouses, corridors, hallways, and exit ways.	5
	Tunnels, shafts, and general underground work areas. (Exception: ≥10 footcandles is required at tunnel and shaft heading during drilling, mucking, and scaling. MSHA-approved cap lights acceptable for use in the tunnel heading).	5
	General construction plant and shops (batch plants, screening plants, mechanical and electrical equipment rooms, carpenter shops, rigging lofts and active storerooms, barracks or living quarters, locker or dressing rooms, dining areas, and indoor toilets and workrooms).	10
	First-aid stations, infirmaries, and offices.	30

Table 11–U. ***Illuminance Categories of IES/ANSI RP-7-1991***

Type of Activity	*Examples*	*Illuminance Category*	*Range of Illuminance (footcandles)*	*Reference Workplane*
Public spaces with dark surroundings	Aircraft ramp area	A	2–3–5	
Simple orientation for short visits	Active storage area of a farm, VDT screens	B	5–7.5–10	General lighting throughout spaces
Working spaces where visual tasks are only occasionally performed	Active traffic area of a garage, elevators/escalators	C	10–15–20	
Performance of visual tasks of high contrast or large size	Simple assembly or inspection	D	20–30–50	
Performance of visual tasks of medium contrast or small size	Hand decorating in a bakery, mail sorting	E	50–75–100	Illuminance on task
Performance of visual tasks of low contrast or very small size	Finished lumber grading, model making	F	100–150–200	
Performance of visual tasks of low contrast and very small size over a prolonged period	Sewing clothes	G	200–300–500	Illuminance on task obtained by a combination of general and local (supplementary) lighting
Performance of very prolonged and exacting visual tasks	Exacting inspection	H	500–750–1,000	
Performance of very special visual tasks of extremely low contrast and small size	Cloth inspection and examining (perching) of sewn products	I	1,000–1,500–2,000	

mentioned, and also the possibility that the supplemental lighting could cause direct glare for people in the surrounding area. Energy conservation and safety needs can be reconciled by using motion detectors to activate area lighting when a person enters an area. Building and lighting cleaning and painting can make a tremendous difference in lighting by causing more of the light emitted from lamps to be reflected to places where people are working. Light, matte-textured surfaces are preferred. Matte textures avoid specular reflections and reflected glare. RP-1 and RP-7 give guidance about how reflective surfaces should be.

Color can be a problem if unusual fluorescent tubes or colored incandescent bulbs are installed. White light contains radiation associated with every color we can see; colored lights radiate selected wavelengths more intensely. Colored lighting is useful for some jobs, such as blue-enhanced fluorescent tubes for greenhouse lighting or yellow-orange low-pressure sodium lamps for abundant yet cheap safety lighting at night. Colored lighting without some benefit can create difficulties. Colors may be harder to perceive when nonwhite lighting is used. Yellow and white objects could, for example, both appear the same in yellow or red lighting, so yellow signs and warning devices could become unreliable and blue surfaces would appear to be black.

Concern has been expressed about the safety of fluorescent tubes. Fluorescent tubes contain a minute amount of mercury that conducts electric current and glows in the ultraviolet portion of the spectrum. The UV is absorbed by phosphors that line the tubes and is reradiated as visible

Table 11–V. ***Factors Influencing Assigning Illumination Levels Within Illuminance Categories of IES/ANSI RP-1-1982 and RP-7-1991***

For Illuminance Categories A Through C in Industrial and Office Settings

	Weighting		
Room and Occupant Characteristics	*Low End of Range*	*Mid-Range*	*High End of Range*
Occupant ages	<40	40–55	>55
Room surface reflectances	>70%	30–70%	<30%

For Illuminance Categories D Through I in Industrial and Office Settings

	Weighting		
Task and Worker Characteristics	*Low End of Range*	*Mid-Range*	*High End of Range*
Occupant ages	<40	40–55	>55
Speed or accuracy of seeing	Not important	Important	Critical
Reflectance of task background	>70%	30–70%	<30%

Table 11–W. ***IES/ANSI RP-7-1991 Recommended Maximum Luminance Ratios***

	Environmental Group		
Situation	*A*	*B*	*C*
Between tasks and adjacent darker surroundings	3 to 1	3 to 1	5 to 1
Between tasks and adjacent lighter surroundings	1 to 3	1 to 3	1 to 5
Between tasks and adjacent more remote darker surfaces	10 to 1	20 to 1	Control not practical
Between tasks and adjacent more remote darker surfaces	1 to 10	1 to 20	Control not practical
Between luminaires (or windows, skylights, etc.) and surfaces adjacent to them	20 to 1	Control not practical	Control not practical
Anywhere within normal field of view	40 to 1	Control not practical	Control not practical

Environmental groups: A—interior areas where reflectances of entire space can be controlled in line with recommendations for optimum seeing conditions; B—areas where reflectances of immediate work area can be controlled, but control of remote surroundings is limited; C—areas (indoor or outdoor) where it is impractical to control reflectances and difficult to alter environmental conditions.

light. ICNIRP issued a position statement that advises that UV emissions from fluorescent tubes are not a problem. Mercury vapor lamps are also used for lighting and they generate UV that is absorbed by an outer glass sheath. Mercury vapor lamps are safe unless the outer sheath is broken. A mercury vapor lamp with a broken sheath should be turned off and replaced immediately. It should be noted that disposing of fluorescent tubes is associated with other industrial hygiene concerns. Tube-breaking equipment can be noisy and heavily contaminated with toxic mercury metal, which can accumulate in tube breaking equipment. Fluorescent tubes contained highly toxic beryllium salts in the 1940s. Cadmium compounds were used, but their use was discontinued in the late 1980s, so cadmium exposure remains a potential hazard for tube breakers.

Lighting measurements are usually made 30 in. above the floor to measure the illumination striking surfaces that are to be seen. Special measurements can be made on surfaces of interest, such as desktops and working surfaces. The instruments used are typically inexpensive photoelectric devices. It is noted that IES developed guidance for lighting VDT workplaces, RP-24-1989, which is listed in the Bibliography.

SUMMARY

- ➢ Nonionizing "radiation" is often not radiation, but rather discrete electric and magnetic fields that exist independently of one another, whereas the fields in radiation are rigidly interrelated. The frequency below which it is assumed one is dealing with fields rather than radiation is 300 MHz.
- ➢ Electric fields are caused by nonmoving or moving electric charges and the electric field increases as the quantity of charge increases. Magnetic fields are caused by the flow of electric charges, or electric current, and increase as more current flows. In other words, electric charges create electric fields and moving them creates magnetic fields.
- ➢ The frequency of electromagnetic radiation times its wavelength equals its speed of travel, very close to 300,000,000 m/s in air or a vacuum. The frequency of electromagnetic radiation is the number of times the fields go through a complete cycle of polarity and strength change. Frequencies are expressed in hertz (Hz), the number of polarity and strength changes that occur in a second. The wavelength is the distance traveled as the radiation goes through that cycle of polarity and strength change. Higher frequencies mean shorter wavelengths and lower frequencies mean longer wavelengths.
- ➢ The various frequencies of the electric and magnetic field are divided into the electromagnetic spectrum. This is divided into subradiofrequency fields, which have frequencies below 3,000 Hz, radiofrequencies from 3,000 to 300,000,000,000 Hz including microwaves, which span 300,000,000 to 300,000,000,000 Hz, and optical radiation with higher frequencies and energies.
- ➢ Electromagnetic devices can be thought of as containing a source of energy, a transmission path, and a receiver of the energy.
- ➢ The exposure guideline for static magnetic fields was set by ICNIRP at 200 mT (2,000 [G]). The exposure guideline for static electric fields was set by ACGIH at 25 kV/m.
- ➢ ACGIH and ICNIRP issued ELF exposure criteria for workers based on avoiding induced currents that are stronger than those already created in the body by the normal functioning of nerves and muscles.
- ➢ Radiofrequency exposure standards are based on avoiding hazardous electric current flows at frequencies below a few MHz and on avoiding excessive rates of energy deposition at higher frequencies. Energy deposition is most significant at frequencies where a person's height is 20–40 percent of the wavelength of the radiation in air (30–300 MHz). At frequencies above a few GHz, energy deposition occurs mainly in the skin. The frequency of 300 GHz has a wavelength of 1 mm and higher frequencies are classified as IR radiation.
- ➢ Optical radiation is described by its wavelength and is divided into IR (760 nm–1 mm), visible (400–700 nm), and UV (variously 4 or 100 nm–400 nm). There are TLVs® for all nonlaser optical radiation from 180–1,400 nm and LIA/ANSI Z136.1-1993 addresses wavelengths from 180 nm to 1 mm. Shorter wavelengths are absorbed by oxygen to make ozone.
- ➢ Laser radiation is monochromatic (literally one color) or has just a few wavelengths, coherent (well-organized), and bright. Coherent radiation is very directional, so lasers can project intense or hazardous energies over longer distances than nonlaser sources of optical radiation.

- ➢ Laser radiation with wavelengths between 400 and 1,400 nm, the ocular hazard region, can be intensely focused on the retina. This makes lasers operating in this wavelength range particularly hazardous.
- ➢ Lasers are controlled by dividing them into hazard classes ranging from 1 (essentially harmless) to 4 (very hazardous). Precautions become more stringent as the hazard class increases.
- ➢ OSHA has limited standards for nonionizing radiation, but can enforce consensus standards according to the *UAW, Brock v. General Dynamics Land Systems Division* decision. These standards come from the ACGIH, the ICNIRP, the IEEE, and the LIA and are referenced in the Bibliography. European international organizations, particularly Swedish and Finnish organizations, are also active in this area.
- ➢ Industrial lighting standards relate to safety and productivity. They are promulgated by the IES.

Nonionizing radiation is becoming more and more a part of our lives on and off the job. Dealing with it will be one of the larger challenges facing the industrial hygiene profession in the future.

Chapter 12

Thermal Stress

by Thomas E. Bernard, PhD, CIH

Thermal stress is a significant physical agent in many working environments. Just considering routine work out-of-doors, air temperatures between –20 to 110 F are expected over different regions of the United States. Other countries may reasonably expect temperatures beyond that range. Human-made environments from freezers to ovens extend the range of thermal environments in which work is expected. Because tasks must be performed under adverse thermal conditions, this chapter provides guidance for recognition, evaluation and control of work in thermal extremes.

DEGREES OF THERMAL STRESS

Conceptually, work can occur in one of five zones along the continuum of thermal stress. In the middle is the comfort zone. Here, most people would report thermal sensations as being acceptable (neither hot nor cold). In the comfort zone, the demands for physiological adaptation are modest and productivity should be the greatest. The comfort zone is described at the end of this chapter to provide information to health and safety professionals who may be asked to evaluate the thermal conditions with comfort as a goal.

On either side of the comfort zone are the discomfort zones for heat and cold stress. Under these conditions, most people should be able to safely work without experiencing a disorder related to the stress (i.e., heat-related or cold-related disorders). They will report sensations of cold or heat, productivity and quality of work may decrease, and the risk of accidents may increase. The goal of most evaluation schemes for occupational heat and cold stress is to limit exposures to the discomfort zone.

The health risk zone for heat and cold stress are the outer zones of the thermal stress continuum. The physiological adaptations have reached their limits and work capacity is severely limited. In the health risk zone, the likelihood of

heat and cold stress-related disorders increases markedly. Health and safety professionals should manage exposures in the health risk zone. Management of exposures in the health risk zone is the principal theme of this chapter.

Of course, there are no firm boundaries to these zones because the boundaries depend on the environment, individuals, and season as well as many unknown variables. But we should try to control the thermal stress factors for the less tolerant workers in order to minimize the risk of injuries and illness to the lowest reasonable level. The major emphasis on evaluation and control is placed on the transition from the discomfort zone to the health risk zone for both heat and cold stress.

THERMAL BALANCE

Model of Thermal Balance

Three factors influence the degree of thermal stress. The most obvious factor is the climatic conditions of the environment. The other two factors are work demands and clothing. The tradition for more than 40 years is to describe thermal balance by an equation with major avenues of heat exchange between the body and the environment represented by a term in the equation. (There is no uniformly accepted version but the reader will not have problems reconciling different versions as they are found.)

$$S = (M + W) + R + C + K + (C_{resp} + E_{resp}) + E \qquad (1)$$

where S = heat storage rate
M = metabolic rate
W = external work rate
R = radiant heat exchange rate
C = convective heat exchange rate
K = conductive heat exchange rate
C_{resp} = rate of convective heat exchange by respiration
E_{resp} = rate of evaporative heat loss by respiration
E = rate of evaporative heat loss

Most versions of the heat balance equation use ± instead of +, especially in front of R and C. The purpose is to emphasize that the heat exchange represented by R, C, K, and C_{resp} can be in either direction. A more rigorous sign convention is used in this chapter. A positive value for any of these terms (as opposed to the sign in front of the term) means that the heat is gained by the body and a negative value means that heat is lost from the body. The values for M and $(M + W)$ can only be positive. The values for W, E_{resp} and E are always negative, meaning that there is only heat loss associated with these terms. Each term has the unit of energy per unit of time; that is, the terms represent rates of energy transfer. The international units (SI units) are watts, and other units that are reported include kcal/h, kcal/min and Btu/h. Sometimes the rates are reported as normalized values to body surface area.

S—HEAT STORAGE RATE

If the value for S is zero, the body is in thermal equilibrium, and heat gain is balanced by loss from the body. If S is positive, the body is gaining heat at the rate indicated by the value of S. If the value of S is negative, the body is losing heat, and body temperature is decreasing.

M—METABOLIC RATE

Chemical reactions occur continuously inside the body. These serve to sustain life (basal metabolism) and meet the demands of work (muscle metabolism). As muscle metabolism increases to meet work demands, the rate of energy conversion from chemical energy to kinetic energy increases. Because the energy conversion from chemical energy to kinetic energy is inefficient, increased metabolism results in increased rates of heat gain to the person. The rate of metabolism depends directly on the rate and type of external work demanded by the job.

W—EXTERNAL WORK RATE

W is the amount of energy that is successfully converted from internal chemical energy to mechanical work on external objects. This route of energy transfer is called external work and it does not contribute to body heat. The rate of external work depends directly on forces applied against external resistance and distance moved. W is usually about 10 percent of M.

R—RADIANT HEAT EXCHANGE RATE (RADIATION)

Solid bodies of different temperatures have a net heat flow from the hotter surface to the cooler surface by electromagnetic radiation (primarily infrared radiation). The rate of heat transfer by radiation depends on the average temperature of the surrounding solid surfaces, skin temperature and clothing.

C—CONVECTIVE HEAT EXCHANGE RATE (CONVECTION)

The exchange of heat between the skin and the surrounding air is referred to as convection. The direction of heat flow depends on the temperature difference between the skin and air. If air temperature is greater than skin, C is positive and heat flows from the air to the skin. If the air is cooler than the skin, C is negative and heat flows from the body. The rate of convective heat exchange depends on the magnitude of the temperature difference, the amount of air motion, and clothing.

K—CONDUCTIVE HEAT EXCHANGE RATE (CONDUCTION)

When two solid bodies are in contact, heat will flow from the warmer body to the cooler body. The rate of heat transfer depends on the difference in temperatures between the skin and the solid surface, the thermal conductivity of the solid body that the person contacts, and clothing that may separate the person from the solid surface.

C_{RESP}—RATE OF CONVECTIVE HEAT EXCHANGE BY RESPIRATION

The fact that air is moved in and out of the lungs, which have a large surface area, means there is an opportunity to gain or lose heat. The rate of heat exchange depends on the air temperature and volume of air inhaled.

E_{RESP}—RATE OF EVAPORATIVE HEAT LOSS BY RESPIRATION

The large surface area of the lungs provides an opportunity to lose heat by evaporation. The rate of heat exchange depends on the air humidity and volume of air inhaled.

E—RATE OF EVAPORATIVE HEAT LOSS

Sweat on the skin surface will absorb heat from the skin when evaporating into the air. The process of evaporation cools the skin and in turn the body. The rate of evaporative heat loss depends on the amount of sweating, air movement, ambient humidity, and clothing.

Because *W, K,* C_{resp} and E_{resp} are small relative to the other routes of heat exchange in industrial applications, they are usually ignored. When calculating heat storage, Equation 1 becomes Equation 2 as a general statement of heat balance.

$$S = M + R + C + E \tag{2}$$

Excessive heating or cooling of a small portion of the skin can occur when it comes in contact with a hot or cold surface. The contact can be either intentional or incidental. Injury occurs when there is sufficient heat gain to cause a burn or heat loss to cause the tissue to freeze (or at least become very cold for a period of time). In these cases, the local storage rate (S_{local}) becomes important.

$$S_{local} = K + D \tag{3}$$

where *K* is conductive heat transfer between the skin and an object, and *D* is the rate of heat transfer to or from the local area by conduction through the local tissue and by the heat supplied or removed via local blood flow.

Factors Affecting Thermal Balance

As mentioned at the beginning of the discussion on thermal balance, three factors play an important role. They are the climatic conditions of the environment, work demands, and clothing. Climatic conditions are widely used to describe the degree of stress, as seen in casual descriptions by air temperature, relative humidity, and wind chill. They are not the only determinant of thermal stress.

The role of metabolic rate in heat balance is very important because it is a substantial contributor to heat gain. In heat stress, metabolic rate can add 10 to 100 times more heat to the body than radiation and convection combined. In cold stress, metabolic rate affects heat balance on the same order as radiation and convection losses.

Clothing is also a major contributor to thermal balance. Clothing has three characteristics: insulation, permeability, and ventilation.

Insulation is a measure of the resistance to heat flow by radiation, convection, and conduction. The greater the amount of insulation, the less the rate of heat flow from the warmer temperature to the cooler temperature. During heat stress exposures, it reduces heat flow by radiation and convection. It also reduces heat flow by conduction if a person has a substantial portion of the body in contact with a warm surface. Insulation plays a very important role (1) in preventing burns by contact with a hot surface and (2) in cold stress. In cold stress, it is used to reduce heat losses by convection and radiation as well as conduction, and it prevents cold injury to local tissues in contact with cold surfaces.

Permeability is a measure of the resistance to water vapor movement through the clothing. It is a factor in thermal stress because it influences the amount of evaporative cooling that can be achieved. Permeability is related to both insulation characteristics and the clothing fabrics. Generally, as insulation increases, permeability decreases. In addition, some clothing fabrics designed as a contamination barrier can reduce the magnitude of permeability. This means that there may actually be a trade-off between the risks of heat stress and the risks from skin contact with harmful chemicals. New protective clothing fabrics are entering the market that provide protection against some chemical hazards while permitting water vapor transmission. These new fabrics provide a greater range of opportunity to find a balance between prevention of chemical exposure and prevention of heat stress.

Clothing ventilation is the third factor. Depending on the nature of the fabric, garment construction, and work demands, ambient air can move through the fabric or around the garment openings. Clothing ensembles that support the movement of air can enhance evaporative and convective cooling; while those that are designed and worn to limit such movement, limit evaporative and convective cooling. A good example of using ventilation characteristics to regulate heat balance is arctic parkas with drawstrings around the waist, cuffs, and hood. As metabolism heats a person, cooling can be achieved by loosening some of the closures to increase the amount of air flow (ventilation) under the clothing.

HEAT STRESS

Remembering that thermal stress is a combination of environmental, work, and clothing factors, heat stress is a combination that tends to increase body temperature, heart rate, and sweating. These physiological adaptations are collectively known as heat strain. Figure 12–1 is a schematic representation of the physiological responses to heat stress.

Looking first at metabolism, the heat generated by muscular work heats the deep body tissues, which means that there is a tendency for core temperature to increase. Blood circulating through the core picks up heat energy, and the

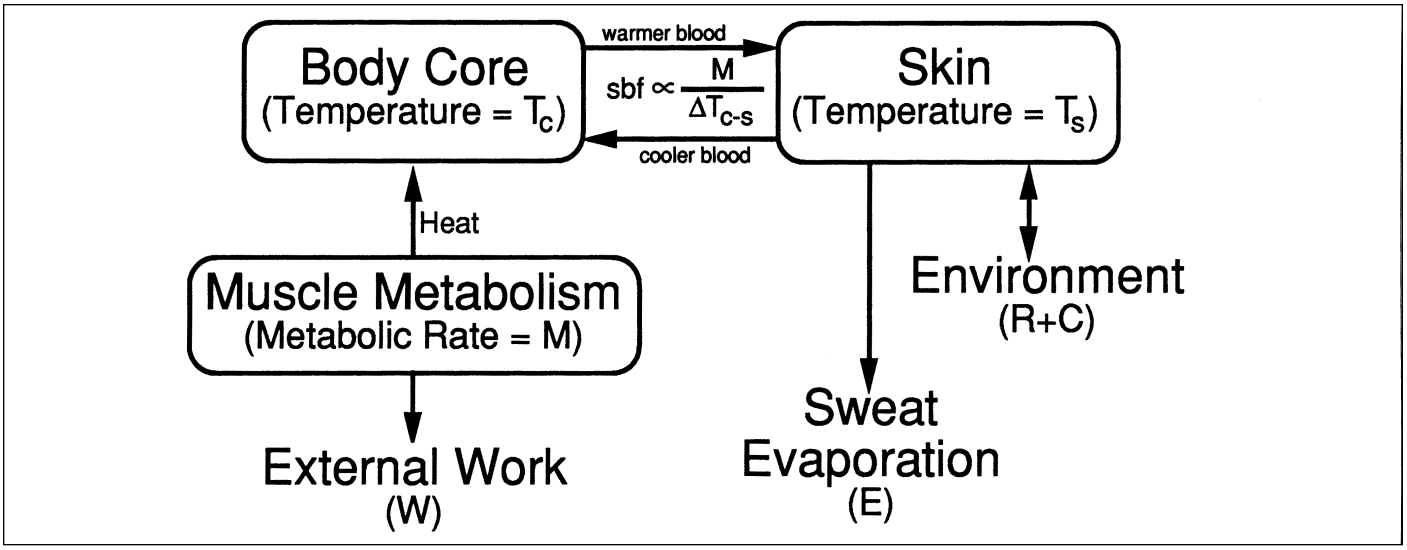

Figure 12–1. Heat flow through the body, beginning with heating the body core by metabolism, the transfer of heat by blood flow to the skin, heat gain or loss to the skin from the environment by radiation and convection, heat loss by sweat evaporation, and cooler blood returning to the core. Skin blood flow (sbf) to promote heat transfer is proportional to metabolic rate (M) divided by the difference between core and skin temperatures (ΔTc-s). (Adapted from T. E. Bernard, et al., *Heat Stress Management Program for Power Plants*, Electric Power Research Institute, NP4453L, 1991.)

warmer blood is directed to the skin where the blood is cooled. The cooler blood returns to the core to pick up more heat energy. The skin is the site of heat exchange with the environment. Convection and radiation depend on temperature differences between the skin and the environment; and the net heat exchange by $R+C$ can be either positive (heat gain) or negative (heat loss). In addition, the skin secretes sweat onto the surface. As the water evaporates, it removes more heat energy from the skin, cooling the skin surface. Under ideal conditions, the body balances heat gains with losses so that the storage rate, S, is zero. This is accomplished by increasing the sweating rate until evaporative cooling is sufficient to remove the heat generated by metabolism plus any heat gained from (or lost to) the environment through $R + C$. The required evaporative cooling is denoted as E_{req}. (Remember that the value of E_{req} is negative because heat flow is away from the body.) Then Equation 2 becomes

$$E_{req} = -(M + R + C) \quad (4)$$

Thus, E_{req} marks the degree of physiological adjustment required to establish a thermal equilibrium between the body and the environment so that the body does not store heat. In many heat stress exposures, M is the dominant term, and E_{req} increases to meet additional cooling requirements of the work demands.

Heart rate is another important physiological parameter in assessing heat strain because it reflects the demands on the cardiovascular system to move blood (and heat) from the core to the skin. The total blood flow through the heart is proportional to the metabolic rate and inversely proportional to the temperature difference between the core and the skin. As work demands and metabolic rate increase, cardiac output increases, as seen in the heart rate. Sometimes skin temperature increases because evaporative cooling is limited or the net heat gain from $R + C$ is high. As the skin temperature increases toward core temperature, more blood must be delivered to the skin to achieve the same rate of cooling.

Finally, sweat rate (and total sweat volume) is another important measure of physiological strain. The greater the level of heat stress, the greater is the sweat loss. The body has a natural ability to increase the tolerance to heat stress exposures through a process called acclimation (sometimes called acclimatization). As people become acclimated, they are able to sweat more and therefore increase their cooling capability. With increased cooling, heart rate and core temperature are lower for the same work conditions.

The following material on heat stress describes recognition, evaluation, and control of heat stress as it may affect the whole body. At the end, there is information on special topics including contact with hot surfaces and breathing of hot air.

Recognition of Heat Stress

Heat stress in the workplace can be recognized in terms of workplace risk factors and in terms of the effects it has on workers. The workplace risk factors, broadly stated, are hot environments, high work demands, and protective clothing requirements. These factors are the traditional considerations in the evaluation of heat stress, and the details are in the section on evaluation of heat stress. In essence, if the workplace is generally considered as being hot through subjective judgment of workers and supervisors, then heat stress may be present. If the demands for external work are high (e.g., high metabolic rate), heat stress may be a factor in environments that are considered comfortable by casual observers (those

Table 12–A. *Heat-Related Disorders Including the Symptoms, Signs, Causes, and Steps for First Aid and Prevention*

Disorder	*Symptoms*	*Signs*	*Cause*	*First Aid*	*Prevention*
Heat stroke	Chills Restlessness Irritability	Euphoria Red face Disorientation Hot, dry skin (usually, but not always) Erratic behavior Collapse Shivering Unconsciousness Convulsions Body temperature ≥104 F (40 C)	Excessive exposure Subnormal tolerance (genetic or acquired) Drug / alcohol abuse	Immediate, aggressive, effective cooling. Transport to hospital. Take body temperature.	Self-determination of heat stress exposure. Maintain a healthy life-style. Acclimation.
Heat exhaustion	Fatigue Weakness Blurred vision Dizziness, headache	High pulse rate Profuse sweating Low blood pressure Insecure gait Pale face Collapse Body temperature: Normal to slightly increased	Dehydration (caused by sweating, diarrhea, vomiting) Distribution of blood to the periphery Low level of acclimation Low level of fitness	Lie down flat on back in cool environment. Drink water. Loosen clothing.	Drink water or other fluids frequently. Add salt to food. Acclimation.
Dehydration	No early symptoms Fatigue / weakness Dry mouth	Loss of work capacity Increased response time	Excessive fluid loss caused by sweating, illness (vomiting or diarrhea), alcohol consumption	Fluid and salt replacement.	Drink water or other fluids frequently. Add salt to food.
Heat syncope	Blurred vision (gray-out) Fainting (brief black-out) Normal temperature	Brief fainting or near-fainting behavior	Pooling of blood in the legs and skin from prolonged static posture and heat exposure	Lie on back in cool environment. Drink water.	Flex leg muscles several times before moving. Stand or sit up slowly.
Heat cramps	Painful muscle cramps, especially in abdominal or fatigued muscles	Incapacitating pain in muscle	Electrolyte imbalance caused by prolonged sweating without adequate fluid and salt intake	Rest in cool environment. Drink salted water (0.5% salt solution). Massage muscles	If hard physical work is part of the job, workers should add extra salt to their food.
Heat rash (prickly heat)	Itching skin Reduced sweating	Skin eruptions	Prolonged, uninterrupted sweating Inadequate hygiene practices	Keep skin clean and dry. Reduce heat exposure.	Keep skin clean and periodically allow the skin to dry.

Note: Salting foods is encouraged as both treatment and prevention of some heat-related disorders. Workers on salt-restricted diets must consult their personal physicians.

not exerting themselves in the environment). Clothing is the third factor. While light-weight, loose-fitting, cotton clothing is the ensemble of choice during exposures to heat stress, many workplaces require protective clothing that decreases permeability and ventilation and increases insulation. The added weight of personal protection may increase the metabolic heat load and therefore the level of heat stress.

The responses of workers are a good tool for the recognition of heat stress in the workplace. At the extreme end are a pattern of heat-related disorders. Intermediate markers are physiological adjustments and worker behaviors.

HEAT-RELATED DISORDERS

Heat-related disorders are manifestations of over-exposures to heat stress. Table 12–A is a list of common or important heat-related disorders. The table includes the signs a trained observer may see, the symptoms the person may report, the likely cause of the disorder, first aid, and steps for prevention. Figure 12–2 is a simple illustration of normal responses to heat stress and how these responses may lead to a heat-related disorder.

Heat stroke is the most serious heat-related disorder. While it may be relatively rare, it must be immediately recognized and treated to minimize permanent damage. The risk of death is high in heat stroke. Heat exhaustion is the most commonly seen disorder when treatment is sought. Dehydration is a precursor to heat exhaustion, but it is usually not noticed or reported by workers.

As part of the recognition process, the health and safety professional examines reports to a medical or first aid facility. Because no specific heat-related disorders are listed does not

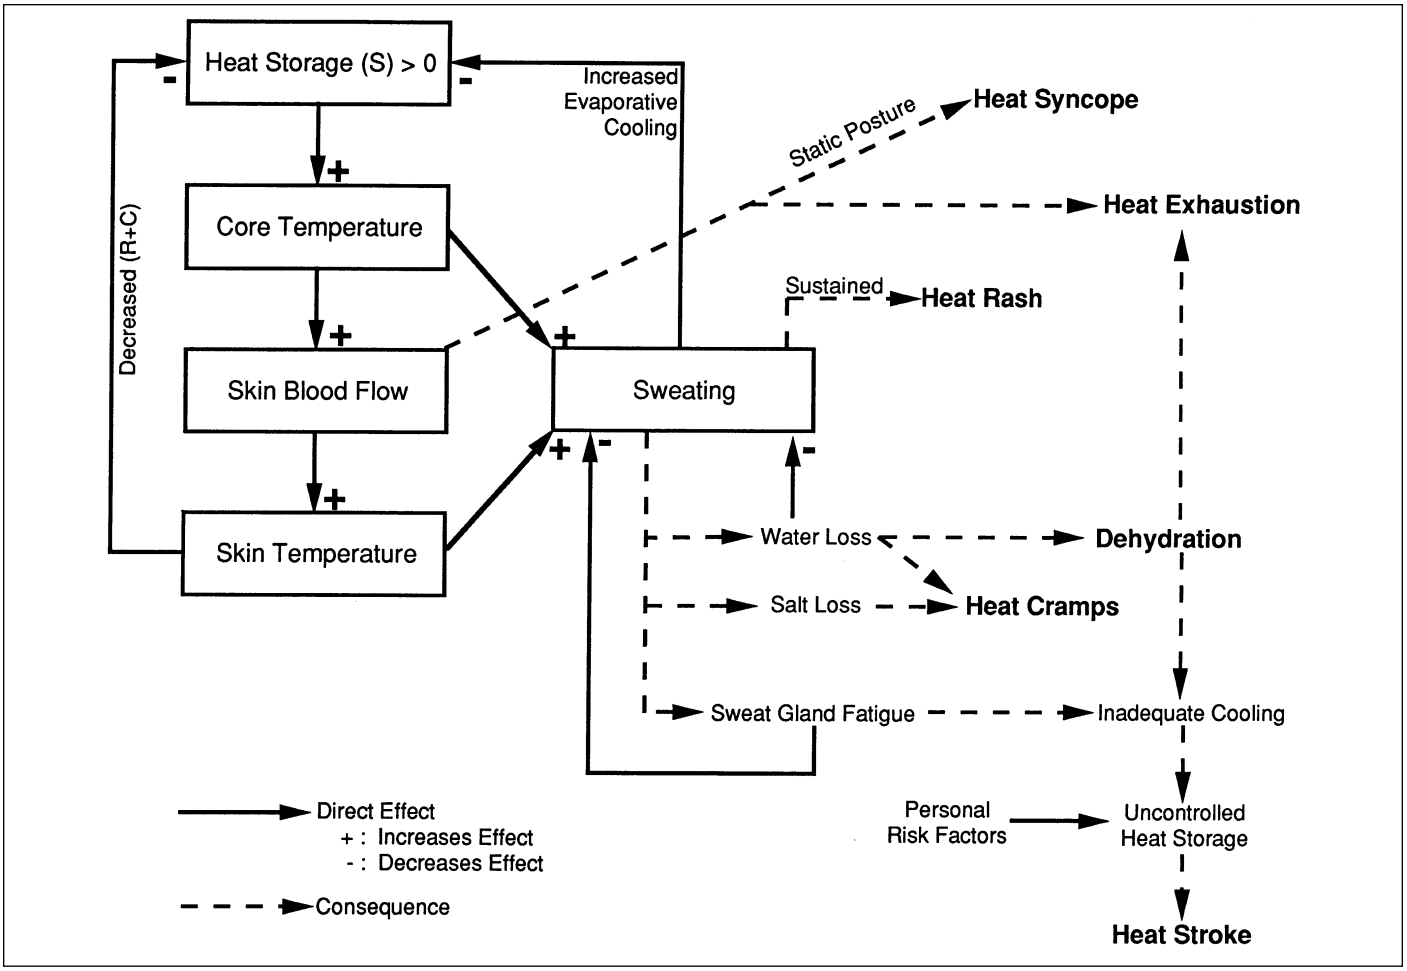

Figure 12–2. Normal responses to heat stress exposures and how they can lead to heat-related disorders.

mean heat stress is not present. It is worthwhile to examine the records for reports of faintness, weakness, nausea, cramps, headaches, and skin rashes. If temperatures are taken, some may be elevated. If urine samples are taken, some may have high specific gravity due to dehydration. There may also be an increase in the number of accidental injuries that are related to heat stress conditions.

PHYSIOLOGICAL MARKERS

Physiological responses to heat exposures can be used as a recognition tool. The most readily accessible are oral temperature, heart rate, and water loss. By noting one or more physiological responses of members of the work force, the health and safety professional can begin to see if a more detailed evaluation is necessary. When selecting workers to sample, it is important not to be biased toward those that appear to be the most tolerant. The sampling process should be random or favoring those who appear to be having more problems (see behaviors below).

While rectal, esophageal, and tympanic temperatures are the preferred measures of core temperature, oral temperature has long been used as an indicator of core temperature in industrial environments. Oral temperature can be measured by a traditional mercury-in-glass thermometer as well as an electronic version and disposable strips. (A caution using oral temperatures is that the person should not eat or drink for 15 minutes prior to taking the temperature and the person must keep the mouth closed.) Core temperature is estimated by adding 0.5 C or 1 F to the measured value of oral temperature. If core temperature is above 38 C (100.4 F), then heat stress is high enough to warrant evaluation.

Heart rate can be estimated by palpation of an artery near enough the surface that the pulse can be felt by the finger tips. There are also devices that can measure heart rate using electronic means. Among heart rate methods, recovery heart rate is most useful as a tool for recognition. Recovery heart rate methods require that the person stop in at the end of a work cycle, sit down, and determine the pulse rate at a given point in recovery. One method of recovery heart rate proposes that the heart rate at 1 min after sitting down be at or below 110 beats per minute (bpm). Another method recommends that the heart rate at three minutes be below 90 bpm. If either of these circumstances does not exist then the work including the heat stress may be excessive and an evaluation is appropriate.

Because there are devices for measuring and logging heart rate readily available, finding the average heart rate over an eight-hour day is reasonable. If the average heart rate over a day is greater than 110 bpm, the work and heat stress may be excessive. Examination of the log for peak heart rates is also informative. If heart rates are above a nominal threshold of 160 bpm, then the demands of the work should be evaluated. (For individually set thresholds, see physiological methods for evaluation below.)

Monitoring dehydration is a third means of recognizing potential heat stress conditions. This is accomplished by noting the change in body weight from the beginning to the end of a shift. If there is more than 1.5-percent loss of body weight, then excessive dehydration is likely and an evaluation is appropriate.

WORKER BEHAVIORS

Heat stress not only induces physiological changes but affects behavior. Likely behaviors associated with heat stress are actions that reduce exposures such as adjusting the clothing to increase evaporative losses, slowing the work rate or taking small breaks to lower the metabolic rate, and taking short cuts in work methods. Attitudes are reflected in irritability, low morale, and absenteeism. There is also an increased number of errors and machine breakdowns, and the frequency of unsafe behaviors increases.

SUMMARY OF RECOGNITION

Basically, there are four questions you may ask to determine whether the work conditions should be evaluated for heat stress.

1. Is the environment recognized as being hot, are the work demands high, or is protective clothing required?
2. Are worker behaviors indicative of attempts to reduce heat stress, is morale low or absenteeism high, or are people making mistakes or getting hurt?
3. Do the medical records show a pattern of fatigue, weakness, headache, rashes, or high body temperature?
4. Are body temperature, heart rate, or sweat losses high on a sample of workers?

When the answers to any of these questions is "yes", an evaluation is probably in order.

Evaluation of Heat Stress

In 1969, the World Health Organization (WHO) set the tone for worker protection against heat stress. One recommendation centers around body core temperature, which may be estimated from oral temperature as described in the discussion above on physiological markers. Core temperature should not exceed 38 C (100.4 F) during prolonged daily exposures to heat stress. The panel did recognize that 39 C (102.2 F) is acceptable as an upper limit for short periods followed by an adequate recovery and that the average heart rate over a day should not exceed 110 bpm. It is the prolonged daily exposure goal that is the foundation of evaluation schemes proposed by the National Institute for Occupational Safety and Health (NIOSH) in a 1986 criteria document and the basis for heat stress assessment as described by the American Conference of Governmental Industrial Hygienists (ACGIH) in earlier TLVs®.

Prolonged daily exposures to heat stress are evaluated assuming that the work conditions are prevalent for a full eight hours with nominal breaks. Often, the heat stress exposure may be more episodic. In this case, heat stress is evaluated in terms of safe exposures times for a given level of heat stress. The safe exposure times are prescribed through work-rest cycles based on prolonged daily exposure criteria or through heat-balance analyses. The methods to evaluate heat stress require at least an assessment of metabolic rate and some measures of the thermal environment. Some methods assume one kind of clothing and others have provisions for different ensembles.

Evaluation of workplace heat stress can also be accomplished by demonstrating that there is not an excessive physiological strain in the work force. That is, the exposure is less important in the evaluation than the dose or the outcome. First, an overview of the current ACGIH TLV® for heat stress and strain is provided to set the stage for the evaluation of occupational exposures to heat stress. This is followed by a discussion of methods to assess metabolic rate and environmental conditions. Methods to evaluate chronic and time-limited exposures to heat stress and methods to evaluate physiological strain are described in this section.

OVERVIEW OF ACGIH TLV® FOR HEAT STRESS AND STRAIN

The current ACGIH TLV for Heat Stress and Strain® (2000) recognizes the differences between eight-hour and short-duration exposures, and the value of physiological monitoring in the evaluation and control of heat stress. A flowchart in the TLV® guides the thought process for the evaluation of heat stress and strain (see Figure 12–3). The flow chart is entered at the top when heat stress is suspected in the workplace.

The first decision centers around the kind of clothing that may be worn. If the clothing is likely to substantially reduce evaporative cooling, then the usual means to evaluate heat stress do not apply and heat strain monitoring is the most feasible approach for evaluation. Not only vapor-barrier clothing restricts evaporative cooling, but multiple layers and some other materials may have high vapor resistances (low permeability).

The second decision is a simple screening test. Using available information on WBGT in the environments and the work demands (Figure 12–4), a table of WBGT limits for broad categories of work and work/rest proportions is provided. If the limits are not exceeded, then heat stress is low. On the other hand, exceeding the limits does not mean that the exposures are excessive. It means that a more detailed analysis is called for.

If the data are not available for a detailed analysis, then physiological monitoring is necessary. The detailed analysis requires a task analysis. From that information, time-

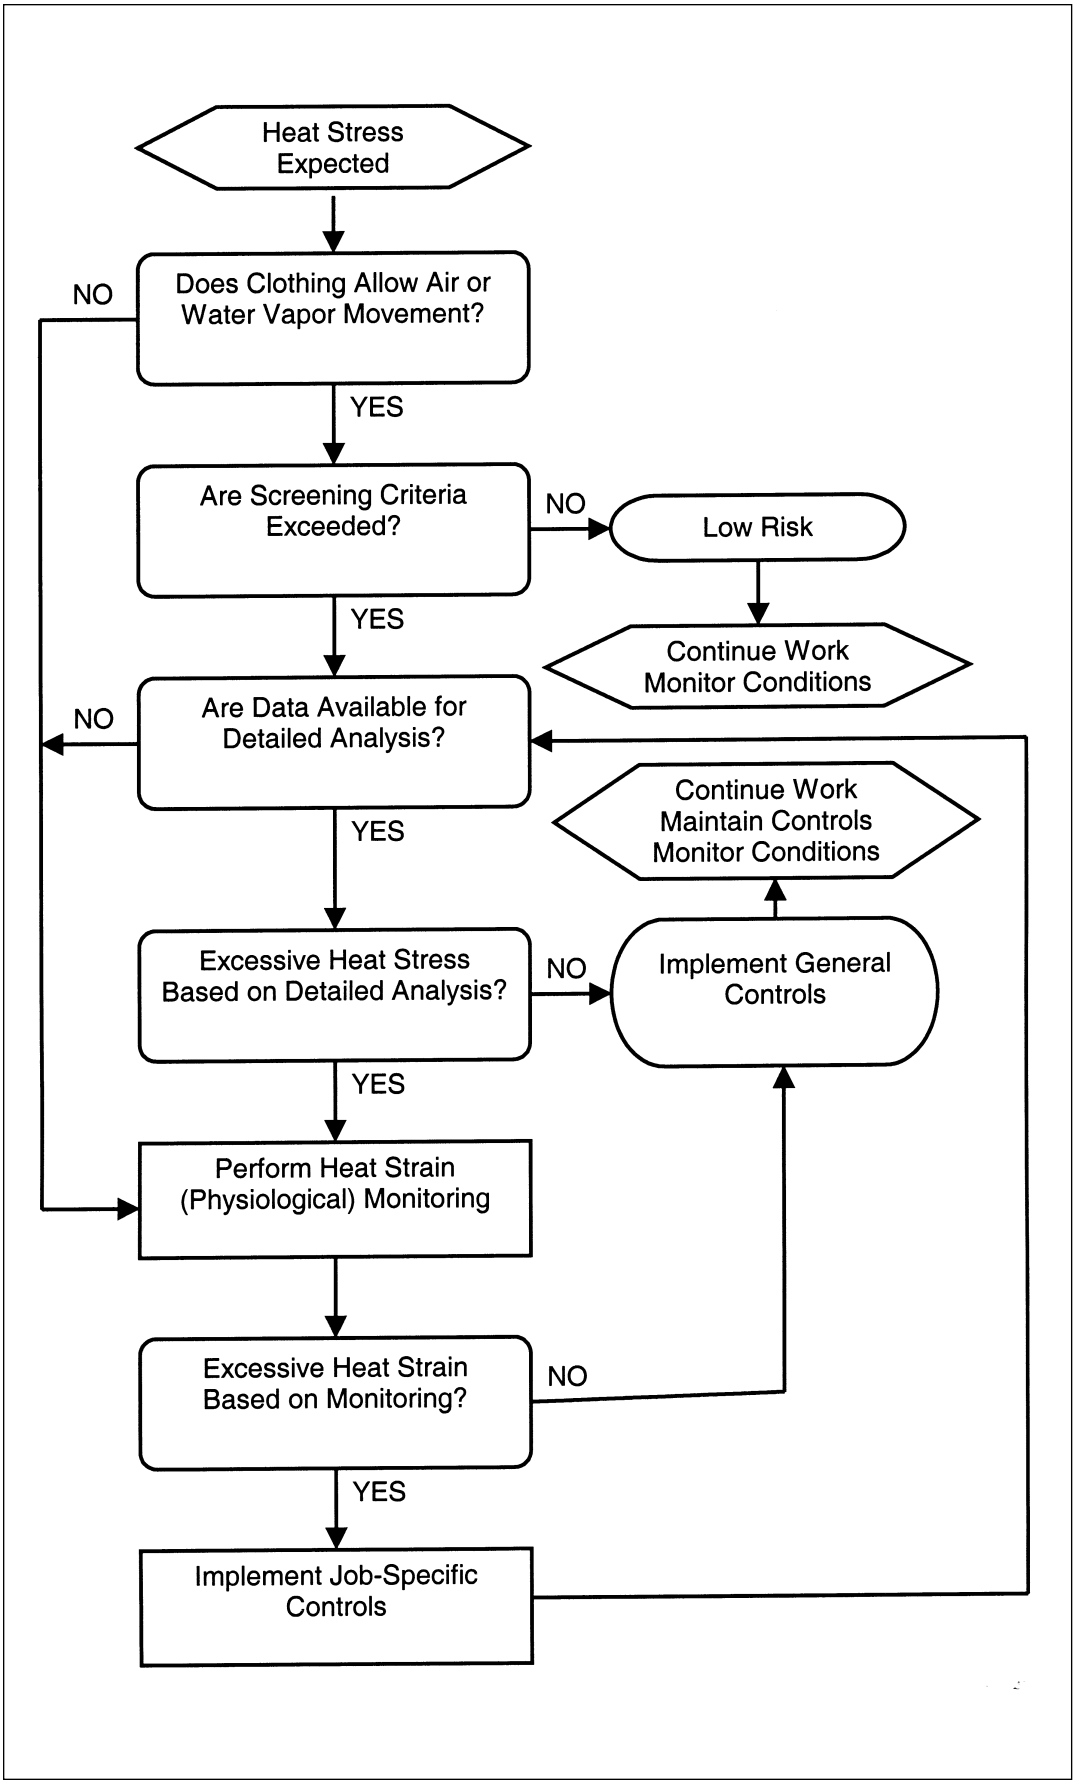

Figure 12–3. Flow chart for the ACGIH TLV® for heat stress and strain.

Figure 12–4. Examples of electronic devices used to measure WBGT. (Courtesy of Metrosonics, Inc., Quest Technologies, and IST.)

weighted averages of WBGT and metabolic rate can be compared to the TLV criteria (see Figure 12–5). In addition, a time-limited analysis using WBGT-based methods like the Navy PHEL (Figure 12–6) or like the heat balance analysis of Figure 12–7 can be done. If the exposures do not exceed the detailed analysis limits, then general controls should be implemented. If the exposures do exceed the time-limited criteria, then physiological monitoring is the next step.

No matter which route is taken to physiological monitoring, at least general controls are necessary. If these alone are associated with acceptable heat strain, then the analysis is complete. If there is excessive physiological strain, then job specific controls must also be implemented. Success is demonstrated when both general controls and job specific controls result in acceptable physiological strain.

ASSESSMENT OF METABOLIC RATE

Metabolic rate is the rate of internal heat generation, which must be dissipated from the body to maintain thermal equilibrium. (In cold stress, metabolic rate is important to maintain deep body temperature.) First, there is a base level of metabolism that is necessary to support life. Beyond basal metabolism, there is a work-driven metabolism that is largely due to muscular effort. The greatest amount of metabolism due to muscular effort

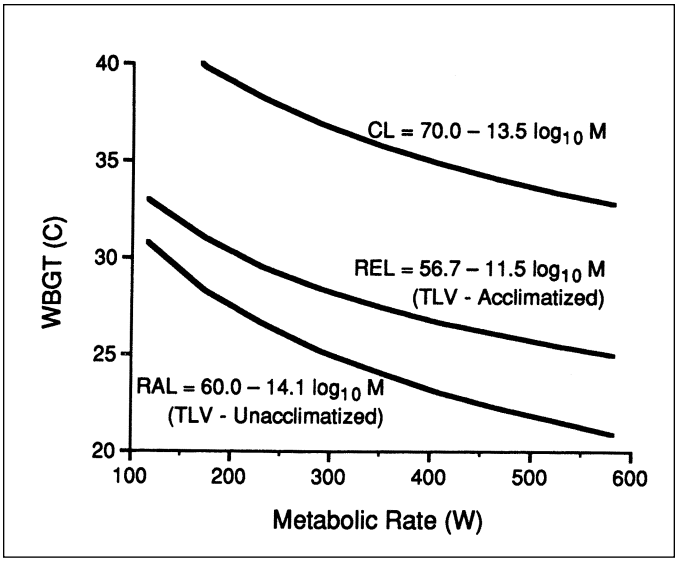

Figure 12–5. Heat stress limits proposed by NIOSH (Ceiling Limit/Ceiling, Recommended Exposure Limit/REL and Recommended Alert Limit/RAL) and ACGIH (TLV for Acclimatized Workers®/Acclimatized and TLV for Unacclimatized Workers®).

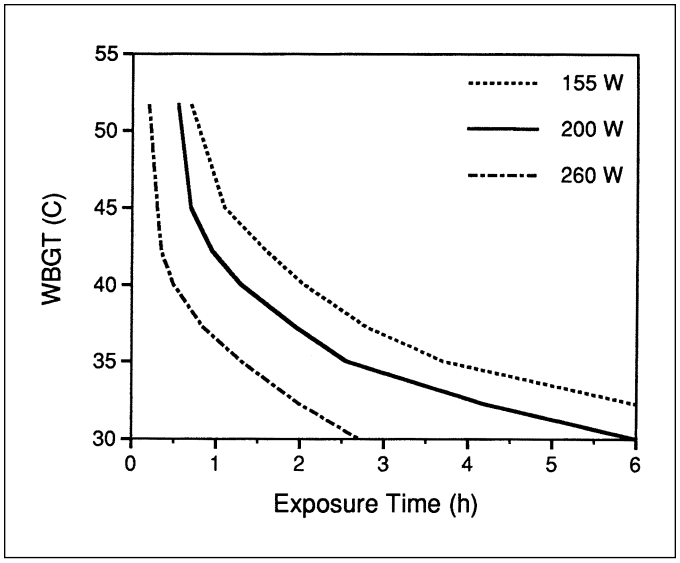

Figure 12–6. Example of U.S. Navy Permissible Heat Exposure Limit (PHEL) chart. Clothing is ordinary summer-weight work clothes.

occurs when the muscles exert a force with motion (dynamic work), and much less metabolism is required to exert a force with no motion (isometric contraction or static work). Therefore, the greatest metabolic rates occur when the body must be moved over a distance, especially upwards, and when objects are moved in space. Lesser metabolic rates are seen for sedentary activities or simply holding objects without any motion.

One very simple method to assess metabolic rate is to assign the work demands into one of three to five categories of metabolic rate (e.g., light, moderate, heavy). Another simple method is to look for similar activities in published tables of metabolic rates for specific activities (or assume the demands are equivalent by subjective matching). Either of these methods are expedient, but not very accurate (and perhaps prone to over-estimation).

Some discipline is required in the assessment of metabolic rate. The first step is to divide the job into discrete, homogeneous tasks, and then determine their frequency and duration. Then a metabolic rate can be assigned to each task. Finally, the time-weighted average for metabolic rate can be determined (TWA-M®). Using categories or tables to assign values of metabolic rate to a task reduces some of the error, but the ISO method is recommended and outlined in the following paragraph. In addition there are other published methods that provide good results.

Following the ISO method for a given task, the metabolic rate can be estimated by summing together five components. The components are basal metabolism (B), posture (P), activity based on degree of body involvement (A), the horizontal travel (H) and vertical travel (V). That is,

$$M_{\text{task}} = B + P + A + H + V \qquad (5)$$

Table 12–B describes values of metabolic rate associated with each of the components. The SI units for metabolic rate are watts, and conversion factors to change from watts to units reported in other sources (i.e., kcal/min, kcal/h, Btu/h, L/min of oxygen consumption) are provided at the bottom.

ASSESSMENT OF THE ENVIRONMENTAL CONDITIONS

The environmental factors that are central to the assessment of heat stress are air temperature, humidity, air speed, and average temperature of the solid surroundings. How these factors are incorporated into the evaluation of heat stress depend on the evaluation tool. The SI unit for temperature is degrees Centigrade.

Dry bulb temperature (T_{db}) is the direct measure of air temperature. The temperature sensor is surrounded by air, which is allowed to freely flow around the sensor. The sensor, however, may be influenced by radiant heat sources and therefore should be shielded from them.

Psychrometric wet bulb temperature (T_{pwb}) is based on the degree of evaporative cooling that can occur. In practice, a wetted wick is placed around a temperature sensor and enough air is forced over the wick to maximize the rate of evaporative cooling (> 3 m/s). The amount of temperature reduction that can be achieved depends directly on the amount of water vapor in the air. When humidity is high (high water-vapor pressure), the reduction in temperature is low. When the humidity is lower, the reduction is higher.

Ambient water vapor pressure (P_v) is commonly known as humidity. There are two ways humidity is expressed—*relative* and *absolute*. At any given temperature, the partial pressure of water vapor that can be in the air has a maximum value, the saturation pressure. At low temperatures, the

Table 12–B. *Values for the Four Components of Equation 5 to Estimate the Metabolic Rate for a Task (in watts)*

		Average (watts)	Range (watts)
Basal metabolism (B)		70	
Posture metabolism (P)			
Sitting		20	
Standing		40	
Walking		170	140–210
Activity (A)			
Hand	light	30	15–85
	heavy	65	
One arm	light	70	50–175
	heavy	120	
Both arms	light	105	70–245
	heavy	175	
Whole body	light	245	175–1,050
	moderate	350	
	heavy	490	
	very heavy	630	

Walking (H)
H_{hor} = rate of horizontal travel (meters/min)
$H = 3.3\ H_{hor}$
Climbing (V)
V_{vert} = rate of vertical ascent (meters/min)
$V = 56 V_{vert}$

Unit Conversions for Metabolic Rate

From Watts to Other Units	From Other Units to Watts
kcal/min = 0.014 × W	W = 70 × kcal/min
kcal/h = 0.86 × W	W = 1.2 × kcal/h
Btu/h = 3.4 × W	W = 0.29 × Btu/h
l O_2/min = 0.0029 × W	W = 350 l × O_2/min

Note: Values are based on a person weighing 70 kg.

saturation pressure is low, and it increases exponentially with temperature. Relative humidity is the ratio of the water vapor pressure in the air to the saturation pressure at that temperature. So 50 percent relative humidity means that the water vapor pressure is 50 percent of the saturation pressure. Unfortunately, relative humidity is not very useful as a tool to assess heat stress because the water vapor pressure represented by a value of relative humidity can be radically different depending on the air temperature. Absolute humidity is expressed as the amount of water vapor in the air in terms of partial pressure or weight per unit volume of air. The usual practice for heat stress evaluation is to use the partial pressure and the SI unit is kPa (kiloPascals). (To convert from kPa to mmHg, the value in kPa is multiplied by 7.5.) Usually a psychrometric chart is used to determine humidity from T_{db} and T_{pwb}. Figure 12–7 provides an equation to estimate water vapor pressure from these temperatures.

Natural wet bulb temperature (T_{nwb}) is similar to the psychrometric wet bulb except that air is allowed to flow over the sensor naturally rather than being forced. When air flow is less than 3 m/s, the temperature reduction is less than psychrometric wet bulb for the same absolute humidity. That is, natural wet bulb temperature is sensitive to both humidity and air movement.

Air speed (V_{air}) is measured using an appropriate anemometer. The anemometer should not be unidirectional. Because the speed will vary in space and time, an average value is used.

Globe temperature (T_g) responds to radiant heat from the solid surroundings and convective heat with the ambient air. The globe temperature is classically measured using a six-inch, thin-walled, copper sphere, painted matte black on the outside. The temperature sensor is placed at the center of the globe. When all the surrounding surfaces are the same temperature as the air, the globe temperature is equal to air temperature. If one or more of the surfaces are different, then the globe temperature will increase or decrease depending on the average temperature of the solid surroundings. Finally, for a given level of radiant heat exchange with the globe, the globe temperature will differ the most from air temperature with little air movement, and will differ the least with a significant air motion because it is also sensitive to convective heat exchange with the air. Globe temperature is used to estimate the average wall temperature of the surroundings.

Effective Temperature (ET) and *Corrected Effective Temperature (CET)* are indices of the thermal environment that were first developed to equate thermal sensation, and later used to describe thermal stress. *ET* is determined from a nomogram that requires knowledge of T_{db}, T_{pwb}, and V_{air}. For a sedentary person dressed in light clothing, equal values of *ET* would indicate similar sensations of warmth. Because of its history, it was used in the early studies of heat stress as an index of the environment.

Because *ET* did not account for radiant heat, *CET* was proposed. It uses T_g instead of T_{db} when entering the nomogram.

Neither *ET* nor *CET* is used to evaluate heat stress today. Instead a new index was required that could be more easily determined and was indicative of thermal stress from the environment. The wet bulb globe temperature was the evolutionary step from *ET* and *CET*.

Wet bulb globe temperature (WBGT) is an index of environmental heat that is widely used to evaluate industrial heat stress. In environments that are inside, in the shade, or on a cloudy day, it is computed as

$$WBGT_{in} = 0.7\,T_{nwb} + 0.3\,T_g \quad (6)$$

Under conditions of direct sun light (outdoors and no cloud cover), it is computed as

$$WBGT_{out} = 0.7\,T_{nwb} + 0.2\,T_g + 0.1\,T_{db} \quad (7)$$

Instrumentation to assess WBGT was originally a large copper globe and mercury-in-glass thermometers. There are several manufacturers of electronic instrumentation and they often use smaller globes. In addition to computing the WBGT directly, some can perform data logging functions as

well as real-time analysis of the environment (e.g., safe work times). The electronic instrumentation has virtually replaced the conventional WBGT "Christmas tree apparatus." (See Figure 12–4.)

EVALUATION OF PROLONGED EXPOSURES TO HEAT STRESS

With a goal of limiting the heat stress dose (core temperature not to exceed 38 C or 100.4 F), the problem becomes one of relating exposure (combinations of environment, metabolism, and clothing) to dose. Lind proposed the concept of the upper limit of the prescriptive zone (Bernard et al, 1994). In a set of classic experiments he demonstrated several important relationships between work, environment, and core temperature. In essence, he found that for a given metabolic rate, core temperature would remain relatively constant for increasing levels of environmental heat until a critical level. Then the core temperature would steeply rise with increasing levels of environmental heat, creating an increased risk for heat disorders. This critical level of heat stress was the upper limit of the prescriptive zone, and the person could work eight hours at or below this level without significant risk of a heat disorder. The upper limit is at lower levels of environmental heat for higher metabolic rates, and vice versa.

By exploring the upper limit of the prescriptive zone for different worker populations, Dukes-Dobos developed protective limits for the 95th percentile of the general worker population. At these protective limits, core temperature should not exceed 38 C (100.4 F) and first-minute recovery heart rates should not exceed 110 bpm. The upper limit of the prescriptive zone was first adapted by NIOSH in 1972 and revised in 1986. It was adopted by the ACGIH in 1973 (and revised in 1990) for the TLV for Heat Stress®. The International Organization for Standardization (ISO) also adapted the NIOSH thresholds in 1983. The limits are expressed in hourly time-weighted averages for both the WBGT and metabolic rate. The thresholds are illustrated in Figure 12–5 using both the NIOSH and ACGIH nomenclature.

The middle curve is called the *Recommended Exposure Limit* (*REL*) by NIOSH. For workers wearing ordinary cloth summer-weight work clothes and who are acclimated to heat, there should be practically no risk of heat-related disorders when working for eight hours with nominal breaks every two hours. Notice that as the metabolic rate increases, the threshold for WBGT decreases. This means that to maintain core temperature below 38 C (100.4 F) requires a "cooler" environment for higher internal heat generation. The ACGIH calls this threshold the TLV for Acclimatized Workers®.

The lower curve is called the *Recommended Alert Limit* by NIOSH and the TLV for Unacclimatized Workers® by the ACGIH. This curve is proposed in recognition that unacclimated workers are less able to tolerate heat-stress exposures and this lower tolerance can be accommodated by a lower level of environmental heat at the same work demands.

The upper curve is the *Ceiling Limit* proposed by NIOSH, but not included in the TLV®. An individual not wearing personal protection should not be exposed to this temperature level for more than 15 minutes.

Table 12–C. ***WBGT Adjustment Factors for Different Clothing Ensembles in Degrees C****

Clothing Type	*ACGIH*	*Other Sources*
Work Clothes	0	0
Coveralls	3.5	
Double Coveralls	5	
SMS Coveralls		–1
Tyvek® 1422A Coveralls		2
Vapor-Transmitting Water-Barrier		2 – 6
Vapor-Barrier		8
Encapsulating Suit		11

* The adjustment factors are added to the measured WBGT.

Because clothing is also a factor in determining the level of heat stress, the ACGIH has proposed a table of adjustment factors that can be added to the measured values of WBGT in the environments of interest. These are given in Table 12–C. Also included in the table are adjustment factors for other kinds of clothing that may be found in the workplace. An important note about using the adjustment factors is that they represent the current best guess about the effects of clothing other than ordinary work clothes, and some caution is necessary in using them. Using physiological strain indicators (i.e., personal monitoring) to confirm the evaluation may be appropriate.

To evaluate a job for heat stress, a one- to two-hour interval for time-weighted averaging must be selected. If the work is repeated in an hourly pattern, a one-hour TWA can be used. If the work is intermittent, a two-hour TWA may be more representative of the demands. TWA-M and TWA-WBGT must be calculated for the selected interval. Adjust the WBGT for each location by adding the clothing adjustment factor to the measured value as appropriate. With these TWA values, the work can be located in the graph of Figure 12–5. If it is below the RAL/TLV for unacclimatized workers, there is no practical risk for heat-related disorders to develop even for the least heat-tolerant but otherwise healthy workers. If it is between the RAL/TLV for unacclimatized workers and REL/TLV for acclimatized workers, then a program of heat-stress management should be in place. The program should include at least the general controls described in the section on controls. If it is above the REL/TLV for acclimatized workers, then heat stress is a hazard in the work environment and control actions should be taken.

EVALUATION OF TIME-LIMITED EXPOSURES TO HEAT STRESS

For heat-stress exposures above the REL/TLV, the question may become, how long can someone safely work? This question can be answered either by WBGT-based methods or by heat-balance analysis.

The following description of the ISO analysis of required sweat rate is divided into three sections. The first describes the steps in computing the individual terms of the heat balance equation (see Equation 1). The second section presents the criteria for unacclimated and acclimated workers at two levels of heat stress risk. The final section describes the computations for the time limit.

Computation of Heat Exchange

Adjust metabolic rate for body surface area. The following values of heat exchange are normalized to body surface area.

$$M = \frac{\text{Metabolic rate}}{1.8} \tag{1}$$

Adjust air velocity for work activities if $M > 58$. The method recognizes that air motion around the body results from both environmental conditions and body motion during work.

$$V = V_{air} + 0.0052\,(M - 58) \tag{2}$$

Limit the increase due to metabolism to 0.7 m/s (at M > 193 W/m^2) and V to 3.0 m/s.

Compute coefficient for convection. The convective heat exchange can be caused by either natural or forced convection. The greater value for natural or forced convection is used.

$$h_{cn} = 2.38\,(|T_{db} - 36|)^{0.25} \tag{3}$$

If $V \leq 1$ m/s, $h_{cf} = 3.5 + 5.2V$; if $V > 1$ m/s, $h_{cf} = 8.7V^{0.6}$

$$h_c = \text{Greater value of } (h_{cn}, h_{cf}) \tag{4}$$

Compute mean radiant temperature. The following equation computes the mean radiant temperature from globe temperature, recognizing that natural convection and air movement influence globe temperature.

$$\zeta = \text{Greater value of } \{0.4\,(|T_g - T_{db}|)^{0.25}, 2.5\,V_{air}^{0.6}\} \tag{5}$$

$$T_r = 100\left[\left(\frac{T_g + 273}{100}\right)^4 + \zeta\,(T_g - T_{db})\right]^{0.25} - 273 \tag{6}$$

Compute coefficient of radiation for a standing person. The rate of radiant heat exchange is lower for other postures.

$$h_r = 4.1 \times 10^{-8}\frac{(T_{sk} + 273)^4 - (T_r + 273)^4}{T_{sk} - T_r} \tag{7}$$

Compute clothing reduction factor for insulation. Because clothing insulation influences (reduces) the rate of heat transfer by radiation and convection with reference to a nude person, the reduction factor must be computed.

$$F_{cl} = \frac{1}{(h_c + h_r)\,I_{cl} + \dfrac{1}{(1 + 1.97I_{cl})}} \tag{8}$$

where I_{cl} is the clothing insulation ("clo" is a unit of clothing insulation: clo $\times$ 0.156 = m$^2 \cdot$ °C/W) For example,

$$\begin{aligned} &\text{light work clothes (reference: 0.6 clo) } 0.093 \text{ m}^2\ ^\circ\text{C/W} \\ &\text{coveralls (reference: 0.8 clo) } 0.125 \text{ m}^2\ ^\circ\text{C/W} \end{aligned} \tag{9}$$

Average skin temperature is often assumed to be between 35 and 36 C. It can also be estimated as

$$T_{sk} = 30.0 + 0.093\,T_{db} + 0.045\,T_r - 0.571\,V_{air} + 0.254\,P_a + 0.00128\,M - 3.57\,I_{cl} \tag{10}$$

Compute convective heat exchange.

$$C = h_c F_{cl}\,(T_{db} - T_{sk}) \tag{11}$$

Compute radiant heat exchange.

$$R = h_r F_{cl}\,(T_r - T_{sk}) \tag{12}$$

Compute required evaporative cooling.

$$E_{req} = -(M + C + R) \tag{13}$$

Compute clothing reduction factor for water vapor permeation for cotton clothing. Because clothing insulation influences (reduces) the rate of heat transfer by evaporation with reference to a nude person, the reduction factor must be computed.

$$F_{pcl} = 1 + 2.22\,h_c\left(\frac{I_{cl} - \left(1 - \dfrac{1}{1 + 1.97I_{cl}}\right)}{h_c + h_r}\right) \tag{14}$$

Compute ambient water vapor pressure (P_a). (An alternative is to determine this from a psychrometric chart.)

$$P_a = 0.6105\,\exp\frac{17.27\,T_{pwb}}{T_{pwb} + 237.3} - 0.0669\,(T_{db} - T_{pwb})(1 + 0.00115\,T_{pwb}) \tag{15}$$

To estimate T_{pwb} from T_{nwb},

$$T_{pwb} = T_{db} - \frac{T_{db} - T_{nwb}}{d} \tag{16}$$

where $d = 0.85$ if $V_{air} \leq 0.03$ m/s
$d = 1.00$ if $V_{air} \geq 3.0$ m/s
$d = 0.69 \log_{10} V_{air} + 0.96$ if $0.03 < V_{air} < 3.0$ m/s

Compute water vapor pressure on the skin. (An alternative is to get this from a psychrometric chart or tables.)

$$P_{sk} = 0.6105\,\exp\frac{17.27\,T_{sk}}{T_{sk} + 237.3} \tag{17}$$

Compute maximal evaporative cooling to the environment.

$$E_{max} = -16.7\,h_c F_{pcl}\,(P_{sk} - P_a) \tag{18}$$

Figure 12–7. Description of computational steps for the heat-balance analysis proposed by the International Organization for Standardization (ISO) for the evaluation of time-limited heat stress. Experimentally derived factors for F_{cl} and F_{pcl} for nonwoven fabrics have been proposed by Barker, Kini, and Bernard. ***(Continues)***

Compute required skin wetness. Skin wetness is the degree to which the skin is covered by water.

$$w = \frac{E_{req}}{E_{max}} \quad (19)$$

$$w_{req} = \text{Lesser value of } (w, 1.0) \quad (20)$$

Compute sweating efficiency. Because some water is lost by dripping, sweating efficiency depends on skin wetness.

$$\eta = 1.0 - \frac{(w_{req})^2}{2} \quad (21)$$

Compute required sweat rate.

$$SW_{req} = \frac{-E_{req}}{\eta} \quad (22)$$

Criteria. Select criteria by acclimation state and by heat strain level (warning or danger).

		Unacclimated		*Acclimated*	
Criteria	*Units*	*Warning*	*Danger*	*Warning*	*Danger*
SW_{max}	W/m^2	200	250	300	400
—	l/hr	0.52	0.65	0.78	1.04
w_{max}	—	0.85	0.85	1.0	1.0
Q_{max}	$W \cdot hr/m^2$	50	60	50	60
SV_{max}	$W \cdot hr/m^2$	1,000	1,250	1,500	2,000
—	l	2.5	3.25	3.9	5.2

Unacclimated: Workers have not had at least 5 days of 2-hour heat stress exposures over the preceding 7 days.

Acclimated: Workers have had at least 5 days of 2-hour heat stress exposures over the past 7 days.

Warning: If work time exceeds recommended time for Warning, controls should be considered. Adequate recovery should be allowed.

Danger: If work time reaches Danger time, controls are necessary.

*If $M < 65$, the $SW_{max} = 0.6\ SW_{max}$.

Once the criteria are selected, predicted values for skin wetness, evaporative cooling, and sweat rate can be determined.

If $w_{req} \leq w_{max}$ and $8SW_{req} \leq SV_{max}$, then the heat stress is not time limited.

Compute Condition A. The predicted values equal required values as follows:

$$w_p = w_{req} \quad (23)$$

$$E_p = E_{req} \quad (24)$$

$$SW_p = SW_{req} \quad (25)$$

If $w_{req} > w_{max}$, compute Condition B (time is limited by skin wetness).

$$w_p = w_{max} \quad (26)$$

$$E_p = w_p E_{max} \quad (27)$$

$$\eta_p = 1.0 - \frac{(w_p)^2}{2} \quad (28)$$

$$SW_p = \frac{-E_p}{\eta_p} \quad (29)$$

If $SW_{req} > SW_{max}$ from Condition A or $SW_p > SW_{max}$ from Condition B, compute Condition C, which is limited by sweat rate.

$$\phi = \frac{E_{max}}{SW_{max}} \quad (30)$$

$$w^*_p = (\phi + 2)^{0.5} - \phi \quad (31)$$

$$w_p = \text{Lesser value of } (w^*_p, w_{max}) \quad (32)$$

$$\eta_p = 1.0 - \frac{(w_p)^2}{2} \quad (33)$$

$$E_p = w_p E_{max} \quad (34)$$

$$SW_p = \frac{-E_p}{\eta_p} \text{ (which is usually } SW_{max}) \quad (35)$$

Compute time limit. The computed time limits are based on the ability to support a sufficient rate of evaporative cooling and on the risk of dehydration.

If Condition C was computed, use Condition C values to compute the time limit. If Condition C was not computed and Condition B was computed, use Condition B values to compute the time limit. If neither Condition B nor C was computed, use Condition A values to compute the time limit.

Evaporative cooling time limit.

$$t_e = \frac{60 Q_{max}}{E_p - E_{req}} \quad (36)$$

Sweat volume time limit.

$$t_d = \frac{60 SV_{max}}{SW_p} \quad (37)$$

Sweat rate for standard man (SR).

$$SR = 0.0026 SW_p \quad (38)$$

The ISO method is best computed on a personal computer using a spreadsheet or computational language such as BASIC or FORTRAN. A commercial software package developed by J. B. Malchaire, Heat Stress Evaluation, Version 2, is available from Lewis Publishers and other packages developed by individuals are also available.

Table 12–D. *Definition of Terms Used in Figure 12–7*

Term	*Description*	*Units*
M	Metabolic rate—normalized	W / m^2
SA	Body surface area	m^2
P_a	Ambient water vapor pressure	kPa
T_{pwb}	Psychrometric wet bulb temperature	C
T_{db}	Dry bulb (air) temperature	C
T_r	Mean radiant temperature	C
T_g	Globe temperature	C
V_{air}	Air speed	m / s
T_{sk}	Average skin temperature	C
I_{cl}	Clothing insulation	(m^2 • C) / W
V	Adjusted air speed	m / s
h_{cn}	Coefficient of convection—natural	W / (m^2 C)
h_{cf}	Coefficient of convection—forced	W / (m^2 C)
h_c	Coefficient of convection	W / (m^2 C)
h_r	Coefficient of radiation	W / (m^2 C)
F_{cl}	Clothing reduction factor	—
C	Convective heat exchange	W / m^2
R	Radiant heat exchange	W / m^2
E_{req}	Required evaporative cooling	W / m^2
F_{pcl}	Clothing reduction factor for water vapor permeation	—
P_{sk}	Water vapor pressure on skin	kPa
E_{max}	Maximum rate of evaporative cooling	W / m^2
w_{req}	Required skin wetness	—
η	Sweating efficiency	—
SW_{req}	Required sweat rate	W / m^2
SW_{max}	Maximum sweat rate	W / m^2
w_{max}	Maximum skin wetness	—
Q_{max}	Maximum heat storage	(W • hr) / m^2
SV_{max}	Maximum sweat loss	(W • hr) / m^2
w_p	Predicted skin wetness	—
E_p	Predicted rate of evaporative cooling	W / m^2
SW_p	Predicted sweat rate	W / m^2
SR	Sweat rate	l/h
t_w	Time limit based on skin wetness	min
t_d	Time limit based on dehydration	min
t	Time limit	min

WBGT techniques. WBGT techniques fall into two methods. One method uses TWAs and the TLV®. Then the question is asked in terms of how much time in an hour can someone work above the TLV compared to the time work or recovery is below the TLV? This first question is a general case of work-rest cycles. For the simple case of one work condition and one recovery condition refer to Figure 12–8. At work, Point A is at [TWA-M and TWA-WBGT]$_{work}$ and recovery (rest or light duty work) [TWA-M and TWA-WBGT]$_{recovery}$ is at Point C. Point B is at the intersection of the line A-C with the threshold line. The ratio of recovery time to heat stress exposure time is equal to the length of A-B to the length of B-C.

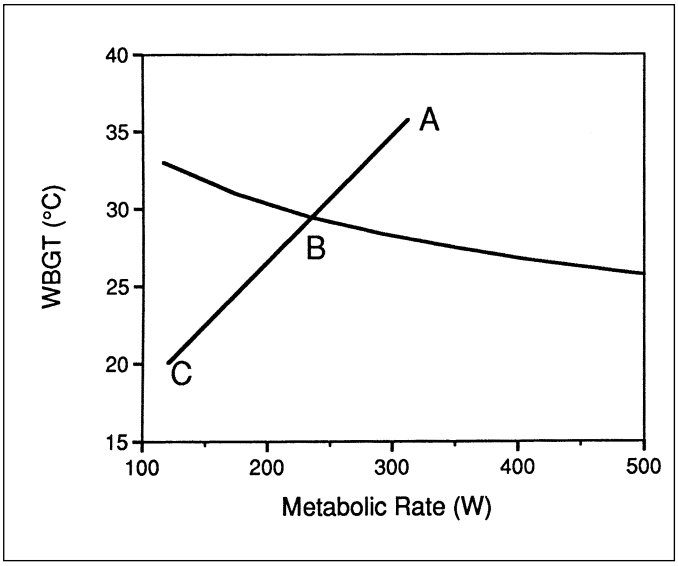

Figure 12–8. Graphical method to determine the ratio of recovery to exposure time. Point A is work conditions and Point C is recovery conditions. Ratio of rest time to work time is equal to length of A-B divided by length of B-C.

Another way to use the WBGT/TLV method is to iterate on a solution by testing various combinations of exposure time and recovery time that equal one hour so that the combination of TWA-M and TWA-WBGT lands on the TLV® line. (A spreadsheet solution can be developed by using the equation for the TLV line provided in the Figure 12–5.)

The U.S. Navy and the Electric Power Research Institute have proposed WBGT methods to determine safe exposures times from charts. An example of the Navy Permissible Heat Exposure Limit (PHEL) chart is illustrated in Figure 12–6 (clothing is ordinary summer-weight work clothes).

Heat-balance analysis. Heat balance analysis uses a model of heat exchange between a hypothetical person and the environment. While the WBGT methods mentioned previously are empirical methods of heat-stress evaluation, the method of heat-balance analysis is considered a rational method. If thermal equilibrium can be established, then there is no risk of an excessive level of heat stress. If thermal equilibrium cannot be established, then the amount of time to reach an upper limit of heat storage (nominally to

a core temperature of 38.5 C or 101.3 F) can be determined. That desktop evaluations of potential countermeasures can be performed is another advantage of heat balance analysis.

One method used by many industrial hygienists is called the Heat Stress Index (HSI) (proposed by Belding and Hatch). It starts from the premise that Equation 2 describes heat balance and Equation 4 describes the evaporative cooling requirements. Equation 4 is repeated here.

$$E_{req} = -(M + R + C) \tag{4}$$

The HSI is based on simple relationships for computing R and C, which have been updated over the years. The equations that follow are for workers wearing ordinary cloth work clothes and the units are watts, degrees C, meters per second (m/s) for air speed (V_{air}), and kiloPascals (kPa) for water-vapor pressure.

Basically, R is equal to a clothing-related constant times the difference between the mean temperature of the surroundings (T_r) and a mean skin temperature of 35 C (95 F). Obviously, if the average surrounding temperature is greater than skin temperature, there is a gain of heat by radiation.

$$R = 7.7\,(T_r - 35) \tag{8}$$

where

$$T_r = T_g + 1.8\,V_{air}^{0.5}\,(T_g - T_{db}) \tag{9}$$

C is equal to a clothing-related constant times a power function of air speed times the difference between air and skin temperature, as follows

$$C = 8.1\,V_{air}^{0.6}\,(T_{db} - 35) \tag{10}$$

If the air temperature is greater than skin temperature, there is a heat gain by convection; if skin temperature is less than air, there is a heat loss.

The method also provides for the determination of the maximum rate of evaporative cooling (E_{max}), which has either an environmental or physiological limit. The environmental limit on E_{max} is determined as a clothing-related constant times a power function of air speed times the difference between skin and air water-vapor pressure (P_v)

$$E_{max} = 122\,V_{air}^{0.6}\,(P_v - 5.6) \tag{11}$$

Because P_v is less than 5.6, E_{max} will have a negative value representing a heat loss. The physiological limit is based on a limiting sweat rate of 1 L/h, which is equivalent to a heat flow of –675 W. Therefore E_{max} is the greater negative number of that computed from Equation 6 or –675. Then

$$HSI = 100\frac{E_{req}}{E_{max}} \tag{12}$$

If the HSI is less than 40 then heat stress is low and no further actions are required. If the HSI is between 40 and 70, heat stress is a significant workplace hazard. If HSI is between 70 and 100, heat stress is high and workers are at risk for heat-related disorders. If HSI is greater than 100, there is significant heat storage and the exposure is time-limited.

A number of variations to HSI as well as alternatives have been proposed. The International Organization for Standardization has published the most recent and comprehensive rational method for heat balance analysis. It is called the Required Sweat Rate (SR_{req}) Analysis and the steps are described in Figure 12–7. (This method is under review by the ISO, and improvements have been proposed but not yet voted on.)

The principle of the ISO method is to determine (1) the amount of evaporative cooling that is required for thermal equilibrium (E_{req}), (2) whether the required cooling can be achieved by sweating and evaporation, and (3) what time limits may apply if sweating or evaporation is insufficient. The limits are based on inadequate cooling and potential dehydration. (The standard was developed with cotton clothing in mind, but experimentally derived values of insulation (I_{cl}) and permeability (F_{pcl}) for other clothing ensembles are becoming available for use, such as the method suggested by Barker, Kini and Bernard [1999].)

If the heat-balance analysis indicates that thermal equilibrium can be achieved, then heat stress does not play a limiting role in the work. If the time limits are less than six hours, then serious consideration must be given to heat-stress controls.

The accuracy of heat-balance analysis is limited because certain variables are not easily measured, but fair assumptions can be made. The important advantage of heat-balance analysis is the ability to compare the relative advantages of proposed changes in the environment, work demands, and clothing requirements.

EVALUATION OF PHYSIOLOGICAL STRAIN

As mentioned earlier, physiological strain due to heat-stress exposures is seen as elevations in core temperature, heart rate, and sweating. They are therefore candidates as evaluation tools for heat stress exposures. Physiological evaluation is a valid approach because it uses direct assessment of the effects of heat stress (dose) rather than an index of exposure, which is then related to dose through empirical evidence and models. The recently adopted TLV for Heat Stress and Strain® reflects the value placed on physiological monitoring. If no excessive physiological strain is demonstrated in the working population at a workplace, then heat stress is controlled by the work practices in place.

Physiological evaluation as an alternative or confirming evaluation of heat stress may be worthwhile when protective clothing is required. It might also be used to demonstrate

compliance with the spirit of the NIOSH and ACGIH thresholds when some work occurs just above the thresholds.

In selecting workers to sample for the physiological evaluations, the choice should be random and sufficient to ensure statistical reliability.

Core temperature is a physiological construct used to describe internal body temperature. There are several laboratory methods used to assess core temperature that are not acceptable in a workplace. Acceptable surrogate methods are available. The surrogate with the longest history is oral temperature. To take an accurate oral temperature, the individual must not eat or drink for 15 minutes prior to the sample and the mouth must remain closed. Core temperature is approximately equal to oral temperature plus 0.5 C or 1 F.

Other alternatives are available. One is a commercial personal monitor with data-logging capabilities that monitors ear canal temperature with a thermistor held in place by a disposable ear plug. Another commercial device estimates core temperature from a surface-mounted sensor placed on the chest (and is part of a heart-rate monitoring device described later in this section). Finally, there are swallowable "pills" that can transmit a value for temperature to a receiver outside of the body.

As a criterion for core temperature, 38 C (100.4 F) is the limit if the temperature is sustained over the course of the work day. If the work is intermittent, then transient increases to 39 C (102.2 F) should be acceptable as long as there is sufficient recovery to allow core temperature to return toward 37 to 37.5 C (98.6 to 99.5 F). That is, the time-weighted average should not exceed 38 C (100.4 F). As a matter of practice, core temperature should not exceed 39 C (102.2 F) for industrial exposures to heat stress.

Heart rate is another indicator of heat strain. Four methods proposed for assessing heart rate are in use. Three methods mentioned previously are recovery heart rate, peak heart rate and average heart rates over an 8-h duration. Another method evaluates a set of averaged heart rates over a typical exposure period.

Recovery heart rate was mentioned previously as a tool for recognition. It has also been used to evaluate workplaces. To demonstrate effective control of heat stress, the recovery heart rate at one minute (HRR_1) should be less than 110 bpm. Alternatively, the heart rate at three minutes (HRR_3) should be less than 90 bpm or the value of $HRR_1 - HRR_3$ should be at least 10 bpm.

If the daily average heart rate exceeds 110 bpm, then heat stress and/or very strenuous work may be the cause. This limiting average has been recommended by the WHO experts and confirmed in laboratory and field studies.

Setting a threshold for heart rate is a third approach. A recording of heart rate during a heat stress exposure is shown in Figure 12–9. As a rule of thumb, peak heart rates should not exceed 90 percent of a person's maximal heart rate (HR_{max}). Sometimes this value is known from a stress test and other times it must be estimated from age (e.g., $HR_{max} = 195 - 0.67$[age–25 years]). Brief periods (less than one minute) above this threshold are not significant, but more than one minute may be excessive. The ACGIH has recommended limiting sustained heart rates of several minutes to 180 – Age.

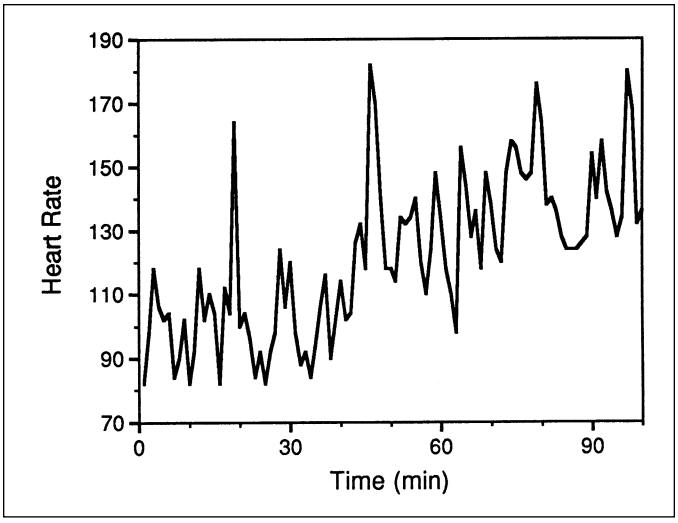

Figure 12–9. Example of a heart rate response to a heat-stress exposure.

When looking over a history of heart rate for the day, an obvious trend toward higher heart rates also indicates heat stress above the thresholds because the body is having trouble maintaining thermal equilibrium. The momentary peaks in Figure 12–9 are not significant, but the trend in the second half is a classic representation of the response to moderately high heat stress and eventually excessive cardiovascular strain.

There is also a personal monitor commercially available that sets multiple thresholds for heart rate based on averages in seven different time windows. The purpose of this approach is to examine the peak demands as well as the overall trends for a broader evaluation. This device is the one mentioned previously that also has a surface sensor surrogate for core temperature. If the sample of workers stay below the thresholds in this device then heat stress is not significant.

Sweat rate and volume are theoretically measures of physiological strain, but less practical than core temperature and heart rate. Sweat volume over a given period of time is equal to an initial body weight plus the weight of food and drink consumed minus the weight of anything excreted minus a final body weight. The overall weight change in kilograms is equal to the sweat volume in liters. If there is more than a five-liter sweat volume, heat stress is sufficient to cause dehydration and therefore must be controlled. Over a two- to four-hour interval, the sweat rate should be less than one liter per hour.

Control of Heat Stress

Control of heat stress and heat strain centers around the causes of heat stress and the resulting physiological strain. It takes the form of general controls that are applicable to all heat-related jobs, and specific controls that must be evaluated and selected based on the constraints of the working conditions. The controls are divided into general and specific controls.

GENERAL CONTROLS

General controls are those actions that are universally applicable to heat stress work. The general controls are training, heat-stress hygiene practices, medical surveillance, and a heat-alert program. Anytime a group of workers may be exposed to heat stress that is above the RAL (or equivalently the TLV for Unacclimatized Workers), the general controls should be implemented.

Training is an essential feature of managing heat stress. It is for those employees working on heat-related jobs and their supervisors. The information gained from the training enables them to recognize heat stress and to control the risks associated with it. Training is divided into two types—preplacement and periodic.

Preplacement training. Preplacement training is directed to an employee who is reporting to a heat-related job for the first time. The preplacement training can be given during other job training including safety or skill training. It is not necessary to repeat preplacement training for an employee who has had it once. The formal content of the preplacement training is the same as that for annual or periodic training (see the next paragraph). A complement to the preplacement training is any counseling medical personnel may give an individual employee relating to that employee's physical condition.

Periodic training. Annual heat-stress training should be given to employees working on heat-related jobs to refresh their knowledge of heat stress and controls. The following topics should be covered during training:

- ➢ Description of Heat Stress
  - ➢ Environment, work demands, and clothing
  - ➢ Physiological responses including acclimation
- ➢ Recognition of and First Aid for Heat-Related Disorders
  - ➢ Description of heat-related disorders including symptoms and causes
  - ➢ Description of first aid measures for each disorder
- ➢ Heat Stress Hygiene Practices (see following for details)
  - ➢ Description of heat stress hygiene practices
  - ➢ Emphasis on individual responsibility
- ➢ Overview of Heat Stress Policy and Guidelines
  - ➢ Company Policy
  - ➢ Management responsibilities
  - ➢ Employee responsibilities

The format of the training can be similar to other health and safety training. Using commercially available videotape and written materials is effective and efficient. However, it is important to point out those issues that may be particular to the work site.

Heat stress hygiene practices. Heat-stress hygiene practices are the actions taken by an individual to reduce the risks of a heat disorder. The individual is responsible for practicing good heat stress hygiene. Site management informs the workers of good practices and helps the workers practice them. Some practices are listed.

Fluid replacement—A great deal of water is lost from the body as sweat for evaporative cooling. Losses may be up to six liters or quarts of water in one day, equivalent to about 13 pounds. This water should be replaced by drinking cool water or flavored drinks (e.g., dilute iced tea, artificially sweetened lemonade, or commercial fluid-replacement drinks). Because thirst is not a sufficient driver for water replacement, workers should drink small quantities as frequently as possible. This helps instill drinking as a habit and the volumes do not cause discomfort. If work is to be performed in a drinking-restricted area, drinking about one pint per hour of work before the work begins will help meet the demands for water during the work.

Unacclimated workers in jobs with exposures near the TLV® may benefit from drinking beverages containing about 0.1 percent salt. Workers on physician-advised salt-restriction should consult their physician. (Note: Salt tablets should never be taken.)

Self-determination—One aspect of self-determination is limiting an exposure to heat stress. It is a responsibility of the worker and supervisor(s). In self-determination, the person terminates an exposure to heat stress at the first symptom of a heat-related disorder or extreme discomfort. Serious injury can occur if the onset of symptoms is ignored.

Another aspect of self-determination is reducing the effects of heat stress by lowering peak work demands and making the work demands lighter. For instance, when a fixed amount of work is assigned to a portion of the shift, peak demands can be reduced by leveling out the work effort over the allocated time or taking more frequent breaks. For those working in crews, the pace should be set for the least heat-tolerant worker.

Diet—A well-balanced diet is important to maintain the good health needed to work under heat stress. Large meals should not be eaten during work breaks because they increase circulatory load and metabolic rate.

Diets designed to lose weight should be directed by a physician who understands that the patient is working under conditions of potential heat stress. Weight control for overweight workers is recommended because obesity increases the risk of heat-related disorders.

Salt intake as part of a normal diet is usually sufficient to meet the salt demands during heat-stress work. Added salt may be desirable when repeated heat stress exposures are first experienced (i.e., during acclimation). If salt is restricted by a physician's order, the physician should be consulted.

Lifestyle—A healthy lifestyle is important to lowering the risk of a heat-related disorder. A worker should have adequate sleep and a good diet. Exercise helps. A healthy lifestyle also means no abuse of alcohol or drugs, which have been implicated in heat strokes. In addition, exposures to heat stress immediately before work may increase the risk of a heat disorder at work.

Health Status—All workers should recognize that chronic illnesses, such as heart, lung, kidney, or liver disease, indicate a potential for lower heat tolerance and therefore an increased risk of experiencing a heat-related disorder during heat-stress exposures. As a matter of principle, workers suffering from any chronic disorder should inform the physician of occupational exposures to heat stress and seek advice about the potential effects of the disorder or drugs used to treat it.

If a worker is experiencing the symptoms of any acute illness and still reports to work, that worker should inform the immediate supervisor.

Acclimation—Acclimation is the adaptation of the body to prolonged daily heat stress exposures. The ability to work increases and the risk of heat disorders decreases with acclimation. Acclimation is lost when there are no heat exposures. The loss is accelerated when an illness occurs. The process should be recognized and expectations adjusted. Workers will be able to work better after several days of heat exposures and they should expect less of themselves in the early days.

Table 12–E provides a framework for how acclimation can be induced and re-induced after an absence from heat exposures. Recommendations for new worker acclimation usually start at lower levels to further account for the lack of familiarity with the job and therefore greater risk of accidents. This is reflected in the five-day schedule that begins at 20 percent of daily exposure. For experienced workers, OSHA recommendations prescribe three days of increasing exposures followed by full exposures. Recognizing that full acclimation is normally lost over three weeks, the reacclimation schedule in Table 12–E is recommended by the author.

Table 12–E. ***Basic Acclimation Schedule and a Schedule for Reacclimation after Periods Away from Heat Stress Exposures Due to Routine Absence or Illness***

Basic Acclimation Schedule

Day	*Activity (% of full work assignment)*	
	Experienced	*New*
Day 1	50	20
Day 2	60	40
Day 3	80	60
Day 4	100	80
Day 5		100

Reacclimation Schedule

Days Away from Heat-Related Schedule		*Exposure Sequence (% of full work assignment)*			
Routine Absence	*Illness*	*Day 1*	*Day 2*	*Day 3*	*Day 4*
<4	—	100			
4–5	1–3	R/E*	100		
6–12	4–5	80	100		
12–20	6–8	60	80	100	
>20	>8	50	60	80	100

* Reduce expectations, some diminished capacity

Medical surveillance—This encompasses the evaluation of individual risk for adverse effects to heat-stress exposures, provides treatment for heat-related disorders, and helps assess the information collected from heat-related disorder incidents. Medical surveillance should be under the direction of a licensed physician.

Evaluation of risk—The medical surveillance activity includes identifying those workers who may be at extraordinary risk for heat-related disorders. Preplacement and routine physicals under the direction of the physician are used to identify these people. The physician should consult the NIOSH Criteria Document for more information, but ultimately the physician must set the criteria.

Before an employee is placed on a heat-related job, the employee should receive a preplacement physical examination that covers the following items:

- ➢ Comprehensive work and medical history with an emphasis on past intolerance to heat stress and relevant information on the cardiovascular, respiratory, and nervous systems; skin; liver; and kidneys
- ➢ Comprehensive physical examination that gives special attention to the cardiovascular, respiratory, and nervous systems; skin; liver; kidneys; and obesity
- ➢ Assessment of the use of prescription and over-the-counter drugs as well as the abuse of alcohol or other drugs that may increase the risk of heat intolerance
- ➢ Assessment of ability to wear and use personal protection that may be required
- ➢ Assessment of other factors that may affect heat tolerance as deemed important by the physician-in-charge. The physician should provide a written opinion of the results, which is placed in the employee's medical file. A copy should be provided to the employee. The written opinion should contain the following:
  - ➢ results of the examination and tests
  - ➢ physician's opinion on potential risk to the employee
  - ➢ physician's opinion on the employee's capability to work on heat-related jobs
  - ➢ any recommended limitations or restrictions
  - ➢ a statement that the employee has been informed of the results

Because an employee's health status can change over time, periodic re-evaluations are appropriate. These periodic physicals should be scheduled approximately yearly. There may be times when the physician or management believes that the ability of an individual to tolerate heat stress has diminished. In this case, the physician may perform a timely physical outside the schedule for a periodic physical examination.

Response to heat-related disorders—The organization's medical department is responsible for providing emergency response to reported heat-related disorders directly through medical department facilities, by medical department

personnel at the job site, or by providing first aid training to selected department foremen or safety personnel.

In addition to providing for emergency response, the physician or designee (e.g., safety department personnel) should periodically review heat-stress incidents to update the program.

Heat-alert programs are a collection of activities taken in anticipation of heat-stress conditions or an unusually high level of heat stress. These conditions may be the approaching of summer, of a maintenance outage, of special operating conditions, or of a heat wave. The first step in a heat-alert program is to appoint a committee whose members are responsible for the annual review of heat stress management activities and to make adjustments as necessary. This committee should be comprised of management representatives from such departments as operations, maintenance, engineering, medical, industrial hygiene, safety, and human resources as well as representatives of labor from different departments that may be affected. It should meet well before the anticipated presence of heat stress in the workplace. At a minimum, the committee should complete the following activities:

- ➢ Review training materials and set training schedule for the current year
- ➢ Oversee the preparation of the facility for heat stress conditions (e.g., reverse winterization) and check the operability of heat stress controls (e.g., fans, air conditioners, drinking stations, personal protection)
- ➢ Oversee the preparations for changes in staffing and work practices if appropriate
- ➢ Review policies and procedures regarding heat-related disorders
- ➢ Prepare for extraordinary heat stress conditions by
  1. setting criteria for a Heat-Alert State (such as a sudden increase in ambient temperatures from a heat wave) and how it will be announced
  2. preparing special administrative controls (see below) such as rescheduling work, increasing the number of workers, further restricting overtime, personal monitoring for excessive heat strain, etc.
  3. closely monitoring workers for heat-related disorders

SPECIFIC CONTROLS

The two major factors in heat stress are work demands and environmental conditions (i.e., air temperature, humidity, air movement, and hot surfaces). Clothing requirements are a third factor when multiple layers, nonwoven clothing, or vapor-barrier fabrics are worn. For specific jobs, the control of heat stress and the resulting physiological strain on workers is accomplished through engineering controls, administrative controls and personal protection.

Table 12–F is a checklist of controls suggested by NIOSH in the revised criteria document. The table is one way to begin to understand what might be done to manage the level of heat stress. While each job must be examined in light of the work to be accomplished and the constraints of the workplace, the following discussion highlights the principles of the control measures and can be used to focus discussion of controls.

To select controls for specific jobs, the first step is to discuss the job among production, engineering, and health and safety functions using the following discussion of control measures. A "long list" of ideas that emphasizes engineering controls, followed by administrative controls, and finally personal protection should be generated. Imagination is essential during the development of candidate controls for the long list, and no candidate control should be rejected out-of-hand. Controls should then be judged on their merits as they relate to being effective and technically and economically reasonable. The result is a "short list" of controls that can be prioritized and implemented over a reasonable timeframe. It is reasonable to have short-term solutions while long-term solutions are planned and executed.

Engineering controls. These are the kind of controls that reduce or contain the hazard. For heat stress, engineering controls are directed toward reducing physical work demands, reducing external heat gain from the air and hot surfaces, and enhancing external heat loss by increasing sweat evaporation and decreasing air temperature.

Reduce physical work demand. The metabolic cost of doing work is the greatest contributor to heat gain by a worker. Reducing the physical work demand can greatly reduce the level of heat stress.

Ways that the physical work demand can be reduced usually include powered tools or new processes to reduce manual effort.

Reduce air temperature. When air temperature is above 40 C (104 F), workers gain a significant amount of heat from the air. If the air temperature is below 32 C (90 F), there is a significant loss of body heat. Lowering air temperature serves to either reduce heat gain or enhance the loss of heat. It is a significant factor in the control of heat stress.

Air temperature can be reduced by dilution ventilation and active cooling. Dilution ventilation brings in a supply of cooler air from another area and reduces the temperature in the work area by diluting the hot air with cooler air. This can be accomplished using general area ventilation or local (spot) ventilation. Active cooling means that mechanical refrigeration, evaporative cooling, or a water chiller is employed to reduce the temperature of supplied air for dilution ventilation. Cool rooms are an example of providing a local area of cooling near work areas. By spending some time of the work cycle in the cooler area, the effective exposure to heat stress is reduced.

Reduce air humidity. The rate of evaporative cooling of sweat is affected by the air humidity. Many times the rate of cooling is sufficiently restricted that excessive heat strain occurs. The rate of evaporative cooling can be enhanced by

Table 12–F. *Overview of Specific Controls for Heat Stress Provided by NIOSH in the Criteria Document for Heat Stress*

Item	*Actions for Consideration*
Controls	
M, Body heat production of task	Reduce physical demands of the work, powered assistance for heavy tasks.
R, Radiative load	Interpose line-of-sight barrier, furnace wall insulation, metallic reflecting screen, heat reflective clothing, cover exposed parts of body.
C, Convective load	If air temperature is above 35 C (95 F), reduce air temperature, reduce air speed across skin, wear clothing. If air temperature is below 35 C (95 F), increase air speed across skin and reduce clothing.
E_{max}, Maximum evaporative cooling by sweating	Increase by: decreasing humidity, increasing air speed Decrease clothing
Work practices	Shorten duration of each exposure; more frequent short exposures better than fewer long exposures. Schedule very hot jobs in cooler part of day when possible.
Exposure limit	Self-limiting, based on formal indoctrination of workers and supervisors on signs and symptoms of overstrain.
Recovery	Air-conditioned space nearby.
Personal protection R, C, and E_{max}	Cooled air, cooled fluid, or ice cooled conditioned clothing. Reflective clothing or aprons
Other considerations	Determine by medical evaluation, primarily of cardiovascular status Careful break-in of unacclimatized workers Water intake at frequent intervals to prevent hypohydration Fatigue or mild illness not related to the job may temporarily contraindicate exposure (e.g., low-grade infection, diarrhea, sleepless night, alcohol ingestion)
Heat wave	Introduce heat alert program

(Reprinted from *NIOSH Criteria for a Recommended Standard . . . Occupational Exposure to Hot Environments—Revised Criteria 1986*. Washington, DC: U.S. Government Printing Office, 1986.)

lowering the water content of the air. Water is best removed from air by cooling the air by water chillers or mechanical refrigeration. Thus heat stress is reduced by both removing water vapor and lowering air temperature. Again, the use of cool rooms reduces heat stress by lower air temperatures and by lower humidity (and the increased rate of evaporative cooling).

Change clothing. Clothing is an important contributor to heat stress if it is not a light-weight cotton work uniform. Frequently, when clothing is chosen for good barrier properties against contaminants, not enough thought is given to the effects on heat stress. For instance, when the WBGT is 32 C (90 F) (T_{db} = 38 C or 100 F) at a moderate rate of work (about 260 W), a person in work clothes can work for about two hours while a person in vapor-barrier clothing can work about 30 min. Changing the vapor-barrier to a water-barrier (vapor-transmitting) clothing can increase the tolerance time to 70 min.

Reduce radiant heat. When the globe temperature is greater than 43 C (109 F), radiant heat is a significant source of heat stress. Radiant heat can come from well-defined or diffuse sources with high surface temperatures.

If a source of radiant heat is well-defined and localized, it can be effectively controlled by shielding. Diffuse sources of radiant heat are more difficult to control. For diffuse sources, control can come from shielding, but two other means are also available. One is insulating surfaces to reduce surface temperature and the other is to decrease emissivity of the surface. Increasing the insulation may also reduce air temperature and decrease energy costs.

Increase air movement. The advantage of increasing air movement is to enhance evaporative cooling and convective cooling if the air temperature is less than 35 C (95 F). Between 35 and 40 C (95 and 104 F), heat gain by convection may increase with increases in air movement, but it will be more than off-set by increases in evaporative cooling. Above 40 C (104 F), increases in air movement actually increase the overall heat stress. The greatest reduction in heat stress occurs when air motion is increased from less than one meter per second (m/s) to 2 m/s. There is no further improvement in evaporative cooling for air speeds greater than 3 m/s. When clothing is fairly heavy, higher air speeds can better penetrate the clothing and move the air near the skin (clothing ventilation is increased).

The chief mechanism for increasing air movement around a worker is to use a fan in the workspace. Another means of increasing air motion is local ventilation. Increasing air movement, however, frequently increases the level of airborne particles.

Administrative controls are controls that change the way work is performed in order to limit exposures or risks. For heat stress, administrative controls are directed toward limiting exposures so that increases in heart rate and core temperature do not exceed accepted limits.

Acclimation. Acclimation is the process that allows a worker to become accustomed to the heat stress; the worker is better able to work in the heat. Acclimation is a powerful adaptation that comes naturally to more than 95 percent of the workforce. Acclimation is usually set according to a schedule of increasing exposures. A schedule for acclimation and reacclimation is provided in Table 12–E.

An alternate method is to control the exposures to a level equivalent to the *Alert Limit*. This alternative approach requires more attention to the work methods and environment and is not routinely done.

Pacing of the work. Because work metabolism is an important contributor to heat stress, methods to reduce the rate of metabolism can go a long way toward reducing heat stress. The rate is reduced when the same amount of work is performed over a longer period of time. Any idle time inherent in the work should be spent in cooler areas to realize the full benefit.

For instance, many jobs have a fixed amount of work to be accomplished, and the workers are given an allotted time. The tendency in cool conditions is to work very fast and have the remaining time idle. The same pace in hot environments can cause excessive heat strain. So when the environment is hot, the work should be leveled out to reduce the rate of metabolism and the potential for excessive heat stress.

Sharing the work. Another way to reduce metabolism is to share or distribute the work among other workers. This may require some work to be delayed to another time. In scheduling the work, thought should be given on how to use the staff most efficiently and effectively. For instance, it may be possible that a worker can move between two crews during the same work period and still have an effect on reducing heat stress. Further, workers might straddle a work shift so that they work the second half of the day shift and the first half of the afternoon shift, when heat stress is most likely to be a problem.

Scheduling of work. An administrative control to reduce the contribution of environmental heat to heat stress is to schedule nonessential work at cooler times of day or during cooler periods.

Work times, self-determination, and personal monitoring. Preplanned work times, self-determination, and personal monitoring are ways to control a heat-stress exposure that is known to be high. Predetermined work times are assigned to a worker or crew before a job begins. They may extend the work time with the knowledge that heat stress will eventually affect their ability to work and there is a risk of heat-related disorder. The extension should be under the controls of self-determination aided by personal monitoring.

The purpose of self-determination with personal monitoring is to allow more heat-tolerant workers to work longer than less-tolerant ones by letting the worker stop an exposure. These kinds of administrative controls apply better to self-paced and nonroutine work, and may be more difficult to manage during externally paced work. Self-determination is best instituted as a periodic query to the individual workers about their subjective judgment of heat strain and their ability to continue. Because subjective decisions are unreliable, objective data on heat strain should be obtained from personal monitoring of body temperature and/or heart rate. In 2000, there are at least three electronic personal monitors designed for industrial use that are commercially available. One device examines body temperature through a measure of ear canal temperature, and the second examines both heart rate and body temperature (through a surface sensor). There is a third type that measures deep body temperature through an ingested "pill." The first two types are shown in Figure 12–10. There are also heart-rate monitors, and oral temperature devices suitable for occupational applications.

Personal protection. Personal protection is a control that provides protection for an individual worker. For heat stress, personal protection is primarily some form of personal cooling, but can include reflective clothing for high radiant heat conditions. Personal cooling systems, if chosen to match the job situation, can significantly increase the safe exposure time. When personal protection is used, conventional evaluation methods do not apply and work practices must be developed for the successful use of personal protection for heat stress.

Circulating air systems. Circulating air as a personal cooling method is achieved by circulating air under the clothing and around the torso. It requires the delivery of air to the individual either (1) through a high-pressure air line and a pressure reducer or (2) through a portable (self-contained) blower. Circulating air under the clothing effectively increases the amount of convective and evaporative cooling of the body. (Note: The circulating air must be breathing-grade air.)

While air-line systems can be used continuously for work that is relatively stationary, the technique can be used profitably by workers as temporary relief during pauses in the work. If there is a sufficient supply of compressed air, vortex devices can be used to significantly reduce the air temperature (on the order of a 10 C [18 F] reduction) going into the clothing.

Portable blower systems are just receiving attention. Because they use air in the work locale, they may not provide as much cooling capacity as air-line systems delivering the same volume flow rate.

Circulating water systems. A second type of personal cooling is a system that circulates cool water through tubes and channels around the body. There are a variety of systems available. First, systems range from those that can cover virtually the whole body to those that cover only portions of the back and chest. There are also portable versions as well

Figure 12–10. Photographs of two commercially available personal monitors developed for heat-stress exposures. (Courtesy of Metrosonics, Inc, and Quest Technologies.)

as versions with a heat sink that is connected to the person through a tether. The degree of cooling that can be achieved depends on surface area covered, rate of water circulation, and the capacity of the heat sink.

The selection of circulating water systems should be done in consultation with the vendors and someone very familiar with personal cooling in order to obtain a good match.

Ice garments. Several frozen-water (ice) garments, frequently called ice vests, are commercially available. They control heat strain by removing body heat via conduction from the skin to packets of ice. The typical vest weighs about 5 kg. The vests provide good mobility with some bulk around the torso. The ability to cool and service time depend on the rate of work, the amount of ice, and design of the garment. For a given amount of work, the time is limited by the ice. Service times up to two hours are reasonable from some models of ice vests.

Nonwater phase-change materials are also available in cooling garments. Appreciating that the service time depends on the total heat-absorbing capacity of the heat sink, a relative comparison can be made to ice vests by comparing the total heat of fusion of a nonwater system to 320 kcal in 4 kg of ice.

Reflective clothing. While personal cooling is designed to take up body heat, reflective clothing is designed to reduce the amount of heat reaching the individual. Reflective clothing is best suited for sources of high radiant heat. There is a trade-off with reflective clothing in that it reduces sweat evaporation. That means that the level of heat stress may actually increase if the reflective clothing is not selected to best match the source of radiant heat and the job.

Hot Surfaces, Hot Air, and Respirators

Work in hot environments usually means that there are hot surfaces with the accompanying potential to cause a burn. The potential for a burn (or to elicit pain at a somewhat lower level of heat transfer) depends on the thermal conductivity of the solid, the temperature of the solid, and the contact time with skin. Table 12–G provides approximate surface temperatures for common surfaces that may elicit pain or a burn with brief (1 s) contact time and burns with longer contact times. For prolonged contact, surface temperature is the dominant characteristic. To avoid tissue injury, the surface temperature should be less than 48 C (118 F) for up to 10 minutes of contact time and 43 C (109 F) for prolonged contact. There will be reports of extreme discomfort with surface temperatures greater than 38 C (100 F).

Sometimes there is a concern about the temperature of the air that is being breathed. If the wet bulb temperature of the air is less than 45 C (113 F), breathing the air is not likely to cause extreme discomfort or ill effects. There are laboratory observations of sustained breathing at wet bulb temperatures of 50 C (122 F) without complaint. Above these temperatures, the probability of individual discomfort will increase.

There is a frequently expressed concern about the effects of tight-fitting, full-face respirator facepieces on heat stress—usually that negative-pressure respirators increase the level of heat stress and that air-supplied respirators may give a false sense of cooling. There are small changes in the level of physiological response, but not enough that the heat-stress guidelines for evaluation described previously should be adjusted to account for respirator use. There is also no doubt that subjectively measured discomfort increases while wearing a respirator facepiece in hot environments, and this may affect performance.

COLD STRESS

Cold stress is fundamentally a different kind of problem than heat stress. While adaptive mechanisms (i.e., sweating and acclimation) are crucial during heat-stress exposures, the physiological adaptations to cold stress have less dramatic effects. The first physiological response to cold stress is to conserve body heat by reducing blood circulation through the skin. This effectively makes the skin an insulating layer. A second physiological response is shivering, which increases the rate of metabolism. Shivering is a good sign that the cold stress is significant and that hypothermia may be present. However, it is relatively weak as a protective mechanism. Behavior is the primary human response to preventing excessive exposure to cold stress. Behaviors include increasing clothing insulation, increasing activity, and seeking warm locations.

Insulation is a critical characteristic of clothing worn during cold-stress exposures. Clothing materials used for their insulating characteristics include cotton, wool, silk, nylon, down, and polyester insulation. Generally, the insulating value of clothing ensembles comes from layering clothes rather than having one garment. The further advantage of layers is that the person can add or remove layers to adjust for differing insulation needs during the work period.

The insulating value of clothing is greatly diminished by moisture. Sources of water are the work environment and sweat. Water-vapor permeability is also important. If sweat is allowed to evaporate through the clothing, it will not accumulate in the clothing. Once clothing becomes wet, it is important to replace it immediately.

Like layering, clothing ventilation is a valuable means to adjust the heat-transfer properties of the ensemble. During low levels of work, insulation demands are high; as the work rate increases, insulation must decrease to maintain thermal equilibrium. Besides removing layers, the effective insulation of the ensemble can be reduced by increasing the air movement under the clothing by increasing the clothing ventilation.

Table 12–G. *Limits on Surface Temperature (in degrees Centigrade) to Avoid Pain and Burns with Different Contact Periods Against Skin*

Material	*Pain (1 s)*	*Burn (1 s)*	*Burn (4 s)*	*Burn (10 min)*	*Burn (prolonged)*
Metals	45	65	60

Wood	75	115–140 (depends on dryness of wood)	95–120		
Any material				48	43

(Adapted from Eastman Kodak, 1983; Siekmann, 1990)

Hazards associated with cold stress are manifested in two distinct fashions: systemic (hypothermia) and local (localized tissue damage). There is also a concern for manual dexterity. The disorders related to cold stress exposures are described in Table 12–H.

As hypothermia progresses, depression of the central nervous system becomes more severe. This accounts for the progression of signs and symptoms from a sluggishness through slurred speech and unsafe behaviors to disorientation and unconsciousness. The ability to sustain metabolic rate and reduced skin blood flow is diminished by fatigue. Thus fatigue increases the risk of severe hypothermia through decreasing metabolic heat and increased heat loss from the skin. Because blood flow through the skin is reduced to conserve heat, the skin and underlying tissues are more susceptible to local cold injury.

Model of Thermal Balance

Systemic cold stress can be examined in terms of heat exchange.

$$S = M + (R + C) + K + E \qquad (13)$$

M is metabolic rate and represents a source of internal heat gain. $(R + C)$ is the combination of heat loss due to cooler air and surroundings. K is conduction to a solid surface in contact with the body. E is evaporative cooling by sweat evaporation; it has a negative value because the flow of heat is away from the body. Thermal equilibrium is established when $S = 0$.

M can be increased as a behavioral response to cold stress, and significant contributions to thermal balance are reductions in $(R + C)$ and K with behavioral adaptations like clothing and avoidance of cold environments. For a given level of clothing, the greater the work demands (greater metabolic rate) the greater the level of cold stress that can be tolerated.

The goal of systemic cold stress control is to avoid hypothermia by limiting the reduction in core temperature to 36 C (96.8 F) for prolonged exposures and to 35 C (95 F) for occasional exposures of short duration.

Table 12–H. *Cold-Related Disorders Including the Symptoms, Signs, Causes, and Steps for First Aid*

Disorder	*Symptoms*	*Signs*	*Causes*	*First Aid*
Hypothermia	Chills Pain in extremities Fatigue or drowsiness	Euphoria Slow, weak pulse Slurred speech Collapse Shivering Unconsciousness Body temperature <95 F (35 C)	Excessive exposure Exhaustion or dehydration Subnormal tolerance (genetic or acquired) Drug/alcohol abuse	Move to warm area and remove wet clothing Modest external warming (external heat packs, blankets, etc.) Drink warm, sweet fluids if conscious Transport to hospital
Frostbite	Burning sensation at first Coldness, numbness, tingling	Skin color white or grayish yellow to reddish violet to black Blisters Response to touch depends on depth of freezing	Exposure to cold Vascular disease	Move to warm area and remove wet clothing External warming (e.g., warm water Drink warm, sweet fluids if conscious Treat as a burn, do not rub affected area Transport to hospital
Frostnip	Possible itching or pain	Skin turns white	Exposure to cold (above freezing)	Similar to frostbite
Trench Foot	Severe pain Tingling, itching	Edema Blisters Response to touch depends on depth of freezing	Exposure to cold (above freezing) and dampness	Similar to frostbite
Chilblain	Recurrent, localized itching Painful inflammation	Swelling Severe spasms	Inadequate clothing Exposure to cold and dampness Vascular disease	Remove to warm area Consult physician
Raynaud's disorder	Fingers tingle Intermittent blanching and reddening	Fingers blanch with cold exposure	Exposure to cold and vibration Vascular disease	Remove to warm area Consult physician

Note: Hypothermia is related to systemic cold stress, and the other disorders are related to local tissue cooling.

Measurement of Cold Stress

Two climatic factors in the environment influence the rate of heat exchange between a person and the environment. These factors are air temperature and air speed. As the difference between skin and ambient temperatures increases and/or the air speed increases, the rate of heat loss from exposed skin increases. The rate of heat loss is approximated by Equation 14.

$$H = 1.16(10\,V_{air}^{\ 0.5} + 10.45 - V_{air})(33 - T_{db})(\mathrm{W/m^2}) \quad (14)$$

The *Equivalent Chill Temperature (ECT)* (also known as the *Wind Chill Index*) was developed by the U.S. Army to account for both air temperature and air speed based on empirical observations of the time for water to freeze. It has been updated by the National Weather Service. The recently published *Wind Chill Index* chart is shown in Table 12–I as it relates air temperature and speed.

Recognition

Subjective responses of workers are a good tool for recognition of cold stress in the workplace. If the workplace is generally described as cold, then cold stress may be present. Worker behaviors to cold stress exposures will generally be those that are seeking warm locations, adding layers of clothing or increasing the work rate. Other behaviors are loss of manual dexterity, shivering, accidents, and unsafe behaviors.

Using the first aid logs and other records, is there a pattern of signs and symptoms that might be attributed to hypothermia? A physiological marker is reduced core temperature, below 36 C (96.8 F).

If there is a noticeable drop in manual dexterity reported by workers or supervision, local cold stress is possible. In addition, if there is a pattern of cold-related disorders reported in the first aid logs, injury and illness logs, and workers compensation records, the work conditions should be evaluated.

Evaluation

WORKPLACE MONITORING

When temperatures fall below 16 C (61 F), workplace monitoring should be instituted. Below –1 C (30 F), the dry bulb temperature and air speed should be measured and recorded at least every four hours. When air speed is greater than 2 m/s (5 miles per hour, mph), the ECT should be determined from Table 12–I. When the ECT falls below –7 C (19 F), it should also be recorded.

Table 12–I. *National Weather Service Wind Chill Index in Degrees F for Different Combinations of Air Temperature and Air Speed (also known as the Equivalent Chill Temperature)*

Air Speed mph	Temperature [F]																		Air Speed m/s

Note: Cross-reference to metric units for air speed and temperature are provided.

SYSTEMIC COLD STRESS

Hypothermia can occur with air temperatures up to 10 C (50 F). The ACGIH recommends that the employer become involved with protective measures when air temperature is less than 5 C (41 F). Equation 15 can be used to approximate the amount of clothing insulation (I_{clo} in clo units, where 1 clo = 0.155 m^2 C / W) required for a specific task in a given air temperature (T_{db} in C) and metabolic rate (M in watts). Figure 12–11 illustrates the relationship among temperature, work rate, and clothing to maintain thermal equilibrium based on Equation 15.

$$I_{clo} = 11.5\,(33 - T_{db}) / M \qquad (15)$$

Remember that the clothing must be kept dry and that I_{clo} will change with different tasks and environments.

As the environmental conditions become very cold, rewarming periods should be provided. Specific rewarming schedules are provided in the TLV for Cold Stress® (see Appendix B, ACGIH Threshold Limit Values and Biological Exposure Indices, Cold Stress, Table 3). The maximum exposure time depends on air temperature and ambient air movement and is followed by a 10-minute warmup break. Reductions in the working time are recommended if the work rate is low to moderate, because internal heat generation will be lower. There is a point at which nonemergency work should not be performed.

LOCAL COLD STRESS

Skin cannot freeze until the air temperature is less than –1 C (30 F) and there is little risk of local cold injury associated with ECTs greater than –30 C (–22 F) (or heat loss rates less than 1750 W / m^2). The limiting surface temperature to protect exposed skin making incidental contact with the surfaces is –7 C (19 F). If the contact is prolonged (e.g., for tools), the limit is –1 C (30 F).

Manual dexterity of hands drops when there is uninterrupted work for 10–20 min at temperatures below 16 C (61 F).

General Controls

As with heat stress, general controls are actions that should be taken when workers may be exposed to cold stress. The general controls include training, hygiene practices, and medical surveillance.

TRAINING

When the air temperature may be below 5 C (41 F), the workers should be informed that cold stress may be a hazard, what is proper clothing, and that self-determination and cold stress hygiene should be practiced.

When work is performed at or below –12 C (10 F) ECT (Equivalent Chill Temperature), additional training topics include safe work practices and the recognition and first aid treatment of hypothermia and other cold-related disorders.

HYGIENE PRACTICES

Cold stress hygiene practices center around fluid replacement with warm, sweet, noncaffeinated drinks and self-determination. Warm drinks are palatable in cold stress and the fluid replacement is important because significant dehydration can

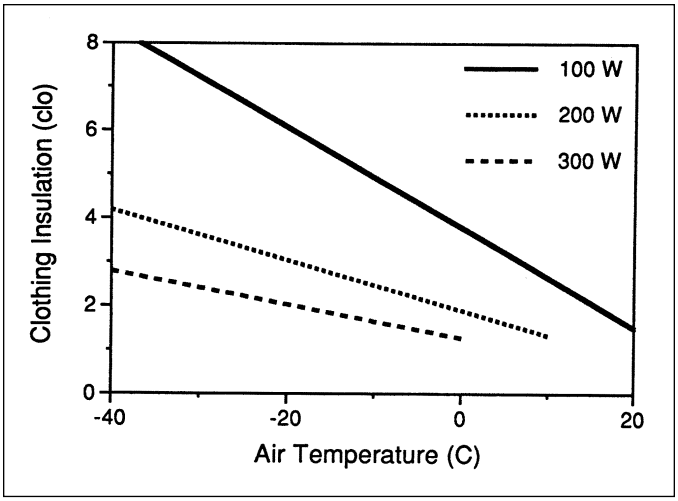

Figure 12–11. Estimation of clothing insulation (clo) required as a function of air temperature for different levels of work.

occur. Sweetened drinks provide a readily usable energy source to reduce the risk of fatigue. In addition, employees should be encouraged to eat a normal, balanced diet. If a worker experiences extreme discomfort or any of the symptoms of hypothermia (or any other cold-related disorder), the person should stop work and seek a place to rewarm.

Safe work practices include at least the following. In air temperatures below 2 C (36 F), anytime clothing becomes wet, it must be replaced immediately and the workers should be treated as if they are experiencing hypothermia. When handling liquids with boiling points below 4 C (39 F), special precautions should be taken that clothes do not become soaked in the liquid.

MEDICAL SURVEILLANCE

Medical certification is suggested for those who are routinely exposed below –24 C (–11 F) ECT. The certification should be based on a physical that considers fitness, weight, cardiovascular health, and other conditions that may affect cold-stress tolerance. Further, the personal-care physician should be consulted by any employee who is under care for chronic disease.

If there is reason to suspect that a person cannot properly thermoregulate, a medical restriction is appropriate in air temperatures below –1 C (30 F).

Specific Controls

ENGINEERING CONTROLS

Engineering controls attempt to reduce heat loss from the person as a whole or from exposed skin. Control includes increasing air temperature and decreasing air speed in the work zone, and providing rewarming areas. Specifically, engineering controls include the following:

- ➢ general or spot heating including hand warming
- ➢ hand warming for fine hand work below 16 C (61 F)
- ➢ minimize air movement (e.g., shielding, adjusting ventilation)
- ➢ reduce conductive heat transfer (e.g., no metal chairs or uninsulated tools)
- ➢ redesign equipment, process, etc. to control systemic and local cold stress
- ➢ provide warming shelters if exposures below –7 C (19 F)

ADMINISTRATIVE CONTROLS

Administrative controls attempt to reduce the exposure time, allow individual control over the work, and provide for mutual observation. Recommended administrative controls include the following:

- ➢ work/rest cycles
- ➢ schedule work to warmest times
- ➢ move work to warmer areas
- ➢ assign additional workers
- ➢ encouraging self-pacing and extra breaks if required
- ➢ buddy system, emphasizing mutual observation
- ➢ avoid long periods of sedentary effort
- ➢ allow for productivity reductions and extra effort from protective clothing
- ➢ provide an adjustment or conditioning period for new employees
- ➢ monitor weight changes for dehydration

PERSONAL PROTECTION

Because clothing is so important, personal protection is fundamental to managing cold stress. Clothing should be carefully selected in consultation with knowledgeable vendors and participation with the workers. The workers must be educated to the role of clothing items and what may compromise effectiveness. Some of these factors follow:

- ➢ properly selected insulated clothing
- ➢ wind-barriers
- ➢ special attention to feet, fingers, ears, nose and face
- ➢ gloves when air temperature is less than 16 C (61 F) for light work, 4 C (39 F) for moderate work and –7 C (19 F) for heavy work
- ➢ mittens when air temperature is less than –17 C (1 F)
- ➢ water-barriers to external liquids
- ➢ appropriate active warming systems (e.g., circulating air or liquids, electric)
- ➢ appropriate eye-protection for snow or ice-covered terrain

THERMAL COMFORT

Thermal comfort is "that condition of mind in which satisfaction is expressed with the thermal environment." Factors that affect thermal comfort include air temperature, humidity, air motion, surface temperatures, metabolic rate, and clothing. Age, sex, season, cultural background, and intraindividual variation play minor roles once the previously mentioned factors are accounted for. For instance, sex and seasonal changes in a comfortable environment can be

explained by differences in clothing. Factors that can disrupt a theoretically comfortable environment are asymmetric thermal radiation, drafts, vertical temperature gradients, and floor temperatures.

The ASHRAE Standard 55-1981 describes comfort zones based on operative temperature and humidity. These are illustrated in Figure 12–12. One zone is for the winter season and another, overlapping zone is for the summer season. The seasonal zones are specified to account for changes in clothing habits in the winter and summer. The operative temperature is approximately the globe temperature, and with little radiant heat it is the air (dry bulb) temperature.

Under ideal conditions, no more than 95 percent of the working occupants will be satisfied with the thermal environment. As the climatic conditions deviate from the "ideal," more people will be dissatisfied with the conditions. For those who wish to gain a better understanding of how a group of people will respond to an environment, the ISO has published a standard on thermal comfort. The standard considers such factors as climate, clothing, and metabolic rate.

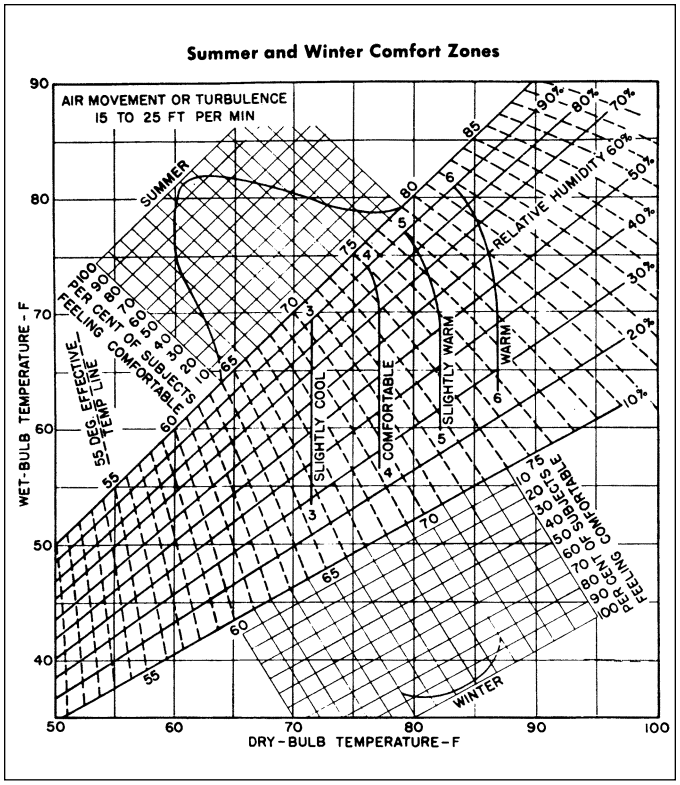

Figure 12–12. ASHRAE chart for comfort zones for sedentary activities. (Reprinted with permission from ASHRAE)

SUMMARY

This chapter was divided into three sections: heat stress, cold stress, and comfort. The heat stress and cold stress sections described methods to recognize that the stress may be present and significant in the workplace. Recognition is through types of work that are usually associated with the stress and the manifestations of disorders and worker behaviors due to the stress. Methods to evaluate the stress are then described with an emphasis on those recommended by the American Conference of Governmental Industrial Hygienists (ACGIH) in the documentation of the Threshold Limit Values® (TLVs) for Heat and Cold Stress. Controls for heat and cold stress are then described in terms of general controls and specific controls.

General controls are broadly applicable when there is a potential for an excessive exposure. General controls include training, hygiene practices, and medical surveillance. With regard to training, annual sessions within the format for other health and safety training is encouraged. The content should include the nature of the hazard, when and how it may occur, the physiological responses, recognition of disorders related to the stress, hygiene practices, and proper use of personal protection and other controls.

Specific controls are those controls that are appropriate to a specific job and are selected based on the job and site constraints. They include the traditional hierarchy of controls: engineering controls, administrative controls, and personal protection.

Finally, means to evaluate thermal comfort were described. The parameters in the evaluation can be manipulated in order to improve the degree of comfort in the work environment.

ACKNOWLEDGEMENT

While direct reference is not made, many ideas in this chapter have been adopted from sources in the bibliography.

Chapter
13

Ergonomics

by Karl H. E. Kroemer, PhD, CPE

The terms ergonomics *and* human factors *(including* human engineering *and* human-factors engineering*) are in essence synonymous. They all indicate the application of scientific principles, methods, and data to the development of engineering systems in which people play a significant role.*

The word ergonomics *was coined in 1950 in the United Kingdom by a group of physical, biological, and psychological scientists and engineers to describe their interdisciplinary efforts to design equipment and work tasks so that they fit the operator. The term is derived from the Greek-language word roots* ergon*, (human) work and strength, and* nomos*, indicating law or rule. In 1957, U.S. behavioral scientists, anthropometrists, and engineers working in this emerging discipline decided to call their new professional association the Human Factors Society. The words "and Ergonomics" were inserted in 1992.*

DEFINITION OF ERGONOMICS

Ergonomics is the study of human characteristics for the appropriate design of the living and work environment. Ergonomic researchers strive to learn about human characteristics (capabilities, limitations, motivations, and desires) so that this knowledge can be used to adapt a human-made environment to the people involved. This knowledge may affect complex technical systems or work tasks, equipment,

and workstations, or the tools and utensils used at work, at home, or during leisure times. Hence, ergonomics is human-centered, transdisciplinary, and application-oriented.

The goals of ergonomics range from the basic aim of making work safe through increasing human efficiency to the purpose of creating human well-being. The National Research Council (1983) stated that human factors engineering can be defined as the application of scientific principles, methods, and data drawn from a variety of disciplines to the development of engineering systems in which people play a significant role. We measure successful application by improved productivity, efficiency, safety, and acceptance of the resultant system design. The disciplines that can be applied to a particular problem include psychology, cognitive science, physiology, biomechanics, applied physical anthropology, and industrial and systems engineering. The systems range from the use of a simple tool by a consumer to multiperson-sociotechnical systems. They typically include both technological and human components.

The National Research Council said (1983): "Human factors specialists are united by a singular perspective on the system design process: that design begins with an understanding of the user's role in overall system performance and that systems exist to serve their users, whether they are consumers, system operators, production workers, or maintenance crews. This user-oriented design philosophy acknowledges human variability as a design parameter."

Figure 13–1 shows how ergonomics interacts with related applied disciplines and sciences. Among the primary foundations of ergonomics are the biological sciences, particularly anatomy and physiology. Leonardo da Vinci in the 16th century, Giovanni Alfonso Borelli in the 17th century, Lavoisier, Amar, Rubner, Johannson, and many others in the 19th and early 20th centuries contributed ideas, concepts, theories, and practical data to forward the understanding of the role of the human body in a work environment. Among the social and behavioral sciences, anthropologists, psychologists, and sociologists have contributed to modeling and understanding the human role in societal and technological systems, including management theories. Among the engineering disciplines, industrial engineers (using, for example, the groundwork laid by Frederick Taylor and the Gilbreths), mechanical and computer engineers, and designers are the major users of ergonomic knowledge. A typical application is in computer-aided design (CAD), which incorporates the systematic consideration of human attributes, especially anthropometric and biomechanical information. Ergonomists have developed their own theories, methods, techniques, and tools to perform scientific research. Formal college degree curricula are offered by many universities, usually in departments of industrial engineering or psychology. Productivity, health, and safety at work, the quality of work life, and participatory management are some well-known programmatic aspects of ergonomics.

There are three levels at which ergonomic knowledge can be used.

- ➢ *Tolerable* conditions do not pose known dangers to human life or health.
- ➢ *Acceptable* conditions are those upon which (according to the current scientific knowledge and under given sociological, technological, and organizational circumstances) the people involved can voluntarily agree.
- ➢ *Optimal* conditions are so well adapted to human characteristics, capabilities, and desires that physical, mental, and social well-being is achieved.

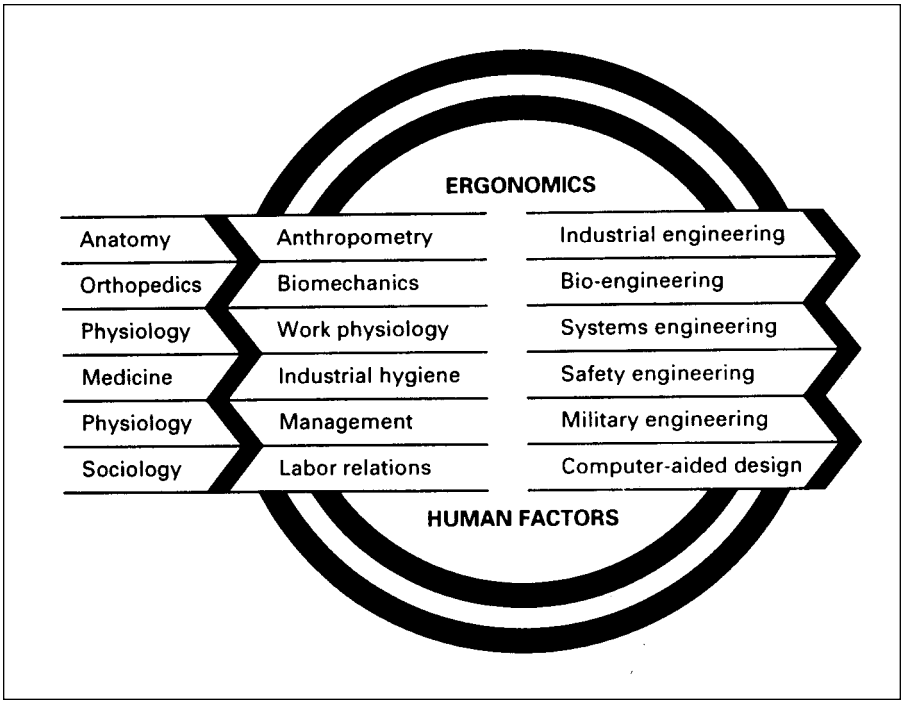

Figure 13–1. Origins and applications of ergonomics/human factors.

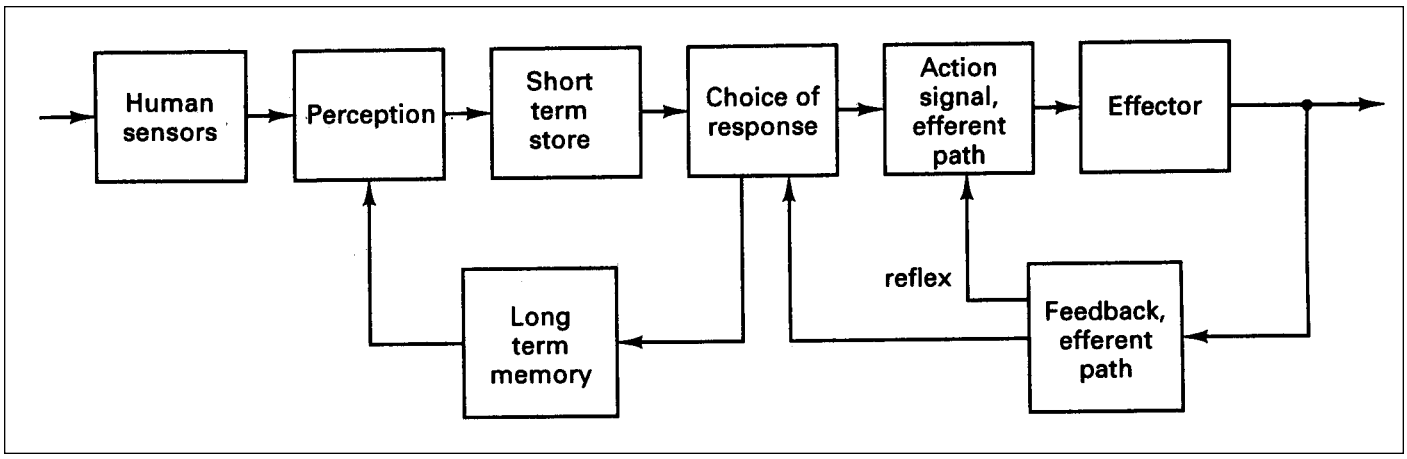

Figure 13–2. The human as energy or information processor. Adapted from Kroemer et al (2001), *Ergonomics: How to Design for Ease and Efficiency.* Upper Saddle River, NJ: Prentice-Hall. With permission by the publisher. All rights reserved.

The aim of ergonomics/human engineering is to achieve ease and efficiency at work.

MATCHING PERSON AND TASK

People perform widely differing tasks in daily work situations. These tasks must be matched with human capabilities to avoid *underloading*, in which human capabilities are not sufficiently used, as well as *overloading*, which may cause the employee to break down and suffer reduced performance capability or even permanent damage. Engineering psychologists, work physiologists, and occupational biomechanists evaluate the capacities and limitations of the worker to perform work; they also determine human tolerance to stresses produced by the environment.

THE HUMAN AS INFORMATION PROCESSOR

In the traditional system concept of engineering psychology, the human is considered a receptor and processor of information or energy, who then outputs information or energy. Input, processing, and output follow each other in sequence. The output can be used to run a machine, which may be a simple hand tool or a space craft. This basic model is depicted in Figure 13–2.

The actual performance of this *human-technology* system (in the past often called a man-machine system) is monitored and compared with the desired performance. Hence, feedback loops connect the output side with the input side. The difference between output and input is registered in a comparator, and corrective actions are taken to minimize any output/input difference. In this system, the human controls, compares, makes decisions, and corrects.

Affordance is the property of an environment that has certain values to the human. An example is a stairway that affords passage for a person who can walk but not for a person confined to a wheelchair. Thus, passage is a property of the stairway, but its affordance value is specific to the user. Accordingly, ergonomics or human engineering provides affordances.

Traditional engineering psychologists describe our activities as a linear sequence of stages, from perception to decision to response. Research is done separately on each of these stages, on their substages, and on their connections. Such independent, stage-related information is then combined into a linear model.

Ecological psychologists believe that this linear model is invalid; they consider human perception and action to be based on simultaneous rather than sequential information. This concept requires fundamentally new models of information, cognition, and performance assessment. Yet, current behavioral knowledge is still almost completely based on the traditional sequential-system concept.

The Nervous System

Anatomically, one divides the nervous system into the following three major subdivisions.

- ➢ The *central nervous system* (CNS) includes brain and spinal cord; it has primarily control functions.
- ➢ The *peripheral nervous system* (PNS) includes the cranial and spinal nerves; it transmits signals to and from the CNS, but usually does not control.
- ➢ The *autonomic nervous system* consists of the sympathetic and the parasympathetic subsystems, which regulate involuntary functions, such as of smooth and cardiac muscle, blood vessels, digestion, and glucose release in the liver. The autonomic system is not under conscious control.

Functionally, there are two subdivisions of the nervous system: the autonomic system (just discussed), and the *somatic* (Greek: *soma*, body) nervous system that controls mental activities, conscious actions, and skeletal muscle.

The brain is usually divided into *forebrain*, *midbrain*, and *hindbrain*. Of particular interest for the neuromuscular con-

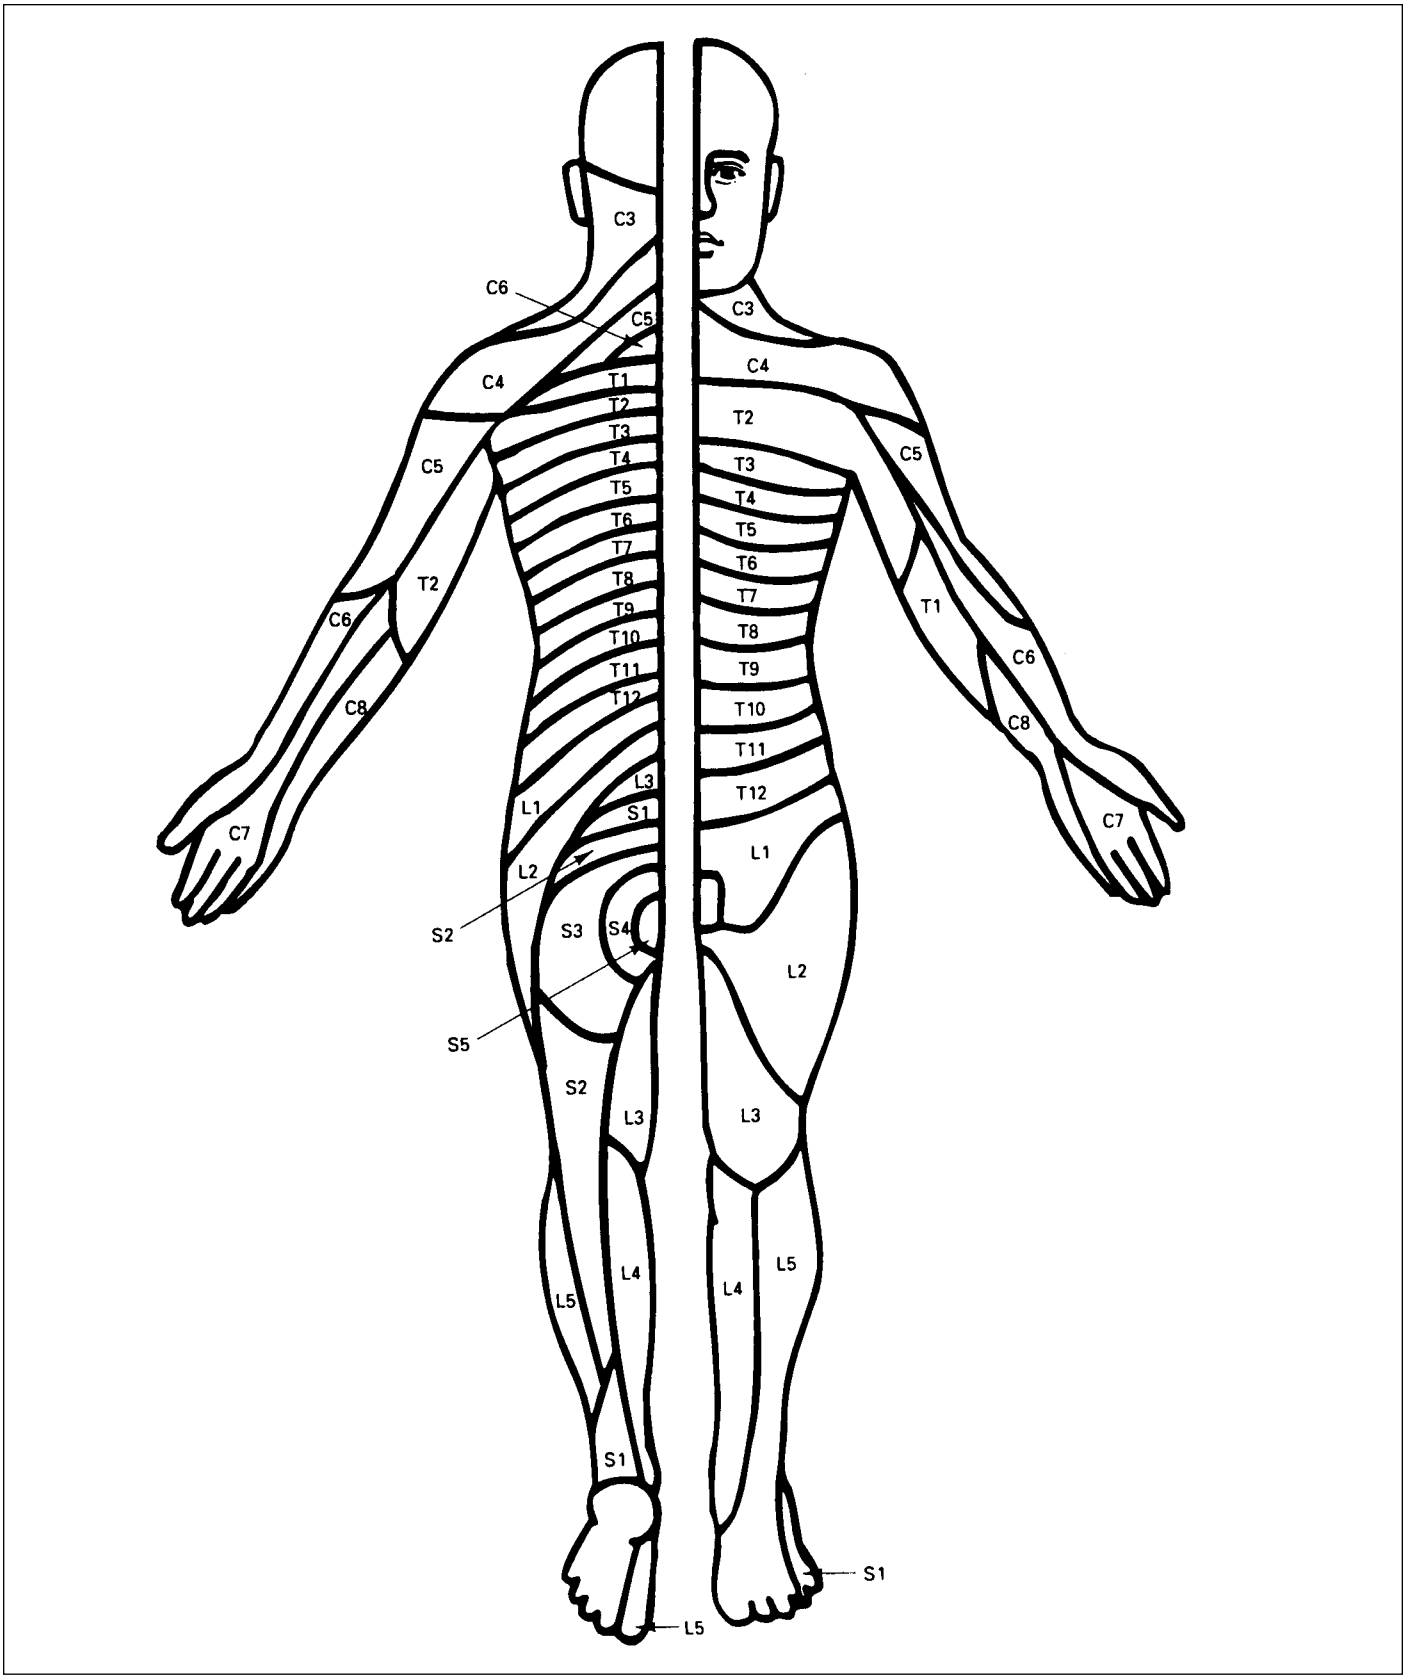

Figure 13–3. Regions of the body innervated by nerves eminating from sections of the spinal column. Adapted from Kroemer et al (2001), *Ergonomics: How to Design for Ease and Efficiency*. Upper Saddle River, NJ: Prentice-Hall. With permission by the publisher. All rights reserved.

trol system is the forebrain with the cerebrum, which consists of the two (left and right) cerebral hemispheres, each divided into four lobes. Control of voluntary movements, sensory experience, abstract thought, memory, learning, and consciousness is located in the cerebrum. The multifolded *cortex* enwraps most of the cerebrum. The cortex controls voluntary movements of the skeletal muscle and interprets sensory inputs. The *basal ganglia* of the midbrain are composed of large pools of neurons, which control semivoluntary complex activities such as walking. Part of the hindbrain is the *cerebellum*, which integrates and distributes impulses from the cerebral association centers to the motor neurons in the spinal cord.

The *spinal cord* is an extension of the brain. The uppermost section of the spinal cord contains the 12 pairs of *cranial nerves*, which serve structures in the head and neck, as well as the lungs, heart, pharynx, and larynx, and many abdominal organs. They control eye, tongue, and facial movements, and the secretion of tears and saliva. Their main inputs are from the eyes, the tastebuds in the mouth, the nasal olfactory receptors, and touch, pain, heat, and cold receptors of the head. Thirty-one pairs of *spinal nerves* pass out between the appropriate vertebrae and serve defined sectors of the rest of the body. Nerves are mixed sensory and motor pathways, carrying both somatic and autonomic signals between the spinal cord and the muscles, articulations, skin, and visceral organs. Figure 13–3 shows how the spinal nerves emanating from sections of the spinal column ("spinal nerve roots") innervate defined areas of the skin (*dermatomes*).

Sensors

The central nervous system receives information from internal receptors, *interoceptors*, which report on changes within the body; on digestion, circulation, excretion, hunger, thirst, sexual arousal, and feeling well or sick. *Exteroceptors* respond to light, sound, touch, temperature, electricity, and chemicals. Since all of these sensations come from various parts of the body (Greek, *soma*), external and internal receptors together are also called *somesthetic sensors*.

Internal receptors include the *proprioceptors*. Among these are the muscle spindles, nerve filaments wrapped around small muscle fibers that detect the amount of stretch of the muscle. Golgi organs are associated with muscle tendons and detect their tension, and hence report to the central nervous system information about the strength of contraction of the muscle. Ruffini organs are kinesthetic receptors located in the capsules of articulations. They respond to the degree of angulation of the joints (joint position), to change in general, and also to the rate of change.

The *vestibular sensors* are also proprioceptors. They detect and report the position of the head in space and respond to sudden changes in its attitude. To relate the position of the body to that in the head, proprioceptors in the neck are triggered by displacements between the trunk and head.

Another set of interoceptors, called *visceroceptors*, reports on the events within the visceral (internal) structures of the body, such as organs of the abdomen and chest, as well as on events within the head and other deep structures. The usual modalities of visceral sensations are pain, burning sensation, and pressure.

External receptors provide information about the interaction between the body and the outside: sight (vision), sound (audition), taste (gustation), smell (olfaction), temperature, electricity, and touch (taction). The sensations of touch, sight, and sound can be used as feedback to the body regarding the direction and intensity of muscular activities transmitted to an outside object. Free nerve endings, Meissner's and Pacinian corpuscles, and other receptors are located throughout the skin of the body, however, in different densities. They transmit the sensations of touch, pressure, and pain. Since the nerve pathways from the free endings interconnect extensively, the sensations reported are not always specific for a modality; for example, very hot or cold sensations can be associated with pain, which may also be caused by hard pressure on the skin.

Since the pathways of interoreceptors and externoreceptors are closely related and anatomically intertwined, information about the body is often integrated with information about the outside.

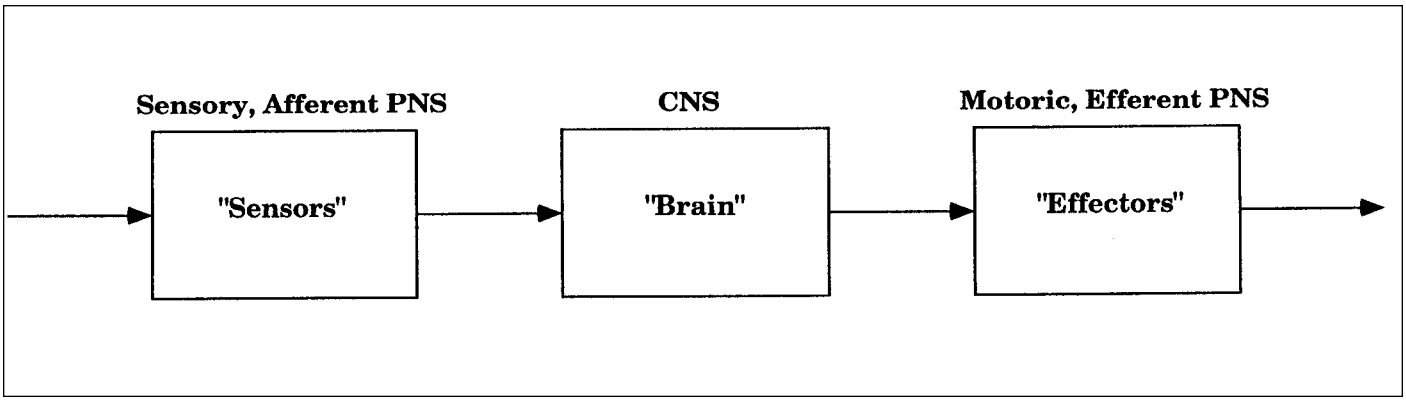

Figure 13–4. The human as receptor, processor, and generator of signals.

The "Signal Loop"

Following the traditional concept, one can model the human as a processor of signals in some detail, as shown in Figure 13–4. Information (energy) is received by a sensor and impulses sent along the afferent (sensory) pathways of the PNS to the CNS. Here, the signals are perceived and compared with information stored in the short-term or long-term memories. The signal is processed in the CNS and an action (including "no action") is chosen. Appropriate action (*feedforward*) impulses are generated and transmitted along the afferent (motor) pathways of the PNS to the *effectors* (voice, hand, etc.). Of course, many feedback loops exist.

Both sides of the processor model can be analyzed further, as shown in Figure 13–5. Information is provided by *distal stimuli*—but to be sensed, they must appear in a form to which human sensors can respond; it must have suitable qualities and quantities of electromagnetic, mechanical, electrical, or chemical energy. If the distal events do not present *proximal stimuli* that can be sensed directly, the distal information must be transformed into energy that can trigger human sensations. For this, *transducers* are designed by the human factors specialist: for example, a sound, a light, or a signal of some kind on a computer screen can serve as transducer.

On the output side, the actions of the human effector (such as hand, foot, or voice box) may directly control a machine or process, or one may need another transducer; for example, auxiliary power may amplify movement of a control effected by the human hand (e.g., "power steering" in an automobile). Figure 13–6 portrays the model. Of course, recognizing the need for a transducer and providing information for its suitable design is again a primary task of the human-factors engineer.

Responding To Stimuli

The time passing from the appearance of a proximal stimulus (for example, a light) to the beginning of an effector action (such as moving a foot) is called *reaction time*. The additional time to perform an appropriate movement (for instance, stepping on a brake pedal) is called *motion* or *movement* time. Motion time added to reaction time results in the *response time*. (Note that, in everyday use, these terms are often not clearly distinguished.)

Experimental analysis of reaction time goes back to the very roots of experimental psychology: many of the basic results were obtained in the 1930s, with additional experimental work done in the 1950s and 1960s. Innumerable experiments have been performed, hence, many tables of such times have been published. In engineering handbooks, some of these apparently have been consolidated from various sources; however, the origin of the data, the experimental conditions (for example, the intensity of the stimulus) under which they were measured, the measuring accuracy, and the subjects participating are no longer known.

The following table is typical of generally used but fairly dubious reaction time information, often applied without much consideration or confidence:

electric shock:	130 ms
touch, sound:	140 ms
sight, temperature:	180 ms
smell:	300 ms
taste:	500 ms
pain:	700 ms

While accepting the experience that, in real-life situations, the times may be considerably longer, there appears to be little difference in reactions to electrical, tactile, and sound stimuli. The slightly longer times for sight and temperature sensations may be well within the measuring accuracy, or within the variability among persons. However, the time following a smell stimulus is distinctly longer, and the time for taste again longer, while it takes by far the longest to react to the infliction of pain.

If a person knows that a particular stimulus will occur, is prepared for it, and knows how to react to it, the resulting reaction time (RT) is called *simple reaction time*. Its duration depends on the stimulus modality and the intensity of the stimulus. If one of several possible stimuli occurs, or if the person has to choose between several possible reactions, one speaks of "choice reaction time." *Choice reaction time* is a

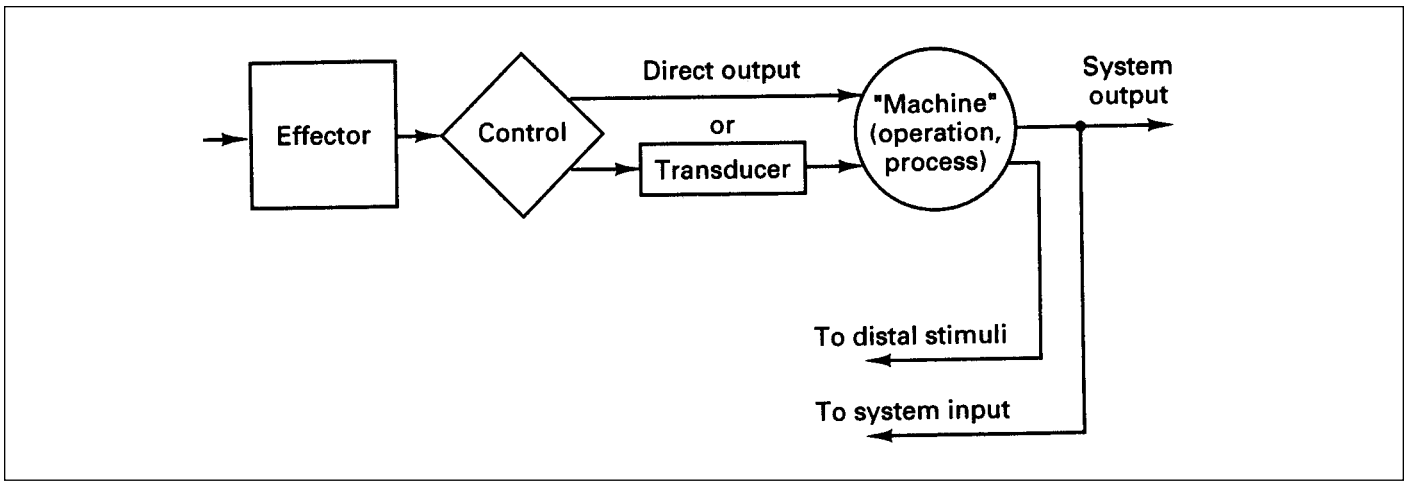

Figure 13–6. Effector outputs of the human, and feedback origins. Adapted from Kroemer et al (2001), *Ergonomics: How to Design for Ease and Efficiency*. Upper Saddle River, NJ: Prentice-Hall. With permission by the publisher. All rights reserved.

logarithmic function of the number of alternative stimuli and responses:

$$RT = a + b \log_2 N \quad (1)$$

with a and b empiric constants and N the number of choices. N may be replaced by the probability $p = 1/N$ *of any particular alternative:*

$$RT = a + b \log_2 p^{-1} \text{ (the Hick-Hyman equation)} \quad (2)$$

Under optimal conditions, simple auditory, visual, and tactile reaction times are about 0.2 seconds. If conditions deteriorate, such as uncertainty about the appearance of the signal, reaction slows. For example, simple reaction time to tones near the lower auditory threshold may increase to 0.4 seconds. Similarly, visual reaction time is dependent on intensity, size, and flash duration of the stimulus. Reactions to visual signals in the periphery of the visual field (such as 45 degrees from the fovea) are about 15 to 30 ms slower than to centrally located stimuli (Boff & Lincoln, 1988).

Reaction times of different body parts to tactual stimuli vary only slightly, within about 10 percent, for finger, forearm, and upper arm. Reaction time slows if it is difficult to distinguish between several stimuli that are quite similar, but only one should trigger the response. Also, reaction time increases if one has to choose between several possible responses to one signal—as described by the Hick-Hyman formula. Simple reaction time changes little with age from about 15 to 60 years, but is substantially slower at younger ages and slows moderately as one grows old.

Motion time follows reaction time. Movements may be simple, such as lifting a finger in response to a stimulus, or complex, such as swinging a tennis racket. Swinging the racket contains not only more complex movement elements, but also larger body and object masses that must be moved, which takes time. Movement time also depends on the distance covered and on the precision required. Related data are contained in many systems of time and motion analyses, often used in industrial engineering.

These relations have been expressed in a Motion Time (MT) equation called Fitts' Law:

$$MT = a + b \log_2 (2D / W) \quad (3)$$

D is the distance covered by the movement, and W is the width of the target. The expression $\log_2 (2D/W)$ is often called *Index of Difficulty*. The constants a and b depend on the situation, such as body parts involved, masses moved, tools or equipment used, on the number of repetitive movements, and on training.

The reduction of response time, the sum of the reaction and motion lags, is a common engineering goal. It can be achieved by optimizing the stimulus and selecting the body member that is best suited to the task. The best proximal signal is the one that is received quickly (primarily according to modality and intensity) and is different from other signals. Afferent and efferent transmission depend on the composition, diameter, and length of nerve fibers and on synaptic connections; practically, the ergonomist usually selects the shortest transmission distance. Yet the best chances for reducing delays are in the processing time needed in the central nervous system for perceptual tasks such as the detection, identification, and recognition of the signal and for cognitive tasks like deciding and planning. Thus, a clear signal leading to an unambiguous choice of action is the most efficient approach to reducing delays.

Choosing the most suitable body member for the fastest response includes making sure that the minimal segment mass must be moved. Thus, moving an eye is faster than moving a finger, which is faster than moving a leg.

HUMAN CAPACITY FOR WORK

Of course, individuals differ from each other in their capacities to perform tasks. Thus, the workload imposed by a given task differs from person to person; also, the workload may depend on the temporal state of an individual—for example on training, fatigue, and motivation.

The assessment of a workload, whether psychological or physical, commonly relies on the "resource construct." It assumes that there is a given (measurable) quantity of capability and attitude available, a known (or unknown) portion of which is demanded by the job. (See Figure 13–7.) Accordingly, workload is often defined as the portion of the maximal performance capacity that is expended in performing a given task.

Following this concept, one should obviously avoid any condition in which more is demanded from the operator than he or she can give. Otherwise, an *overload* condition results: the performance of the task will not be optimal and the operator is likely to suffer, physically or psychologically, from the overload. However, a task demand that is below the operator's capacity leaves a residual capacity. Its measurement provides an assessment of the actual workload. (Note that using too little of a person's capacity creates an *underload* with negative effects of its own, such as boredom.)

More complex models have been proposed—for example, a multiple-resource model in which separate reservoirs are postulated, such as for stages of information processing (afferent, central, and efferent), codes of processing (eg, verbal or spatial), and input/output modalities (visual, auditory or verbal, and manual).

Properties of Workload Measures

Metrics to assess workload should meet the following requirements.

- ➢ Diagnosticity: How precisely is the nature of the load revealed?
- ➢ Sensitivity: How well is a change in workload detected?
- ➢ Intrusiveness: Does the measurement interfere with task performance?
- ➢ Validity: Does the metric measure what it is supposed to?
- ➢ Reliability: Is the metric stable and consistent over time, i.e., repeatable?
- ➢ Operator acceptance
- ➢ Ease of use

Human Capacity for Mental Work

Common sense and general understanding make the distinction between physical (physiological) and mental (psychological) workload obvious and, in that juxtaposition, explain the meaning of both. Yet, as Tsang and Wilson (1997) state, there is no distinct, universally accepted definition of mental workload. In fact, its meaning has shifted and changed. During World War II, attention was of predominant interest, which was followed by concern about information processing and cognitive issues as human-operated systems became increasingly complex. With more internal automation, the system demands on the operator shifted to supervisory control responsibility, situation awareness and strategic task management. However, these concepts do not completely replace, nor totally encompass, each other. Criteria that have been developed for classic workload metrics also apply to measurement of situation awareness in complex environments, even though the two load concepts are not interchangeable.

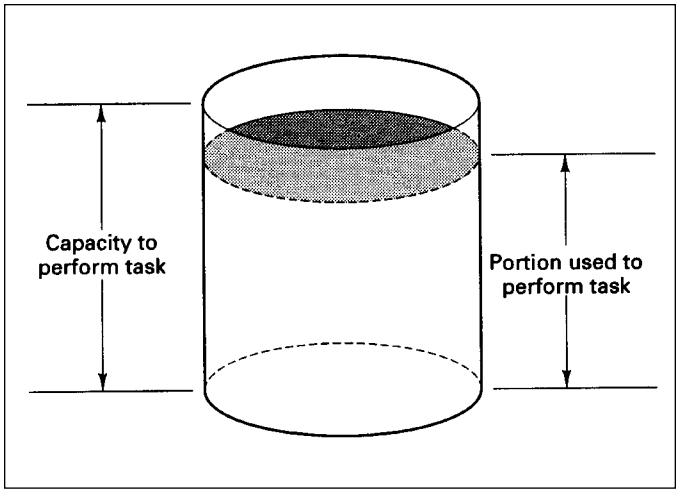

Figure 13–7. The "resource model". Adapted from Kroemer et al (2001), *Ergonomics: How to Design for Ease and Efficiency.* Upper Saddle River, NJ: Prentice-Hall. With permission by the publisher. All rights reserved.

Measuring Mental Workload

We can use four different approaches to empirically assess mental workload. Three rely on objective measures: of primary-task performance, of secondary-task performance, and of physiological events. The other measurement uses subjective assessments. Measures of task performance, as well as of subjective assessment, presume that both *zero* and *full* capacities are known, since they assess the portion of capacity loading.

The fourth empirical approach to measure workload relies on the measurement of the primary-task performance by observing how *noncritical* components of the primary task are performed. The hypothesis is that, as the workload increases, performance changes measurably. Candidates for such unobtrusive measures are the status of a person's speech, the depletion of stock, disorder, or clutter at the workplace, and the length of a line of customers. Such embedded measures of workload would not add to the task at hand. The following are examples of secondary tasks employed in measuring workload:

- ➢ Simple reaction time—draws on perceptual and response execution resources.
- ➢ Choice reaction time—same as for simple reaction time, but with greater demands.
- ➢ Tracking—requires central processing and motor resources, depending on the order of control dynamics.

- ➢ Monitoring of the occurrence of stimuli—draws heavily on perceptual resources.
- ➢ Short-term memory tasks—heavy demand on central-processing resources.
- ➢ Mathematics—draws most heavily on central-processing resources.
- ➢ Shadowing—subject repeats verbal or numerical material as presented: Heaviest demands on perceptual resources.
- ➢ Time estimations—(a) subject estimates time passed: Draws upon perceptual and central processing resources; (b) subject indicates sequence of regular time intervals by motor activity: Makes large demands on motor output resources.

Physiological measures, especially heart rate, eye movements, pupil diameter, and muscle tension can often be measured without intruding on the primary task. However, these measures may be insensitive to the task requirements or may be difficult to interpret.

Subjective assessments are a common means to assess mental workload. Humans are able to internally integrate the demands of the task, and to make statements about the perceived demand, often in terms of ratings and rankings. However, the subjective assessment of the perceived workload may be unreliable, invalid, or inconsistent with other performance measures. If subjective measures are taken after the task has been completed, they are not real-time evaluations; on the other hand, if performed during the task, they may intrude on the task.

Several pragmatic measures of the workload have been widely used, even though they have been criticized on both theoretical and technical grounds (Tsang & Wilson 1997). Prominent among them are the modified Cooper-Harper scale (Wierwille et al, 1985), the overall workload scale (OW, Tsang & Wilson 1997), the NASA task load index (TLX, Hart & Staveland 1988), and the subjective workload assessment technique (SWAT, Colle & Reid 1998). The first two are unidimensional rating scales; the last two are subjective techniques using multidimensional scales. While there are good theoretical and statistical reasons for using the TLX, SWAT, and OW, they are more complex to administer than the Cooper-Harper scale, which is fairly self-explanatory.

Human Capacity for Physical Work

An individual's capacity for physical work is usually determined by the limits of his or her respiratory and cardiovascular systems to deliver oxygen to the working muscles, and by the limits of the metabolic system to use chemically stored energy to do muscular work. *Maximal oxygen uptake* often is used to describe the upper limit of the aggregate capacity. Tolerance times for maximal efforts are measured in hours and minutes, even in seconds for a sprint runner. In a modern industrial setting, maximal effort may be required for brief periods, such as when an employee must heave heavy loads onto a hand truck; but during an eight-hour shift, the average energy required usually falls well below human peak capacity.

The biochemical steps to transform foodstuffs into energy available for work are quite complex; some are anaerobic, but, altogether, the process is aerobic. Consequently, measurement of the volume of oxygen consumed provides an overall index of energy consumption and hence of the energy demands of work. Use of one liter (L) of oxygen yields approximately five kilocalories (kcal or Cal; equivalent to about 21 kiloJoules, kJ). To put oxygen consumption and energy demands into proper perspective, consider that a trained athlete may reach a maximal oxygen uptake of 6 L/min. Aside from a person's physique and training, age and gender influence the oxygen intake capacity substantially. Men in their 20s have an average maximal capacity of 3–3.5 L/min; women of the same age have an average capacity of 2.3–2.8 L/min. At age 60, the capacities commonly diminish to about 2.2–2.5 L/min for men, and 1.8–2.0 L/min for women. As with most physiological characteristics, there is considerable individual variability.

Energy Cost of Work

Industrial jobs seldom demand continuous energy expenditure close to the maximum over the course of a workday. Rest pauses, fetching tools, mopping the brow, and receiving instruction reduce the average energy expenditure considerably. Table 13–A lists several typical activities and their average metabolic costs; resting values are included for reference. The given values must be adjusted according to one's body weight; the table applies to a man of 70 kg (155 lb). Other tables published in the physiological literature may be in different units (Calories, Joules, Btu; per hour or minute), and may or may not include basal rates—be careful to use these tables correctly.

Many jobs consist of intermittent tasks of different energy requirements. The total metabolic expenditure for the job may be calculated using the following formula:

$$M = M_1 t_1 + M_2 t_2 + \ldots M_n t_n \qquad (4)$$

In this formula, M is the total metabolic energy cost, $M_1 \ldots Mn$ are the metabolic costs of individual tasks; $t_1 \ldots tn$ indicate the durations of each individual task. Using the values listed in Table 13–A, an example of estimating energy expenditures during the day is shown in Table 13–B.

There is close interaction between the human circulatory and metabolic systems. Nutrients and oxygen must be brought to the working muscles and metabolic by-products removed from them to ensure proper functioning. Therefore, heart rate (which is an important indicator of circulatory functions) and oxygen consumption (representing the metabolic processes taking place in the body) have a linear and reliable relationship in the range between light and heavy work. (However, when very light work or extremely heavy work is done, that relationship may not be stable. It is also not reliable under severe environmental conditions or when workers are under mental stress.) Assuming such a linear relationship, one can often simply substitute heart-rate

Table 13–A. ***Metabolic Energy Costs of Several Typical Activities***

Activity	*kcal/h*	*Btu/h*
Resting, prone	80–90	320–360
Resting, seated	95–100	375–397
Standing, at ease	100–110	397–440
Drafting	105	415
Light assembly (bench work)	105	415
Medium assembly	160	635
Driving automobile	170	675
Walking, casual	175–225	695–900
Sheet metal work	180	715
Machining	185	730
Rock drilling	225–550	900–2,170
Mixing cement	275	1070
Walking on job	290–400	1,150–1,570
Pushing wheelbarrow	300–400	1,170–1,570
Shoveling	235–525	930–2,070
Chopping with axe	400–1,400	1,570–5,550
Climbing stairs	450–775	1,770–3,070
Slag removal	630–750	2,500–2,970

Values are for a male worker of 70 kg (154 lb). (Reprinted with permission from "Ergonomics guide to assessment ot metabolic and cardiac costs of physical work." *American Industrial Hygiene Association Journal,* 32: 560–564, 1971.)

recording for measurement of oxygen consumption. This is a very attractive shortcut, since heart rate can be recorded rather easily. Heart rate reacts faster to work demands and therefore more easily indicates quick changes in body functions due to changes in work requirements.

The simplest technique for heart-rate assessment is to palpate an artery, often in the wrist. The measurer counts the number of heartbeats over a given period of time—such as 15 seconds—and then calculates the average heart rate per minute. More refined methods use various plethysmographic techniques, which rely on the deformation of tissue that results when imbedded blood vessels fill with blood with each pulse. More expensive techniques rely on electric signals that are associated with the contractions of the heart. When using this technique, electrodes are usually placed on the person's chest.

Instead of measuring a person's reactions to actual job loads, it is often desired to determine the individual's capabilities using standardized loadings in the laboratory. Bicycle ergometers, treadmills, or steps are commonly used to simulate stressful job demands. The reactions of the individual in terms of oxygen consumption, heart rate, and blood pressure are used to assess that person's ability to meet or exceed such demands. However, the examining physician needs to know what the actual work demands are. The industrial hygienist may be called upon to help in the assessment of the existing work demands.

For more information on the assessment of physical work capacity and of energy cost of work, consult the texts by Astrand and Randahl (1986), Eastman Kodak (1983, 1986), Bernhard and Joseph (1994), Kinney (1980), Kroemer et al (1997, 2001), Mellerowicz and Smodlaka (1981), and the *Ergonomics Guides* published by the American Industrial Hygiene Association (AIHA).

Table 13–B. ***Example of Energy Expenditure During Leisure and at Work***

		Energy Cost	
Activity	*Duration (h)*	*kcal/h*	*kcal/Duration*
Sleeping	8	85	680
Sitting, resting	4.5	100	450
Walking	1.5	170	255
Driving automobile	1	200	200
Subtotal for leisure	15		1,585
Work, light assembly	7	105	735
Work, walking	1	200	200
Work breaks, sitting	1	100	100
Subtotal for work	9		1,035
Total per day	24		2,620

Classification of Work

The work demands listed in Table 13–C are rated from light to extremely heavy in terms of energy expenditure per minute, and the relative heart rate in beats per minute is also given. Light work is associated with rather small energy expenditures and is accompanied by a heart rate of approximately 90 beats/min. At this level of work, the energy needs of the working muscles are supplied by oxygen available in the blood and by glycogen in the muscle. There is no buildup of lactic acid or other metabolic by-products that would limit a person's ability to continue such work.

At medium work, which is associated with about 100 heart beats/min, the oxygen required by the working muscles is still covered, and lactic acid developed initially at the beginning of the work period is re-synthesized to glycogen during the activity.

In heavy work, during which the heart rate is about 120 beats/min, the oxygen required is still supplied if the person is physically capable to do such work and specifically trained

Table 13–C. ***Classification of Light to Heavy Work According to Energy Expenditure and Heart Rate***

Classification	*Total Energy Expenditure (kcal/min)*	*Heart Rate (beats/min)*
Light work	2.5	90 or less
Medium work	5	100
Heavy work	7.5	120
Very heavy work	10	140
Extremely heavy work	15	160 or more

in this job. However, the lactic acid concentration produced during the initial phase of the work is not reduced but remains high until the end of the work period. The concentration returns to normal levels after cessation of the work.

In the course of light, medium, and, if the person is capable and trained, even heavy work, the metabolic and other physiological functions can attain a steady-state condition during the work period. This indicates that all physiological functions can meet the demands and will remain essentially constant throughout the duration of the effort.

However, no steady state exists in the course of very heavy work, during which the heart rate level attains or exceeds 140 beats/min. In this case, the original oxygen deficit incurred during the early phase of the work increases throughout the duration of the effort and metabolic by-products accumulate. This accumulation makes intermittent rest periods necessary, sometimes even forcing the person to stop this effort completely. At even higher energy expenditures, which are associated with heart rates of 160 beats/min or more, the lactic acid concentration in the blood and the oxygen deficit achieve such magnitudes that frequent rest periods are needed. Even highly trained and capable persons are usually unable to perform such a demanding job throughout a full working day.

Hence, energy requirements or heart rate allow one to judge whether a job is energetically easy or hard. Of course, such labels as light, medium, or heavy reflect judgments of physiological events (and of their underlying job demands) that rely very much on the current socioeconomic concept of what is comfortable, acceptable, permissible, difficult, or excessive.

Rating the perceived effort is another way to classify work demands. We are all able to perceive the strain generated in our body by a given work task and we can make absolute and relative judgments about this perceived effort. Around the middle of the 19th century, Weber and Fechner described models of the relationship between physical stimulus and the perceptual sensation of that stimulus, i.e., the *psychophysical correlate*. Weber suggested that the "just noticeable difference" that can be perceived increases with the absolute magnitude of the physical stimulus *I:*

$$\Delta I = \alpha \bullet I \qquad (5)$$

with α a constant.

In the 1950s, Stevens at Harvard and Ekman in Sweden introduced ratio scales, which assume a zero point and equidistant scale values. These scales have since been used to describe the relationships between the perceived intensity and the physically measured intensity of a stimulus in a variety of sensory modalities (e.g., related to sound, lighting, and climate) as follows:

$$P = \beta .\ I^n \qquad (6)$$

where β is a constant, and n ranges from 0.5–4.

Since the 1960s, Borg and his co-workers have modified these relationships to take deviations from previous assumptions (such as zero point and equidistance) into account and to describe the perception of different kinds of physical efforts (Borg, 1982, 1990). Borg's "general function" is as follows:

$$P = a + c\ (I + b)^n \qquad (7)$$

In the formula, the constant a represents "the basic conceptual noise" (normally less than 10% of I), and the constant b indicates the starting point of the curve; c is a conversion factor that depends on the type of effort.

Ratio scales indicate proportions between percentages but do not indicate absolute intensity levels; they neither allow intermodal comparisons nor comparisons between intensities perceived by different individuals. Borg has tried to overcome this problem by assuming that the subjective range and intensity level are about the same for each subject at the level of maximum intensity. In 1960, this led to the development of a category scale for rating the perceived exertion (RPE). The scale ranges from 6 to 20 and matches heart rates from 60–200 beats/min. A new category begins at every second number. Borg (1990) claims that his General Scale is a category scale with ratio properties that could yield ratios, levels, and allow comparisons but still retain the same high correlation with heart rate as the 1960 scale. Table 13–D shows Borg's General scale.

The instructions for the use of the scale are as follows (modified from Borg's publications): While the subject looks at the rating scale, the experimenter says, "I will not ask you to specify the feeling, but do select a number that most accurately corresponds to your perception of [specific symptoms]. If you don't feel anything, for example, if there is no [symptom], you answer zero—nothing at all. If you start feeling something, just about noticeable, you answer 0.5—extremely weak, just noticeable. If you have an extremely strong feeling of [symptom], you answer 10—extremely strong, almost maximal. This would be the absolute strongest you have ever experienced. The more you feel—the stronger the feeling—the higher the number that you choose. Keep in mind that there are no wrong numbers; be honest, and do not overestimate or underestimate your ratings. Do not think of any other sensation than the one I ask you about. Do you have any questions?"

Let the subject get well acquainted with the rating scale before the test. During the test, let the subject do the ratings toward the end of every work period, i.e., about 30 seconds before stopping or changing the workload. If the test must be stopped before the scheduled end of the work period, let the subject rate the feeling at the moment of stoppage.

Work/Rest Cycles

If a task demands more of the worker than can be sustained, rest pauses must be taken. A general principle governing the schedule of work/rest cycles is to break up excessively heavy

Table 13–D. ***Borg's "General" RPE Scale (Ratings of Perceived Exertion CR-10)***

The Borg General Scale (1980)
0—nothing at all
0.5—extremely weak (just noticeable)
1—very weak
2—weak (light)
3—moderate
4—somewhat strong
5—strong (heavy)
6
7—very strong
8
9
10—extremely strong (almost maximal)
11 or higher–the individual's maximum

(The terms "weak" and "strong" may be replaced by "light" and "hard," respectively).

work into bouts of work that are as short as is practical for the task at hand. Frequent short rest periods reduce cumulative fatigue better than a few long breaks. The worst procedure is to let the worker go home early, exhausted.

A formula has been used to estimate the percentage of time that should be allotted to rest:

$$T_{rest}\,(\%) = \frac{M_{max} - M}{M_{rest} - M} 100 \qquad (7)$$

In the formula, T_{rest} is the percentage of rest time; M_{max} is the upper limit of the metabolic cost for sustained work; M is the metabolic cost of the task; and M_{rest} represents the resting (sitting) metabolism.

For example, suppose that M_{max} equals 350 kcal/h; and that an average value for M_{rest} is 100 kcal/h. Then assume that the task requires 525 kcal/h, which is obviously too high. Apply these values to the formula as follows:

$$T_{rest}\,(\%) = \frac{350 - 525}{100 - 525}\,100 = \frac{-175}{-425}\,100 = 41\% \qquad (8)$$

Thus, for this kind of work, rest pauses should be scheduled to last a total of 41 percent (24 min) of the hour.

As an alternative to the idle-rest pause, one may consider intermingling a light task with the heavy task. To calculate the proportion of time that should be allocated to the two tasks, consider a heavy task that requires 500 kcal/h, interrupted by a light task that requires 250 kcal/h. Again, assume that M_{max} equals 350 kcal/h.

$$T_{light\ task}\,(\%) = \frac{350 - 500}{250 - 500}\,100 = \frac{-150}{-250}\,100 = 60\% \qquad (9)$$

Accordingly, the hard work could consume 40 percent of the time, the light task 60 percent. The light, secondary work task thus actually constitutes rest time from the heavy, primary task. Sharpening tools or walking to get material or cleaning the work place can provide productive respites from heavy work.

Fatigue

If the energetic work demands exceed about half the person's maximal oxygen uptake, anaerobic energy-yielding metabolic processes play increasing roles. Anaerobic metabolism results in accumulations of potassium and lactic acid, believed to be the primary reasons for muscle fatigue, that forces the muscle to stop working. The length of time during which a person endures anaerobic work depends on the person's motivation and will to overcome the feeling of fatigue. The sense of fatigue usually coincides with the depletion of glycogen deposits in the working muscles, a drop in blood glucose, and an increase in blood lactate. However, the processes involved are not fully understood, and highly motivated subjects may maintain work that requires very high oxygen uptake for many minutes, while others feel that they must stop after just a brief effort.

Fatigue is operationally defined as a reduced muscular ability to continue an existing effort. The phenomenon of fatigue is best researched in regard to maintained static (isometric) muscle contraction. If the effort exceeds about 15 percent of a maximal voluntary contraction (MVC), blood flow through the muscle is reduced—even cut off in a maximal effort—in spite of a reflex increase in systolic blood pressure. Insufficient blood flow brings about an accumulation of potassium ions and depletion of extracellular sodium in the extracellular fluid. Combined with an intracellular accumulation of phosphate (from the degradation of ATP), these biochemical events perturb the coupling between nervous excitation and muscle-fiber contraction. This uncoupling of CNS control and muscle action signals the onset of fatigue. The depletion of ATP or creatine phosphate as energy carriers, or the accumulation of lactate, once believed the reasons for fatigue, also occur also but are not the primary reasons. Also, the increase in the number of positive hydrogen ions resulting from anaerobic metabolism causes a drop in intramuscular pH, which then inhibits enzymatic reactions, notably those in the breakdown of ATP (Kahn & Monod 1989).

When severe exercise brings about a continuously growing oxygen deficit and an increase in lactate content in the blood because of anaerobic metabolic processes, a balance between demand and supply cannot be achieved; no steady state exists, and the work requirements exceed capacity levels. The resulting fatigue can be counteracted by the insertion of rest periods. Given the same ratio of "total resting time" to "total working time," many short rest periods have more recovery value than a few long rest periods.

Avoiding fatigue:

- ➢ Allows short bursts of dynamic work and avoids long periods of static effort.
- ➢ Keeps energetic work and muscle demands low.
- ➢ Encourages taking many short rest pauses; this is better than taking a few long breaks.

The subjective sensation of fatigue is feeling tired. When tired, a person has reduced capability and desire for either physical or mental work, and feels heavy and sluggish. The sensation of fatigue has a protective function similar to hunger and thirst. Feeling fatigued forces one to avoid further stress and allows recovery to take place.

Subjective feelings of lowered motivation and deteriorated mental and physical activities may result from fatigue. Fatigue may occur together with monotony, a sensation associated with the lack of stimuli. Fatigue-induced low performance can be completely restored to its full level by rest.

The most important factors that produce fatigue are: physical work intensity (static and dynamic work); illness, pain, lack of rest (sleep), and poor eating habits; and psychological factors—worry, conflict, and possibly monotony. Hence, many different sources can be responsible for the sensation and the state of fatigue, which may be the result of an accumulation of effects stemming from various sources.

ENGINEERING ANTHROPOMETRY

Anthropometry literally means "measuring the human," traditionally in metric units, of heights, breadths, depths, and distances—all straight-line, point-to-point measurements between landmarks on the body and/or reference surfaces. Also, curvatures and circumferences following contours are measured, as is weight.

For the measurement, the body is placed in one of two defined postures with body segments at 180 degrees or 90 degrees with respect to each other. In one standard posture, the subject is required to stand erect; heels together, buttocks, shoulder blades, and back of head touching the wall; arms vertical (or extended straight forward), fingers straight. This is similar to the so-called anatomical position. The second standard posture is employed when measurements are taken on a seated subject. The (flat and horizontal) surfaces of seat and foot support are so arranged that the thighs are horizontal, the lower legs are vertical, and the feet are flat on their support. The subject is nude, or nearly so, and unshod. Figure 13–8 shows reference planes and descriptive terms often used in anthropometry. Figures 13–9 and 13–10 show important anatomical landmarks of the human body. The NASA-Webb *Anthropometric Sourcebook* (1978) contains much information on measurement techniques in general and on military anthropometric data in particular. More recent publications by Gordon, Churchill, Clauser et al (1989), Kroemer, Kroemer, and Kroemer-Elbert (1997, 2001), Lohman, Roche, and Martorel (1988), and Roebuck (1995) condense and update this information.

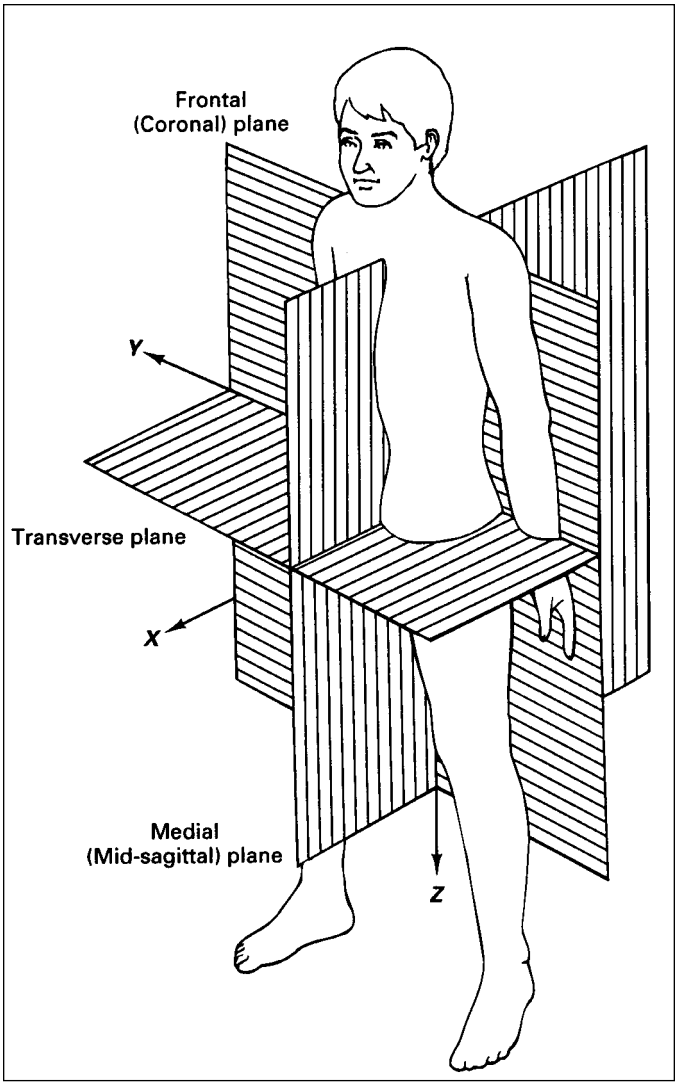

Figure 13–8. Measuring planes and terms used in anthropometry. Adapted from Kroemer et al (2001), *Ergonomics: How to Design for Ease and Efficiency.* Upper Saddle River, NJ: Prentice-Hall. With permission by the publisher. All rights reserved.

The existing anthropometric information has been gathered while the subjects assume highly stylized and standardized postures.These postures are quite different from the body positions assumed while working, particularly when the worker is moving around. Hence, the ergonomic designer for practical applications must interpret current data.

Body-build typologies (somatotypes), such as those developed by Kretschmer, Sheldon, or Heath-Carter, have neither proven to be suitable for engineering anthropometry, nor are they reliable predictors of attitudes, physical capabilities, or limitations relative to performance in industrial systems. Hence, somatotyping is of little or no value for engineers or managers.

Civilian Body Dimensions

The anthropometric literature abounds with data on military personnel. No large and reliable surveys of the complete U.S.

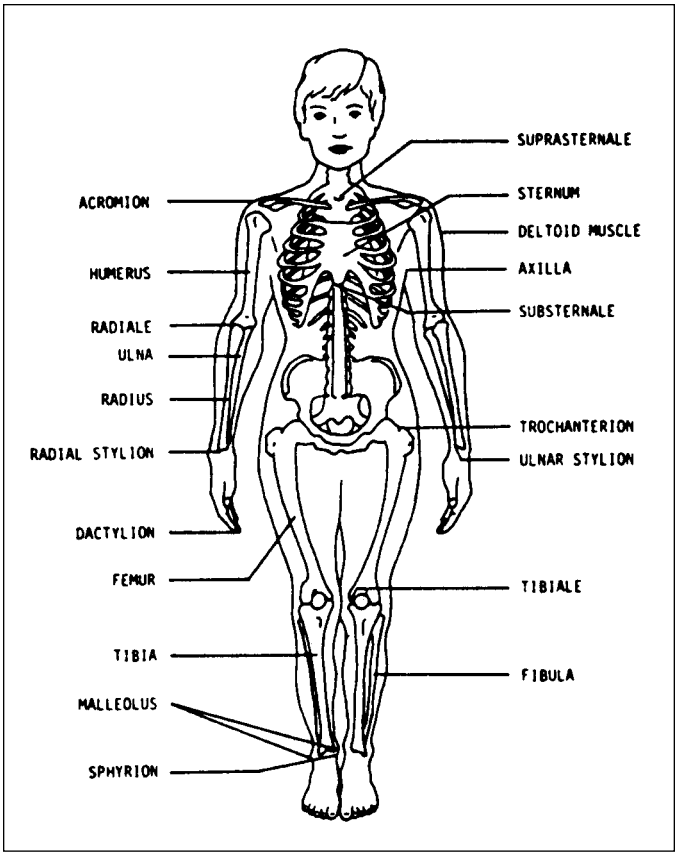

Figure 13–9. Landmarks on the human body in the frontal view.

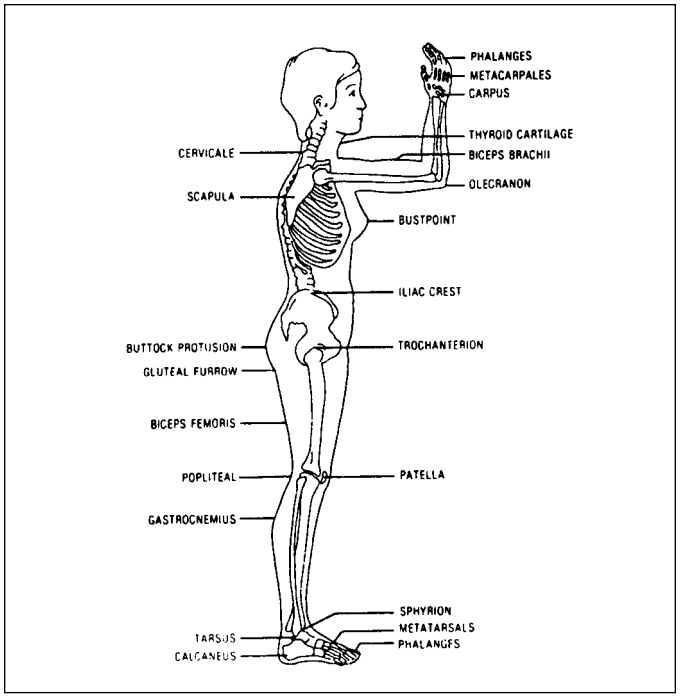

Figure 13–10. Landmarks on the human body in the lateral view.

civilian population have been performed during recent decades. Hence, anthropometric data applied describing the body sizes of the civilian population are taken from those of soldiers who are generally young and healthy. Head, hand, and foot dimensions are the same for soldiers and civilians; and the other body dimensions measured in the (latest) 1988 survey of the U.S. Army (Gordon, Churchill, Clauser et al, 1989) compare well with the few data available on the working population (Marras & Kim, 1993). Yet body weight is distinctly different between soldiers and civilians; civilians have more extreme values. An up-to-date compilation of estimated civilian body dimensions is presented in Table 13–E. This table shows the 5th, 50th, and 95th percentile dimensions as well as the standard deviations. Assuming a normal distribution of the data, the 50th percentile coincides with the mean (average) value.

Anthropometric Statistics

Fortunately, anthropometric data are usually dispersed in a reasonably normal (Gaussian) distribution (with the occasional exception, especially of muscle strength data). Hence, regular parametric statistics apply in most cases. The data cluster in the center of the set at the 50th percentile, which coincides with the mean m (the average). The peakedness or flatness of the data cluster is measured by the standard deviation. The commonly used formulae to calculate the most often needed statistical descriptors of normal distributions follow.

A normally distributed set of n data is described by two simple statistics:

The *50th percentile* is by definition the same as the mean m (also commonly called average):

$$m = \sum x/n \tag{10}$$

where $\sum x$ is the sum of the individual measurements.

The *Standard Deviation (SD)* describes the distribution of the data:

$$SD = [\sum (x-m)^2/n-1]^{1/2} \tag{11}$$

It is often useful to describe the variability of a sample by dividing the standard deviation SD by the mean m. The resulting

Coefficient of Variation (CV) (in percent) is:

$$CV = 100\ SD\ /\ m \tag{12}$$

A percentile value p of a normal distribution is calculated by multiplying the standard deviation SD by a factor k, selected from Table 13–F. Then subtract the product from the mean m if p is below the mean:

$$p = m - k\ SD \tag{13}$$

36. *Weight* (kg), estimated by Kroemer	58	78	99	13	39	62	85	14

Excerpted from Gordon, Churchill, Clauser, et al (1989) and Greiner (1991), who used the numbers in brackets. These are measured, not estimated, data that may be slightly different from values calculated from Mean plus or minus 1.65 Standard Deviation—see Table 13–F.

If p is above the average add the product to the mean m:

$$p = m + k\,SD \tag{14}$$

A new mean from the sum of two distributions is simply the sum z of the means of the x and y:

$$m_z = m_x + m_y \tag{15}$$

The standard deviation of the summed distribution z is

$$SD_z = [SD_x^2 + SD_y 2 + 2\,r\,SD_x\,SD_y\,]^{1/2} \tag{16}$$

The mean of the difference between two distributions is

$$m_z = m_x - m_y \tag{17}$$

The standard deviation of the new distribution is

$$SD_z = [SD_x^2 + SD_y^2 - 2\,r\,SD_x\,SD_y\,]^{1/2} \tag{18}$$

Equations 16 and 18 contain (Pearson's) correlation coefficient r. It describes the relationship between two sets of data. The value of r ranges from +1 (a "perfect" positive correlation; as x increases, y increases as well) over 0 (no correlation at all between x and y) to –1 (also perfect, but negatively so: as x increases, y decreases).

Determining Percentiles

Anthropometric data often are best presented in percentiles. They provide a convenient means of describing the range of body dimensions to be accommodated, making it easy to locate the percentile equivalent of a measured body dimension. Also, the use of percentiles avoids the misuse of the average in design (as is discussed later). There are two ways to determine given percentile values p.

One is to calculate values of p, as described above. The other is to simply graph the data distribution and find the critical percentile values from the curve by measuring, counting, or estimating. This technique works well whether the distribution is normal, skewed, binomial, or in any other form.

The following examples for calculating p-values are selected and adapted from those used by Kroemer, Kroemer and Kroemer-Elbert (2001).

ARM LENGTH

The Task: Calculate the 95p shoulder-to-fingertip length.

The Solution: You know that the mean lower arm (LA) link length (with the hand) is 442.9 mm with a standard deviation of 23.4 mm. The mean upper arm (UA) link length is 335.8 mm and its standard deviation is 17.4 mm.

The multiplication factor of k = 1.65 (from Table 13–F) leads to the 95th percentile. But simply adding the two 95p lengths would be a mistake because that would disregard their correlation; instead, establish the sum of the mean values first, using Equation 15:

$$m_A = m_{LA} + m_{UA} = 442.9 + 335.8 = 778.7 \text{ mm}$$

Then compute the standard deviation for m_A from Equation 16 with an assumed correlation coefficient of 0.4:

$$SD_A = [23.4^2 + 17.4^2 + 2\,(0.4)\,(23.4)\,(17.4)]^{1/2} \text{ mm} = 34.3 \text{ mm}$$

Finally, the 95p total arm length can be calculated via Equation 14:

$$A_{95} = 778.7 \text{ mm} + 1.65\,(34.3 \text{ mm}) = 835.3 \text{ mm}$$

Table 13–F. *Calculation of Percentiles*

Percentile p		Central Percentage	
$x_i = \bar{x} - kS$ (below mean)	$x_j = \bar{x} + kS$ (above mean)	Included in the Range x_{pi} to x_{pj}	k
0.5	99.5	99	2.576
1	99	98	2.326
2	98	96	2.06
2.5	97.5	95	1.96
3	97	94	1.88
5	95	90	1.65
10	90	80	1.28
15	85	70	1.04
16.5	83.5	67	1.00
20	80	60	0.84
25	75	50	0.67
37.5	62.5	25	0.32
50	50	0	0

KEYBOARD HEIGHT ABOVE THE SEAT

The Task: Establish the surface height of a keyboard so that the sitting operator has the forearms and wrists horizontal.

The Solution: Assume that having the tops of the keys at elbow height will allow the operator to keep the wrists straight and the forearms horizontal while the upper arms hang vertically from the shoulder joints. It appears appropriate to adjust the key height in a range that lowest is proper for the 10th percentile female elbow clearance and highest fits the 90th male clearance.

The elbow height above the seat pan is listed for Americans in Table 13–E: females have a mean of 220.5 mm with a SD of 26.8 mm; the corresponding numbers for males are 230.6 mm and 27.2 mm.

To use Equation 14 above, take k = 1.28 from Table 13–F as the multiplication factor for determining the 10th and 90th percentiles. The calculations show 10p values of 186 mm for females and 196 mm for males; the 90p values are 265 mm for males and 255 mm for females.

Consequently, under the assumptions made, the height of the key tops should be adjustable from about 19 to 27 cm above the seat pan level.

Percentiles serve the designer in several ways. First, they establish the portion of a user population that will be included in (or excluded from) a specific design solution. For example: a certain product may need to fit everybody who is taller than the 25th percentile or smaller than the 95th percentile in a specified dimension, such as grip size or arm reach. Thus, the 25 percent having values smaller than 25th percentile and the five percent having values larger than 95th percentile will not be fitted while 70 percent of all users will be accommodated.

Second, percentiles are easily used to select subjects for fit tests. For example: if a product needs to be tested, persons with 25- or 95-percentile values in the critical dimensions can be employed for use tests.

Third, any body dimension, design value, or score of a subject can be located exactly. For instance: a certain foot length can be described as a given percentile value of that dimension, a certain seat height can be described as fitting a certain percentile value of *popliteal height* (a measure of lower leg length), or a test score can be described as being a certain percentile value.

Fourth, the use of percentiles helps in the selection of persons who can use a given product. For example: if the cockpit of an airplane is designed to fit 5th to 95th percentiles, one can select cockpit crews whose body measures are between those percentiles in the critical design dimensions.

The Phantom of the Average Person

Several simple—but false—ideas about the proportions of the human body have been used in the past. They assumed that all body dimensions, such as lengths, breadths, and circumferences, can be represented as given fixed proportions (percentages) of one body dimension—most often, stature. Obviously, such a simplistic assumption contradicts reality: The relationships among body dimensions are neither necessarily linear nor the same for all persons. In spite of the obvious fallacy of the model, *single-percentile constructs* have been generated. These assume that persons exist whose body segments are all of the same percentile value. Not only the 50th-percentile phantom (the average person) was used as a design template, but other ghostly figures were created that have, for example, all 5th- or 95th-percentile values. Of course, designs for these figments do not fit actual users.

Designing to Fit the Human Body

It is not suitable to design for the average person phantom because no one is average in many or all body dimensions. The correct design approach is to select the specific anthropometric dimension(s) to be fitted and to establish (for each dimension) the design range (such as from the 5th to the 95th percentile) so that proper fit will be achieved.

"MIN-MAX STRATEGY" FOR FITTING SMALL AND LARGE PERSONS

Instead of the thoughtless and useless average-person concept, the *min-max strategy* is often successfully applied when workstations, tools, and tasks must be designed to fit small and large operators, as well as everybody in-between. The minimal dimensions are derived from the smallest operators' needs to see, to reach, or to apply force; yet these dimensions may not accommodate large persons who can reach farther, can see higher, and need more open space for their bodies. These larger individuals' dimensions establish the *maximal* boundaries. One good solution, if feasible, is to have workplaces and tools and other work objects in different sizes between minima and maxima; another other good solution is to have *adjustable* dimensions. *Adjustability* allows good fit, but is often expensive; therefore, one often attempts to design just one workstation that suits all workers, or at least most of them. This requires that the designer first decides what the important minimal and maximal values are that will be accommodated (for example, in body size, reach, or strength).

See the Bibliography for references by Eastman Kodak Company (1983, 1986), Kroemer et al (1997, 2001), and Roebuck (1995), which guide readers on ergonomic designs to fit the body.

Population Changes

Since World War I, increases in certain body dimensions have been observed. Many children grow to be taller than their parents. This increase in stature has been in the range of about 1 cm per decade, but now seems to be leveling off. Another even more conspicuous increase has occurred in body weight, with increments of 2 to 3 kg per decade.That gain is still going on, in spite of public emphasis on proper nutrition and exercise.

Altogether, such secular developments of body dimensions are rather small and slow (except for weight). Hence, for most engineers, the changes in body data should have little practical consequences for the design of tools, equipment, workstations, or work clothes, since virtually none are designed for use over many decades. However, one may have to consider increased ranges of variability in certain dimensions—and this is best expressed by percentile values.

The working population in North America has been changing in gender, occupation, age, and composition. Today, the general work force has many more women in occupations that were dominated by men just a few decades ago. Occupations have changed drastically; computers and service industries are pulling people from traditional blue-collar work. Average life expectancy has increased in the United States since 1900 by 27 years to nearly 80 years.

Design for special population subgroups does require the consideration of other-than-normal ranges of body sizes. These groups of people include pregnant women and the elderly (Annis et al, 1991; Annis & McConville, 1996; and Kroemer et al, 2001). Approximately one of five North Americans is 65 years and older; thus, the number of elderly

workers in the U.S. work force is expected to increase within the very near future.

Another population subgroup is a result of immigration, for example, Central and South Americans, who may be relatively short in stature. This can have a conspicuous effect on the anthropometry of the working population in certain regions. Hence, the anthropometric data that describe local workers on the shop floor, in the office, or users and operators of equipment can be quite different from national statistics.

BIOMECHANICS

Biomechanics explains characteristics of the human body in mechanical terms. More than 300 years ago, Giovanni Alfonso Borelli described a model of the human body that consisted of links (bones) joined in their articulations and powered by muscles bridging the joints. This *stick person*, refined and embellished with mass properties and material characteristics, still underlies most current biomechanical models of the human body. More than 100 years ago, Harless determined the masses of body segments; Braune and Fischer investigated the interactions between mass distribution, body posture, and external forces applied to the body; and von Meyer discussed the body's statics and mechanics. Biomechanical research has investigated responses of the body to vibrations and impacts, functions and strain properties of the spinal column, and human motion and strength characteristics. (See Chaffin et al, 1999, or Kroemer et al, 2001, for more information.)

When treating the human body as a mechanical system, many gross simplifications are necessary, and many functions, such as mental processes, may be disregarded. However, within its limitations and simplifications, a large body of useful biomechanical information is already available, and this scientific and engineering field is developing rapidly. (See Chaffin et al, 1999; Kroemer et al, 1997, 2001; Nordin et al, 1997; Oezkaya & Nordin, 1991.)

Body Strength

Assessment of human muscle strength is a biomechanical procedure. This assessment uses Newton's Second and Third Laws, which state that force is proportional to mass times acceleration, and that each action is opposed by an equivalent reaction. Since human muscle strength currently is not measurable at the muscle in vivo and in situ, human strength is described by the amount of force or torque applied to an external measuring instrument—which is the kind of data that the engineer needs to design tools and equipment.

Inside the body, muscular force vectors develop torque (also called moment) around the body joint bridged by the muscle. *Torque* is the product of force and its lever arm to the body joint; with the direction of the force perpendicular to its lever arm. In kinesiology, the lever arm is often called the mechanical advantage.

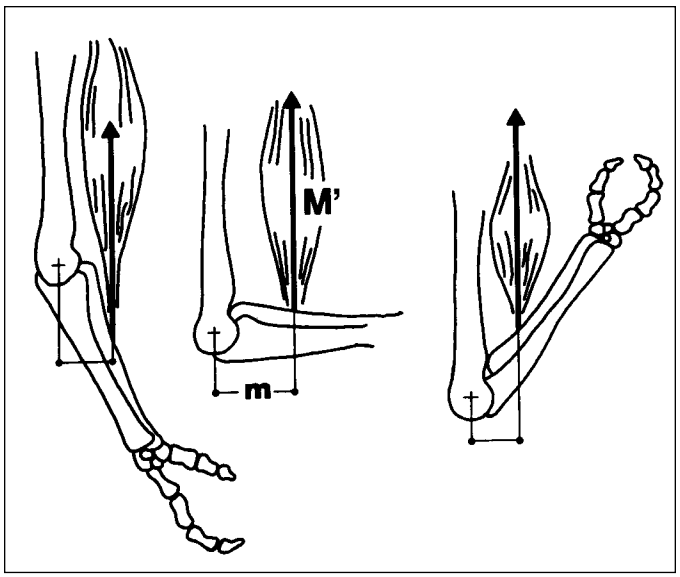

Figure 13–11. Changing lever arm (m) of the muscle force (M) with varying elbow angle.

Figure 13–11 uses the example of elbow flexion to illustrate these relationships. The primary flexing muscle (biceps brachii) exerts a force (M) at the forearm at its lever arm (m) about the elbow joint. This generates a torque: $T=mM$. Since, by torque definition, a right angle must exist between lever arm and force vector, the useful lever arm is smaller when the elbow angle is wide open, or acute, than when the elbow angle is a right angle.

The correct unit to express force is the newton (N) while torque (moment) is measured in newton-meter (Nm). A 1-lb force is approximately 4.45 N, and 1-kg force (kgf) equals 9.81 N. The pound, ounce, and gram are not force but mass units. According to Newton's Second Law, force equals mass times acceleration; hence, weight (of a mass) generates a force proportional to gravitational acceleration. Force (as well as torque) has vector qualities, which means that it must be described not only in terms of magnitude, but also by direction, by the line of force application, and the point of its application.

Figure 13–12 shows a more realistic model of the muscle forces that flex or extend the forearm about the elbow joint. It indicates an external force, E, and hand/forearm weight, W, at their respective lever arms, e and w. It also shows the force vectors of the two major flexor muscles, the biceps, B, and the radiobrachialis, R, acting at their specific lever arms, b and r, about the elbow. Also shown is the force vector of the triceps, T, with its lever arm, t. With a change in elbow angle, α, all force vectors change their angles of application, τ, ρ, β, and ε.

For static equilbrium, all forces and all torques must sum to zero. This provides three equilbrium equations, one each for the horizontal forces, the vertical forces, and the moments about the elbow joint. Including the joint reactions, indicated by H for horizontal and V for vertical force, and M for moment, these equations are as follows:

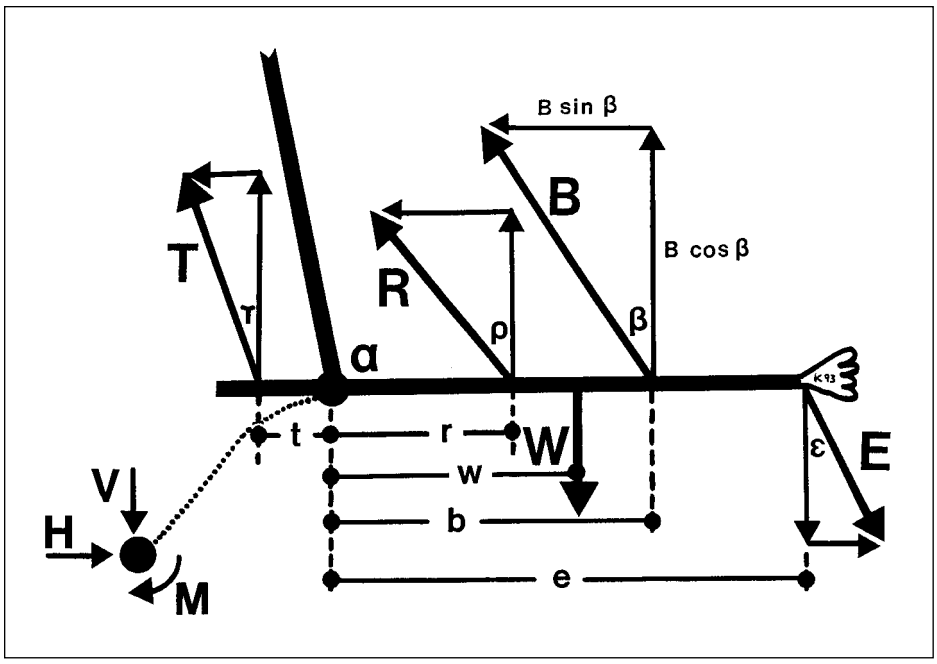

Figure 13–12. A more sophisticated biomechanical model of elbow flexion with indications of force vectors, vector directions, and lever arms.

➢ (Horizontal Forces) = 0
➢ $= T \sin\tau + R \sin \rho + B \sin \beta - E \sin \varepsilon - H$ (19)

➢ (Vertical Forces) = 0
➢ $= T \cos \tau + R \cos \rho + B \cos \beta - E \cos \varepsilon - W - V$ (20)

➢ (Moments About Joint) = 0
$= tT \cos \tau - rR \cos \rho - bB \cos \beta + eE \cos \varepsilon + wW - M$ (21)

These equations can be solved only if there are no more unknowns than equations. One can determine the length of the lever arms from anatomy. The angles are measured or taken from anatomy and geometry. The weight of the forearm can be calculated from geometry or taken from biometric tables (see, for example Chaffin et al, 1999, or Kroemer et al, 1997). The external force can be measured. Still, this leaves the muscular force vectors (*T*, *R*, *B*) unknown, as well as the joint reaction forces (*H* and *V*), and the joint reaction moment (*M*). Various possibilities exist to reduce that number of unknowns to three, ie, the same as the number of equations. These approaches include assumption of no coactivation, or of certain coactivation ratios (e.g., according the cross-sections of the muscles) or according to electromyographic (EMG) signals. Other techniques rely on statistical optimization procedures (Karwowski & Marras 1999; Salvendy 1997).

When movement occurs the biomechanical conditions become more complex than those just described for the static case. In dynamics, additional forces must be considered as body segments rotate about their proximal joints. This introduces tangential, centrifugal, and Coriolis forces, which may also generate new torques, as does the inertia of the segment and possibly of an external load.

The principles of vector algebra can be applied to a chain of body segments; for example, pushing or lifting with the hands transmits torques (forces) from the wrist to the elbow joint, to the shoulder, down the spinal column, and across hip, knee, and ankle joints to the ground where the torques (forces) are generated that counteract the hand effort. Such kinematic chain models are used to assess the weakest links of the human body. These are often in the spinal column where especially low-back injuries are frequent.

Measuring Body Strength

Voluntary muscle strength moves the segments of the body and generates energy exerted on outside objects when one performs work. There are more than 200 skeletal muscles in the body. They consist of bundles of muscle fibers: each is wrapped—as is the total muscle—in connective tissue in which nerves and blood vessels are embedded. At the ends of the muscle, the tissues combine to form tendons that connect the muscle to bones.

The only active action a muscle can take is to contract; elongation is brought about by force external to the muscle. Contraction actually occurs in fine structures of the muscle, called filaments, that slide along each other. The nervous control for muscular contraction is provided by the neuromuscular system, which carries signals from the brain forward to the muscle and also provides feedback. Electrical events associated with contraction of motor units of the muscle are observable in an electromyogram.

Model of Strength Generation

Figure 13–13 shows a simple model of the generation of muscular strength. Activation signals *E* travel from the central nervous system (CNS) along the efferent pathways to the muscle. Here, they generate contraction, which, modified by the existing physical conditions, generates the strength that is applied to a measuring instrument (or a work piece or

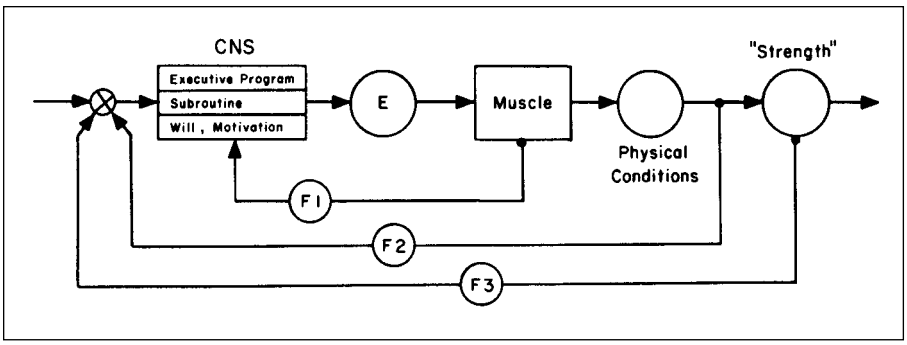

Figure 13–13. Model of generation and control of muscle strength exertion. (Reprinted with permission from Kroemer, Kroemer, and Kroemer-Elbert, 2001.)

hand tool). Three feedback loops are shown—the first one indicates reflexes; the second, transmitted sensations of touch, pressure, and kinesthetic signals; the third, sound and vision events related to the strength exerted.

Consider the feed-forward section of the model. Currently there is no suitable means to measure the executive program or the subroutines in the CNS, or the effects of will or motivation, on the motor signals generated. The efferent excitation impulses travel along the efferent nerves to the muscles where they generate contraction signals. These signals can be observed in an EMG, which, however, is difficult to interpret especially under dynamic conditions. Although it would be very useful to directly measure the tension within muscles in situ, at the time of this writing, there are no instruments available that can do so. It is difficult to record and control the mechanical conditions within the body (i.e., the lever arms of the tendon attachments or the pull angles of muscles with respect to the bones to which they are attached), but the mechanical conditions outside the body can be observed and controlled. This concerns the kind and location of the coupling between the body and the device; the direction of exerted force or torque; the time history of this exertion; the position and support of the body; and environmental conditions, such as temperature and humidity.

Hence, with current means, only the output of this complex system, called muscle strength, can be defined and measured. Since strength has vector qualities and is time-dependent, it must be recorded not only in magnitude, but also in direction, point of application, and time history.

Measuring Techniques

According to Newton's Second Law (force equals mass times acceleration, or torque equals moment of inertia times rotational acceleration), the measurer first has to decide whether or not acceleration shall be present.

If there is no acceleration, there will be no change in speed. If speed is set to zero, then adjacent body segments will not move with respect to each other. Hence, the length of the muscle(s) spanning the joint remains constant. Physically, this means that the measurement of muscle strength is performed in the static condition. Biologically, this condition is called isometric, meaning constant muscle length. Thus, in this case, the terms *static* and *isometric* are factually synonymous. Measurement of static strength is straightforward and involves only simple instrumentation; and almost all current information on muscle strength reflects data on isometric exertions.

If velocity is not zero but is constant, the condition is called *isokinematic*, meaning constant motion. Measurement devices that establish a constant angular velocity around a given body articulation are commercially available. During their constant-speed phase (but neither at the beginning nor at the end of the motion), these devices provide a defined condition for which the exerted strength can be recorded. Only the angular velocity is controlled, while the amount of strength actually exerted at any moment remains under control of the subject. (Hence, the devices are not isokinetic even if falsely labeled so.)

During acceleration (the velocity is not constant but variable), strength is exerted under dynamic conditions that need to be defined and controlled depending on the circumstances selected. Such experimental control is possible in the laboratory, but likely to be very difficult and often impractical. Extreme cases of dynamic conditions are feats of strength at sports events, which can neither be easily measured nor controlled since they are highly specific to the situation and the person. Table 13–G presents an overview of classifications of strength exertions and their experimental control and measurement.

One technique commonly used to control dynamic conditions is to have the subject work isoinertially, that is, move constant masses (weights). To assess lifting capability, the weight is usually increased from test to test until one can determine the largest mass that the subject can lift (see the section on material handling later in this chapter).

THE STRENGTH TEST PROTOCOL

After choosing the type of strength test to be done and the appropriate measurement technique, an experimental protocol must be devised. This includes the protection of the subjects and of the information obtained from them; the control of the experimental conditions; the use, calibration, and maintenance of the measurement devices; and (usually) the avoidance of training and fatigue effects.

When selecting subjects, take care to ensure that they are a representative sample of the population about which data are to be gathered. When managing experimental condi-

Table 13–G. ***Dependent and Independent Variables in the Measurement of Muscle Strength***

Indep = independent
Dep = dependent
C = variable can be controlled
* = set to zero
0 = variable is not present (zero)
X = can be dependent variable
The boxed constant variable provides the descriptive name.
(Adapted from Kroemer, Marras, McGlothlin, et al., 1990.)

tions, control of motivational aspects is particularly difficult. It is widely accepted (outside sports and medical function testing) that the experimenter should not give exhortations and encouragements to the subject. The so-called "Caldwell regimen" (Caldwell et al, 1974) pertains to isometric strength testing, but can be adapted for a dynamic test. The following is an edited excerpt of this regimen.

Definition: "Static body strength is the capacity to produce torque or force by a maximal voluntary isometric muscular exertion. Strength has vector qualities and therefore should be described by magnitude and direction."

1. Measure static strength according to the following conditions: (a) Static strength is assessed during a steady exertion sustained for four seconds. (b) The transient periods of about one second each, before and after the steady exertion, are disregarded. (c) The strength datum is the mean score recorded during the first three seconds of the steady exertion.

2. Treat the subject as follows: (a) The person should be informed about the purpose of the test and the involved procedures. (b) Instructions should be kept factual and not include emotional appeals. (c) The subject should be told to "increase to maximal exertion (without jerk) in about one second and then maintain this effort during a four-second count." (You may want to use a different procedure and time for special conditions, e.g., for the measurement of finger strength.) (d) During the test, the subject should be informed about his/her general performance in qualitative, non-comparative, positive terms. Do not give instantaneous feedback during the exertion. (e) Rewards, goal setting, competition, spectators, fear, noise, etc. can affect the subject's motivation and performance and therefore should be avoided.

3. Provide a minimal rest period of two minutes between related efforts; more if symptoms of fatigue are apparent.

4. Describe the conditions existing during strength testing: (a) Body parts and muscles chiefly used. (b) Body position (or movement). (c) Body support or reaction force available. (d) Coupling of the subject to the measuring device. (e) Strength measuring and recording device.

5. Describe the subjects: (a) Population and sample selection including sample size. (b) Current health: a

medical examination and a questionnaire are recommended. (c) Gender. (d) Age. (e) Anthropometry (at least height and weight). (f) Training related to the strength testing.

6. Report the experimental results: (a) Number of data collected. (b) Minimum and maximum values. (c) Median and mode. (d) Mean and standard deviation for normally distributed data points; for a non-normal distribution, lower and upper percentile values such a 1st, 5th, 10th, 25th, 75th, 90th, 95th, or 99th percentiles.

DESIGNING FOR BODY STRENGTH

The engineer or designer who wants to consider human strength has to make a number of decisions, including the following:

- Is strength use mostly static or dynamic? If it is static, information about isometric strength capabilities can be used. If it is dynamic, other additional considerations apply, concerning, for example, physical endurance (circulatory, respiratory, metabolic) capabilities of the operator, prevailing environmental conditions, etc. Physiology and ergonomic texts (e.g., Astrand & Randahl, 1986; Kroemer et al, 1997, 2000; Winter, 1990) provide such information.
- Is the exertion by hand, by foot, or with the whole body? For each of these situations, specific design information is available. If a choice is still possible, it must be based on physiological and ergonomic considerations to achieve the safest, least strenuous and most efficient performance. In comparison to hand movements over the same distance, foot motions consume more energy, and are less accurate and slower, but they are stronger.
- Is a maximal or a minimal strength exertion the critical design factor? *Maximal user output* usually determines the structural strength of the object, so that the strongest operator may not break a handle or a pedal. The design value is set, with a safety margin, above the highest perceivable strength application.
- *Minimal user output* is that exertion expected from the weakest operator, which still yields the desired result, so that a door handle or brake pedal can be successfully operated or a heavy object moved.
- The range of expected strength exertions is, obviously, that between the specified minimum and maximum. Average user strength is usually of no design value.
- Most body-segment strength data are available for static (isometric) exertions. They provide reasonable guidance also for slow motions, although they are probably a bit too high for concentric motions and too low for eccentric motions. As a general rule, strength exerted in motion is less than that measured in static positions located on the path of motion.
- Measured strength data are often treated statistically as if they were normally distributed and reported in terms of averages (means) and standard deviations. This dubious procedure is not of great practical concern, however, because usually the data points of special interest are the extremes. Often the 5th and 95th percentile values are selected. These can be determined easily, if not by calculation, then by estimation.

HANDLING LOADS: LIFTING, LOWERING, PUSHING, PULLING, CARRYING

We all handle material daily. We lift, hold, carry, push, pull, and lower while moving, packing, and storing objects. The objects may be soft or solid, bulky or small, smooth or with corners and edges; the objects may be bags, boxes, or containers that come with or without handles. We may handle material occasionally or repeatedly. We may handle material during leisure activities as part of the paid work. Manual handling involves lifting light or heavy objects. Heavy loads pose additional strain on the body owing to their weight or bulk or lack of handles. But even lightweight and small objects can strain us because we have to stretch, move, bend, or straighten out body parts, using fingers, arms, trunk, and legs.

Material handling is among the most frequent and the most severe causes of injury all over the world and in U.S. facilities. The most common injuries are strains in the low back. The direct and indirect costs are enormous, and the human suffering associated with material-handling injuries is severe.

Seven Keys of Load Handling

Kroemer identified *seven keys* (1997) as the major ergonomic tools for safe and efficient material handling:

Key 1. Facility Layout—Initial layout or improvement of facilities contributes essentially towards safe and efficient material transfer. The selection of either product or process layout and accordingly how the flow of material is organized and designed in detail, determines how people are involved and how they must handle material.

Key 2. Job Design—Job design determines the stress imposed on the worker by the work. Initially, the engineer must decide whether to assign certain tasks to a person or a machine. Furthermore, the layout of the task, the kind of material-handling motions to be performed, the organization of work and rest periods, and many other engineering and managerial techniques determine whether a job is well-designed, safe, efficient, and agreeable for the operator.

Key 3. Equipment—Selection, use, and improvement of equipment, machines, and tools, strongly affect material handling requirements. Ergonomic principles must be considered, for example, operator space requirements, control design, visibility, and color and sign coding.

Key 4. People—This key concerns people as material handlers, particularly with regard to body size, strength, and

energy capabilities. People are the kingpins in manual material activities because they supervise, control, operate, drive, and actually handle material. If people are not needed in the system, then it should be automated. If they are needed, the system must be designed for them.

Key 5. Training Material Handlers—For decades training in safe lifting procedures has been advocated and conducted. Training is expected to reduce severity and frequency of injuries, develop specific material handling skills, further awareness and responsibility for one's own safety, and improve specific physical fitness characteristics. Participants have been selected at random, or chosen according to risk, previous injuries, age, etc.; they were volunteers or they included all employees.

Many studies on training outcomes are scientifically deficient because they do not follow an experimental design that allows the assessment of reliability and validity of the results of the experimental treatment. Granted, it is difficult (because of work interference, time needed and expenses) to conduct a field experiment in which one varies only the independent variable and excludes confounding variables and uncontrollable interferences. Still, including a control group in the experimental design is often feasible, and it allows the evaluation of the claimed effect of the experimental training treatment.

Key 6. Screening Material Handlers—While training is one approach to "fit the person to the job," another is to select suitable persons, i.e., screening individuals to place on strenuous jobs those who can do them safely. This screening may be done either before employment, before placement on a new job, or during routine examinations during employment.

A basic premise of personnel selection by physical characteristics is that the risk of overexertion injury from manual material handling decreases as the handler's capability to perform such activity increases. This means that a test should be designed to allow judgment about the match between a person's capabilities for load handling, and the actual load-handling demands of the job. Hence, this matching process requires that one quantitatively knows both the job requirements and the related capabilities of the individual. (Of course, if the job requirements are excessive, they should be lowered before any matching is attempted.)

Key 7. Ergonomic Design of Workplace and Work Task—The most effective and efficient way to reduce material handling injuries is to design equipment ergonomically, so that job demands are matched to human capabilities. Designing to fit the human can take several approaches. The most radical solution is to design out manual material movement by assigning it to machines: *no people involved, no people at risk.* If people must be involved, load weight and size shall be kept small, best accompanied by ergonomic design of the work task, i.e., by selecting the proper type of material handling movements (e.g., horizontal push instead of vertical lift) and their frequency of occurrence. The location of the object with respect to the body is very important: best between hip and shoulder height, directly in front of the body so as to avoid twisting or bending the trunk. The object itself is important, of course, regarding its bulk, its pliability (e.g., firm box versus pliable bag), and whether it can be grasped securely (shape, handles). Naturally, the workplace itself must be well designed and maintained. Important aspects are: proper working height; material provided in containers from which it can be removed easily; nonslip floor and a clean, orderly environment that is free of avoidable noise and climate stressors.

Other publications address these issues in great detail (see Christensen & Manuele, 1999; Kroemer, 1997; Kroemer et al, 2001); therefore, only Keys 5 and 7 will be treated here.

Training

TRAINING IN PROPER LIFTING TECHNIQUES

Instructions on how to lift are meant to improve lifting technique and behavior and thus to reduce the likelihood of an overexertion strain or injury. In the laboratory, it has been shown that training regimens can increase the ability for lifting. Sharp and Legg (1988) reported that after four weeks of training, initially inexperienced lifters increased their work output significantly while maintaining their energy expenditures. The improvement was attributed to better skill through improved neuromuscular coordination and to possible increases of muscular endurance. Genaidy et al (1990) used six weeks of training and also found that muscular endurance, muscular strength, and cardiovascular endurance were improved. Yet, to date, there have been no reports of tightly controlled studies with large numbers of industrial material handlers, and the validity of laboratory findings for industrial environments has not been established.

WHAT TO TRAIN?

From the 1940s on, the advocated lift method was the *straight-back/bent-knees lift* (*squat lift*), in which workers lowered themselves to the load by bending the knees and then lifted by using the leg muscles. Yet, results of biomechanical and physiological research have shown that the leg muscles used in this lift method do not always have the needed strength. Also, awkward and stressful postures may be assumed if one tries to enforce this technique under unsuitable circumstances, e.g., when the object is bulky. Hence, the straight-back/bent-knees action evolved into the so-called *kinetic lift*, in which the back is kept mostly straight while the knees are unbent; but feet, chin, arm, hand, and torso positions are prescribed. Another variant was the free-style lift that appeared to be better for some workers than the straight-back/bent-knees technique. In some situations the stoop lift (with a strong bend at the waist and straight knees) may be superior to the squat (bent knees, flat back) posture, which is usually advocated. Sedgwick and Gormly (1998) discussed the suitability of leg and stoop lifts and believed

that an intermediate "semi-squat" lift was most versatile. The contradictory findings confirm Jones' 1972 statement that no single lifting method is best for all situations. Therefore, training of proper lifting technique is an area of confusion: What method should be taught?

UNSUCCESSFUL TRAINING

Reviews by Brown (1972, 1975), Snook (1988), and Yu et al (1984) detected no significant reductions in back injury as a result of training during a four-decade period. Several studies on nurses did not find effects on the incidence of low-back injury after receiving repeated instruction on lifting procedures; the principles taught were seldom used (Torres, 1998). Although neither the quality nor the content of the programs was investigated, the general conclusion was that training was not an effective preventive program for low-back injuries. Scholey and Hair (1989) reported that 212 physical therapists involved in back care education had the same incidence, prevalence, and recurrence of back pain as a carefully matched control group.

SUCCESSFUL TRAINING

In 1981 Hayne suggested that the three essential components of a training program are "knowledge, instruction, and practice," but did not provide sufficient information on the contents of such a program nor indicate how to make reliable evaluations of its effectiveness. Davies (1978) reported decreases in back-injury incidence after three carefully designed and properly carried-out training programs. Miller (1977) reported success in decreasing the frequency of back injuries by using a five-minute slide/cassette program, a film, and posters to emphasize the theme "when you lift, bend your knees." A cohort was not observed.

"BACK SCHOOLS"

The back-school concept is often traced to Fahrini (1975), who suggested education as a conservative treatment for low-back pain patients, as opposed to surgery. He began using this form of treatment as early as 1958; other schools have since developed and in the 1980s health-care providers, physicians, nurses, and physical therapists popularized these schools for rehabilitation of patients with back injuries. This training approach emphasizes knowledge, awareness, and attitude change by instructing the individual in anatomy, biomechanics, and injuries of the spine. The overall goal is to encourage the individual to take responsibility for his or her own health by means of proper nutrition, physical fitness, and awareness of the effects of posture and movement on the back. Such programs may also provide vocational guidance and information on stress management, even on drug use and abuse.

Controlled research concerning back schools has been limited, but back-school patients usually express increased understanding of their own back problem and a feeling of better control of pain after attending.

Typical industrial case studies of training involve use of a training program, new safety rules and job redesign, and a "publicity" effort using posters, booklets, and paycheck stuffers. Reported results frequently indicate large reductions in compensation costs and fewer lost workdays per injury. However, these studies do not usually include a control group. One exception is a study of 3,424 employees of the Boeing Company by Battie et al (1989), who found that in this study no significant differences in the occurrence of back pain nor in the number of lost work days between (healthy) employees who attended back school and a control group that did not.

Only a few reports on the effectiveness of training mention control groups; according to these, back school therapy was successfully applied to patients with back pain. Daltrov et al (1997) conducted a controlled study with nearly 4,000 postal employees. Experienced physical therapists trained 2,534 workers and 134 supervisors. Work units of workers with their supervisors participated in a two-session back school (three hours of training) followed by three to four reinforcement sessions over the next five years. Persons from either the intervention or the control groups who were injured during that time period were randomized again to receive either training or not after return to work. During the observation period of more than five years, 360 persons reported back injuries: the rate was 21.2 injuries per 1,000 worker-years of risk. The median time off work was 14 days, the median cost $204. A comparison of the intervention and control groups showed no effects of the education program on the rate of low back injuries, the cost per injury, the time off work per injury, or the rate of injury repetition. Curiously, the trainees showed an increased knowledge of safe behavior.

TRAINING FOR FITNESS AND FLEXIBILITY

Physical fitness training is a related approach to training workers in prevention of low-back injury. Material handling is physical work, and it is reasonable to assume that many aspects of physical fitness, especially musculoskeletal strength, aerobic capacity, and flexibility may be associated with the ability to perform load handling without injury. Exercise has been used in the treatment of back injury for many years, although its exact role and effectiveness are not completely understood.

Musculoskeletal strength, one aspect of physical fitness, is generally believed to be related to back injury. Experience seems to indicate that the occurrence of musculoskeletal injuries in weaker workers is greater than that for stronger workers. But there is the unexpected finding that "strong" persons may be more often injured than their weaker colleagues (Battie et al, 1989). Although the concept of strength training within an industrial environment as a means of back injury prevention is occasionally mentioned, at the time of this writing, we could not locate major research literature on this topic.

Flexibility, particularly of the trunk, appears to be needed for bending and lifting activities, which are part of material handling tasks. Chenoweth (1983a, 1983b) reported that an

industrial fitness program was successful with volunteer participants, compared to their control-group worker colleagues. Unfortunately, the control group seems not to have been selected from volunteers. An empirical study of 1,652 Los Angeles County firefighters investigated the relationship between fitness and low-back injury to determine the relationships between five strength and fitness measures with the occurrence of back injury over a three-year period (Cady et al, 1979a, 1979b). Individuals were rated to be on one of three levels of fitness (high, middle, or low) based on measurements of flexibility, isometric lifting strength, recovery heart rate, blood pressure, and endurance. The results show that the fittest firefighters had the lowest percentage of back injuries and the least fit group the largest percentage; but the fittest had the most severe injuries. This study often has been used to suggest that physical fitness may help to prevent back injuries, but Nordin (1991) cited two more recent longitudinal studies that did not show an association between fitness level (measured via maximal oxygen uptake) and reported back pain. Nordin stated that flexibility measures were found to be poor predictors of back problems.

Regaining and improving fitness, including flexibility, while recovering from a back injury or other disability has always been of concern to patients and their health caretakers. Parts of the back-school concept have been incorporated in *work hardening*, where specific body abilities deemed necessary to perform the job are improved through purposeful designed exercises. Fitness training for preventing back injury is viewed with great interest; to date, however, there is not enough evidence on the effectiveness of this approach in general, or on specific programs to support its effectiveness.

CONTENT OF TRAINING

A basic question, "What to teach?" has not yet been answered: the content of a training course depends on its aims. Previous efforts usually were in three areas;

1. Training specific lifting techniques, i.e., skill improvement.
2. Teaching biomechanics, awareness of and self-responsibility for back injuries, thereby changing attitudes.
3. Making the body physically fit so that it is less susceptible to injury.

Although the aim, injury prevention, is the same in each case, the methods of how to achieve that aim are quite different. The traditional approach of training a specific lifting technique alone does not appear effective, mainly because there is no one technique appropriate for all lifts. Most courses are therefore considered "unrealistic" and centered too much on protecting the back, as Sedgwick and Gormly (1998) reported from consensus meetings with more than 900 Australian health professionals—yet, they proposed to teach "semi-squat" lifting throughout their course.

Preventing injury by increasing knowledge of the body and promoting attitude changes so that workers feel responsible for their bodies has a basic, almost simplistic, appeal and should be quite applicable. However, exactly what should be taught, and how, is still open. How much knowledge is needed of kinesiology, biomechanics, physiology? What method is most effective? Barker and Atha (1994) reported that written guidelines, such as commonly handed to untrained industry personnel, worsened lifting performance.

Another key to awareness and attitude change may be the attention paid to material handling problems by management, supervisors, or training instructors. Making employees aware of management's concern is an underlying theme in the training received from back schools.

WHO TO TRAIN

Most industrial back injuries are not associated with objective pathological findings, and about every second back pain episode cannot be linked to a specific incident Yet, many actions and events at work are associated with low-back injuries. In the mining industry, overexertion, slips/trips/falls, and jolts in vehicles are the most frequently mentioned events (Bobick & Gutman 1989). Back injuries have been directly associated with lifting (37% to 49% of the cases), pulling (9% to 16%), pushing (6% to 9%), carrying (5% to 8%), lowering (4% to 7%), bending (12% to 14%), twisting (9% to 18%). The percentages vary considerably among industries and occupations. Construction and mining industries have reported the largest incidence ratios for compensation claims for back injuries. Other ccupations with high ratios were garbage collectors, tire makers, truck drivers, nurses, and, as expected, material handlers.

Load handling specifics differ much among industries and jobs (tire-making, mining, nursing) as well as within one industry or profession. They depend on the specific task, on available handling aids and equipment, and on many other conditions. Therefore, it is a question of how training recommendations are applied across settings. Even the group characteristics of material handlers in different industries might be important in designing a training program. For example, hospital workers might have higher educational skills than heavy-industry workers. Female employees may predominate in a given industry or occupation, which might influence the type of training, because usually women are about two-thirds as strong as men. It is not known how personal or task-specific characteristics should influence training.

In the United States, only about 2 of every 100 employees report a back injury per year. This poses another problem regarding the effectiveness and cost of back-care instructions. Of the actually reported injuries, about every tenth is serious, yet these few serious injuries cause the largest portion of the total cost. Hence, to prevent specifically these serious injuries, 2 of every 1,000 employees would be the target sample, while all 1,000 must be in the educational program. Even to address all persons who may suffer from any kind of back problem, about 20 out of 1,000, this is still a rather expensive approach, which may not appear cost-effective to the administrator.

Most training targets the individual worker or groups of workers. But one can also educate supervisors, health and safety professionals, and management personnel in:

- ➢ awareness of load-handling problems
- ➢ ergonomic job design principles
- ➢ how to respond to low-back pain and injury once it has occurred.

Such supervisor and manager training is probably important for an effective injury prevention program—but there are no actual data to support that.

REVIEW OF TRAINING

Immediately after training, there can be an increase in the incidences of reported pain. This can be attributed to a change in management attitude and a willingness on the part of employees to report back problems early—positive steps toward avoiding more serious injury.

With currently available information, hardly any specific (or general) training guidelines are well supported by controlled research. This leaves much room for speculation, guesswork, and charlatanism regarding the "best" way to train people for the prevention of back injuries related to load handling. This condition is deplorable and needs to be remedied, since common sense indicates that training should be successful.

The issue of training to prevent back injuries in material handling still is confused, at best. Some, possibly most, training approaches are not effective in injury prevention, or their effects may be so uncertain and inconsistent that money and effort paid for training programs might be better spent on ergonomic job design. "In spite of more than 50 years of concerted effort to diminish task demand, the incidence of compensable back injuries has not wavered. Rather than pursuing the 'right way to lift,' the more reasonable and humane quest might be for workplaces that are comfortable when we are well and accommodating when we are ill" (Hadler 1997, p. 935).

The legal responsibility of employers to provide training cannot be ignored; thus, the idea to abandon material handling training appears unrealistic. "Yet so long as it is a legal duty [in the United States] for employers to provide such training or for as long as the employer is liable to a claim of negligence for failing to train workers in safe methods of MMH, the practice is likely to continue despite the lack of evidence to support it." (NIOSH 1981, p. 99)

If the job requirements are stressful, "doctoring the symptoms" such as behavior modification will not eliminate the inherent risk. Designing a safe job is fundamentally better than training people to behave safely. Yet it appears plausible to expect that at least certain training approaches should show positive results. Among these, training for:

- ➢ "lifting skills" (body and load positioning and movement)
- ➢ "awareness and attitude" (physics and biomechanics associated with lifting, self-control)
- ➢ "fitness, strength and endurance"

appeal to common sense and appear theoretically sound, even though none of these has yet proven successful according to the literature. It appears plausible that back pain may be related to job satisfaction and attitude. This finding generates important questions regarding psychosociological aspects on and off the job which, so far, have found few answers.

DESIGN OF WORK TASK AND WORKPLACE

The first design decision is to allocate load-handling tasks to either machines or humans. If people must handle material, then the specific job requirements must be analyzed.

Human versus Machine Load Handling

For the initial design decisision, the *unit size principle* is of particular interest. According to it, one can either increase the quantity (size, weight) of the unit load so that equipment use becomes feasible and appropriate for the movement of material—this is the *big unit outcome*. Or one may reduce the size and weight of the load so that one operator can safely handle the material—this is the *small unit outcome*.

If all opportunities to automate or mechanize the movement of material have been exhausted, some material handling may have to be assigned to people. In this case, establish job requirements that will not overload the person or pose possible hazards. One must organize the task, establish job procedures, and determine details to enable the operator to perform the work safely and efficiently. Here are some guidelines:

- ➢ If people must move material, make sure the movement is predominantly in the horizontal plane. Push and pull, rather than lift or lower, and avoid severe bending of the body.
- ➢ If people must lift or lower material, let them do so between knuckle height and shoulder height. Lifting and lowering below knuckle height or above shoulder height are most likely to result in overexertion injuries.
- ➢ If lifting and lowering must be done by people, make sure these activities occur close to and in front of the body. If the worker must bend forward or, worse, twist the body sideways, overexertion injuries are most likely.
- ➢ If people must move material, make sure the material is light, compact, and safe to grasp. A light object will strain the spinal column and body tissues less than heavy objects. Compact material can be held more closely to the body than a bulky object. A solid object with good handles is more safely held and more easily moved than pliable material.
- ➢ If people must handle material, make sure it does not have sharp edges, corners, or pinch points.
- ➢ If material is delivered in bins or containers, make sure it can be easily removed from them, particularly that the operator does not have to "dive" into the container to reach the material.
- ➢ People tend to revert to previous habits and customs if practices to replace previous ones are not reinforced and refreshed periodically.

- ➢ Emergency situations, the unusual case, the sudden quick movement, increased body weight, or impaired physical well-being may overly strain the body, since training usually does not include these conditions.
- ➢ If the job requirements are stressful, "doctoring the system" through behavioral modification will not eliminate the inherent risk. Designing a safe job is basically better than training people to behave safely in an unsafe job.

Rules for Lifting

There are no comprehensive and sure-fire rules for "safe" lifting. Manual load handling is a very complex combination of moving body segments, changing joint angles, tightening muscles, and loading the spinal column. The following DOs and DO NOTs appear helpful, however:

- ➢ DO design manual lifting and lowering out of the task and workplace. If a worker nevertheless must do it, perform it between knuckle and shoulder height.
- ➢ DO be in good physical shape. If you are not used to lifting and vigorous exercise, do not attempt to do difficult lifting or lowering tasks.
- ➢ DO think before acting. Place material conveniently within reach. Have handling aids available. Make sure sufficient space is cleared.
- ➢ DO get a good grip on the load. Test the weight before trying to move it. If it is too bulky or heavy, get a mechanical lifting aid or somebody else to help, or both.
- ➢ DO get the load close to the body. Place the feet close to the load. Stand in a stable position with the feet pointing in the direction of movement. Lift mostly by straightening the legs.
- ➢ DO NOT twist the back or bend sideways.
- ➢ DO NOT lift or lower awkwardly.
- ➢ DO NOT hesitate to get mechanical help or help from another person.
- ➢ DO NOT lift or lower with the arms extended.
- ➢ DO NOT continue heaving when the load is too heavy.

Permissible Load Handling

Tables of lift weights for men, women, and children, were used in the United States until the National Institute of Occupational Safety and Health (NIOSH) *Work Practices Guide for Manual Lifting* appeared in 1981. Since then new knowledge about human material handling capabilities has been gained, based on epidemiological, medical, physiological, biomechanical, and psychological approaches. However, even new guidelines are still based on assumptions and approaches that need refinement and further evaluation.

Limits for Lifting and Lowering

In 1981, a panel of experts prepared for the U.S. NIOSH a *Work Practices Guide for Manual Lifting* (NIOSH, 1981). For the first time, this document contained distinct recommendations for acceptable masses to be lifted.This differed from the previous assumptions that one could establish just one given weight each for men, women, or children that would be safe to lift. This 1981 NIOSH guide established two different threshold curves. The lower, called *Action Limit* (*AL*) was thought to be safe for 99 percent of working men and 75 percent of women in the United States. The AL values depended on the starting height of the load, the length of its upward path, its distance in front of the body, and the frequency of lifting. If the existing weight was above the AL value, engineering or managerial controls had to be applied to bring the load value down to the acceptable limit. However, under no circumstances was lifting allowed if the load was three times larger than the action limit values. This threshold was called the *Maximum Permissible Load* (*MPL*).

A decade later, NIOSH revised the technique for assessing overexertion hazards of manual activity (Putz-Anderson & Waters, 1991; Waters et al, 1993, Waters et al, 1998, 1999). The new NIOSH guideline no longer contains two separate weight limits, but has only one *Recommended Weight Limit* (*RWL*). It represents the maximal weight of a load that may be lifted or lowered by about 90 percent of American industrial workers, male or female, physically fit and accustomed to physical labor.

The 1991 equation used to calculate the RWL resembles the 1981 formula for AL, but includes new multipliers to reflect asymmetry and the quality of hand-load coupling. Yet, the 1991 equation allows as maximum a *load constant* (LC), permissible only under the most favorable circumstances, with a value of 23 kg (51 lb). This is quite a reduction from the maximal 40 kg in the 1981 NIOSH guidelines.

The following assumptions and limitations apply:

- ➢ The equation does NOT include safety factors for such conditions as unexpectedly heavy loads, slips, or falls, or for temperatures outside the range of 19 C (66 F) to 26 C (79 F) and for humidity not within 35 to 65 percent.
- ➢ The equation does NOT apply to one-handed tasks while seated or kneeling, or to tasks in a constrained workspace.
- ➢ The equation assumes that other manual handling activities and body motions requiring high energy expenditure such as in pushing, pulling, carrying, walking, climbing, or static efforts as in holding, are less than 20 percent of the total work activity for the work shift (Waters, 1991).
- ➢ The equation assumes that the worker/floor surface coupling provides a coefficient of static friction of at least 0.4 between the shoe sole and the standing surface.
- ➢ The equation may be applied under the following circumstances:
  - ➢ Lifting or lowering tasks, i.e., the acts of manually grasping and moving an object of definable size without mechanical aids to a different height level.
  - ➢ The time duration of such an act is normally between two and four seconds. The load is grasped with both hands.
  - ➢ The motion is smooth and continuous.

- ➢ The posture is unrestricted (see above).
- ➢ The foot traction is adequate (see above).
- ➢ The temperature and humidity are moderate (see above).
- ➢ The horizontal distance between the two hands is no more than 65 cm (25 in.).

For these conditions, NIOSH provides an equation for calculating the Recommended Weight Limit (RWL):

$$RWL = LC \bullet HM \bullet VM \bullet DM \bullet AM \bullet FM \bullet CM \quad (22)$$

LC is the Load Constant of 23 kg (51 lb).
Each multiplier can assume values between zero and one:
HM represents the Horizontal Multiplier where *H* is the horizontal location (distance) of the hands from the mid-point between the ankles at the start and at the end points of the lift.
VM is the Vertical Multiplier where *V* is the vertical location (height) of the hands above the floor at the start and end points of the lift.
DM is the *Distance Multiplier* where *D* is the vertical travel distance from the start to the end points of the lift.
AM is the *Asymmetry Multiplier* where *A* is the angle of asymmetry, i.e., the angular displacement of the load from the medial (midsagittal plane), which forces the operator to twist the body. It is measured at the start and end points of the lift, projected onto the floor.
FM is the *Frequency Multiplier* where *F* is the frequency rate of lifting, expressed in lifts per minutes. It depends on the duration of the lifting task.
CM is the *Coupling Multiplier* where *C* indicates the quality of coupling between hand and load.

The following values are entered in the equation for RWL:

	Metric	*U.S. Customary*
LC = Load constant =	23 kg	51 lb
HM = Horizontal multiplier =	25/*H*	10/*H*
VM = Vertical multiplier =	1 – (0.003|*V*–75|)	1 – (0.0075|*V*–30|)
DM = Distance multiplier =	0.82 + (4.5/*D*)	0.82 + (1.8/*D*)
AM = Asymmetry multiplier =	1 – (0.0032*A*)	1 – (0.0032*A*)
FM = Frequency multiplier (see listing below)		
CM = Coupling multiplier (see listing below)		

These variables can have the following values:

H is between 25 cm (10 in.) and 63 cm (25 in.). Although objects can be carried or held closer than 25 cm in front of the ankles, most objects that are closer cannot be lifted or lowered without encountering interference from the abdomen. Objects farther away than 63 cm (25 in.) cannot be reached and cannot be lifted or lowered without loss of body balance, particularly when the lift is asymmetrical and the operator is small.

V is between zero and (175–*V*) cm [(70–*V*) in.] because few people can lift higher.
For a lifting task, $D = V_{end} - V_{start}$; for
a lowering task, $D = V_{start} - V_{end}$.

A is between 0° and 135°.

F is between one lift or lower every five minutes (over a working time of eight hours) to 15 lifts or lowers every minute (over a time of one hour, or less), depending on the vertical location V of the object. Table 13–H lists the Frequency Multipliers (FM).

C is between 1.00 ("good") and 0.90 ("poor"). The effectiveness of the coupling may vary as the object is being lifted or lowered: a "good" coupling can quickly become "poor". Three categories are defined in detail in the NIOSH publication and result in the following listing of values for the Coupling Multiplier CM:

Couplings	*V < 75 cm (30 in.)*	*V = 75 cm (30 in.)*
Good	1.00	1.00
Fair	0.95	1.00
Poor	0.90	0.90

To help apply the 1991 NIOSH recommended weight limit, a *Lifting Index* (LI) is calculated: LI = *L*/RWL, with *L* the actual load. If LI is at or below one, no action must be taken. If LI exceeds one, the job must be ergonomically redesigned.

Limits for Lifting, Lowering, Pushing, Pulling, and Carrying

In 1978, Snook published extensive tables of loads and forces found acceptable by male and female workers for continuous manual material handling jobs. These data were first updated in 1983 by Ciriello and Snook, then revised in 1991 by Snook and Ciriello and in 1993 by Ciriello, Snook, and Hughes (Tables 13–I to 13–M). The following prerequisites apply for the application of their data:

- ➢ Two-handed symmetrical material handling in the medial (midsagittal) plane, i.e., directly in front of the body; yet, a light body twist may occur during lifting or lowering
- ➢ moderate width of the load such as 75 cm or less
- ➢ good couplings, of hands with handles, shoes with floor
- ➢ favorable physical environment, such as about 21 degrees C at a relative humidity of 45 percent
- ➢ only minimal other physical work activities
- ➢ material handlers who are physically fit and accustomed to labor.

The format of the recommendations of Ciriello, Snook, and Hughes differs from the layout of the NIOSH guidelines. The NIOSH values are unisex, while the Ciriello et al data are separated for female and males. The Ciriello et al (1993) data are also grouped by the percentages of the worker population to whom the values are acceptable. The data do not indicate individual capacity limits; rather, they represent the opinions of more than 100 experienced material handlers as to what they would do willingly and without overexertion.

Tables 13–I through 13–M show, in much abbreviated form, the recommendations of Ciriello et al for suitable loads and forces in lifting, lowering, pushing, pulling, and carrying. The tables are shown here only as examples; the original tables as updated in 1993 by Ciriello, Snook, and Hughes must be consulted for complete information.

15	0	0	0	0	0	0.28
>15	0	0	0	0	0	0

* *V* is expressed in centimeters.

(From Putz-Andersson & Waters, 1991.)

Note that, similar to NIOSH recommendations, the data in the Snook and Ciriello studies also indicate that lack of handles reduces the loads that people are willing to lift and lower by an average of about 15 percent. If the objects become so wide or so deep as to be difficult to grasp, the lifting and lowering values are again considerably reduced. If several material handling activities occur together, the most strenuous task establishes the handling limit.

If actual loads or forces exceed table values, engineering or administrative controls should be applied. Snook believes

(Adapted from Snook & Ciriello, 1991.)

that industrial back injuries could be reduced by about one third if the loads that lie above the values acceptable to 75 percent of the material handlers could be eliminated.

COMPARING NIOSH WITH THE CIRIELLO ET AL RECOMMENDATIONS

The guidelines by NIOSH are based mostly on biomechanical considerations, particularly referring to a threshold compression of force in the lower spine of 3,400 N, with some consideration of physiological strains. The calculation of the RWL of the lifting or lowering is done twice, once for the beginning point, and again for the ending point.

The guidelines by Ciriello et al, in contrast, rely on the psychophysical assessments of experienced industrial material handlers performing controlled material handling activities in the laboratory. These activities go beyond lifting and lowering;

(Adapted from Ciriello, Snook, and Hughes, 1993.)

they also include pushing/pulling, carrying, and holding. Thus, the Ciriello et al tables have wider applicability than what can be calculated from the NIOSH formula.

Direct comparisons are possible only between the lifting and lowering recommendations. In general, the results are quite similar, however, with some larger deviations in the extremes of frequencies. To be prudent one should take the lower values of either set of recommendations.

In general, one should prefer pushing and pulling to carrying, and to lifting and lowering. Figure 13–14 schematically shows engineering interventions applied to solve the problems associated with material handling. The main intent is to eliminate or at least to reduce the overexertion injury risks to material handlers. Kroemer et al (2001) provide detailed recommendations for activities other than industrial material handling, including outdoors load transport or moving of patients in hospitals and nursing homes. They also discuss ergonomic selection of material transport and handling equipment, and the design and use of trays and containers.

Use of Back Belts

When preparing to lift or lower a load, we instinctively

develop intra-abdominal pressure within the trunk cavity. This pressure is believed to help support the curvature of the spine during the lifting or lowering effort. An external wrapping around the abdominal region might help to maintain this internal pressure because it makes the walls of the pressure column stiffer. Porters and workers in Nepal traditionally wear a cloth wound around the waist, called *patuka*, while weight lifters commonly use fairly stiff, wide and contoured belts. It has been advocated that people who do heavy manual material handling should also wear such abdominal belts (called variously back belts, lift belts, back braces, or back supports). A large number of studies have been performed, summarized, and reviewed by McGill (1999), Lavender et al (1998), and Thoumier et al (1998). Their conclusions neither summarily support nor condemn the wearing of support belts in industrial jobs.

- ➢ Certain material handlers, especially persons who have suffered a back injury, may benefit from a suitable belt.
- ➢ Candidates for belt wearing should be screened for cardiovascular risk, which may be increased by belt pressure.
- ➢ Belt wearers should receive training similar to that given in back school because the presence of the belt may provide a false sense of security.
- ➢ Belts should not be considered for long-term use.
- ➢ Belts are not a substitute for ergonomic design of work task, workplace, and work equipment.

Altogether, the use of lifting belts for professional material handling does not seem to be an effective way of preventing overexertion injuries: even competitive weight lifters do suffer back injuries.

HAND TOOLS

Many hand tools are really extensions of the hand. Pliers, for example, amplify the hand's strength, extend its reach, and protect sensitive tissues. Other tools are used to perform tasks that the hand cannot do—such as soldering—but they are held and directed by the hand. Too often design efforts have been focused on the working end of the tool rather than how it interfaces with the hand. Some hand tools are difficult to use because of inappropriate design, for instance, if the wrist is forced to bend, or because of pressure points between the hand and the handle. Many of our everyday hand tools are acceptable if we use them only occasionally, but must be redesigned for frequent handling over long periods of time, such as in occupational tasks where hand tools are used as part of the job. Figure 13–15 shows an example of straight-nose pliers that require an acute bend in the wrist because, as shown, the line of thrust of a hand tool is at approximately 30 degrees from the line of thrust of the forearm. Hence, one should bend a handle so that the wrist can be straight. Furthermore, fitting the handle surface to the enclosing surfaces of the hand helps to hold the tool securely and to employ it efficiently.

There are many ways to manipulate an object. Figure 13–16 organizes these from a simple touch applied by finger, or

1. Finger Touch: One finger touches an object without holding it.

2. Palm Touch: Some part of the inner surface of the hand touches the object without holding it.

3. Finger Palmar Grip (Hook Grip): One finger or several fingers hook(s) onto a ridge, or handle. This type of finger action is used where thumb counterforce is not needed.

4. Thumb-Fingertip Grip (Tip Grip): The thumb tip opposes one fingertip.

5. Thumb-Finger Palmar Grip (Pinch or Plier Grip): Thumb pad opposes the palmar pad of one finger (or the pads of several fingers) near the tips. This grip evolves easily from coupling #4.

6. Thumb-Forefinger Side Grip (Lateral Grip or Side Pinch): Thumb opposes the (radial) side of the forefinger.

7. Thumb-Two-Finger Grip (Writing Grip): Thumb and two fingers (often forefinger and index finger) oppose each other at or near the tips.

8. Thumb-Fingertips Enclosure (Disk Grip): Thumb pad and the pads of three or four fingers oppose each other near the tips (object grasped does not touch the palm). This grip evolves easily from coupling #7.

9. Finger-Palm Enclosure (Collet Enclosure): Most, or all, of the inner surface of the hand is in contact with the object while enclosing it.

10. Power Grasp: The total inner hand surface is grasping the (often cylindrical) handle which runs parallel to the knuckles and generally protrudes on one or both sides from the hand.

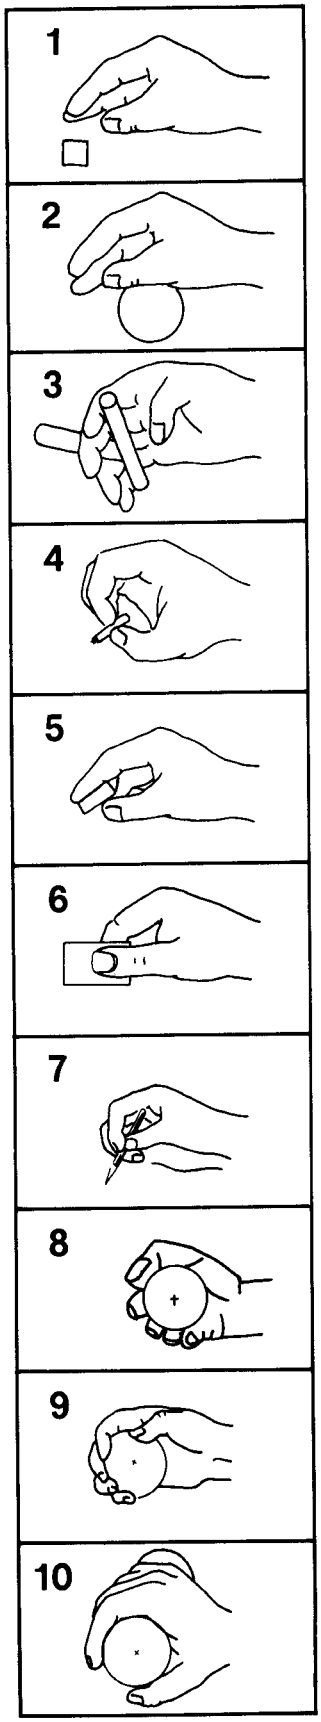

Figure 13–16. Couplings between hand and handle.

thumb, or palm (couplings 1 through 3) to tip and pinch grips (couplings 4 through 7) including the so-called "precision grip", to powerful grasps in which thumb, fingers, and palmar surfaces are involved (couplings 8 through 10). Any of these couplings evolves easily from the ones shown adjacently.

For the touch-type couplings, relatively little attention must be paid to fitting the surface of the handle to the touching surface of the hand. Yet, one may want to put a slight cavity into the top of a push button so that the fingertip does not slide off; to hollow out the handle of a scalpel slightly so that the tips of the digits can hold on securely; or to roughen the surface of a dentist's tool and, instead of making it round in cross-section, flatten it out or otherwise contour it for a secure hand-hold.

Such considerations of "secure tool handling" are most important for the enclosure couplings, which are used to transmit large energies between hand and tool. The tool designer's task is to make sure that the handle can be held securely (without fatiguing muscle unnecessarily, and avoiding pressure points) while one exerts linear force or rotating torque to it. In most tools, force must be applied by the hand in two directions: one perpendicular to the handle surface (e.g., by the palm closing the handles of pliers), the other perpendicular to that direction (in pulling an object with the pliers). Hence, both the cross-sectional and longitudinal shape of the tool must be considered. Furthermore, the presence of grease or dirt between the hand and handle or the wearing of gloves can have profound effects on the coupling.

Several publications address the problem of handle design. Chaffin et al, 1999; Cochran and Riley, 1986; Drury, 1980; Karwowski, 2001, Konz and Johnson, 2000; Mital, 1991, Woodson et al, 1991, Astin (1999), and Kroemer et al (2001) supply information about forces that can be generated by male operators in various hand-handle couplings; for female operators, about two thirds of these strengths can be expected—see Tables 13–N, 13–O, and 13–P.

Given the various tasks and uses of hand tools, only a few general guidelines can be provided; details have to be decided according to the given conditions:

- ➢ While manipulating the hand tool, the wrist should stay straight with respect to the forearm; that is, be neither rotated (pronated or supinated) nor bent (flexed-extended, laterally deviated). This often requires that the working side of the hand tool be at an oblique angle with the handle. (However, such special arrangement may make the tool useful only for certain tasks.)
- ➢ The handle should be of such cross-sectional size that the hand nearly encircles the handle, with no more space than about 1.3 cm (0.5 in.) between the fingertips and the thumb side. This means that the diameter, if circular, or the largest distance between two opposing sides of the handle should be between 2.5 and 6.5 cm (1.0–2.5 in.).
- ➢ The shape of the handle, in cross section, depends on the task to be performed; that is, on the motions involved in opening and closing the handle and on the magnitude of force or torque (moment) to be developed for use of the tool. In many cases, elliptical shapes (or rectangular ones with well-rounded edges) are advantageous if twisting (torquing or turning such as with screwdrivers) must be performed. However, more circular cross sections are preferred if the tool must be grasped in many different manners.
- ➢ The handle should easily accommodate the length of the hand in contact with it; for example, a knife handle should be at least as long as the hand enclosing it is broad. The contour of the handle can follow the contour of the inside of the hand enfolding the handle. However, strongly formfitting the handle shape might prevent people with different hand sizes or people who grasp the handle in a different way from handling the tool comfortably.
- ➢ Pressure points should be avoided. These are often present if the form of the handle has pronounced shape components, such as deep indentations for the fingers or sharp edges or contours.
- ➢ Rough surfaces of the handle might be uncomfortable for sensitive hands but can counteract the effects of grease that make the handle slippery.
- ➢ Flanges at the end of the handle can guide the hand to the correct position and prevent the hand from sliding off the handle.

Table 13–N. ***Average Digit Poke Forces* Exerted by 30 Subjects in Direction of the Straight Digits***

Digit	*10 Male Mechanics*	*10 Male Students*	*10 Female Students*
Thumb	83.8 (25.19) A	46.7 (29.19) C	32.4 (15.36) D
Index finger	60.4 (25.81) B	45.0 (29.99) C	25.4 (9.55) DE
Middle finger	55.9 (31.85) B	41.3 (21.55) C	21.5 (6.46) E

Entries with different letters are significantly different from each other ($p \leq 0.05$).

Improperly designed hand tools, particularly when combined with ill-conceived workplaces and job procedures, can cause acute injuries to surface tissues and the musculoskeletal system of the hand-arm complex. Often, the repetition of biomechanical insults, each in itself insignificant, can lead to cumulative trauma disorders in the upper extremities, a major cause of lost work in many hand-intensive industries. Many of these disorders can be averted easily by paying attention to the following recommendations.

- ➢ Avoid repetitive or sustained exertions, particularly if they are accompanied by deviations from a straight wrist and/or by forceful exertions.

Table 13–O. *Grip and Grasp Forces* Exerted by 21 Male Students and 12 Machinists*

Couplings	*Digit 1 (Thumb)*	*Digit 2 (Index)*	*Digit 3 (Middle)*	*Digit 4 (Ring)*	*Digit 5 (Little)*	*All Digits Combined*
Push with digit tip in direction of the extended digit ("poke")	91 (39)** 138 (41)	52 (16)** 84 (35)	51 (20)** 86 (28)	35 (12)** 66 (22)	30 (10)** 52 (14)**	
Digit touch (Coupling #1) perpendicular to extended digit	84 (33)** 131 (42)	43 (14)** 70 (17)	36 (13)** 76 (20)	30 (13)** 57 (17)	25 (10)** 55 (16)	—

- ➢ Keep the shoulder relaxed, the elbow at the side of the body, the forearm semipronated, and the wrist straight.
- ➢ Use tools with handles of appropriate size and shape, as already discussed.
- ➢ Round off all edges and sharp corners on the hand tool or at the workstation with which the worker might come in contact.
- ➢ Avoid excessive cooling of the hand, either by a cold environment or by strong air movement (particularly important with air-powered tools) or by contact with metal handles that easily conduct heat energy away from the hand.
- ➢ Ensure that gloves worn actually help the activity but do not hinder motion or enforce awkward wrist positions.

➢ Minimize vibrations of hand tools to avert cumulative trauma disorders—covered later in this chapter.

WORKSTATION DESIGN

The goal in designing a workstation is to promote ease and efficiency for the working person. Productivity will suffer in quantity and quality if the operator is uncomfortable, if the layout of the workstation or the job procedures are awkward. Conversely, productivity will be enhanced if the operator is comfortable physiologically and psychologically and if the layout of the workstation is conducive to performing the task well. Keeping this in mind, try to establish an ideal workstation, task, and work environment first and to make concessions to practical limitations only if absolutely necessary.

General Principles

Five general rules govern the design of workplaces:

1. Plan the ideal, then the practical.
2. Plan the whole, then the detail.
3. Plan the work process and the equipment to fit the human.
4. Plan the workplace layout around the process and the equipment.
5. Use mockups to evaluate alternative solutions and to check the final design.

In this design process, the following aspects are of primary importance:

➢ *Space:* clearance for the operator's body entrance and egress (including emergency exit); suitable body movements and postures at work; operation of controls and equipment (without bumping elbows, knees, or head);

➢ *Manipulation:* operation of tools, controls, and work pieces by hand (or foot) including seat adjustment; avoidance of excessive forces or inadvertent operation of controls; use of emergency items (stop button, flashlight, survival equipment);

➢ *Seeing:* visual field and information both inside (displays and control settings) and outside (road, machine being controlled); visual contact with co-workers; lighting (illumination, luminance, shadows; avoid glare).

➢ *Hearing:* auditory information, such as oral communication with other workers, signals (including warning signals), and sounds from equipment (engine underload, cutting tool).

More detailed design guidelines depend on the special workstation, on the specific work task, and on the environment. Such guidelines can be found, for example, in books by Cushman and Rosenberg (1991); Eastman Kodak Company (1983, 1986); Fraser (1989); Konz and Johnson (1999); Karwowski and Marras (1999); Kroemer et al (2001) Salvendy (1997); and Woodson et al (1991). *Military Standards 759* and *1472* also provide a wealth of human engineering information.

Standing or Sitting

Whether the operator should stand or sit at the workstation depends on several factors: the mobility required, the forces needed, the size of the work piece, and the required precision. The advantages of standing over sitting include more mobility, more body strength available, less front-to-rear room required, no seat needed, and greater latitude in workstation design. The advantages of sitting are that pedals can be operated with the foot more effectively (more strongly, and with more precision), it is less fatiguing to maintain the sitting posture (if a good seat is available), and manipulation and vision may be more precise. Unless the specific work task or the environment or conditions strictly demand either sitting or standing, provisions should be made to allow the operator to sit or stand at will. Figure 13–17 shows "stand-seats," which can offer a useful compromise. (More information on seat design is contained in the section on computer workstations of this chapter.)

WORKPLACE DESIGN

The most basic requirement for a workplace is that it must accommodate the person working in it. Specifically, this means that the workspace for the hands should be between hip and chest height in front of the body. Within this region, the lower locations are preferred for heavy manual work, and the higher locations are suitable for tasks that require close visual observation. Contours of reach envelopes indicate the maximum distances at which objectives can be manipulated or placed. Figure 13–18 shows an example of such reach capabilities.

Work objects should be located close to the front edge of the work surface so that the worker does not have to bend over and lean across the surface to grasp items. To allow the person to be close to the front edge of the work surface, sufficient room must be provided so that thighs, knees, and toes can be placed somewhat under the work surface if the work is performed while standing. For sitting operators, deeper and wider leg room must be provided under the bench, table, or desk. If foot controls are used, additional room for foot and leg motions may be needed. Pedals that must be operated continuously or frequently normally require a seated operator because if a person operated them while standing, the body weight would have to be supported on one foot.

Visual displays including instruments, counters, dials, and signal lights are preferably placed in front of the body and below eye level so that the line of sight (which runs from the eyes to the visual target) is declined 10 degrees to 40 degrees below the horizontal level. Table 13–Q lists general principles for workstation design; specifics for computer workstations follow later in this chapter.

Work-Space Dimensions

Work-space dimensions can be grouped into three basic categories: minimal, maximal, and adjustable dimensions. *Minimal* work-space dimensions provide clearance for the worker. Many minimal clearance dimensions, such as the open leg space under a work table, can be determined using large percentile values from anthropometric tables (see

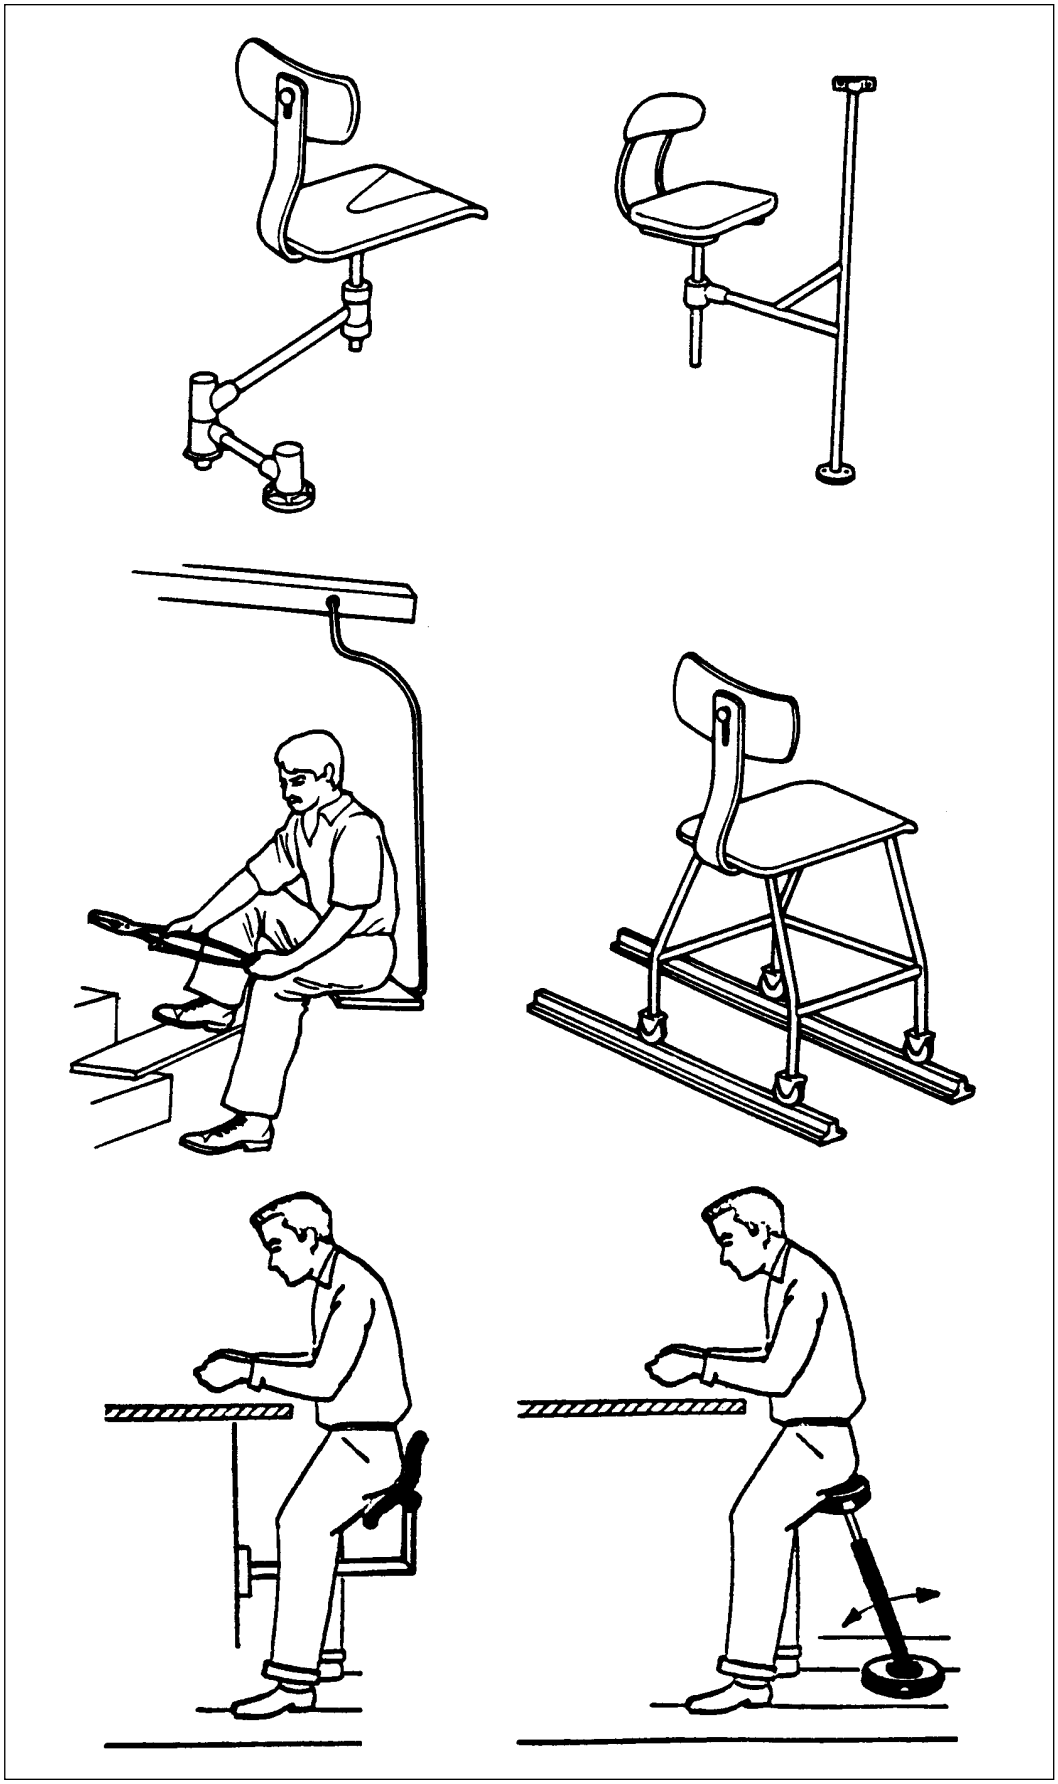

Figure 13–17. Examples of stand-seats. Adapted from Kroemer et al (2001), *Ergonomics: How to Design for Ease and Efficiency.* Upper Saddle River, NJ: Prentice-Hall. With permission by the publisher. All rights reserved.

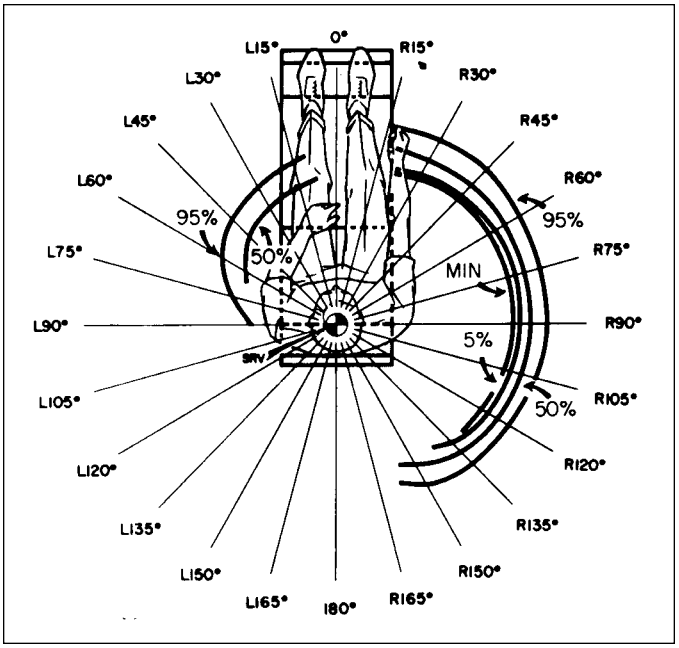

Figure 13–18. Grasping reach contours of the right hand in a horizontal plane 25 centimeters above the seat reference point. (Reprinted with permission from Damon, Stoudt, and McFarland, *Human Body in Equipment Design*, 1966.)

Table 13–E). For example, if a 95th-percentile knee height were used to determine the height of the legroom, nearly everybody's legs would fit under the table. Even larger values need to be considered for other clearances: if the opening of a doorframe were at the 95th-percentile value, at least five percent of all users would bump their heads. *Maximal* dimensions are selected to permit smaller workers to use the equipment; for example in terms of the distance at which one can reach. A related case is setting force requirements so low that even a weak person can operate the equipment. Often, the fifth percentile value of the relevant body attribute is used for determining minimal design measurements.

Adjustability permits the operator to modify the work environment and equipment so that it conforms to that individual's particular set of physical (anthropometric, biomechanical) characteristics as well as to subjective preferences. A six-way adjustable seat in a truck is an example of the proper adjustability that accommodates individual operators. Adjustable dimensions are particularly important when optimal performance with minimum effort is necessary to accomplish the work task.

The requirements for an industrial work seat are essentially the same as those for an office chair (see the following section in this chapter on computer workplaces). However, the industrial work seat is probably somewhat more rugged and has soil-resistant upholstery. As shown in Figure 13–19,

Table 13–Q. ***Ergonomic Guidelines for Workplace Design***

1. In the design of the facility, assure a proper match between the facility and the operator to avoid static efforts, such as holding a work piece or hand tool. Static (isometric) muscle tension is inefficient and leads to rapid fatigue.
2. The design of the task and the design of the workplace are interrelated. The work system should be designed to prevent overloading the muscular system. Forces necessary for dynamic activities should be kept to less than 30% of the maximal forces the muscles are capable of generating. Occasionally, forces of up to 50% are acceptable when maintained for only short durations (approximately 5 minutes or less). If static effort is unavoidable, the muscular load should be kept quite low—less than 15% of the maximal muscle force.
3. Aim for the best mechanical advantage in the design of the task. Use postures for the limbs and body that provide the best lever arms for the muscles used. This avoids muscle overload.
4. Foot controls can be used by the seated operator. They are not recommended for continuous use by a standing operator because of the imbalanced posture imposed on the operator. If a pedal must be used by the standing operator, it should be operable with either foot. Avoid hard floors for the standing operator; a soft floor mat is recommended, if feasible.
5. Maintain a proper sitting height, which is usually achieved when the thighs are about horizontal, the lower legs vertical, and the feet flat on the floor. Use adjustable chairs and, if needed, footrests. When adjusting the chair, make sure that:
   a. elbows are at proper height in relation to work surface height;
   b. the footrest is adjusted to prevent pressure at undersides of the thighs;
   c. the backrest is large enough to be leaned against, at least for a break, and
   d. special seating devices are used if the task warrants them.
6. Permit change of posture—static posture causes problems in tissue compression, nerve irritation, and circulation. The operator should be able to change his or her posture frequently to avoid fatigue. Ideally, the operator should be able to alternate between sitting and standing; therefore, a workplace that can be used by either a sitting or standing operator is recommended.
7. In designing the facility, accommodate the large operator first and give that operator enough space. Then provide adjustments and support so that the smaller operator fits into the work space. For standing work, the work surface should be designed to accommodate the taller operator; use platforms to elevate shorter operators. (But watch out for stumbles and falls!) For reach, design to accommodate the shorter operator.
8. Instruct and train the operator to use good working postures whether sitting or standing, working with machines and tools, lifting or loading, or pushing or pulling loads.

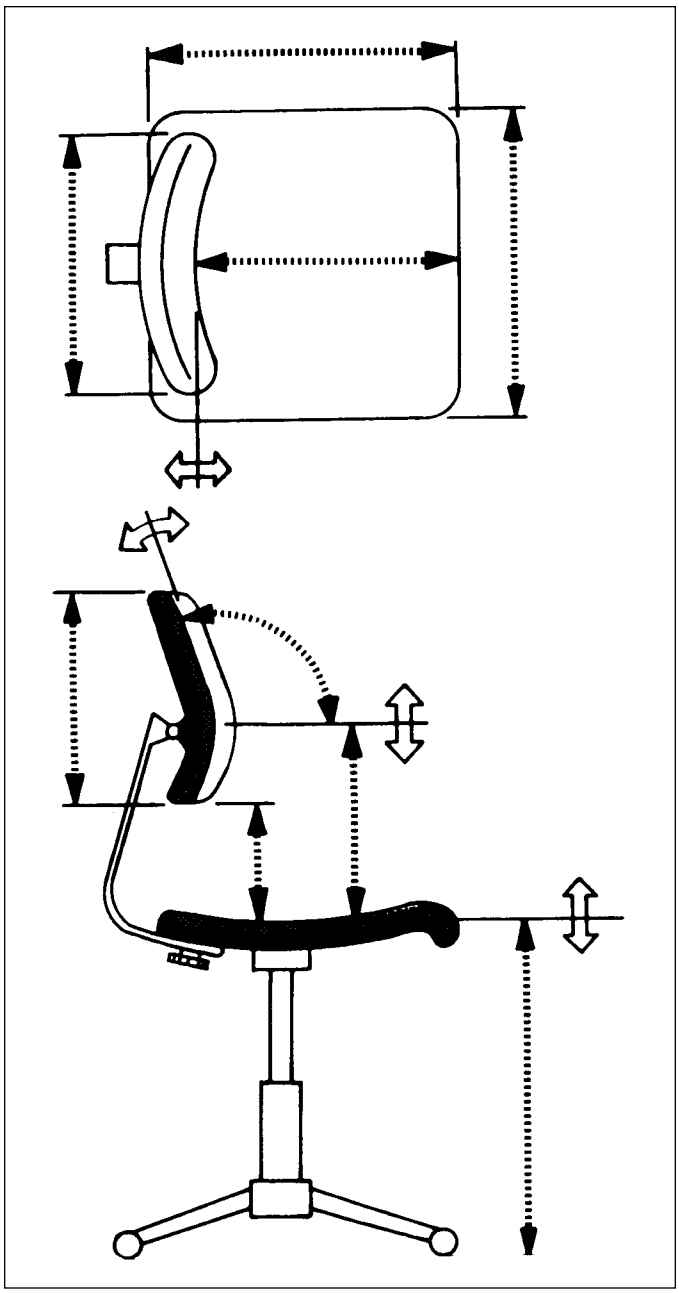

Figure 13–19. Main design features of an industrial work seat. (Reprinted with permission from the American Industrial Hygiene Association.)

the industrial work seat should be adjustable in seat pan height between about 38 and 51cm (15–20 in.). Its front edge should be well rounded to avoid pressure to the underside of the thighs. A backrest should be provided, if the work activities allow it. The backrest should be adjustable in height and in distance from the front edge of the seat pan. To allow free mobility of the arms and shoulder blades, the backrest probably should not extend up to the neck (as the office chair may); however, a large backrest allows relaxing during a break from the work activities. The backrest should have a protrusion or pad at lumbar height, just like an office chair.

Objects that must be seen and observed (displays, signal lights, controls, dials, keyboards, written documents) should be placed well within the worker's visual field. This is the area, described in degrees, in which form and color of objects can be seen by both fixated eyes. The more important visual targets, especially those that must be read exactly, should be placed in the center of the preferred viewing area. To determine this preferred visual field, one first establishes a reference line, the Ear-Eye line, which runs—seen on the side of the head—through the ear and the juncture of the eyelids, as shown in Figure 13–20. (The Ear-Eye is much more easily established than the Frankfurt line, often used in older texts; for more information, see Kroemer et al, 2001.) When the angle between the horizon and the Ear-Eye line, P in Figure 13–20, is about 15 degrees, the head is held erect on an upright neck and trunk. Looking at an object in the distance, the preferred line of sight is approximately horizontal, i.e., about 15 degrees below the Ear-Eye line. But for focussing at close targets, such as when reading a text either printed or displayed on a computer screen, most people prefer to look down steeply, as much as 60 degrees below the Ear-Eye line.

OFFICE (COMPUTER) WORKSTATIONS

Complaints related to posture (musculoskeletal pain and discomfort) and vision (eye strain and fatigue) are, by far, the most frequent health problems voiced by computer operators in North America and Europe. Apparently, some of these complaints are related. Difficulties in viewing (focusing distance, angle of the line of sight, glare), together with straining curvatures of the spinal column, particularly in the neck and lumbar regions, if joined by fatiguing postures of shoulders and arms result in a stress-strain combination in which causes and effects intermix, alternate, and build on each other, especially if socio-psychological conditions are faulty (Carayon, Smith, & Haims 1999).

Improperly designed workstations, ill-selected furniture, and poorly arranged equipment are the principal causes of postural problems. The questionable design idol of "sitting upright" at the old office desk has been carried over to the computer workplaces. Even the 1988 ANSI 100 standard on visual display terminal workstations used an "upright, or near straight" posture for deriving furniture dimensions. In reality, many other working postures exist that are suitable for the work, and subjectively comfortable. Current design strategies recognize and build upon the great variety of individually preferred body movements and work postures in the computerized office (Kroemer and Kroemer 2001).

Successful ergonomic design of the office workstation depends on proper consideration of several interrelated aspects, sketched in Figure 13–21. The postures that a person assumes and the ways to perform activities are strongly influenced by

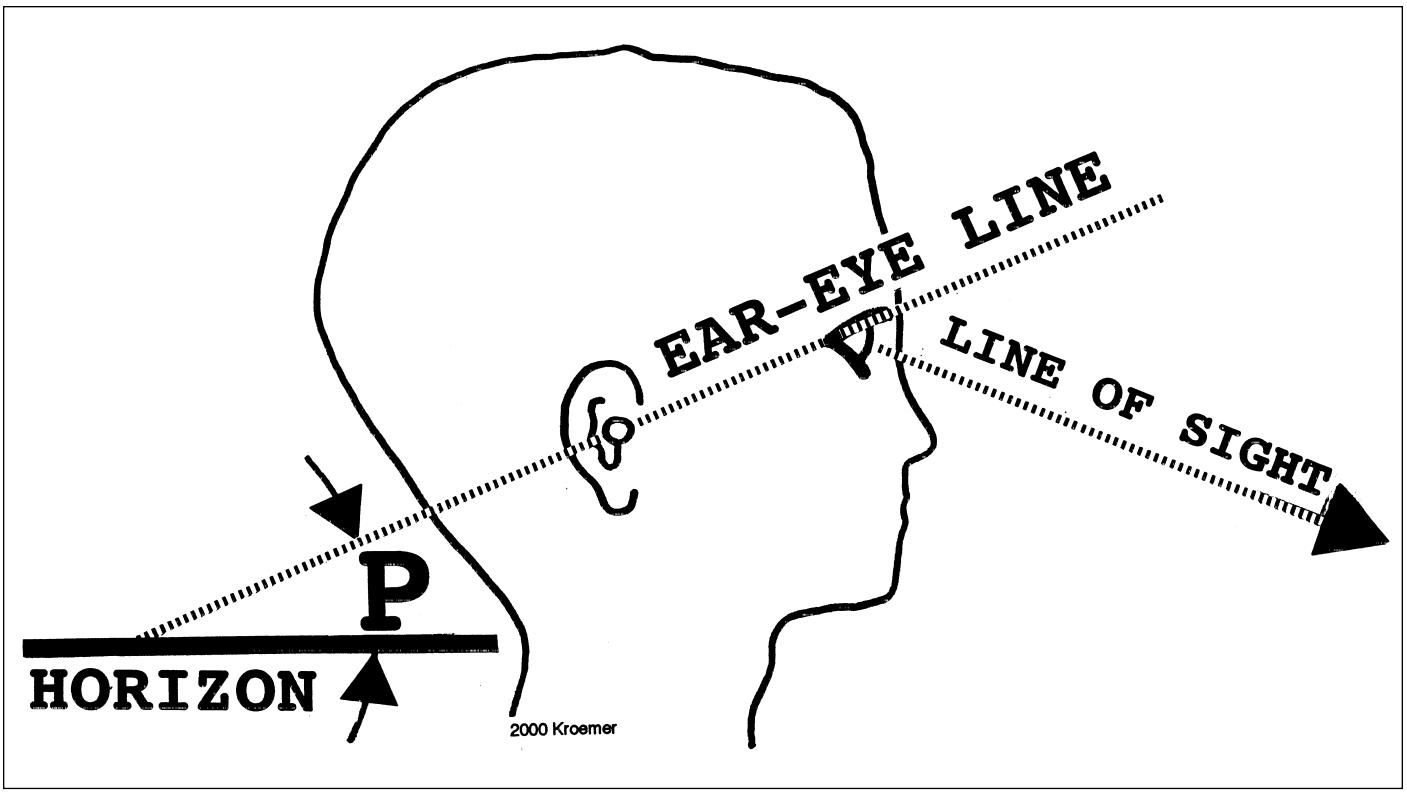

Figure 13–20. Ear-eye line and the line of sight

workstation conditions including furniture, equipment, and environment. All must "fit" the person and the task.

The actual work postures and motions affect physical and psychological well being, while the work activities determine the output of the person working with the equipment. Feeling well, both physically and about one's performance, affects health, work attitudes, and work output. Of course, the interpersonal and organizational "climate" is a major factor also. These interactive relationships are not static but vary with time, and they are somewhat different from person to person.

This brief discussion of the many and multileveled relationships among work variables is meant to emphasize the need for carefully designing the workstation—particularly its furniture, equipment, and lighting—so that the desired results of well-being and high performance are achieved.

Work Task

Within about a decade, the use of computers has profoundly changed many tasks in the office, in the company building or at home. Most "typing" is now performed on a computer rather than with a traditional typewriter. This allows the operator to control the layout of texts and graphics while it eliminated the frustrating and time-consuming job of retyping large chunks of material to incorporate relatively minor changes.

Compared to a typist's job, word processing affords more control functions and detail responsibilities, and it requires different and more complex skills. Working with a computer establishes special demands on the operator's visual and motor capabilities. The eyes have three important tasks:

1. to search for specific keys (the exorbitant number of keys on most computer keyboards requires visual search and identification; "blind" touch typing is seldom possible)
2. to read a source document (for input into the computer)
3. to scan the display of the monitor (either to obtain new information or to receive feedback about the material already transmitted to the computer system)

The fingers input information to the system via keyboard, mouse, trackball, and other controls, such as light pen and touch panel. Voice communication with the computer, both as input and output, is being developed.

Positioning the Body in Relation to the Computer

With today's state of the art, the operator interfaces with the computer mostly through eyes and fingertips. The ears are input channels to the operator, and the mouth is a natural output device. However, sound and speech are not often used to communicate with computers even though these signals can travel through the air or can be transmitted through speaker phones attached to the head. Use of acoustic signals would not restrict the operator's head position and hence, the posture of the whole body. However, with current technology, the operator receives primary input through the eyes, as they focus their sight on the monitor, on the source document, and on the keys. Thus, the position of the person's eyes is rather immovable with

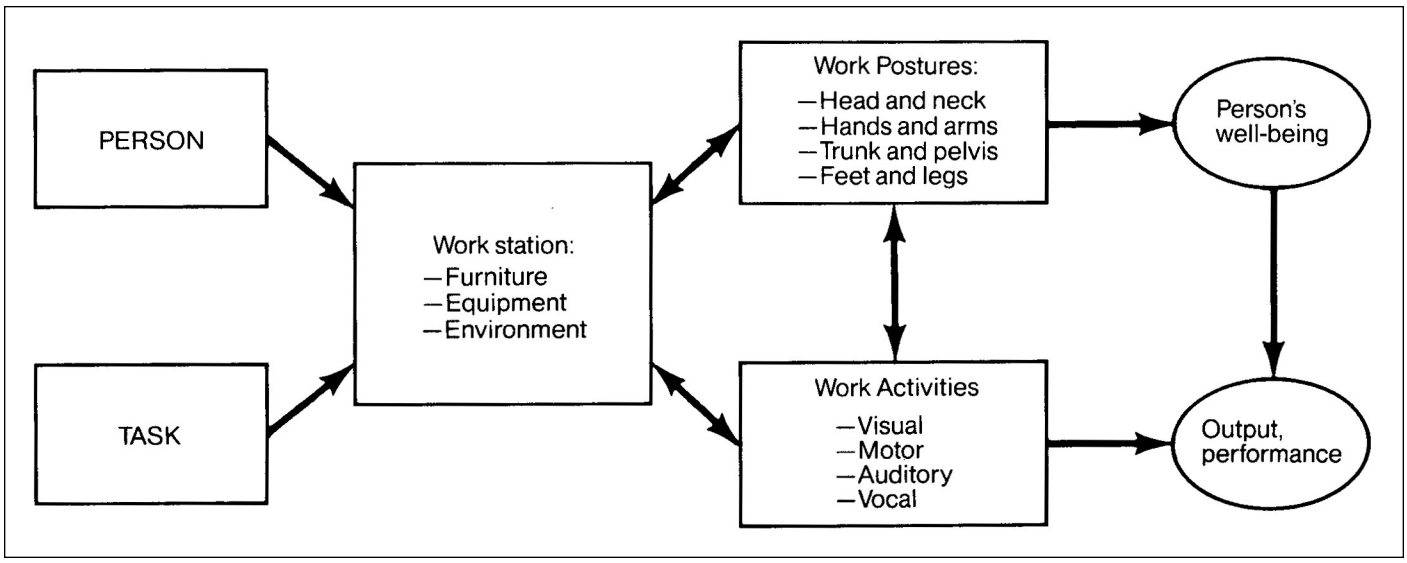

Figure 13–21. Interactions among workstation design, work postures, and work activities and their effect on the computer operator's well being and performance.

respect to the visual target. This eye fixation has the consequence that head, neck, and hence, trunk cannot be moved much but must remain in place, making for a rigid body posture at work.

Instead of voice, the digits of the hands are the user's major output links to the computer, just as they are with the old-fashioned typewriter. As keys, mouse pad, trackball, or touch panel are fixed within the workstation, the operator has no choice but to keep the hands on them. This often determines, in fact, fixates, the person's body posture, even more so if foot controls are in use.

Healthy Work Postures?

In the 1880s, it was generally believed that an "upright" trunk, as when standing still and erect, was part of a healthy posture (Staffel 1884, 1889). For about 100 years, this idea had been used—usually with presuming right angles at hips, knees and ankles—to design office chairs and other furniture. However, contrary to what we have been taught, today there are no compelling physiological or orthopedic reasons to make people stand or sit "straight." Nothing is wrong with this posture when it is freely chosen, but, if left alone, few people choose and maintain this posture over extended periods of time.

An upright trunk has a straight spinal column on the frontal or posterior view but, in the lateral view, the spine forms one forward bend (lordosis) each in the neck and in the low-back region, and a slight rearward bulge (kyphosis) in the chest region. This, sitting (or standing) upright, does not mean that the spinal column is ramrod straight.

For nearly a century, physicians, orthopedists, physical therapists, parents, teachers, and military officers advocated the 19th-century "normal" posture of erect standing, as recommended by Staffel and his contemporaries. Even today, that upright standing posture is commonly considered "good and proper." But it is certainly impractical for working since we do move about—and should do so—instead of standing (or sitting) stiff and still. Maintaining any body position becomes unpleasant after a while: even while we rest in bed, or relax in our most comfy easy chair, we humans must move our bodies and reposition ourselves after some time.

In recent years, the term *neutral posture* has become popular. It suggests a healthy, desirable, or central position of body members. What does neutral mean? Is that the middle of the total motion range in a joint? This would make some sense for the wrist, indicating the hand is straight, i.e., in line with the forearm. But there is no obvious significance to the middle joint position in elbow or knee, shoulder or hip, or the spinal column. Does the term "neutral" suggest that all tissue tensions about a joint are balanced, so that the position is stable? Does the term infer a minimal sum of tissue tensions (torques) around a body joint? Or does this apply to tensions about several joints, or all body joints? Does "neutral" imply minimal joint discomfort? Does it infer a relaxed posture? Or a posture instinctively assumed for a task, to generate high body strength, or to avoid fatigue?

The simplistic concept that sitting upright, with thighs horizontal and lower legs vertical, is "sitting healthily" endured for a surprisingly long time. Even today, that upright posture with slight lordoses (forward bends) in the lumbar and cervical spine areas and a light kyphosis (backward bend) in the thoracic spine is stereotypically considered healthy, balanced, or neutral (Merrill, 1995). Obviously, this posture can be quite appropriate for a while, but it is erroneous to use it as the overriding guiding principle for the design of the chair or other workstation furniture. To simply design for this postural idol completely disregards that it is healthy to change among various postures while sitting, not to stay in any one position for too long.

Figure 13–22. Moving, not sitting still, at work.

FREE-FLOWING MOTION

In 1984, Grandjean, Huenting, and Nishiyama found that persons sitting in offices did not sit upright but leaned backward even if their chairs apparently were not designed for such a posture. Bendix et al (1996) reported that persons, while reading, often assumed a kyphotic lumbar curve even when sitting on a chair with a lumbar pad that should have produced a lordosis. These finding support the everyday observation that people sit any way they want, regardless of how experts think they should sit!

Allowing persons freely to select their posture has led in two instances to surprisingly similar results. In 1962, Lehmann showed the contours of five persons "resting" under water where the water fully supports the body. Sixteen years later, NASA astronauts were observed when they relaxed in space. The similarity between the postures under water and in space is remarkable. One might assume that, in both cases, the sum of all tissue torques around body joints has been nulled. Apparently not incidentally, the shape of so-called easy chairs is quite similar to the contours of the relaxed body.

Dynamics is a label than can be applied to current design of office chairs, as opposed to the "statics" of maintained posture. People do move about as they please. Design should encourage and support free-flowing motions, as sketched in Figure 13–22, with halts for temporary postures at personal whim.

The *free-flowing motion* design idea has these basic tenets:

- ➢ Allow the user to freely move in and with the chair and to halt at will in a variety of sitting postures, each of which is supported by the chair; and to get up and move about.
- ➢ Make it easy for the user to adjust the chair and other furniture, especially keyboard and display, to the changing motions and postures.
- ➢ Design for a variety of user sizes and user preferences.
- ➢ Consider that new technologies develop quickly and should be usable at the workstation. For example, radically

new keyboards and input devices, including voice recognition, may be available soon; display technologies and display placement are undergoing rapid changes; laptop and heldheld computers with small key sets and attached screens are widely used.

Designing for Vision, Manipulation, and Body Support

It is helpful for the layout of a work task and workstation to think of three main links between a person and the task.

- ➢ The first link is the *visual interface*. One must look at the keyboard, the computer screen, or the printed output, and source documents.
- ➢ The second link is *manipulation*. The hands operate keys, a mouse, or other input devices; manipulate pen, paper, and telephone. Occasionally, the feet operate controls, for example, starting and stopping a dictation machine. The intensities of the visual and motor requirements depend on the specific job.
- ➢ The third link is *body support*. The seat pan supports the body at the undersides of the thighs and buttocks, and the backrest supports the back. Armrests or a wrist rest may be other support links.

DESIGNING FOR VISION

The location of the visual targets greatly affects the body position of the computer operator. Many studies have shown what is intuitively apparent: objects upon which we focus our eyesight should be located directly in front, at a convenient distance and height from the eyes. If one is forced to turn the head to the side or tilt it up to view the computer screen or the document, he or she will often experience *eyestrain*. Eyestrain is often accompanied by pain in neck, shoulders, and back. Yet, two basic mistakes are often made in many workstations: the monitor is set up much too far and too high and source documents are often laid flat to the side. In either case, the operator must crane his or her neck.

Monitor Support. It is advantageous to use a separate support for a separate computer monitor so that the display can be adjusted in height independently from keyboard, work surface, and table or desk. Easy adjustment is facilitated if the surface can be moved up or down easily, such as by a hand crank or an electric motor.

The common practice of putting the monitor on the CPU box, and possibly also on an stem for angle adjustment, lifts the screen much too high for most users, who consequently tilt their heads back and then may suffer from neck and back problems. Instead, the monitor should be located low behind the keyboard so that one looks down at it.

As a rule, the screen or source document should be about half a meter from the eyes, at the proper viewing distance for the operator's eyes. This is the distance for which corrective eye lenses are usually ground.

Document holder. If one reads from a source document often, one should use a document holder that holds the document close and parallel to the monitor screen, about perpendicular to the line of sight. A document placed far to one side causes a twisted body posture and lateral eye, head, and neck movements.

Proper lighting. The computer office should be illuminated at about 200 to 500 lx with today's self-lit displays. Paper documents may be difficult to read at this fairly low level, so one might want to shine a special task light on them—making sure that this does not create glare. For offices without computers, the proper illumination range is from 500 to 1,000 lx, even more if there are many dark (light-absorbing) surfaces present.

DESIGNING FOR MANIPULATION

In addition to the eyes, our hands are usually very busy doing various office tasks: grasping and moving papers, taking notes, dialing phone numbers, and using various computer input devices. If our hands do many different activities, the varied manipulation is likely to keep our arms and the upper body moving around in our workspace. Motion is desirable—in contrast to maintaining a fixed posture, such as when tapping the keyboard over an extended time.

Keyboards and other computer input gadgets should all be placed directly in front of the body, at about elbow height when the shoulders are relaxed and the upper arms hang by the sides of the upper body. A keyboard set up higher forces one to lift the arms and shoulders, requiring unnecessary muscle tension. Placing the keyboard and mouse at different levels, to the side, or too far away will cause muscle tension in the back, neck, and arms to get and hold the hands there. This often leads to irritation and pain, and occasionally to overuse disorders such as bursitis, tendinitis, or cervicobrachial syndrome. These and other overuse disorders are discussed later in this chapter.

Resting one's wrist or arm on a hard surface or, worse, on a hard edge often occurs when a working surface is pushed up too high, above the operator's elbow height. This leads to sharp local pressure at the point of contact that can cause painful reactions. Examples are cubital tunnel syndrome, when the cubital nerve is compressed by placing the elbow on a hard surface, or carpal tunnel syndrome, when a sharp edge (for example, of a keyboard housing) presses into the wrist and palm area of the hand. These conditions can be avoided by placing the manipulation area low, by softening surfaces that support the arm and hand (rounding edges, padding surfaces, giving wrist supports), and by proper working habits.

DESIGNING FOR MOTION

The human body is built to move about, not to hold still. It is uncomfortable and tiresome to maintain a body position without change over extended periods. While driving a car, a

driver must hold his or her head in much the same position in order to see the road and instruments, and keep hands and foot fixed on wheel and pedal. After a while, it becomes very difficult to stay in the same seated position and posture, even though the nearly immobile posture is supported by a relatively comfortable seat. A similar situation arises often at computer workstations—where the chair is often much less suitable than the car seat. But, unlike when driving, in the office one can get up and move around at will—a good habit!

At work, the body needs to move to not keep a static posture. Therefore, the primary aim of ergonomic workstation design is to facilitate body movement, not to support maintenance of certain body positions. A convenient way to do so is for the designer to consider the extreme body postures expected to occur and to lay out the workspace for motion between these. In the computerized office this means to design for walking (standing) and for sitting. The seat should be designed for relaxed and upright sitting, for leaning backward and forward, and for getting in and out.

Several chair designs have gone beyond the concept of a user-adjustment. They incorporate seat pans and backrests that follow the motions of the sitting person and provide support throughout the range. Other designs flow from the thought that the seat must not be a passive device but an active one: The chair as a whole, its pan, or backrest, can automatically change the configuration slightly over time, perhaps in response to certain sitting postures maintained by the person. The change can be in angles, or in stiffness of the material. Seat and back cushions that pulsate were tried in the 1950s to alleviate the strain that military aircrews felt when they had to sit for hours on end to fly extended missions. An "intelligent seat" can remind the user to move, or to get up, after sitting in a static position for some period of time.

COMFORT VERSUS DISCOMFORT?

Comfort (as related to sitting) has long been defined, simply and conveniently, as the absence of discomfort. However, the underlying concept is false: in 1997 Helander and Zhang showed that, in reality, these two aspects are not the opposite extremes of one single-judgment scale. Instead, there are two scales, one for the agreeable feelings of "comfort" and the other for such unpleasant experiences as not being at ease, fatiguing, straining, smarting, hurting. All are terms that indicate some degree of discomfort. These two scales partly overlap but are not parallel.

Using the term *annoyance* (instead of discomfort as the descriptive label for the scale containing the unpleasant statements) helps to avoid the false concept of one scale that has comfort and discomfort as opposites. The other scale, containing the agreeable statements, is labeled with the term *comfort*, as has been the convention.

The Annoyance Scale

Feelings of annoyance (formerly described as discomfort) are expressed by such words as stiff, strained, cramped, tingling, numbness, not supported, fatiguing, restless, soreness, hurting, and pain. Some of these attributes can be explained in terms of circulatory, metabolic, or mechanical events in the body; others go beyond such physiological and biomechanical phenomena.

Users can rather easily describe design features that result in feelings of annoyance such as chairs in wrong sizes, too high or too low, with hard surfaces or edges; but avoiding these mistakes does not, per se, make a chair comfortable.

The Comfort Scale

Feelings of comfort when sitting are associated with such descriptive words as warm, soft, plush, spacious, supported, safe, pleased, relaxed, and restful. However, exactly what feels comfortable depends very much on the individual and his or her habits, on environment and task, and on the passage of time.

Esthetics plays a role. If we like the appearance, the color, the ambience, we are inclined to feel comfortable. Appealing upholstery, for example, especially when it is neither too soft nor too stiff but distributes body pressure along the contact area, and "breathes" by letting heat and humidity escape as it supports the body, can contribute to the feeling of comfort.

Ranking Chairs by Annoyance or Comfort

Helander and Zhang used six specific statements about chair annoyance or comfort (each with nine steps from "not at all" to extremely") followed by one general statement.

The statements for annoyance are as follows:

1. I have sore muscles.
2. I have heavy legs.
3. I feel uneven pressure.
4. I feel stiff.
5. I feel restless.
6. I feel tired.
7. *I feel annoyed.*

The following statements characterize comfort:

1. I feel relaxed.
2. I feel refreshed.
3. The chair feels soft.
4. The chair is spacious.
5. The chair looks nice.
6. I like the chair.
7. *I feel comfortable.*

Helander and Zhang's subjects said it was easy to rank chairs in terms of overall comfort or annoyance (answer 7 in the lists) after having responded to the preceding, more detailed descriptors.

The researchers concluded that it is apparently more difficult to rank chairs, unless truly unsuitable, by attributes of annoyance (as opposed to comfort) because the body is surprisingly adaptive (except when the sitter has a bad back). In contrast, comfort descriptors proved to be sensitive and discriminating for ranking chairs in terms of preference.

Preference rankings of chairs could be established early during the sitting trials; they did not change much with sitting duration. Still, it is not clear whether a few minutes of sitting on chairs are sufficient to assess them, or whether it takes longer trial periods.

Designing the Sit-Down Workstation

One of the first steps in designing the office workstation for seated persons is to establish the main clearance and external dimensions. The size of the furniture derives essentially from the body dimensions and work tasks of the people in the office. Main vertical anthropometric inputs to determine the height requirements are lower leg (popliteal and knee) heights, thigh thickness, and the heights of elbow, shoulder, and eye—all listed in Table 13–E for North Americans.

The common design procedure is to start from the floor: upon it one stacks the height of the chair, then the height of supports for input devices (such as the keyboard, mouse pad, etc.), finally the height of table and desk surfaces. To truly fit all the sizes and preferences of everyone in the office, all the furniture heights should be widely and easily adjustable.

Another furniture design strategy starts with the premise of a fixed height of the major work surface (the desk or table in traditional offices), with adjustable heights of the seat and of the computer support. This regularly requires narrower height adjustment ranges for seat and equipment, but smaller persons need footrests. Another design approach relies on the same seat height for all, which results in the smallest adjustment needs for desks, tables, and supports, yet all but the most long-legged individual need footrests (Kroemer et al, 2001). The depths and widths of the furniture must fit the horizontal body dimensions (especially popliteal and knee depths, hip breadth and reach capabilities) as well as work task and equipment space needs.

The furniture at the computer workstation consists primarily of the seat, the support for the data-entry device, the support for the display, and a working surface (table or desk). It is best, and most expensive, to have all of these independently adjustable. These ranges should make the office furniture fit practically everybody in Europe or North America, tall or short. Of course, if the workplace is used by just one person, such as in the case of a personal home office, then only that one user must be fitted and little or no subsequent adjustments may be necessary.

THE OFFICE CHAIR

As discussed earlier, "proper sitting" at work was long believed to mean an upright trunk, with the thighs (and forearms) in essence horizontal and the lower legs (and upper arms) vertical. This model, with all major body joints at zero, 90, or 180 degrees makes for a convenient but misguiding design template: the "0-90-180 posture" is neither commonly employed nor subjectively preferred, and it is not even especially healthy. To suit the seated person, the designer of office furniture, especially of chairs, has to consider a full range of motions and postures, as discussed by Kroemer and Kroemer (2001).

Seat Pan

When one sits down on a hard flat surface, not using a backrest, the *ischial tuberosities* (the inferior protuberances of the pelvic bones) act as fulcra around which the pelvic girdle rotates under the weight of the upper body. Since the bones of the pelvic girdle are linked by connective tissue to the lower spine, rotation of the pelvis affects the posture of the lower spinal column, particularly in the lumbar region. If the pelvis rotation is rearward, the normal lordosis of the lumbar spine is flattened.

Leg muscles (hamstrings, quadriceps, rectus femoris, sartorius, tensor fasciae latae, psoas major) run from the pelvis area across the hip and the knee joints to the lower legs. Therefore, the angles at hip and knee affect the location of the pelvis and hence the curvature of the lumbar spine. With a wide-open hip angle, a forward rotation of the pelvis on the ischial tuberosities is likely, accompanied by lumbar lordosis. (These actions on the lumbar spine take place if associated muscles are relaxed; muscle activities or changes in trunk tilt can counter the effects.)

Accordingly, in 1884 Staffel proposed a forward-declining seat surface to open up the hip angle and bring about lordosis in the lumbar area. In the 1960s, a seat-pan design with an elevated rear edge became popular in Europe. Since then, Mandal (1975, 1982) and Congleton et al (1985) again promoted that the whole seat surface slope fore-downward. To prevent the buttocks from sliding down on the forward-declined seat, the seat surface may be shaped to fit the human underside (Congleton et al), or one may counteract the downward-forward thrust either by bearing down on the feet (Mandal) or by propping the upper shins on special pads. A seat surface that can be tilted throughout the full range (from declined forward, kept flat, to inclined backward) naturally allows one to assume various curvatures of the lower spinal column, from kyphosis (forward bend) to lordosis (backward bend).

The surface of the seat pan must support the weight of the upper body comfortably and securely. Hard surfaces generate pressure points that can be avoided by suitable upholstery, cushions, or other surface materials that elastically or plastically adjust to body contours.

The only inherent limitation to the size of the seat pan is that it should be short enough that the front edge does not press into the sensitive tissues near the knee. Usually, the seat pan is between 38 and 42 cm deep and at least 45 cm wide. A well-rounded front edge is mandatory. The side and rear borders of the seat pan may be slightly higher than its central part.

The height of the seat pan must be widely adjustable, preferably down to about 37 cm and up to 51 or even 58 cm, to accommodate persons with short and long lower legs. It is very important that all adjustments, especially in height and tilt angle, can be easily done while one sits on the chair.

Figure 13–23 illustrates major dimensions of the seat pan.

Backrests

Two opposing ideas have been promoted. One advocates not having a backrest at all, so that trunk muscles must remain

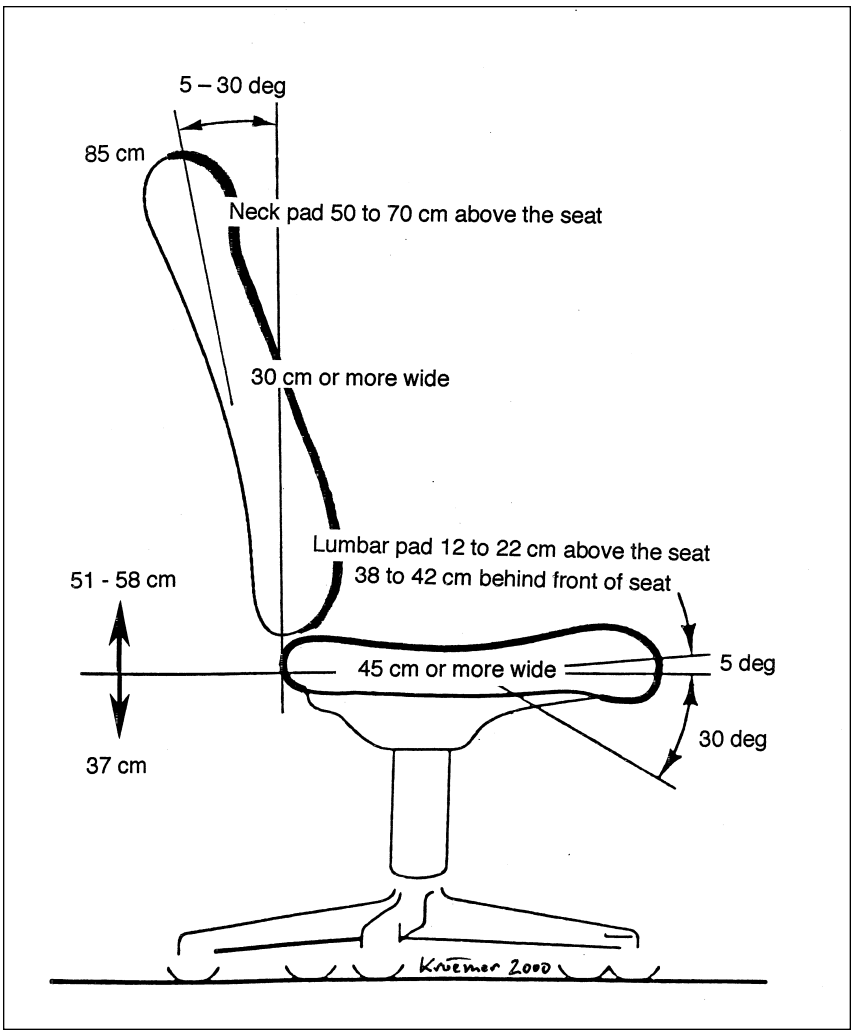

Figure 13–23. Essential dimensions of seat pan and backrest. Adapted from Kroemer et al (2001), *Ergonomics: How to Design for Ease and Efficiency*, 2nd ed. Upper Saddle River, NJ: Prentice-Hall.

continually active to keep the upper body in balance. However, this concept (called active sitting) has not become very popular, for obvious reasons.

Most people think that a backrest is desirable for several reasons. One is that the back support carries some of the weight of the upper body and hence reduces the load that otherwise the spinal column must transmit to the seat pan. A second reason is that a lumbar pad, protruding slightly in the lumbar area, helps to maintain lumbar lordosis, believed to be beneficial. A third, related reason is that leaning against a suitably formed backrest is relaxing.

Studies have shown the importance of supporting the back by leaning it on a rearward-declined backrest. Andersson et al summarized the available findings in 1987 and concluded, "In a well-designed chair the disc pressure is lower than when standing" (p.1113). Relaxed leaning against a declined backrest is the least stressful sitting posture. This is often freely chosen by persons working in the office if there is a suitable backrest available: "... an impression which many observers have already perceived when visiting offices or workshops with VDT workstations: Most of the operators do not maintain an upright trunk posture.... In fact, the great majority of the operators lean backwards even if the chairs are not suitable for such a posture" (Grandjean et al, 1984, pp 100–101).

Of course, the backrest should be shaped to support the back fittingly. Apparently independently from each other, Ridder (1959) in the United States and Grandjean and his co-workers (1963) in Switzerland found in experiments that their subjects preferred similar backrest shapes. In essence, these shapes follow the curvature of the rear side of the human body. At the bottom, the backrest is concave to provide room for the buttocks, above is slightly convex to fill in the lumbar lordosis. Above the lumbar pad, the backrest surface is nearly straight but tilted backward to support the thoracic area. At the top, the backrest is again convex to follow the neck lordosis.

Combined with a suitably formed and upholstered seat pan, this shape has been used successfully for seats in automobiles, aircraft, passenger trains, and for easy chairs. In the traditional office, the boss enjoyed these first-class shapes while the rest of the employees had to use simpler designs. The so-called secretarial chairs had a small, often hard-surfaced seat pan and a slightly curved back support for the

low back. The more recently designed task chair is an improved version.

The backrest should be as large as can be accommodated at the workplace: this means up to 85 cm high and at least 30 cm wide. To provide support from the head and neck on down to the lumbar region, it is usually shaped to follow the back contours, specifically in the lumbar and the neck regions. Many users appreciate an adjustable pad or an inflatable cushion for supporting the lumbar lordosis. The lumbar pad should be adjustable from 12 to 22 cm, the cervical pad from 50 to 70 cm above the seat surface.

The angle of the backrest must be easily adjustable while the person using it is seated. It should range from slightly behind upright (95 degrees from horizontal) to about 30 degrees behind vertical (120 degrees), with further declination for rest and relaxation desirable. Whether or not the seatback angle should be mechanically linked to the seat pan angle is apparently a matter of personal preference.

Figure 13–23 illustrates major dimensions of the backrest.

Armrests

Armrests can provide support for the weight of hands, arms, and even portions of the upper trunk. Thus, armrests can be of help, when they have a suitable load-bearing surface and are padded, even if only for short periods of use. Adjustability in height, width, and possibly direction is desirable. However, armrests can also hinder moving the arm, pulling the seat toward the workstation, or getting in and out of the seat. In these cases, having short armrests, or none, is appropriate.

Footrests

Hassocks, ottomans, and footstools have long been popular to put up one's feet, but footrests in the office usually indicate deficient workplace design, especially that a seat pan cannot be sufficiently lowered for the seated person. If a footrest is used, it should not be so high that the sitting person's thighs are nearly horizontal. A footrest should not consist of a single bar or other small surface because this restricts the ability to change the posture of the legs. Instead, the footrest should provide a support surface that is about as large as the total legroom available in the normal work position.

WORK SURFACE, KEYBOARD SUPPORT

The height of the workstation depends largely on the activities to be performed with the hands, and how well and exactly the work must be viewed. Thus, the main reference point for ergonomic workstations is the elbow height of the person, and the location of the eyes. Both depend on how one sits or stands, upright or slumped, and how one alternates among postures.

The table or other work surface should be adjustable in height between about 60 and 70 cm, even a bit higher for very tall persons, to permit proper hand/arm and eye locations. Often, a keyboard or other input device is placed on the work surface, or connected to it by a tray. A keyboard tray can be useful, especially if the table is a bit high for a person, but it also may reduce the clearance height for the knees. The tray should be large enough for keyboard and trackball or mousepad unless these are built into the keyboard.

SITTING AND BACK PAIN

The posture and movements of the spinal column have been of great concern to physiologists and orthopedists. This is due to the fact that so many persons suffer from annoyance, pain, and disorders in the spinal column, particularly in the low back and neck areas. Explanations have been sought in the human body's "not being built for long sitting or standing," or not being fit because of lack of exercise, or having undergone degeneration, particularly of the intervertebral discs. Physical activities and special exercises can improve fitness. Caution must be applied, however, when selecting exercises; some are appropriate, others are of questionable value, but several are outright dangerous or injurious, as Lee and co-authors pointed out in 1992.

The most easily applied remedy is to alternate often between walking, standing, and sitting. When long-time sitting is required, then the design of the seat and other furniture and equipment are critical; e.g., a tall and well-shaped backrest that reclines helps to support the back and head during work and allows one to take relaxing breaks. While sitting, one should change position often. This can be done purposefully by the person, perhaps with the help of automatic devices that make cushions on the seat or backrest pulsate on and off, or that effect small changes in the angles of seat pan and backrest

Designing the Stand-Up Workstation

Standing up while doing computer work seems like a return to the habits of office clerks common around 1900. Yet, moving about and standing on one's feet, at least for a period of time, can be a welcome change from sitting, provided that the person does it at his or her own choosing. One may opt to stand for reading or writing or telephoning. Stand-up workstations can use a second computer to which work activities can be switched from the sit-down workstation for a while, or one can use a lap-top computer there. Some people prefer standing and walking altogether to sitting in the office.

Stand-up workstations should be adjustable to have the working area used for writing or computer inputs at approximately elbow height when standing, between 0.9 and 1.2 meters above the floor. As in the sit-down workstation, the display should be located close to the other visual targets and directly behind the keyboard. If the work surface is used for reading or writing, it may slope down slightly toward the person. A footrest at about two-thirds knee height (approximately 0.3 m) allows the person to prop one foot up on it temporarily. This brings about welcome changes in pelvis rotation and spine curvature.

Nonresilient floors, such as made of concrete, can be hard on peoples' feet, legs, and backs. Carpets, elastic floor mats,

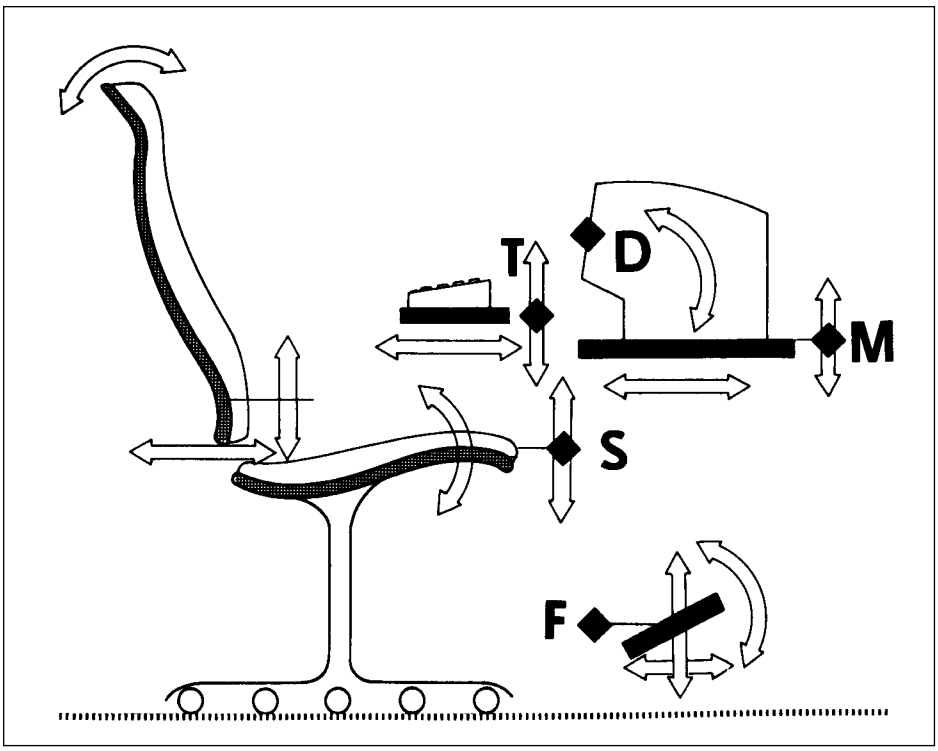

Figure 13–24. Adjustment features of a computer workstation. Key: S = seat height; T = table height; F = footrest height; D = monitor height; M = support height. (Reprinted with permission from Kroemer 2001.).

and soft shoe soles can reduce strain. Appropriate friction between soles and the walkway surface helps to avoid slips and falls.

Designing the Home Office

Everything said previously applies to the home office. If you work only for short periods of time in your office at home, then the old dining table and the odd kitchen chair probably will not harm you. But as soon as you get serious about using your home office, working in it for hours, you should become very conscious about the working conditions there. Equip your office with carefully selected furniture, where the chair and other components of the workstation fit each other well—and, most importantly, fit you well. Don't fall for furnishings that are un-ergonomic, such as shelving units that make you put up the monitor higher than the keyboard, or that do not provide sufficient space for the mouse pad. This is your own workspace, put together for your comfort and ease at work, and it does not have to be similar to anybody else's set-up—nor does it have to be expensive, because some simple furniture on the market can serve you well.

Get a quality computer with an up-to-date display and with input-suitable devices. Select a keyboard that feels convenient to you, but consider voice input that might serve you well. If you travel much with your hand-held or lap-top computer, consider a docking station. Do you want to use a lap-top computer in your office as well? Select a room with good lighting that is separate and quiet and well heated and cooled. You will probably spend more time in your home office than you expected, and your well-being is worth the effort and money that you spend.

Fitting It All Together

A bad or mediocre office is not instantly converted into a good one by changing to a different computer or by simply putting up a better chair. All the components, equipment, furniture, lighting, and climate, must fit each other (see Figure 13–24) and the person in the office must be willing and able to take advantage of all the offered possibilities. Equipment change must go with change in mental attitude. This applies not only to the working person, but also to the attitude of management: The expectation that all furniture and the postures of all the office workers must look alike is not reasonable; the micromanaging style of the 1980s is insufferable; the 1990s' "lean and mean" behavior of the almighty boss who calls all the shots is counterproductive.

Healthy, productive organizations use ergonomics on all levels. In 1999, Liberty Mutual Insurance Company completed an investigation of the impact of flexible office workspaces and ergonomic training on employee health and performance. Twenty office workers moved into new, adjustable workspaces while another twenty occupied new but corporate-specific workplaces. All 40 people received training in ergonomics. The expectation was that by giving employees more control over their environment and a better understanding of ergonomic principles, performance would improve and health problems diminish. The results of the 18-month study confirmed the expected: Combined with ergonomic training, the flexible workspace increased individual performance and group collaboration. This was accompanied by a nearly one-third reduction in back pain and a two-thirds reduction in upper limb pains among the employees who had more control over their environment.

CONTROLS AND DISPLAYS

Much research has been performed on controls and displays; in fact, in human factors engineering, the period after World War II is often called the "knobs and dials era." Summaries of the findings have been published in *Military Standards* (see especially 1472F of 1999) and by Cushman and Rosenberg (1991), Kroemer et al (2001), Salvendy (1997), and Woodson et al (1991). The following recommendations are brief excerpts from Chapter 10 of the Kroemers' book.

Light Signals

A *red* signal light shall be used to alert an operator that the system or any portion of the system is inoperative or that a successful mission is not possible until appropriate corrective or override action is taken. Examples of indicators that should be coded in red light are those that display such information as "no-go," "error," "failure," "malfunction."

A *flashing red* signal light shall be used only to denote emergency conditions that require immediate operator action or to avert impending personnel injury, equipment damage, or both.

A *steady red* signal alerts the operator that the system or a portion thereof is inoperative and that a successful operation is not possible until appropriate correcting or overriding action has been taken.

A *yellow* signal light shall be used to advise an operator that a marginal condition exists. Yellow shall also be used to alert the operator to situations for which caution, rechecking, or unexpected delay is necessary.

A *green* signal light shall be used to indicate that the monitored equipment is in satisfactory condition and that it is all right to proceed; i.e., green signifies "go ahead," "in tolerance," "ready," "function activated," "power on," and the like.

A *white* signal light shall be used to indicate system conditions that do not have right or wrong implications, such as alternative functions (e.g., "rear steering on") or transitory conditions (e.g., "fan on"), provided such indication does not imply the success or failure of the operation.

A *blue* signal light may be used as an advisory, but common use of blue should be avoided.

Labels

Controls, displays, and any other items of equipment that must be located, identified, manipulated, or read shall be appropriately and clearly labeled to permit rapid and accurate performance. No label will be required on equipment or controls whose use is obvious to the user.

Labeling characteristics are determined by such factors as

- the accuracy of identification required
- the time available for recognition or other responses
- the distance at which the labels must be read
- the illumination level and color characteristics of the illuminant
- the critical nature of the function labeled
- the consistency of label design within and between systems

Orientation. Labels and the information printed thereon should be oriented horizontally so that the labels may be read quickly and easily from left to right.

Location. Labels shall be placed on or very near the items they identify so as to eliminate confusion with other items and labels.

Standardization. Placement of labels shall be consistent throughout the equipment and system.

Equipment functions. Labels should primarily describe the functions of equipment items. Secondarily, the engineering characteristics or nomenclature may be described.

Abbreviations. Standard abbreviations shall be selected. If a new abbreviation is required, its meaning shall be obvious to the intended reader. Capital letters shall be used. Periods shall be omitted except when needed to preclude misinterpretation. The same abbreviation shall be used for all tenses and for both singular and plural forms of a word.

Brevity. Labels shall be as concise as possible without distorting the intended meaning or information and shall be unambiguous. Redundancy shall be minimized. If the general function is obvious, only the specific function shall be identified (e.g., "frequency" as opposed to "frequency factor").

Familiarity. Words shall be chosen on the basis of operator familiarity whenever possible, provided the words express exactly what is intended. Brevity shall not be stressed if the results will be unfamiliar to operating personnel. Common, meaningful symbols (e.g., %, and +) may be used as necessary.

Visibility and legibility. Labels and placards shall be designed to be read easily and accurately at the anticipated operational reading distances, within the anticipated vibration/motion environment, and at minimally expected illumination levels. The following factors must be taken into consideration: contrast between the lettering and its immediate background; the height, width, stroke width, spacing, and style of letters; and the specular reflection of the background, cover, or other components.

AVOIDING CUMULATIVE TRAUMA DISORDERS

One distinguishes single-event injuries, called acute or traumatic, from those disorders that stem from oft-repeated actions whose cumulative effects result in an injury. In the United States, OSHA is making the reduction of such injuries a major goal of its investigation and enforcement program, which is of great concern to industry and the legal profession.

Cumulative strain injuries are the result of a series of *microtraumata,* each of which can "insult" the body, but not

lead to discernible damage. In their accumulation over time, however, the microstresses can cause discernible health complaints, and result in clinically manifest disorders or injuries which reduce the ability to perform related work. Different terms have been used to describe these conditions, such as cumulative trauma disorder (or injury, or syndrome), overuse disorder, repetitive motion injury, repetitive strain injury, occupational motion-related injury, regional musculo-skeletal disorder, work-related disorder, osteoarthrosis, rheumatic disease, etc. In this text, the term "cumulative trauma disorder" (CTD) is used.

Putz-Anderson (1988) defined CTD as a "*disorder of the muscular and/or tendinous and/or osseous and/or nervous system(s); caused, precipitated, or aggravated by repeated exertions or movements of the body.*"

Not a New Problem

Nearly 300 years ago, Bernadino Ramazzini (Wright, 1993) described health problems (that today we would call CTDs) appearing in workers who do violent and irregular motions and assume unnatural postures. Yet, Ramazzini also reported CTDs to occur among office clerks, believing that these events were caused by repetitive movements of the hands, by constrained body postures, and by excessive mental stress. Such activity-related disorders have been known for a long time, for example, washer woman's sprain, game keeper's thumb, telegraphist's cramp, writer's cramp, trigger finger, and tennis or golfer's elbow.

CTDs in Industry

Early in the 20th century, many CTD cases were reported from various kinds of industrial and agricultural work. In 1961, Peres wrote on page 6 in his treatise on "Process Work Without Strain":

> *It has been fairly well established, by experimental research overseas and our own experience in local industry, that the continuous use of the same body movement and sets of muscles responsible for that movement during the normal working shift (not withstanding the presence of rest breaks), can lead to the onset initially of fatigue, and ultimately of immediate or cumulative muscular strain in the local body area.*

Peres listed the muscles most frequently affected in this order: those which control the movements of the fingers, of the hand, the forearm, and the upper arm. His special concerns were movements of the hand and fingers, and in particular injuries to tendons and tendon sheaths due to excessively repetitive motions of fingers. He said that fairly few cases were the result of a direct trauma while many were related to repetitive use.

Thus, around 1960, it was known (as Peres stated on page 10) that "cumulative muscle strain in industry is probably the reason for more injuries than has been generally thought." On page 11, Peres said:

> *It is sometimes difficult to see why experienced people, after working satisfactorily for, say, 15 years at a given job, suddenly develop pains and strains. In some cases these are due to degenerative arthritic changes and/or traumatic injury of the bones of the wrist or other joints involved. In other cases, the cause seems to be compression of a nerve in the particular vicinity, as for example, compression of the median nerve in carpal tunnel syndrome. However, it may well be that many more are due to cumulative muscle strain arising from wrong methods of working.*

CTDs of Keyboard Users

In 1964, Kroemer reported:

> *Steno-typists and other persons working with keyboards are often afflicted with disorders of tendons, tendon sheaths, and synovial tissues of tendons, and of the tendon and muscle attachments. At this moment it is unknown what causes or aggravates these disorders. Possible sources may be, for example, the force needed to operate the keys, the displacement of the keys, or the frequency of operation. Hettinger (1957) attributes particular importance to the frequency. Practical experiences give reason to assume that "electrical" typewriters are advantageous over "mechanical" ones. With electrical machines, the typing frequency is certainly not lower, but the key displacement and the operational force are smaller.—The body posture is indicted in several publications. Inappropriate posture and extensive muscle tension of the arms are mentioned, and the working position and direction of arms and hands are indicated. The disadvantageous posture of arms and hands appears to be an important but generally little considered attribute of the work with typewriters and other keyboard machines as indicated already in 1926 by Klockenberg and in 1931 by the Allgemeiner Freier Angestelltenbund.*

What Causes CTDs?

Cumulative trauma disorder (CTD) is used here as a collective term for syndromes with or without physical manifestations. It is commonly characterized by discomfort, persistent pain, impairment, or disability in joints, muscles, tendons, and other soft tissues. It is often caused, precipitated or aggravated by repetitive and/or forceful motions. It can occur in diverse occupational activities such as assembly, manufacturing, meat processing, agricultural work, packing, sewing, and keying.

While the occurrence of CTDs, their diagnoses, and medical treatments were fairly well-known and established

by the middle of the 20th century, their relationships to occupational activities have been hotly argued. There is the point of view that body "usage within reason" should not lead to repetitive injuries. Individuals may be predisposed, particularly persons suffering from arthritis, diabetes, endocrinological disorders; also, such events as pregnancy, use of oral contraceptives, and gynecological surgery seem to be related to statistical occurrence. The fear of contracting CTDs or other psychosocial circumstances may lead to a sudden lowering of thresholds for discomfort which are normally acceptable, in the so-called RSI (repetition strain injury) epidemic in Australia in 1983–1988. Some people who claim repetitive injuries are suspected to suffer from normal fatigue, to be malingerers, or to have compensation neurosis.

Yet, the prevalent position taken in the current literature is that repetitive activities, as well as vibrations acting on the body, are causative, precipitating, or aggravating, regardless of whether they occur at work or during leisure (Bernard, 1997; Kuorinka & Forcier, 1995; National Research Council, 1998, 1999; Nordin et al, 1997). The major activity-related factors in repetitive strain injuries are rapid, often repeated movements, forceful exertions, static muscle loading (often to maintain posture), vibrations, and cooling of the body. Their negative effects are, or may be, aggravated by inappropriate organizational and social factors (Carayon et al, 1999; Moon & Sauter, 1996). Yet, how and whether they do so is difficult to assess.

Psychosocial factors include social support and workplace stress, job content, variety, demand, control, satisfaction, and enjoyment. Social support appears to have a mediating effect on stress. Among the organizational variables, poor job content (e.g., in terms of task identity and integration) and high demand have been found to be related to higher rates of musculoskeletal disorders; to a smaller extent, this also seems to be true for job control. Psychological stress has some causal plausibility but it is weaker than for individual and biomechanical variables. Altogether, social and organizational variables, even when found statistically significant for the generation of musculoskeletal disorders, are not large factors (National Research Council, 1999).

Work Factors That Can Cause CTDs

Repetitiveness is a matter of definition ("more than once per time unit") and what is slow or high depends on the specific activities or body part involved. For industrial work, Silverstein (1985) proposed that high repetitiveness be defined as a cycle time of less than 30 seconds, or as more than 50 percent of the cycle time spent performing the same fundamental motion.

Forcefulness is also a matter of definition and what is low or high depends on the specific activities or body part involved. Silverstein (1985) suggested that high force exerted with the hand, e.g., more than 45 N, may be a causative factor for occupational disorders. Yet the force applied to a computer key is only about one newton, which, however, translates to a multiple thereof in tension force in the finger tendon (Rempel et al, 1997, 1999).

Static muscle tension, often generated to maintain body posture, when high enough is stressful. If muscles must remain contracted at more than about 15 percent of their maximal capability, circulation is impaired. This can result in tissue ischemia and delayed dissipation of metabolites. Body position can also affect passage space for blood, nerves, and tendons. For example, extended (dropped) or flexed (elevated) wrists reduce the available lumen (cross section) of the carpal tunnel, and hence generate a condition that may cause carpal tunnel syndrome, particularly in persons with small wrists (Morgan, 1991). In fact, any strong deviation of the wrist from the straight position, and pronation (inward twisting) or supination (outward twisting) of the forearm especially with a bent wrist, and the pinch grip, are stressful.

Cumulative Injuries to the Body

Biomechanically, one can model the human body as consisting of a bony skeleton whose segments connect in joints and are powered by muscles that bridge the joints. The muscle actions are controlled by the nervous and hormonal systems and maintained through a network of blood vessels.

Cumulative injuries occur often in connective soft tissues, particularly to tendons and their sheaths. They may irritate or damage nerves and impede blood flow. They are frequent in the hand-wrist-forearm area (one example is the carpal tunnel syndrome, discussed in more detail below), in shoulder and neck, and in the back (often associated with load handling, especially lifting—see earlier in this chapter). Repetitive strains may even damage bone, such as the vertebrae.

BONES

The skeletal system of the human body is composed of some 200 bones and articulations and connective tissue. *Bones* provide the stable internal framework for the body. One distinguishes between flat axial bones, such as in the skull, sternum and ribs, and pelvis; and long cylindrical bones such as in the arms and legs. The long bones act, in mechanical terms, as the lever arms at which muscles pull about the articulations that join the bones. While bone is firm and hard and thus can resist high strain, it still has certain elastic properties. In childhood, when mineralization is low, bones are highly flexible. In contrast, bones of old people are highly mineralized and changed in geometry and therefore more brittle, effects often connected with osteoporosis. Bones can be shattered or broken through sudden impact or torque, and they can be damaged through continual stresses, such as in vibration.

CONNECTIVE TISSUES

Bones are connected to each other and with other elements of the body through connective tissues. *Cartilage* is a translucent and elastic material found at the ends of the ribs, in

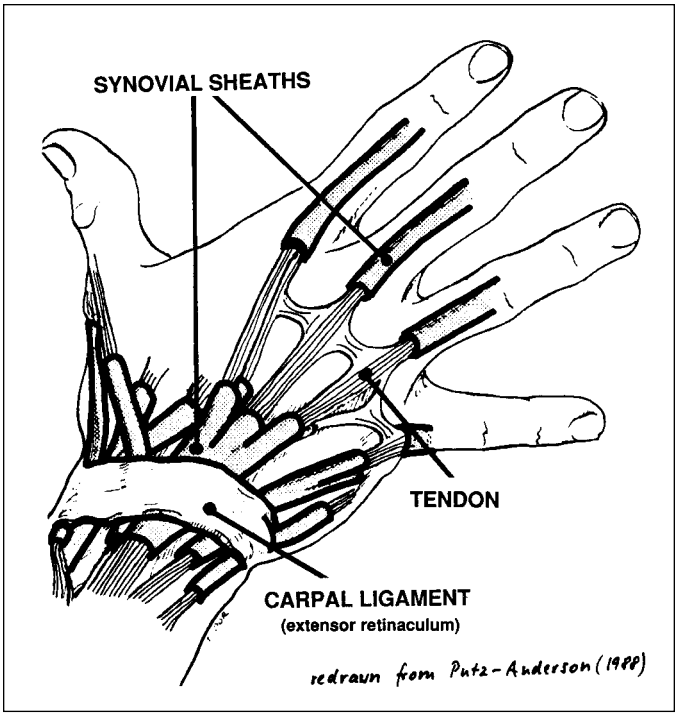

Figure 13–25. Tendons and their sheaths in the back of the hand. (Redrawn from Putz-Anderson 1988.)

joint surfaces of the articulations, and as discs between the vertebrae of the spinal column. Other connective tissues that are less elastic are called *ligaments* when they connect bones, and *tendons* when they connect muscle with bone. *Fascia* wraps organs or muscles. Fascial tissue condenses at the origin and insertion ends of muscle to tendons. Many but not all tendons are encapsulated by fibrous *sheaths* (see Figure 13–25). They allow a gliding motion of the tendon against surrounding materials which is facilitated by a viscous fluid, synovia, that reduces friction with the inner lining of the sheath. Particularly in the wrist and digits, sheaths keep tendons close to bones, acting as guides or pulleys for the pulling actions of the muscles.

NERVOUS CONTROL

The "peripheral" nervous system transmits information about events outside and inside the body from various sensors along its feedback pathways to its "central" part, the spinal cord and brain. Here, decisions about appropriate reactions and actions are made. Accordingly, action signals are generated and sent along the feed-forward pathways to the muscles. Thus, proper functioning of the sensors, such as in the hands, and of the nervous pathways to and from the brain is essential for the flow of information and of control signals in the nervous system.

BLOOD NETWORK

A network of arterial blood vessels provides oxygen and nutrients contained in working muscles and other organs. While passing through a muscle, metabolic waste products (such as lactic acid, carbon dioxide, heat, and water) are removed into the venous network. In addition, arterial blood transports hormones and other products of the internal glands which, parallel to the nervous system, regulate actions of body organs. Thus, blood flow is essential to working muscles for their proper functioning.

Which Body Components Are at Risk for CTDs?

While bones (except vertebrae) are not usually injured in the context of CTD, joints, muscles, and tendons and their related structures are at risk, as well as nerves and blood vessels.

SOFT TISSUES

A strain is an injury to muscle or tendon. Muscles can be stretched, which is associated with aching and swelling. A group of fibers torn apart is a more serious injury. If blood or nerve supply is interrupted for an extended time, the muscle atrophies.

Tendons contain collagen fibers, which neither stretch nor contract. Tendon surfaces can become rough, impeding their motion along other tissues. If overly strained, tendon fibers can be torn and scar tissue may form that creates chronic tension and is easily re-injured.

Gliding movement of a tendon in its sheath, caused by muscle contraction and relaxation, can be 5 cm in the hand when a finger is moved from fully extended to completely flexed. Synovial fluid in the tendon *sheath*, acting as a lubricant to allow easy gliding, may be diminished, which causes friction between tendon and its sheath. First signs of inflammation are feelings of tenderness and warmth, followed by discomfort and pain.

Inflammation of a tendon sheath is a protective response of the body. The feeling of warmth and swelling stems from the influx of blood. Compression of tissue either from swelling or mechanical pressure produces a sensation of pain. Movement of the tendon within its compressive surroundings is hindered. Forced movement, particularly when often repeated, may cause the inflammation of additional fiber tissue, which in turn can establish a permanent (chronic) condition of a swollen tendon and/or sheath that, in course, impedes tendon movement.

A *bursa* is a small, flat, synovia-filled sac lined with a slippery cushion which prevents rubbing of a muscle or tendon against bone. An often used muscle or tendon, particularly if it has become roughened, may irritate its adjacent bursa, setting up an inflammatory reaction, which inhibits free movement.

When a joint is displaced beyond its regular range, fibers of a *ligament* may be stretched, torn apart, or pulled from the bone. This is called a "sprain," often resulting from a single trauma but also possibly caused by repetitive actions. Injured ligaments may take weeks or even months to heal because their blood supply is poor. A ligament sprain can bring about a lasting joint instability and hence increases the risk of further injury.

NERVES

Nerves can also be affected by repeated or sustained pressure. Such pressure may stem from bones, ligaments, tendons, tendon sheaths, and muscles within the body, or from hard surfaces and sharp edges of work places, tools, and equipment. Pressure within the body can occur if the position of a body segment reduces the passage opening through which a nerve runs. Another source of compression, or an added one, may be swelling due to inflammation of other structures within this opening, such as tendons and tendon sheaths. The carpal tunnel syndrome (discussed below) is a typical case of nerve compression.

There are three different systems of nerve fibers which serve different functions: motor, sensory, and autonomic.

Impairment of a *motor nerve* reduces the ability to transmit signals to the innervated motor units in muscle. Thus, motor nerve impairment impedes the controlled activity of muscles, and hence reduces the ability to generate force or torque to tools, equipment, and other external objects.

Sensory nerve impairment reduces the information that can be transmitted from sensors to the central nervous system. Sensory feedback is very important for hand activities because it contains information about force applied, position assumed, and motion experienced. Sensory nerve impairment usually brings about sensations of numbness, tingling, or even pain. The ability to distinguish hot from cold may be reduced.

Impairment of an *autonomic nerve* reduces the ability to control such functions as temperature by sweat production in the skin. A common sign of autonomic nerve impairment is dryness and shininess of skin areas controlled by that nerve.

BLOOD VESSELS

Like nerves, *blood vessels* may be compressed. Compressing an artery results in reduced blood flow to the affected area; compression of a vein hinders the return of blood. Blood vessel compression thus means reduced supply of oxygen and nutrients to muscles, and impaired temperature control of tissues near tendons and ligaments. Such ischemia limits the possible duration of muscular actions and impairs muscle recovery from fatigue after activity. Vascular compression together with pressure on nerves is often found in neck, shoulder and upper arm. Names like thoracic outlet (or hyperabduction) syndrome, cervicobrachial disorder, brachial plexus neuritis, and costoclavicular syndrome describe the location of the condition.

Vibrations of body members, particularly of the hand, may trigger "vasospasms," which reduce the diameter of arteries, down to their complete closure. Of course, this impedes blood flow to the body areas supplied by the vessels, which become visible by blanching of the area, known particularly as white finger (or Raynaud's) phenomenon. Exposure to cold may aggravate the problem because it also can trigger vasospasms. Associated symptoms include intermittent or continued numbness and tingling in the fingers, with the skin turning pale and cold, and eventually loss of sensation and control in the fingers. The symptoms are often caused by vibrating tools such as pneumatic hammers, chainsaws, power grinders, power polishers. Frequent operation of keyboards may also constitute a source of vibration strain to the hand-wrist area.

Carpal Tunnel Syndrome

Among the best known cumulative trauma injuries is the carpal tunnel syndrome (CTS) first described 125 years ago (Armstrong, 1991). In 1959, Tanzer discussed 22 cases. Two of his patients had been working in large kitchens with much stirring and "ladled soup" twice daily for about 600 students. Two patients had recently started to milk cows on a dairy farm, two had done gardening with considerable hand weeding. One had been using a spray gun with a finger trigger, three worked in a shop in which objects were handled on a conveyor belt.

In 1966 and 1972, Phalen published reviews of 1,252 cases of CTS. These publications have become classics in the field; one of the most often applied tests for signs of CTS is called "Phalen's test." In 1975, Birkbeck and Beer described the results of their survey of work and hobby activities of 658 patients who suffered from CTS. Seventy-nine percent of these patients were employed in work requiring light, highly repetitive movements of the wrists and fingers. The authors indicated that this type of manual activity can be a causal factor in the development of CTS. They referred to a report published in 1947 by Brain, Wright, and Wilkinson, which described six cases of compression of the median nerve in the carpal tunnel. According to Birkbeck and Beer, even then it had been concluded that occupation is a causal factor. In 1976, Posch and Marcotte analyzed another 1,201 cases of CTS.

In 1964, Kroemer described the occurrence of syndromes in typists—see the quote presented earlier. In 1980, Maeda, Huenting, and Grandjean stated that impairments in hands and arms were found frequently with operators of accounting machines and that the disorders were related to working posture and operation of the keys. In 1981, Cannon, Bernacki, and Walter described a case-control study on the factors associated with the onset of carpal tunnel syndrome. They linked the occurrence of carpal tunnel syndrome to diverse etiological factors, which included injury and illness, use of drugs, and hormonal changes in women. *"Ergonomic theory relates the occurrence of the condition to repetitive movements of the wrists, performance of tasks with the wrists in ulnar deviation and chronic exposure to low-frequency vibrations*" (page 255). To support their statements and findings they listed 12 publications, all of them published in the 1970s.

In 1983, the American Industrial Hygiene Association acknowledged the prevalence and importance of CTS by publishing Armstrong's *An Ergonomics Guide to Carpal Tunnel Syndrome*. Carpal tunnel syndrome is one of the "occupational illnesses" in the hand/arm system among other repetitive trauma disorders such as tendinitis, synovitis, tenosynovitis, bursitis, trigger finger, and epicondylitis.

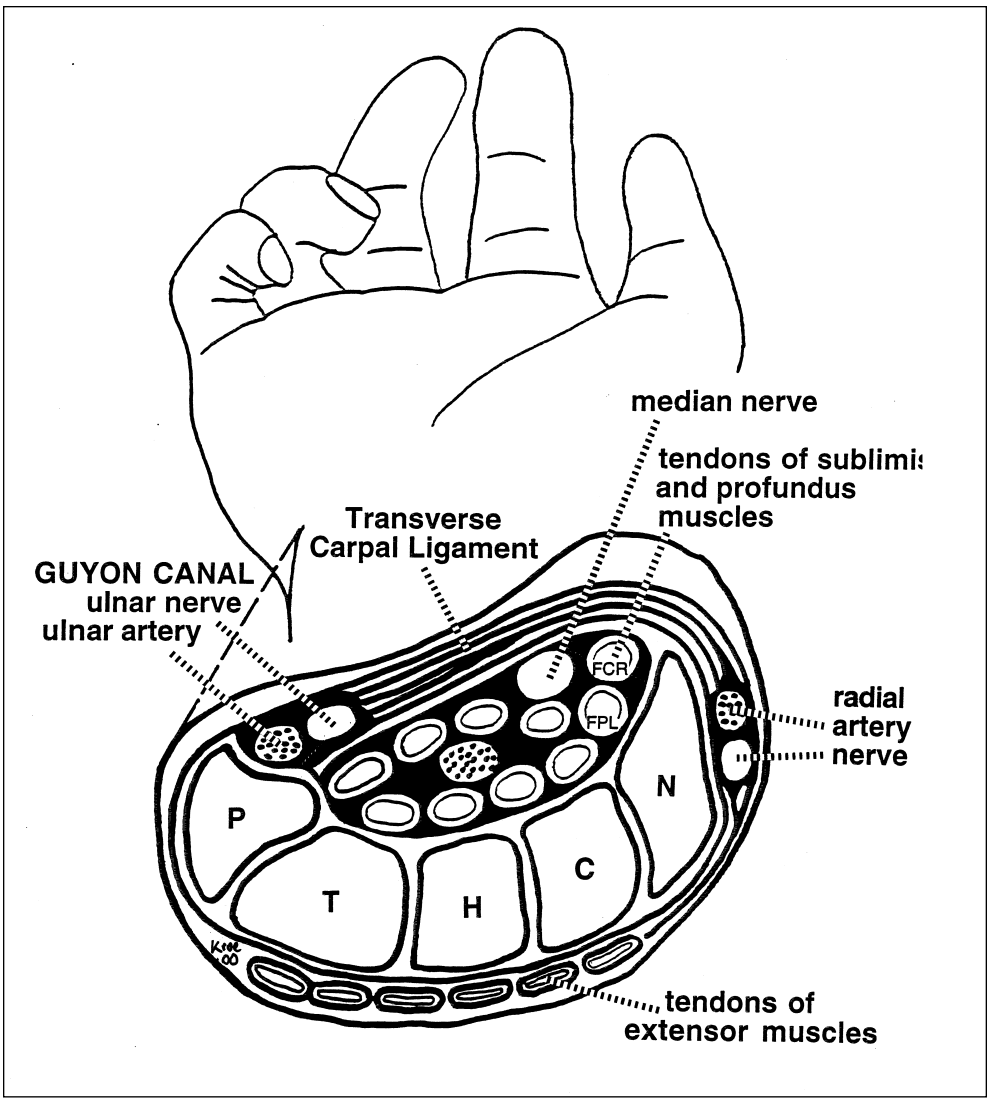

Figure 13–26. Cross-section of the carpal tunnel. The carpal bones (P, T, H, C, N) form the carpal "canal" which ligaments cover. Also shown are the tendons of the superficial (S) and profound (P) finger flexor muscles, flexors of the thumb (FCR, FPL), nerves, and arteries. (Adapted from Kroemer 1989.)

Thus, in the 1960s, 1970s, and early 1980s, CTS was well recognized as an often-occurring, disabling condition of the hand that can be caused, precipitated, or aggravated by certain work activities in the office and on the shop floor; of course, leisure activities may be involved as well.

On the palmar side of the wrist, near the base of the thumb, the carpal bones form a concave "floor" and the "walls" of the carpal canal. It has a "roof" that consists of three ligaments (the radial carpal, intercarpal, and carpometacarpal) covered by the transverse carpal ligament, which is firmly fused to the carpal bones. Thus, these bones and ligaments form a covered canal or tunnel, called the carpal tunnel. It is shown in Figure 13–26. In cross-section, it is roughly oval in shape. Through it pass the flexor tendons of the digits, as well as the median nerve. The radial nerve and artery, as well as the ulnar nerve and artery, are also confined in similar fashion. This crowded space is reduced if the wrist is bent up or down (flexed or extended), or pivoted to either side (ulnarly or radially). Any swelling of the tendons and of their sheaths reduces the space available for the tendons, the blood vessels, and the nerves.

The median nerve innervates the thumb, much of the palm, and the index and middle fingers, as well as most of the ring finger, but not its ulnar side. Pressure on the nerve reduces its ability to transmit signals: feed-forward to control proper functioning, feedback to report on existing conditions to the brain.

Occupational Activities and Related CTDs

Table 13–R lists conditions that are often associated with cumulative trauma (Kroemer 1992, Kroemer et al 2001). Of course, this list is neither complete nor exclusive. New occupational activities occur, and several activities may be part of the same job.

Repetitive and forceful exertions, particularly if combined, are generally thought to be responsible for a large portion of the CTD. Silverstein (1985) proposed that *high repetitiveness* may be defined as a cycle time of less than 30 seconds, or as more than 50% of the cycle time spent performing the same fundamental motion. Silverstein also suggested that *high force* by itself (for hand force, more than 45 newtons) may be a causative factor.

Table 13–R. *Common Cumulative Trauma Disorders*

Disorder Name	*Description*	*Typical Job Activities*
Carpal tunnel syndrome (writer's cramp, neuritis, median neuritis) (N)	The result of compression of the median nerve in the carpal tunnel of the wrist. This tunnel is an opening under the carpal ligament on the palmar side of the carpal bones. Through this tunnel pass the median nerve, the finger flexor tendons, and blood vessels. Swelling of the tendon sheaths reduces the size of the opening of the tunnel and pinches the median nerve and possibly blood vessels. The tunnel opening is also reduced if the wrist is flexed or extended or ulnarly or radially pivoted.	Buffing, grinding, polishing, sanding, assembly work, typing, keying, cashiering, playing musical instruments, surgery, packing, housekeeping, cooking, butchering, hand washing, scrubbing, hammering.
Cubital tunnel syndrome (N)	Compression of the ulnar nerve below the notch of the elbow. Tingling, numbness, or pain radiating into ring or little fingers.	Resting forearm near elbow on a hard surface or sharp edge or reaching over obstruction.
DeQuervain's syndrome (or disease) (T)	A special case of tendosynovitis that occurs in the abductor and extensor tendons of the thumb where they share a common sheath. This condition often results from combined forceful gripping and hand twisting, as in wringing cloths.	Buffing, grinding, polishing, sanding, pushing, pressing, sawing, cutting, surgery, butchering, use of pliers, 'turning' control such as on motorcycle, inserting screws in holes, forceful hand wringing.
Epicondylitis ("tennis elbow") (T)	Tendons attaching to the epicondyle (the lateral protrusion at the distal end of the humerus bone) become irritated. This condition is often the result of impacting or jerky throwing motions, repeated supination and pronation of the forearm, and forceful wrist extension movements. The condition is well-known among tennis players, pitchers, bowlers, and people hammering. A similar irritation of the tendon attachments on the inside of the elbow is called medial epicondylitis, also known as "golfer's elbow."	Turning screws, small parts assembly, hammering, meat cutting, playing musical instruments, playing tennis, pitching, bowling.
Ganglion (T)	A tendon sheath swelling that is filled with synovial fluid, or a cystic tumor at the tendon sheath or a joint membrane. The affected area swells up and causes a bump under the skin, often on the dorsal or radial side of the wrist. (Because it was in the past occasionally smashed by striking with a bible or heavy book, it was also called a "bible bump.")	Buffing, grinding, polishing, sanding, pushing, pressing, sawing, cutting, surgery, butchering, use of pliers, 'turning' control such as on motorcycle, inserting screws in holes, forceful hand wringing.
Neck tension syndrome (M)	An irritation of the levator scapulae and trapezius group of muscles of the neck, commonly occurring after repeated or sustained overhead work.	Belt conveyor assembly, typing, keying, small parts assembly, packing, load carrying in hand or on shoulder.

(Continues)

Table 13–R. *(Continued)*

Disorder Name	*Description*	*Typical Job Activities*
Pronator (teres) syndrome (N)	Result of compression of the median nerve in the distal third of the forearm, often where it passes through the two heads of the pronator teres muscle in the forearm; common with strenuous flexion of elbow and wrist.	Soldering, buffing, grinding, polishing, sanding.
Shoulder tendinitis (rotator cuff syndrome or tendinitis, supraspinatus tendinitis, subacromial bursitis, subdeltoid bursitis, partial tear of the rotator cuff) (T)	This is a shoulder disorder located at the rotator cuff. The cuff consists of four tendons that fuse over the shoulder joint, where they pronate and supinate the arm and help to abduct it. The rotator cuff tendons must pass through a small bony passage between the humerus and the acromion, with a bursa as cushion. Irritation and swelling of the tendon or of the bursa are often caused by continuous muscle and tendon effort to keep the arm elevated.	Punch press operations, overhead assembly, overhead welding, overhead painting, overhead auto repair, belt conveyor assembly work, packing, storing, construction work, postal letter carrying, reaching, lifting, carrying load on shoulder.
Tendinitis (tendinitis) (T)	An inflammation of a tendon. Often associated with repeated tension, motion, bending, being in contact with a hard surface, vibration. The tendon becomes thickened, bumpy, and irregular in its surface. Tendon fibers may be frayed or torn apart. In tendons without sheaths, such as within elbow and shoulder, the injured area may calcify.	Punch press operation, assembly work, wiring, packaging, core making, use of pliers.
Tendosynovitis (tenosynovitis, tendovaginitis) (T)	This disorder occurs to tendons inside synovial sheaths. The sheath swells. Consequently, movement of the tendon with the sheath is impeded and painful. The tendon surfaces can become irritated, rough, and bumpy. If then inflamed sheath presses progressively onto the tendon, the condition is called stenosing tendosynovitis. DeQuervain's syndrome is a special case occurring in the thumb, while the trigger finger condition occurs in flexors of the fingers.	Buffing, grinding, polishing, sanding, punch press operation, sawing, cutting, surgery, butchering, use of pliers, 'turning' control such as on motorcycle, inserting screws in holes, forceful hand wringing.
Thoracic outlet syndrome (neurovascular compression syndrome, cervicobrachial disorder, brachial plexus neuritis, costoclavicular syndrome, hyperabduction syndrome) (V, N)	A disorder resulting from compression of nerves and blood vessels between clavicle and first and second ribs at the brachial plexus. If this neurovascular bundle is compressed by the pectoralis minor muscle, blood flow to and from the arm is reduced. This ischemic condition makes the arm numb and limits muscular activities.	Buffing, grinding, polishing, sanding, overhead assembly, overhead welding, overhead painting, overhead auto repair, typing, keying, cashiering, wiring, playing musical instruments, surgery, truck driving, stacking, material handling, postal letter carrying, carrying heavy loads with extended arms.

(Continues)

Table 13–R. *(Concluded)*

Disorder Name	*Description*	*Typical Job Activities*
Trigger finger (or thumb) (T)	A special case of tendosynovitis where the tendon becomes nearly locked so that its forced movement is not smooth but snaps or jerks. This is a special case of stenosing tendosynovitis crepitans, a condition usually found with digit flexors at the A1 ligament.	Operating finger trigger, using hand tools that have sharp edges pressing into the tissue or whose handles are too far apart for the user's hand so that the end segments of the fingers are flexed while the middle segments are straight.
Ulnar artery aneurysm (V, N)	Weakening of a section of the wall of the ulnar artery as it passes through the Guyon tunnel in the wrist; often from pounding or pushing with heel of the hand. The resulting "bubble" presses on the ulnar nerve in the Guyon tunnel.	Assembly work.
Ulnar nerve entrapment (Guyon tunnel syndrome) (N)	Results from the entrapment of the ulnar nerve as it passes through the Guyon tunnel in the wrist. It can occur from prolonged flexion and extension of the wrist and repeated pressure on the hypothenar eminence of the palm.	Playing musical instruments, carpentering, brick laying, use of pliers, soldering, hammering.
White finger ("dead finger," Raynaud's syndrome, vibration syndrome) (V)	Stems from insufficient blood supply bringing about noticeable blanching. Finger turns cold, numb, tingles, and sensation and control of finger movement may be lost. The condition is due to closure of the digit's arteries caused by vasospasms triggered by vibrations. A common cause is continued forceful gripping of vibrating tools, particularly in a cold environment.	Chain sawing, jack hammering, use of vibrating tool, sanding, paint scraping, using vibrating tool too small for the hand, often in a cold environment.

N = nerve disorder; T = tendon disorder; M = muscle disorder; V = vessel disorder. (Adapted from Kroemer, 1992. Reprinted with permission of the American Industrial Hygiene Association.)

If muscles must remain contracted at more than about 15 to 20 percent of their maximal capability, circulation is impaired. This can result in tissue ischemia and delayed dissipation of metabolites, which constitute conditions of general physiological strain. *Posture* may be highly important. For example, dorsiflexion of the wrist ("dropped wrist") generates a condition likely to cause CTS. Maintained isometric contraction of muscles needed to keep a body part in an extreme position is often associated with a CTD condition. Inward or outward rotation of the forearm, especially with a bent wrist, any severe deviation of the wrist from its neutral position, and the pinch grip can be stressful.

Ergonomic Countermeasures

Exercise as a prophylactic measure is of questionable value. Proponents hope to "strengthen" tissues, but inappropriate exercising may worsen conditions. Lee, Swanson, Sauter et al (1992) evaluated a large number of proposed exercises and selected those that have been shown to be useful.

Ergonomic intervention depends on the stage. Early symptoms of CTD are reversible through work modification, rest breaks and possibly exercises. In the later stages, the patient must abstain from performing the causing work, and rest. This may go along with major changes in life-style and working capacity. Further medical treatments are physiotherapy, drug administration, and in some cases surgery, such as carpal tunnel release.

Of course, one should purposefully avoid the conditions that may lead to CTD. This is best done in the planning stage of a new job. For existing jobs, it is important to identify problems and symptoms early, to prevent injury through ergonomic work re-organization and work redesign.

At work, various ergonomic interventions can be taken. They start with suitable design of the work object and of the equipment and tools used. They include instruction on and training in proper habits. Among the managerial interventions are work diversification (the opposite of job simplification and specialization leading to repetition), relief workers, and rest pauses.

Suspicious jobs should be analyzed for their movement and force requirements using variants of the well-established industrial engineering procedure of motion and time study. Each element of the work should be screened for factors that can contribute to CTDs. After the job analysis has been completed, workstations, equipment, and work procedures

Table 13–S. *Ergonomic Measures to Avoid Cumulative Trauma Disorders*

CTD	*Avoid in General*	*Avoid in Particular*	*Do*	*Design*
Carpal tunnel syndrome	Rapid, often-repeated finger movements, wrist deviation	Dorsal and palmar flexion, pinch grip, vibrations between 10 and 60 Hz		
Cubital tunnel syndrome	Resting forearm on sharp edge or hard surface			
DeQuervain's syndrome	Combined forceful gripping and hard twisting			
Epicondylitis	"Bad tennis backhand"	Dorsiflexion, pronation		
Pronator syndrome	Forearm pronation	Rapid and forceful pronation, strong elbow and wrist flexion	Use large muscles, but infrequently and for short durations	The work object properly
Shoulder tendinitis, rotator cuff syndrome	Arm elevation	Arm abduction, elbow elevation	Let wrists be in line with the forearm	The job task properly
Tendinitis	Often-repeated movements, particularly with force exertion; hard surface in contact with skin; vibrations	Frequent motions of digits, wrists, forearm, shoulder	Let shoulder and upper arm be relaxed	Hand tools properly (" bend tool, not the wrist")
Tendosynovitis, DeQuervain's syndrome, ganglion	Finger flexion, wrist deviation	Ulnar deviation, dorsal and palmar flexion, radial deviation with firm grip	Let forearms be horizontal or more declined	Round corners, pad
Thoracic outlet syndrome	Arm elevation, carrying	Shoulder flexion, arm hyperextension		Place work object properly
Trigger finger or thumb	Digit flexion	Flexion of distal phalanx alone		
Ulnar artery aneurysm	Pounding and pushing with the heel of the hand			
Ulnar nerve entrapment	Wrist flexion and extension	Wrist flexion and extension, pressure on hypothenar eminence		
White finger, vibration syndrome	Vibrations, tight grip, cold	Vibrations between 40 and 125 Hz		
Neck tension syndrome	Static head posture	Prolonged static head/neck posture	Alternate head/neck postures	

(Adapted from Kroemer, 1992. Reprinted with permission of the American Industrial Hygiene Association.)

can be ergonomically re-engineered and re-organized to reduce the stress on the operator's body. Table 13–S, adapted from Kroemer (1989, 1992), provides an overview of generic ergonomic countermeasures.

Safe Thresholds and Doses?

The American National Standards Institute (ANSI) has established the Z365 committee to determine what is known about cumulative trauma disorders, and what standard procedures could be established to avoid these. The deliberations of the ANSI Z365 committees in the early 1990s indicated that much research must be conducted to single out and describe the components of activities that may lead to CTDs, and to understand how physical events overload body structures and tissues, and how, if at all, psychosocial conditions contribute. When these relationships are understood, it should be possible to establish threshold values or exposure doses for activity (job) factors such as force, displacement, repetition, duration, and posture, which separate suitable from unacceptable conditions. Such thresholds or doses could replace generic guidelines by specific ergonomic recommendations.

SUMMARY

The industrial hygienist is largely responsible for the health and well-being of people employed in industry, commerce,

service, and administration. Of course, this concern must be seen in the light of the goal to be productive, both in quantity and in quality. Fortunately, ergonomic/human factors recommendations usually bring about, directly or indirectly, improved job performance together with increased safety, health, and wellness. In recent years, both management and employee representatives, including unions, have cooperated in using ergonomics to increase the ease and efficiency at work.

Chapter 14

Biological Hazards

by A. Lynn Harding, MPH, CBSP (ABSA)
Diane 0. Fleming, PhD, CBSP (ABSA)
Janet M. Macher, ScD, MPH

This chapter provides basic information on those hazards that are considered biological in nature. While the chapter focuses on work-related exposures to infectious microbiological agents, exposures to other biohazardous materials not associated with infectious agents are reviewed. Background on the development of the field of biological safety and considerations on the role of industrial hygienists and environmental health and safety professionals in the field are discussed. The principles of hazard identification, assessment, classification, and control and the diverse environments associated with biological exposures are examined. Material on current topics in biological safety including bloodborne pathogens, tuberculosis, bioterrorism, legionellosis, building-related bioaerosol problems, organic dust toxic syndrome, mycotoxins, endotoxins, and Pfiesteria is covered. Information on assessing compliance, current regulations and guidelines including large-scale containment guidelines, standard-setting groups, and relevant professional associations is reviewed. This chapter cannot begin to adequately cover biological hazards, so the reader is encouraged to use the provided references and resources to further gain insight into the field of biological safety.

Exposure to biological hazards in the workplace results in a significant amount of occupationally associated disease. Work-related illnesses due to biological agents such as infectious microorganisms, biological allergens, and toxins have been widely reported. However, in many workplaces their presence and resultant illnesses are not recognized. It has been estimated that the population at risk from occupational biohazards may be several hundred million workers worldwide (Dutkiewicz et al, 1988).

Dutkiewicz et al (1988), in a review of occupational biohazards, noted that some 193 biological agents are known to produce infectious, allergenic, toxic, and carcinogenic reactions in workers. Most of the identified biohazardous agents belong to the following groups:

- ➢ *Microorganisms and their toxins (viruses, bacteria, fungi, and their products): infection, inflammatory disease, or allergic reaction*
- ➢ *Arthropods (crustaceans, arachnids, and insects): bites or stings resulting in skin inflammation, systemic intoxication, transmission of infectious agents, or allergic reaction*
- ➢ *Allergens and toxins from higher plants: dermatitis from skin contact or allergic rhinitis or asthma as a result of inhalation*
- ➢ *Protein allergens from vertebrate animals (urine, feces, hair, saliva, and dander): hypersensitivity and inflammatory disease*
- ➢ *Other groups that pose a potential biohazard include lower plants other than fungi (lichens, liverworts, and ferns) and invertebrate animals other than arthropods (parasites such as protozoa, flatworms such as* Schistosoma*, and roundworms such as* Ascaris*)*

Workers engaging in agricultural, medical, and laboratory activities have been identified as being most at risk to occupational biohazards, but many varied workplaces have the potential for such exposure. A number of potentially hazardous workplaces are described in this chapter. Although biological hazards encompass a wide variety of biological agents, in large part this chapter concentrates on exposures to microorganisms and the substances associated with them. Although the chapter deals extensively with laboratory and medical environments, the concepts, principles, and exposure controls discussed here can be extrapolated to suit most occupations.

BIOLOGICAL SAFETY

The discipline of biological safety (biosafety) grew out of research involving biological warfare agents at Fort Detrick in Frederick, Md. The Chemical Warfare Service (for chemical and biological warfare) was established by the U.S. Army in 1941, and in 1942 the National Academy of Sciences (NAS) formed a biological warfare committee. Microbiologists from the American Society for Microbiology (ASM) served as advisors for biological warfare activities instituted by the Chemical Warfare Service.

From 1955 to 1968, the ASM maintained an advisory committee for the Fort Detrick Biological Defense Research Program (BDRP) to provide scientific advice on research programs, peer review for publications, and assistance with staff recruitment. Members of the safety staff at Fort Detrick were well-trained microbiologists capable of advising on safety matters related to work with virulent microorganisms. Because of the considerable concern for worker safety, as well as the need to protect the surrounding community, great care was taken to prevent accidental exposure and release of infectious agents. The containment principles developed at Fort Detrick by Dr. Arnold G. Wedum and his colleagues form the framework for the discipline of biosafety today. It is noteworthy to observe that this profession, which was formed as the result of concerns about biological warfare, is once again forced to address that same threat.

Following the discovery of recombinant DNA technology in the 1970s, the new era of biotechnology began. The ability to insert into host cells specific pieces of foreign DNA that replicate to produce a desired product has revolutionized the field of biology. Recombinant DNA technology, hybridoma technology, and protein and enzyme engineering are all components of the new biotechnology. The impact of biotechnology on research in health care, diagnostics, and agriculture, as well as many other industries such as food, chemical, mining, and petroleum, has been significant. Whether real, potential, or imaginary, genetic manipulation of microorganisms and cells brought with it a renewed concern for biological hazards. Employers and regulatory agencies took note of these concerns and began implementing or strengthening workplace biosafety programs. Today, with numerous human gene therapy experiments underway, scientists are moving closer to achieving the promise of this technology. The responsibility of the biosafety professional, infection control practitioner, or hospital epidemiologist again shifts to include the task of assessing the need for appropriate containment at the patient's bedside, in the pharmacy where the preparations are made, and among the attending staff and family members.

The appearance of a virus capable of destroying the human immune system (human immunodeficiency virus, or HIV) in the 1980s, coupled with the high incidence of occupationally acquired hepatitis B virus infection among healthcare workers, prompted the Occupational Safety and Health Administration (OSHA) to establish a standard that mandates protection of workers from occupational exposure to bloodborne pathogens (OSHA, 1991). This standard has heightened awareness and improved biosafety controls in the workplace considerably.

The biosafety professional uses similar practices to define and control hazards in the workplace as those used by industrial hygienists. Both are responsible for helping to anticipate, recognize, evaluate, and control hazards in the workplace. The biosafety professional has a microbiology background and the primary focus of their work is biological hazards (microorganisms), while the industrial hygienist is trained to deal with multiple hazards in the workplace—biohazards usually represent only a small portion of their work load. Biosafety professionals include microbiologists, biologists, molecular biologists, environmental health scientists, industrial hygienists, clinical health care professionals, veterinarians, chemists, and engineers. Regardless of their background and education, they must develop knowledge of the principles of epidemiology, disease transmission patterns, risk-assessment management, disinfection and sterilization, disease prevention, aerobiology, and environmental control.

HAZARD IDENTIFICATION

Microorganisms are a diverse group of microscopic organisms that includes bacteria, fungi, algae, protozoa, viruses,

and prions. Although pathogenic or disease-producing microorganisms represent only a small portion of the total microbial population, attention is often focused on them because of their negative impact on humans, plants, and animals. In addition to their ability to produce infectious diseases, microorganisms such as fungi produce spores capable of causing allergic and inflammatory reactions among workers. Toxins such as endotoxin, a component in the cell walls of gram-negative bacteria, and mycotoxins, natural products produced by fungi, have also been identified as occupational biohazards. Other biological agents such as pollen, mites, urine proteins, animal dander, and snake venoms, to list only a few, also fit within the broad scope of biological hazards.

Microorganisms

Microorganisms are divided into two categories: prokaryotes (organisms in which DNA is not physically separated from the cytoplasm) and eukaryotes (organisms containing a membrane-bound nucleus). Prokaryotes and eukaryotes are organisms because they contain all of the enzymes required for their own replication, as well as the biological equipment necessary to produce metabolic energy. This distinguishes them from viruses, which depend on host cells for replication.

Prokaryotes, characterized by their relatively small size (around 1 μm in diameter) and the absence of a nuclear membrane, are divided into two major groups: eubacteria and archaebacter (Brooks et al, 1998). The more commonly known bacteria fall into the eubacteria category and they are further divided into three groups: gram-negative eubacteria with cell walls, gram-positive eubacteria with cell walls, and cell wall-less eubacteria (*Mycoplasma*). The fourth group, archaebacteria, differ from eubacteria in that they live in extreme environments (high temperatures, high salt, or low pH) and carry out unusual metabolic reactions. The majority of microorganisms of medical interest are gram-negative or -positive cell walled organisms that are either aerobic, microaerophilic, or anaerobic rods, cocci, or spirals. These characteristics are used as the framework for an identification scheme in *Bergey's Manual of Determinative Bacteriology* (Holt et al, 1994).

In contrast to prokaryotes, eukaryotes are larger and contain a membrane-bound nucleus and organelles such as mitochondria. The microbial eukaryotes, or protists, fall into four major groups: algae, protozoa, fungi, and slime molds, with protozoa such as species of *Giardia*, *Trypanosoma*, *Toxoplasma*, and *Plasmodium* and species of fungi such as *Histoplasma*, *Aspergillus*, *Cryptococcus*, and *Coccidioides* being infectious agents of medical importance.

Viruses, whose unique properties distinguish them from other microorganisms, are totally dependent on their hosts for replication. They are inert outside of a host cell, and host-virus interactions are highly specific. Viruses, the smallest infectious agents, are 20–300 nm in diameter. Viral particles consist of nucleic acid molecules, either DNA or RNA, enclosed in a protein coat, or *capsid*. The capsid protects the nucleic acid and facilitates attachment to and penetration into the host cell by the virus. Once inside a cell, viral nucleic acid uses the host's enzymatic machinery for functions associated with viral replication. The host range of a given virus may be broad or extremely narrow, and viruses can infect unicellular organisms such as mycoplasmas, bacteria, algae, and all higher plants and animals. Classification of viruses is based on a number of properties such as nucleic acid type, size and morphology, susceptibility to physical and chemical agents, and presence of enzymes.

Viroids—small, single-stranded, covalently closed circular RNA molecules—cause diseases in plants. Because of their characteristics it is thought that they have evolved from transposable elements or retroviruses by deletion of internal sequences. To date, viroids have not been detected in animals or humans.

Prions—agents smaller by an order of magnitude than viruses—have been reported that have properties similar to viruses and cause degenerative disease in humans and animals. Scrapie, a disease of the nervous system of sheep, is caused by such an agent. Because of the novel properties of this agent, the term, prion, has been designated to denote these small proteinaceous infectious particles, which are resistant to inactivation by most procedures that modify nucleic acids (Prusiner, 1982). The tropical disease kuru and Creutzfeldt-Jakob (a form of human dementia) are caused by similar agents.

Although the amount of information provided here is necessarily limited, a wealth of accessible material is readily available. Readers are encouraged to consult microbiology references such as *Medical Microbiology* (Brooks et al, 1998), *ASM Manual of Environmental Microbiology* (ASM, 1997), *Microbial Ecology* (Atlas & Bartha, 1998), *Manual of Clinical Microbiology* (Murray et al, 1999), *Bioaerosols Handbook* (Cox & Wathes, 1995), and *Bioaerosols* (Burge, 1995).

Infection

Infection is a general term applied to the entry and development or multiplication of an infectious agent such as bacteria, protozoa, and the larval forms of multicellular organisms such as the helminths (intestinal parasites including roundworms and tapeworms) in the body of people, animals, or plants. It is further defined as an invasion of the body by pathogenic microorganisms and the reaction of the tissues to their presence and to the toxins generated by them (Chin, 2000, p 572).

Although human beings have microorganisms on every surface and in every external orifice of their bodies, only a small proportion of those agents are capable of producing an infection that could lead to disease in that person or, if communicable, in others. If the disease-causing agent arises from the microbial flora normally present in or on the body of a person (indigenous flora), its resulting infection is called endogenous. For example, most urinary tract infections are caused by agents such as *Escherichia coli* or *Pseudomonas* spp,

which are normally found in the feces of the patient. This example demonstrates the disease-causing potential of normal flora when they are able to reach a different site in the body. Normal flora can also take advantage of a lowering of host immunity to produce an infectious disease. Such infections occur in those who are immunocompromised by underlying disease processes or certain medications such as steroids and chemotherapy. Further information on normal flora can be found in Isenberg and D'Amato, 1991.

Individuals harboring communicable infectious agents without exhibiting signs of disease are called carriers. They can be a source of infection in coworkers, especially if the agent is transmitted by the aerosol route, as with measles or tuberculosis. Certain of these "wild-type" agents—strains found in nature, and therefore in the community—can sometimes also contaminate a sterile product in a laboratory environment. A vaccine strain being grown in cell culture can be contaminated by a worker who carries a different, potentially more virulent strain obtained in the community. The restriction of visitors and the use of approved vaccines are thus recommended when appropriate to protect the work being done.

Infections from microorganisms not normally found in or on the human body, but which gain entrance from the environment, are called exogenous infections. These agents gain entry into the host by inhalation, indirect or direct contact, penetration, or ingestion. Some agents routinely cause disease in healthy adult humans, whereas others, known as opportunists, require special circumstances of lowered host defense or overwhelming dose of exposure. Thus, infectious disease is not always the end result of the exposure to and colonization by an infectious agent. The end result depends on the virulence of the agent, the route of infection, and the relative immunity and health of the host.

Workers are expected to be healthy human adults, but should be medically assessed during a preplacement examination to determine fitness for specific work. Because exposures can occur to those involved with the work and, potentially, to those who merely enter the work area, all such individuals should be identified and assessed in order to prevent exposure and subsequent infection. The spread of infectious agents used in research or production to the outside environment, including the neighboring community, is rare.

Epidemiology of Work-Associated Infections

An unfortunate consequence of working with infectious microorganisms or materials contaminated with them is the potential for acquiring a work-associated infection. The literature includes numerous descriptions of occupational exposures indicating that persons who handle infectious materials are clearly at higher risk for infection than the general population.

It is generally accepted that work-associated infections are underreported in the scientific literature. This may be the result of employees' unwillingness to report such incidents for fear of loss of employment, issues of liability, or an employer's refusal to publish such material. Literature on work-associated infections, reported as case studies, usually focuses on diagnosis and treatment of the patient and frequently fails to assess the circumstances related to the occupational exposure.

In the absence of a comprehensive database on work-associated infections, epidemiological methods provide the tools to evaluate the extent and nature of worker exposure. Defining the event or illness/infection, determining the population at risk, establishing the factors affecting exposure, and developing intervention controls are all part of the process to prevent occurrence or recurrence of infections. Several times during the past 79 years these tools have been applied to the study of laboratory-associated infections. A review of this information is instructive.

A comprehensive survey of laboratory-associated infections gathered by Sulkin and Pike (Sulkin & Pike, 1951; Pike, 1978; Pike, 1979) focuses specifically on laboratory-acquired infections. Data compiled between 1930–1978 revealed 4,079 cases of clinically apparent infection classified by agent, source of infection (when known), and type of work involved. Of the total, 168 cases resulted in the worker's death. These numbers are considered low because the reporting of work-related infections is not required, and data on seroconversion (the production of antibodies in response to an infectious agent) or asymptomatic response to occupationally acquired microorganisms are rarely reported. The 10 most frequently reported agents or diseases associated with laboratory-acquired infections described by Pike were brucellosis, Q fever, hepatitis, typhoid fever, tularemia, tuberculosis, dermatomycosis, Venezuelan equine encephalitis, psittacosis, and coccidiodomycosis.

The Sulkin and Pike surveys revealed the most common routes of exposure to be percutaneous inoculation (needles/syringes, cuts or abrasions from contaminated items, and animal bites), inhalation of aerosols generated by accidents or by work practices and procedures, contact between mucous membranes and contaminated material (hands and surfaces), and ingestion (Pike, 1979). Eighteen percent of the infections were attributable to known accidents caused by either carelessness or other human error. Twenty-five percent of these acknowledged accidents involved needles or syringes. Most of the remaining accidents involved spills and sprays, injury with broken glass or other sharp objects, accidental aspiration using a pipet, and animal bites, scratches, or contact with ectoparasites. Unfortunately, the sources of exposure for the remaining 82 percent of infections were not easily identifiable. Although some could be attributed to handling infectious animals, clinical specimens, and discarded glassware and to aerosols, all that was known about most exposures was that the person had worked with or was in the vicinity of work with the agent.

From these laboratory data, it is apparent that people engaged in research activities acquired the greatest number of infections. Trained investigators, technical assistants, animal

caretakers, and graduate students experienced over three-quarters of the research-associated illnesses. The remainder occurred among clerical staff, dishwashers, janitors, and maintenance personnel. With rare exceptions, laboratory-acquired infections were not spread to the outside community.

In an attempt to extend the Sulkin and Pike data, Harding and Byers reviewed 206 U.S. and worldwide publications between 1979–1999 to determine the microorganisms associated with laboratory infections, the types of facilities in which the infection occurred, and the type of work activity associated with the event (Harding & Byers, 2000). During this 20-year period 1,267 symptomatic laboratory-associated infections were reported with 22 deaths. Aborted fetuses accounted for five of the deaths with four of these associated with *Brucella melitensis* (Al-Aska & Chagla, 1989; Georghiou & Young, 1991; Young, 1983; Young, 1991) and one with Parvovirus B19 (Cohen et al, 1988). The 10 most frequently reported infections were associated with *Mycobacterium tuberculosis*, *Coxiella burnetii*, hantavirus, arboviruses, hepatitis B virus, *Brucella* spp, *Salmonella* spp, *Shigella* spp, non-A, non-B hepatitis virus, and *Cryptosporidium* spp. Clinical (diagnostic) and research laboratories accounted for 96 percent (45% and 51% respectively) of the symptomatic infections in this recent survey, whereas 76 percent of the infections occurred in clinical and research laboratories (17% and 59% respectively) in the earlier Pike and Sulkin data. While it would appear that clinical laboratory infection may be increasing, these increases may be due more to active employee health programs, an absence of containment equipment in some laboratories, or the fact that during the early stages of culture identification personnel are working with unknowns and not using adequate containment procedures. Similar findings to those observed by Pike and Sulkin were seen in this recent survey with respect to the number of laboratory infections associated with accidents.

More recently, workplace infections have been associated with new or emerging viruses such as human immunodeficiency virus (HIV), the etiologic agent associated with acquired immune deficiency syndrome (AIDS), and the hantavirus that causes Korean hemorrhagic fever. Herpes B virus continues to infect workers who handle certain nonhuman primates and their tissues, and an Ebola-related filovirus was associated with workplace asymptomatic seroconversions following an exposure to nonhuman primates in 1989 in Virginia (CDC, 1989). While the number of hepatitis B infections has decreased due to widespread immunization, improved work practices, and the use of engineering controls, hepatitis C virus (formerly non-A, non-B) has become a significant concern for workers because of the number of infected persons who develop chronic (long-term) infections (Mahoney et al, 1997; CDC, 1998c).

Attempts to determine incidence rates of occupationally acquired infections among laboratory personnel must be interpreted cautiously, because estimates of the number of infections and the population at risk are imprecise. Sulkin and Pike (1951) indicated that the risk of infection for researchers was six to seven times higher than for hospital and public health workers. They estimated that the annual attack rate for researchers was 4.1 per 1,000 employees (the attack rate being the number of cases divided by the population at risk). A 1971 survey of laboratory-acquired cases of tuberculosis, shigellosis, brucellosis, and hepatitis in England and Wales reported an annual incidence of 4.3 infections per 1,000 medical laboratory workers (Harrington & Shannon, 1976). A 1988 survey of laboratory-associated infections and injuries among public health and hospital clinical laboratory employees estimated the annual incidence rate for full time equivalent (FTE) employees to be 1.4 infections per thousand for public health and 3.5 infections per thousand for hospital laboratories, whereas rates for those working directly with infectious agents were 2.7 and 4.0 per thousand for public health and hospital laboratories, respectively (Vesley & Hartmann, 1988). Another study showed an estimated annual incidence rate for clinical laboratories of 3.0 infections per 1,000 employed and 9.4 infections per 1,000 when only microbiologists were considered (Jacobson et al, 1985). A recent Japanese survey of clinical laboratory workers revealed an annual incidence rate of 2.0 infections per 1,000 workers (Masuda & Isokawa, 1991).

Despite the admitted flaws in the existing data and the fact that much of the information on work-associated infections focuses specifically on laboratory-associated infections, it seems reasonable to accept the fact that some workers handling infectious materials will become infected. Epidemiological data provide the information necessary to make decisions regarding prevention or minimization of work-related infections. Accurate estimates of and surveillance for occupationally-associated infections are lacking because reports of infections usually do not include occupational data. A report of proportionate mortality from pulmonary tuberculosis as associated with occupation reflects a new effort to identify the potential for exposure (CDC, 1995). Ideally, though, infections rather than death should have been used to identify the risk of exposure in certain workplaces. For additional information on laboratory-associated infections, see Sewell, 1995 and Collins & Kennedy, 1999.

Potentially Hazardous Workplaces

Although most pathogenic microorganisms have the potential to cause occupationally acquired infections, knowledge of the hazard, containment practices, and preventive therapeutic measures such as use of vaccines greatly reduce their incidence. In workplaces where awareness of the hazard is high and the potential risk is understood, compliance with control practices minimizes exposure. However, there are some workplaces where controls are difficult to implement or are not readily available and where hazard recognition of the potential for work-associated infections is low, for example, agricultural environments and processing facilities. Workers in these environments may be exposed to potentially infectious microorganisms that are intrinsically associated with

some of the animals or plants. Controls and barriers become challenging to implement in these environments.

Because workplaces are varied and microbial habitats diverse, it can be difficult to find concise, detailed information on microbial agents. The American Public Health Association publication *Control of Communicable Diseases Manual* is an excellent resource for information on a disease, the infectious agent, its occurrence, reservoir, mode of transmission, incubation period, and methods of control (Chin, 2000).

The prevention of emerging infectious diseases presents an increasing problem as societal, technological, and environmental factors continue to have a dramatic effect on infectious diseases worldwide (CDC, 1998b). Modern demographic and ecologic conditions that favor the spread of infectious diseases include rapid population growth; increasing poverty and urban migration; more frequent movement across international boundaries by tourists, workers, immigrants, and refugees; alterations in habitats of animals and arthropods that transmit disease; increasing numbers of persons with impaired host defenses; and changes in the way food is processed and distributed. As research, clinical, and public health laboratories respond to the disease problems of the 21st century, workers will handle microorganisms that are increasingly resistant to antimicrobials (such as *Staphylococcus aureus*, *M. tuberculosis*, *Enterococcus* spp). Food and waterborne diseases (hepatitis A virus, *E. coli* 0157:H7, *Cryptosporidium* spp) and vector-borne and zoonotic diseases including disease not previously known to infect humans (Asian flu virus-Hong Kong, a new variant of Creutzfeldt-Jakob disease—bovine spongiform encephalopathy [BSE], hemorrhagic fevers) will continue to infect developing as well as developed countries.

MICROBIOLOGY, PUBLIC HEALTH, CLINICAL, AND MOLECULAR BIOLOGY LABORATORIES

The potential threat of occupational infection has long been recognized by microbiologists. However, new potential for exposure exists with the increasing number of non-microbiologists who work in the field of molecular biology. The previous review of laboratory-related infections summarizes experiences to date. Exposures tend to be directly related to the hazard classification of the organisms being manipulated, the potential for release of the organism during required manipulations, and the level of competency of personnel.

Staff in research laboratories, the type of workplace where the majority of laboratory-acquired infections have occurred, tend to work with more hazardous agents, including those of emerging diseases. They often handle concentrated preparations of infectious microorganisms, and some test procedures require complex manipulations. Because of inherent containment difficulties, the use of infected laboratory animals, including those taken from the wild, also increases the potential for worker exposure to infectious agents. More information on animals is covered later in this section.

Increased rates of occupational infections has also been noted among public health and clinical laboratory workers as compared to the general population (Vesley & Hartmann, 1988; Jacobson et al, 1995). A recent review of laboratory-associated infections noted an increased number of clinical lab infections being reported (Harding & Byers, 2000).

HOSPITALS AND HEALTH CARE ESTABLISHMENTS

In addition to infectious agents, health care facilities (which include physicians' and dentists' offices, blood banks, and outpatient clinics) may expose their personnel to multiple hazards including cytotoxic drugs, anesthetic gases, ethylene oxide, radiation sources, steam, injuries from lifting heavy objects, and electrical shock. Infections in hospitals can be categorized as community acquired (transmitted to either patients or workers); occupationally acquired (resulting from worker exposure); and nosocomial (hospital-acquired infections of patients).

The Joint Commission on Accreditation of Healthcare Organizations (JCAHO), the CDC guidelines for hospital infection control, the OSHA bloodborne pathogens standard, and the CDC/NIH biosafety guidelines (1999) all provide guidance concerning the control of nosocomial infections in patients and the protection of health care personnel. Because of the nature of hospital activities, nosocomial infections have become a complication of hospitalization. To prevent or reduce the incidence of such complications, infection control programs were developed and implemented in U.S. hospitals during the 1950s and 1960s. The CDC coordinates surveillance of hospital infections and recommends infection control practices and procedures.

In most instances a hospital epidemiologist (usually a physician who specializes in infectious diseases) and an infection control practitioner (often a nurse or, occasionally, a microbiologist) manage and oversee infection control activities. The prevalence of hospital infections has created a need for infection control procedures (barriers), rigorous disinfection and sterilization techniques, meticulous cleaning and waste-handling procedures, and, in some cases, special design criteria. The role of the industrial hygienist or environmental health and safety professional in hospital infection control may include assisting in the selection and testing of personal protective equipment, environmental testing in outbreak situations such as nosocomial fungal infections in oncology patients, and the design of engineering controls such as ventilation and containment systems.

Because it is not within the scope of this chapter to provide detailed material on the many topics covered here, the reader is referred to the Hospital Infection Program at the CDC in Atlanta and the JCAHO in Oakbrook Terrace, Ill., for guidelines and standards covering infection control programs and practices in the United States. For more information, two journals in the United States provide current information on hospital infection control: the *American Journal of Infection Control* from the Association of Professionals

in Infection Control (APIC) in Washington DC; and *Infection Control and Hospital Epidemiology*, the journal of the Society for Healthcare Epidemiology of America (SHEA), published by Slack, Inc., in Thorofare, NJ.

BIOTECHNOLOGY FACILITIES

With the discovery of recombinant DNA technology and the resulting advances in the field of molecular biology, many opportunities for the development of products in medicine, industry, agriculture, and environmental management are now possible. Industrial microbiology, long associated with the chemical and pharmaceutical industries, has attained a position of prominence with the advent of "the age of biotechnology."

From the early stages of discovery to the ultimate marketing of a pharmaceutical, large volumes of material, whether it be a metabolite or an organism, are required. Depending on the hazard level (pathogenicity or biological activity), an increase in the production or concentration of a material brings with it the need for adequate barriers to protect personnel, the product, and the community.

With some exceptions, the microorganisms most often used in manufacturing operations are those requiring minimum containment, such as genetically engineered bacteria (*E. coli* K12), fungi, plant and animal cells. Production operations usually involve the use of closed systems (either a primary container or a combination of primary and secondary containers) and validated inactivation of waste materials and contaminated by-products.

In addition to the possibility of experiencing the direct effects of the biological activity of an agent, workers may develop allergies to proteins (that is, biological products that are derived from raw materials, fermentation products, or enzymes), other chemicals, or animal dander, aerosolized urine, or other matter from animals. Allergic responses following exposure to proteins in the work environment can produce significant health effects, but they are not addressed here. For additional information on allergic response and safety issues in biotechnology, consult Nellis and Van Houten, 1995; Ducatman and Liberman, 1991; Cottam, 1994; AIHA, 1995.

ANIMAL FACILITIES AND VETERINARY PRACTICES

Although generally only work activities in research, medical, and industrial facilities involve handling laboratory animals, there are a wide range of occupations in which workers are exposed to animal-related allergens and to infectious agents or their toxins. Agricultural workers, veterinarians, workers in zoos and museums, taxidermists, and workers in animal product-processing facilities are all at risk for occupational exposure to animal-related biological hazards. A number of these workers may be exposed to wild (captured) or exotic animal populations. Factors to be considered when handling animals include the nature of the animal (its aggressiveness and tendency to bite or scratch), the normal flora and natural ecto- and endoparasites of the animal, the zoonotic diseases to which it is susceptible, and the possible dissemination of allergens.

The development of laboratory animal allergy (LAA) is a significant and common problem for laboratory personnel, veterinarians, and others who work with animals (Hunskaar & Fosse, 1990; Merchant et al, 1994; Sjöstedt et al, 1995). The manifestations of LAA include cough, wheezing (asthma), watery and itchy eyes, itchy skin, sneezing, and skin rash. Following contact with animals, symptoms can develop in less than one year, but may take up to several years to develop. Often, workers react to the proteins in shed animal dander and hair or to those in animal urine, serum, saliva, or tissues. Aerosolized mold spores and proteins from animal food and bedding can also act as allergens. The prevalence in Europe and the United States of LAA among lab workers and animal handlers has been reported to range between 11 and 44 percent (Sjöstedt et al, 1995). Specific equipment is available to reduce exposures to animal fur and dander, such as electric shavers with built-in vacuum attachments (Fisher et al, 1998).

During the past 50 years, diseases that affect both humans and animals (zoonotic diseases) have been among the most commonly reported occupational illnesses of laboratory workers. Most of these have been caused by viral and bacterial (including rickettsial) agents.

Infection is most often the result of one of the following types of exposure:

- ➢ Animal bites or scratches
- ➢ Contaminated needles, scalpels, or other inanimate objects
- ➢ Infectious aerosols resulting from animal respiration or excretion, or dust from infectious materials such as bedding
- ➢ Contact with infected tissue and cells during histological procedures, homogenization, or manipulation of cells in culture

Zoonotic infections among veterinarians are common. Several excellent references listing zoonotic diseases of laboratory animals and zoonotic pathogens causing diseases in man have been published (Fox & Lipman, 1991; National Research Council, 1989, pp 175–186; Constantine, 1998; Merchant et al, 1994, pp 688–693).

Animal-related infections can be expected at certain kinds of worksites. The infections frequently observed among personnel involve microorganisms with a low infectious dose (ID) where exposure results from aerosolized infectious materials. Numerous accounts of *C. burnetii*, the rickettsial agent that causes Q fever, have been reported. *C. burnetii* has an estimated $ID^{25\text{-}50}$ of 10 organisms by inhalation (Wedum et al, 1972). This means that 25 to 50 percent of a population becomes infected after inhaling only 10 *C. burnetii* bacteria. Many hospital and laboratory personnel have been exposed to *C. burnetii* as the result of research involving naturally infected asymptomatic sheep. In addition to being extremely

infectious, the organism is very resistant to drying and remains viable for long periods of time. Q fever control measures for research facilities using sheep were published in 1982 (Bernard et al, 1982).

Hantavirus, the etiologic agent of Korean hemorrhagic fever, produces an asymptomatic infection in wild rodents. In the past twenty years, at least 169 work-related hantavirus infections (Harding & Byers, 2000), apparently resulting from inhalation of aerosols produced by chronically infected laboratory animals, were reported in the scientific literature (Desmyter et al, 1983; Lee & Johnson, 1982; Lloyd & Jones, 1986; Wong et al, 1988). In the 1990s a unique hantavirus, the sin nombre virus (SNV), was detected in the southwestern United States. Reports of a pulmonary illness (HPS) caused by SNV underscore the infectious potential of this zoonotic agent (CDC, 1993d). Cases continue to be reported from throughout the United States and abroad now that the virus has been identified. Refer also to Weigler (1995) for a review of zoonotic hantaviruses in the United States.

Work-acquired infections contracted while handling nonhuman primates have been a concern for many years. Serious health consequences, including hemorrhagic disease and death, have resulted from Marburg virus (a human filovirus) infections in Europe (Martini & Siegert, 1971) and Ebola and Marburg viruses in Africa (WHO, 1978; Baron et al, 1983; Gear et al, 1975).

Ebola-related filovirus seroconversion was documented among several animal handlers in U.S. primate facilities (CDC, 1990b, p 221). No evidence of clinical disease was detected, but these events warrant close scrutiny of nonhuman primate colonies. Guidelines for handling nonhuman primates during transit and quarantine have been published (CDC, 1990b, pp 22–30).

At least 50 cases of *Herpesvirus simiae* (*Cercopithecine herpesvirus* or B virus) infections have been documented, most with lethal or serious outcomes (CDC-NIH, 1999). In all instances exposure was related to activities involving macaques. Fifteen infections occurred between 1979 and 1999 (Harding & Byers, 2000) and in 1987 the CDC published guidelines for prevention of *Herpesvirus simiae* (B virus) infection in monkey handlers (CDC, 1987a).

Significant similarities between the simian immunodeficiency virus (SIV) and HIV have led to the development of guidelines to prevent simian immunodeficiency virus infection in laboratory workers and animal handlers (CDC, 1988). While no illnesses has been noted in workers to date, seroconversions (one of them persistent) have been reported (CDC, 1992).

Certainly not all agents associated with zoonotic disease carry the same potential for occupational exposure as some of those described above. Nevertheless, it is critical to evaluate the risk and to determine the control measures necessary to contain the hazard before initiating work with potentially infectious or experimentally infected animals.

Agriculture

Agriculture, mining, and construction were considered to be among the most hazardous occupations of the 20th century. Agricultural workers and those who process agricultural products are exposed to numerous safety and physical hazards as well as chemical and biological agents. Workers are readily exposed to infectious microorganisms as well as their spores and toxins through inhalation, ingestion resulting from contact with contaminated materials, direct exposure of non-intact skin and mucous membranes, and inoculation resulting from traumatic injury. Factors such as host susceptibility, virulence of the agent, dose and exposure route all influence the potential for disease development.

Biological agents associated with fungal diseases (such as coccidioidomycosis, histoplasmosis, and blastomycosis) are found on plants and animals and in soils. These agents cause endemic disease and, as occupational hazards, affect primarily farmers and horticultural workers. Food and grain handlers, farmers, and laborers are exposed to parasitic diseases such as echinococcosis and toxoplasmosis. Processors who handle animal products may acquire bacterial skin diseases such as anthrax from working with contaminated hides, tularemia from skinning and dressing infected animals, and erysipelas from skin abrasions infected during contact with contaminated fish, shellfish, meat, or poultry. Infected turkeys, geese, squab, and ducks or the aerosolized feces from these birds expose poultry processing workers and farmers to psittacosis, a bacterial infection caused by *Chlamydia psittaci*.

At least 24 out of the 150 zoonotic diseases known worldwide are considered to be a hazard for agricultural workers in North America (Donham, 1985; Constantine, 1998, Merchant, 1994; Merchant et al, 1994; Acha & Szyfres, 1980). These diseases can be contracted directly from animals, but more often they are acquired in the work environment. Risk of infection varies with the type and species of animal and geographic location. Controls include awareness of specific hazards, use of personal protective equipment (PPE), preventive veterinary care, worker education, and medical monitoring or prophylactic therapy, where appropriate.

There is an extensive literature on occupational exposure of agricultural workers. For additional information, the reader is referred to Macher & Rosenberg, 1999; Popendorf & Donham (1991); AIHA (1995); and the 1986 Agricultural Respiratory Hazards Education Series published by the American Lung Association.

Miscellaneous Worksites

The potential for exposure to occupational biohazards exists in most work environments. The following list, though incomplete, cites many of the diverse workplaces where the potential for exposure to biohazardous agents exists, along with the diseases or agents to which workers may be exposed. For additional references of infectious dis-

eases by occupations see Macher & Rosenberg, 1999, pp 291–295; Dutkiewicz et al, 1988, pp 612–615; Cohen, 1997.

- ➢ Workers maintaining water systems: *Legionella pneumophila* and *Naegleria* spp.
- ➢ Workers associated with birds (such as parrots, parakeets, and pigeons) in pet shops, aviaries, zoos with avian exhibits, or on construction and public works jobs near perching or nesting sites: *Chlamydia psittaci*, *Histoplasma capsulatum.*
- ➢ Workers in wood-processing facilities: wood dust, endotoxins, allergenic fungi growing on timber, and fungi that cause deep mycoses.
- ➢ Miners: zoonotic bacteria, mycobacteria, dermatophytic fungi, fungi causing deep mycoses, mycotoxin-producing fungi. (Miners may be immunocomprornised because of exposure to coal dust, which results in black lung disease.)
- ➢ Sewage and compost workers: enteric bacteria and other infectious bacteria, endotoxin, hepatitis A virus, parasitic protozoa such as *Giardia* spp, allergenic fungi.
- ➢ Renovators of items such as books, buildings, and paintings; librarians: endotoxin, allergenic microorganisms and toxigenic fungi growing on surfaces.
- ➢ Workers in textile manufacturing who process plant fibers (such as cotton, flax, hemp): organic dust, endotoxin.
- ➢ Workers in the fishing industry: zoonotic bacteria (such as *Leptospira interrogans*, *Erysipelothrix rhusiopathiae*, and *Mycobacterium marinum*) and parasitic flukes (such as *Schistosoma* spp).
- ➢ Forestry workers: zoonotic diseases or agents (such as rabies virus, Russian spring summer fever virus, Rocky Mountain spotted fever, Lyme disease, and tularemia), viruses and bacteria transmitted by ixodid ticks, and fungi that cause deep mycoses.
- ➢ Workers who handle animal hair and rough leather: zoonotic diseases (such as Q fever, anthrax, and tularemia) and dermatophytic fungi.
- ➢ Workers who handle products of plant origin: endotoxin, allergenic actinomycetes, allergenic or mycotoxin-producing storage fungi, allergenic or toxic substances of plant origin, and allergenic storage mites.
- ➢ Child care workers: bacterial enteric diseases (*Campylobacter*, shigellosis), viruses (hepatitis A, chickenpox, measles), dermatophycoses, and protozoal diseases (cryptosporidiosis and Giardiasis).
- ➢ Public safety workers: bloodborne pathogens (hepatitis B and C viruses), viral respiratory diseases including influenza.

RISK ASSESSMENT

In the late 19th century, as scientists became aware of the presence of microorganisms and their potential to cause illness, many microbiologists suffered significant health consequences as a result of their work. Diseases such as cholera, typhus, yellow fever, Rocky Mountain spotted fever, and tuberculosis claimed the lives of those dedicated to studying or eradicating these diseases. Health care and agricultural workers suffered ongoing exposure to biological hazards before advances in medical science and animal husbandry could reduce the consequences of infectious diseases.

As has been previously stated it is possible to work with infectious agents (or people, animals, or substances infected or contaminated by them) and still avoid exposure and subsequent infection or illness. Infections do not necessarily occur simply because the exposed person works with a disease-producing agent or substance. A series of circumstances are necessary for an exposure to lead to infection or illness. By performing a risk assessment on an operation or event, it is possible to make a systematic evaluation of the exposure potential, and then to make decisions as to how the exposure can best be avoided, reduced, or otherwise managed.

Factors Affecting Infection and Exposure

The following factors can affect the type of infection and exposure that workers encounter. They will be covered in the next section.

MODES OF TRANSMISSION

The principal modes of transmission for infectious microorganisms and other biological materials include contact transmission (direct or indirect), vector-borne transmission, and airborne transmission. Direct contact of an infected person with another person is rare in the laboratory environment, but such transmission occurs commonly in the community and in medical settings where patients are treated. Animal-to-human (zoonotic) transmission through bites and scratches can occur when animals are associated with work activities. Spills or splashes of infectious materials (gross contamination) onto a receptive site such as an open wound, cut, eczematous skin, or mucous membranes are an effective means of transmitting microorganisms. Indirect transmission occurs when common environmental surfaces (such as equipment, work benches, or laboratory accessories) become contaminated, and the infectious material is transferred to a host.

Vector-borne infection results when a causative agent is transmitted to a host mechanically or biologically by a living vector (such as a mosquito or tick) through a bite, directly through the skin in rare cases, or by mechanical means. Biological transmission involves propagation, multiplication, cyclic development, or a combination of these in the host before the arthropod can transmit the infective form of the agent. Infected ticks and mosquitoes have transmitted Rocky Mountain spotted fever, malaria, and yellow fever to investigators in the laboratory and in the field and are a potential hazard for other outdoor workers.

The inhalation of airborne infectious particles into the respiratory system constitutes airborne transmission. This mode is important in the transmission of certain pathogens such as *M. tuberculosis*. The contaminated air in a room may escape to the outside and act as a conduit for contamination of the environment. Additional information on airborne transmission can be found later in this section of the chapter, under the heading "Aerosols".

ROUTES OF ENTRY

The routes of entry for microorganisms associated with occupationally-acquired infection include inhalation, ingestion, penetration through skin (intact or non-intact), and contact with the mucous membranes of the eyes, nose, and mouth. Many technical procedures (such as pressurizing liquids, sonicating, and grinding or sawing infectious materials), equipment, and spills in the workplace release microbes into the air, where workers can inhale them.

Ingestion of infectious materials can occur when workers mouth-pipet or suction infectious materials or by hand-to-mouth contamination as the result of eating, drinking, smoking, or applying cosmetics in contaminated work areas. Hand-washing minimizes the opportunity for oral and ocular exposure.

Infectious agents are introduced into the body when contaminated objects (such as hypodermic needles, broken glassware, scalpels, and other tools) or animals puncture, cut, or scratch the skin (percutaneous exposure). This type of exposure also occurs through skin surfaces that are not intact, that is, when open wounds, cuts, hangnails, dermatitis, or eczema are present. Unbroken skin is a barrier to infectious agents. Exceptions occur only in instances where skin penetration is the normal route of entry for an agent, such as with the infective cercariae stage of the parasitic agent *Schistosoma* spp.

The mucous membranes of the eyes, nose, and mouth are readily exposed to agents when rubbed with contaminated fingers or gloved hands and when splashes or sprays of infectious material occur. There have been reports of HIV and *Trypanosoma cruzi* infections related to splashes of the eyes and mucous membranes (Ippolito et al, 1999; Herwaldt & Juranek, 1995).

INFECTIOUS DOSE

The infectious, or infective, dose is the number of microorganisms required to initiate an infection. Although there are data available from animal studies on ID^{50} (the number of organisms needed to infect 50 percent of a test population), only a modest amount of information exists for humans. Data accumulated by the NIH on route of entry and infectious dose are shown in Tables 14–A and 14–B (Wedum et al, 1972).

Table 14–A. ***Infectious Dose for 25 to 50 Percent of Volunteers***

Disease or Agent	*Inoculation Route*	*Dose**
Scrub typhus	Intradermal	3
Q fever	Inhalation	10
Tularemia	Inhalation	10
Malaria	Intravenous	10
Syphilis	Intradermal	57
Shigella flexneri	Ingestion	180
Anthrax	Inhalation	≥1,300
Typhoid fever	Ingestion	10^5
Cholera	Ingestion	10^8
Escherichia coli	Ingestion	10^8
Shigellosis	Ingestion	10^9

* Dose given in number of organisms.

Adapted from Wedum et al, 1972, p 1558.

AGENT VIABILITY AND VIRULENCE

The viability and virulence of an agent are also important in determining whether a person becomes infected. If a microorganism is not viable and able to replicate, the opportunity for infection does not exist. The external environment is critical in the replication of microorganisms. Factors such as temperature, humidity, and the presence or absence of growth factors or other chemicals all play an important role in viability. For example, some bacterial agents, such as *Bacillus anthracis*, are capable of producing spores that survive under adverse conditions, and agents such as *M. tuberculosis* or *S. aureus* are unaffected by drying and remain viable on environmental surfaces, whereas other agents such as the herpes viruses are very susceptible to drying.

The virulence, or relative pathogenicity, of microorganisms varies greatly among types and strains. Some microbes are highly pathogenic, even in healthy adults, whereas others are opportunistic pathogens, able to infect only hosts with lowered immunity or sites other than their normal habitat. Some microbial strains are attenuated, or weakened, after reproducing through numerous generations in the laboratory. Certain vaccine strains, selected because they are immunogenic and do not produce significant disease, are also examples of attenuated organisms. Even though the vaccine strain of an organism may be attenuated, it is best to limit exposure to planned circumstances such as vaccination rather than by an accidental, work-related exposure.

HOST SUSCEPTIBILITY

Host susceptibility is often underestimated because the majority of persons working with potentially infectious material are healthy. The risk assessments and biosafety levels recommended by the CDC and NIH presume a population of immunocompetent workers (CDC/NIH, 1999). Employees working with infectious agents can be put at increased risk of infection because of a variety of medical conditions such as diseases, allergies, inability to receive particular vaccines, and pregnancy or by taking drugs that alter host defenses.

Table 14–B. ***Minimal Human Infective Dose in Volunteers***

Viral Agent	*Inoculation Route*	*Dose**
Measles virus	Intranasal spray	0.2**
Rhinovirus	Nasal drops	≤1
Venezuelan encephalitis virus	Subcutaneous	1†
West Nile fever virus	Intramuscular	1††
Parainfluenza 1 virus	Nasal drops	≤1.5
Poliovirus 1	Ingestion	2**§
Rubella virus	Pharyngeal spray	≤10**
Coxsackie A21 virus	Inhalation	≤18
Rubella virus	Subcutaneous	30**
Adenovirus 27	Conjunctival swab	≤32
Rubella virus	Nasal drops	60**
Adenovirus 7	Nasal drops	≤150
Respiratory syncytial virus	Intranasal spray	≤160–640
Influenza A2 virus	Nasopharyngeal	≤790
SV-40 virus	Nasopharyngeal	10,000

Note: There was illness after all inoculations except poliovirus, rubella virus (nasal drops), adenovirus (nasal drops), and SV-40 virus; in these four there were serologic conversions.

Conditions that alter host defenses at body surfaces or impair the functioning of the immune system may put a worker at risk for certain infections. Skin disorders such as chronic dermatitis, eczema, and psoriasis leave a worker without an intact skin barrier against infection. The gastrointestinal mucosa, colonized by a resident population of normal bacterial flora, offers protection against infection by pathogenic microorganisms. However, this protection is usually disrupted when antibiotic therapy is administered. The body's immune system, consisting mainly of antibody-mediated B-cells, cell-mediated T-cells, and phagocytic cells, offers a significant line of defense against invading microorganisms (Ammann, 1987).

Women who are pregnant or intend to become pregnant are at risk of exposure to certain infectious agents, as well as other potentially hazardous materials in their work environment. Foremost among the infectious hazards is the potential for congenital infection of the fetus, due to exposure to cytomegalovirus (CMV), rubella, hepatitis B virus (HBV), herpes simplex virus, varicella virus, syphilis, or toxoplasmosis (Sheretz & Hampton, 1986).

The development of allergies to proteins (such as biological products from raw plant and animal materials, fermentation products or enzymes, chemicals, animal dander, or aerosolized animal urine proteins) also presents a risk to employees. If an employee cannot be immunized because of an allergy to a constituent of a vaccine, the safety of that person may be compromised. A higher level of work practices and personal protective equipment may provide the required level of protection for such a worker. All of these factors must be recognized and evaluated in relation to an employee's potential exposure. Decisions should be made on a case-by-case basis, with input from the employee, the employee's physician, institutional management, and an occupational health service professional (Goldman, 1995). All activities or actions associated with worker health or medical surveillance must be performed in such a manner, so that their confidentiality is not compromised. The results of medical testing or evaluation may only be released with the worker's permission.

Other Factors

Additional factors associated with risk assessment of microbial work include the ability to tolerate prophylactic or therapeutic measures (vaccines and effective interventions), knowledge of the host range of the microorganism, and an understanding of the organism's potential for escape to the community. The importance of assessing the work activity (including the facility, contamination potential, volume of material, and the agent concentration) in relation to the host and agent cannot be overemphasized.

AEROSOLS—A SPECIAL FACTOR

As noted earlier, Pike's survey of laboratory-associated infections indicated that only 18 percent of the documented infections had resulted from known accidents (Pike, 1976). For the remaining 82 percent, a connection between the infected person and the causative agent was difficult to determine. In many instances, all that is known is that the person worked with or was in the vicinity of work being done with the causative agent. The fact that no specific event could be associated with so many infections led earlier reviewers to implicate many routine laboratory procedures as the source of airborne contamination. Workers are exposed to airborne microorganisms through direct contact with or inhalation of minute airborne particles or by contact following the deposition of droplets, through splashing or spilling, onto surfaces, equipment, and personnel. Contamination as the result of splashing and spilling can also occur through transmission routes other than inhalation.

Liquid, when under pressure and passed through a small opening or when dropped onto a solid surface, is aerosolized into a cloud of very small droplets. The droplets vary in size; the larger ones settle quickly onto surfaces, inanimate objects, clothing, and skin, whereas the water in smaller particles evaporates rapidly. Bacteria and other material in the droplets remain in a dried state as droplet nuclei. These particles, or droplet nuclei, can remain suspended in air for some time and be moved to remote areas by air currents or ventilation systems.

Laboratory procedures involving the manipulation of infectious materials generate infectious particles of various sizes. For example, particles released by opening or dropping lyophilized cultures are ~ 10 μm in diameter, and particles generated by mixing, sonicating, or blending cultures range from 2–5 μm, depending on the operation (Kenny & Sabel, 1968; Reitman & Wedum, 1956). It has been shown that particles <5 μm in diameter are most effective in producing respiratory infection in animals (Hatch, 1961). See Chapter 2, The Lungs, and Chapter 8, Particulates, for additional aerosol information.

Infectious airborne particles can be generated not only from aerosolized liquids but also from lyophilized cultures, dried bacterial colonies, dried material on stoppers and caps of culture tubes and bottles, dried exudates, fungal and actinomycete spores released when cultures are opened or contaminated material is disturbed, and dusts from animals. Diseases documented to have been associated with airborne infection in the laboratory and other workplaces as well as in the community include tuberculosis, psittacosis, Q fever, pulmonary mycoses, influenza, measles, legionnaires' disease, Pontiac fever, HPS, and, in special circumstances, brucellosis, rabies, and plague.

The use of epidemiological tools to study workplace infections confirms the observation that people whose work brings them into contact with pathogenic microorganisms are at greater risk of infection than the general population. However, the mere presence of an agent does not necessarily lead to occupational exposure and infection. Certain conditions—the multiple interrelated factors of route of entry, dose, viability, virulence, mode of transmission, and host susceptibility—must be present before an infection occurs. For an infection to occur, the agent must be pathogenic and viable, present in sufficient numbers to produce infection, and be transmitted successfully and delivered to a susceptible host at a suitable entry site. It may be possible to reduce or eliminate susceptible hosts through immunization.

HAZARD CLASSIFICATION

Biological agents are not all equally dangerous to workers. An understanding of the potential for the hazardous agent to cause human disease, known as its pathogenicity, and through what routes of infection the agent is efficiently delivered to a worker permits one to develop a classification based on risk.

Hazard Categories

The following section covers biosafety containment levels, guidelines, and the interpretation of the guidelines.

BIOSAFETY CONTAINMENT LEVELS—BACKGROUND

In the 1970s, the CDC classified etiologic agents on the basis of hazard (CDC, 1974). The list compiled for that purpose still exists in slightly modified form in some government documents, including a document describing interstate shipment of etiologic agents (CDC, 1980). For appropriate identification of the categories to be used in packaging, labeling, and shipping etiologic agents, lists were provided by the CDC in 1974 and in 42 *CFR* Part 72 (CDC, 1980). The 1974 list came to be used as a classification scheme in which an organism, genus, or group of microorganisms can be categorized into a specific hazard group by users and other federal agencies. The 1980 list identified organisms that were required to be sent by registered mail. At the present time, etiologic agents and other infectious materials are considered hazardous materials under the U.S. Department of Transportation (U.S. DOT) 49 *CFR* Parts 171-180, although they are not included as hazardous agents under the OSHA hazard communication standard. The U.S. DOT inclusion and the OSHA hazard communication MSDS (material safety data sheet) exemptions cause some confusion. Obviously, information similar to that found in certain sections of an MSDS is needed to allow appropriate spill cleanup and to alleviate inappropriate public perception of risk for any shipment of microorganisms. On the other hand, if the organism being shipped is not pathogenic, there should be a mechanism for declaring an exemption from the U.S. DOT list so as not to restrict packaging to the small size limitations required for infectious substances.

Lists currently in use should be reviewed at least annually and updated accordingly because of numerous taxonomic changes and the recognition that any species of organism may have avirulent and virulent strains. Information on the more commonly recognized human pathogens can be found in peer-reviewed scientific literature and in numerous microbiology textbooks. Unfortunately, it is rare to find an assessment of the level of risk or any directives regarding the containment to be used in working with pathogens in such references. However, if the agent is listed in one of the guidelines, the first estimation of its biosafety containment level can be ascertained (OSHA, 1991; NIH, 1999; CDC/NIH, 1999; U.S. PHS, 1974).

Opportunistic microbes and normal flora that can cause disease are often inferred to be at the same risk level as a frank pathogen, because the case reports in the literature do not routinely account for host factors by differentiating between an immunocompromised host and a healthy one. Organisms that cause infections in immunocompromised adults should be evaluated to determine whether they pose a risk to healthy adults as well. Organisms that have been attenuated to make live vaccines may no longer require the same containment level as their wild-type, parent organism (*Official Journal of the European Communities*; 1990, Annex VI). For example, BCG (an attenuated strain of *Mycobacterium bovis* that may confer immunity against TB) is handled at biosafety level 2 (BSL-2), which is less restrictive than BSL-3, the level at which its parent organism, *M. bovis*,

is classified (CDC, unpublished data, 1994). Influenza vaccine strains are handled at BSL-1, whereas the parent virus is BSL-2 (CDC, 1974). The CDC Center for Infectious Diseases, Bacterial and Mycotic Diseases Branch (or other branches as appropriate) should be able to provide information on human pathogenicity of microbial agents.

Poliovirus vaccine that is given orally to children and adults was previously considered to be safely handled at BSL-1, and the wild-type strains of polio were handled at BSL-2. There are two vaccines that afford protection against all three types of poliovirus. Because of the effectiveness of the vaccines and because there is no reservoir for the virus other than humans, there is an ongoing international program to eradicate the disease. If the eradication program is successful, the BSL level for polioviruses will be reassigned. Polioviruses from any and all sources are now considered more hazardous than previously thought. The World Health Organization (WHO) has recommended a program to destroy stocks of poliovirus. Early in 2000, the poliovirus was to be handled at BSL 2/polio, a special containment designation. The WHO has indicated that poliovirus will eventually become a Risk Group 4 agent to be handled under BSL 4 conditions (WHO, 1998, 1999).

After an estimated biosafety containment level for a microbial agent is provided to the appropriate supervisor, the remainder of the risk assessment involving host-environment interactions should be done by the institution (the biosafety committee or a biosafety officer).

Although not microorganisms, cell lines and primary cells in culture must be mentioned because of their potential to be contaminated with infectious agents. When assessing the potential hazard associated with cells in culture, consider the source of the cells (human, rodent, etc.), the potential for the cells to harbor viruses or mycoplasma, whether they are tumor cells or have been transformed with virus, or whether they are established lines or only recently isolated from a host (primary cells).

If allergens or chemical agents are used, appropriate precautions to prevent sensitization should be based on exposure control limits that have been established by a reputable association, as was done by the working party of the European Federation of Biotechnology (Kuenzi et al, 1985). Biosafety levels were developed for use in protection against living microorganisms that have the potential to cause infectious disease in healthy human adults; they are not usually appropriate for the control of other hazards.

PUBLISHED GUIDELINES OF CONTAINMENT LEVELS

The biosafety guidelines most commonly used in the United States for containment of biohazardous agents in the workplace are those recommended by the CDC, the NIH, and the National Research Council (NRC) (NIH, 1999; CDC/NIH, 1999; CDC, 1974; National Research Council [NRC], 1989). Other guidelines found in the literature are based on interpretations of the recommendations of these agencies (OSHA, 1991; Kent & Kubica, 1985; Kruse et al, 1991; Fleming et al, 1995; National Committee for Clinical Laboratory Standards [NCCLS], 1997; AIHA, 1995).

The CDC/NIH Guidelines for Microbiological and Biomedical Laboratories (CDC/NIH, 1999). The CDC/NIH guidelines (*Biosafety in Microbiological and Biomedical Laboratories [BMBL]*) recommend that laboratory directors establish work practices involving containment equipment and facilities in the workplace. In doing this, they must take into account interactions of the virulence of the agent, immune status of potential hosts, and the hazards of the procedure. In addition, laboratory directors are responsible for making appropriate risk assessment of agents not included among the *BMBL* agent summary statements. The director must be familiar with the subject of risk assessment regarding biological agents or seek the advice of one who has such expertise.

Although the guidelines assign the responsibility for risk evaluation to the laboratory director, no method is suggested for determining the virulence of agents. Except for agents that have caused laboratory-acquired infections or those that pose a serious hazard to healthy adults, the CDC/NIH guidelines do not account for the use of most agents. A mechanism for updating the agent summary statements in *BMBL* was proposed through publication in the *Morbidity and Mortality Weekly Report* (*MMWR*). The only agent summary statement added between 1986 and 1993 was one for the human immunodeficiency virus. Information on the epidemiology and safety recommendations for the new hantavirus sin nombre was published in a special report in 1994 (CDC, 1994b). Following the outbreak of encephalitis in horses, birds, and humans in the late summer of 1999, the West Nile virus (WNV) was identified as the causative agent. The WNV had never before been found in the Western Hemisphere. The CDC published guidelines for surveillance, prevention, and control in *Morbidity and Mortality Weekly Report* on January 21, 2000 (CDC, 2000b).

Risk management is achieved through use of practices, facilities, and equipment specified in defined biosafety containment levels. Biosafety practices are an important part of a program to manage the risk of exposure to potentially infectious agents. The general agent descriptions and applicable work environments described by the CDC and NIH in each of the biosafety levels for both small and large scale are listed below as compiled directly from the guidelines (NIH, 1991, 1994, 1999; CDC, 1974; and CDC/NIH, 1999). An addendum at the end of this chapter outlines large-scale guidelines applicable to nonrecombinant organisms.

Biosafety level 1 (BSL-1) is used for work involving defined and well-characterized strains of viable microorganisms of no known or of minimal potential hazard to laboratory personnel or the environment. This level is appropriate for high school and undergraduate college teaching and training laboratories. No special competence is required, although training in the specific procedures should be provided, and there should be supervision by a scientist with general training in microbiology or a related science. The

laboratory is not separated from general building traffic, and work is conducted on the open bench. Examples of organisms used under these conditions are *Bacillus subtilis*, *Naegleria gruberi*, and canine hepatitis virus. Much of the recombinant DNA work with *E. coli* K12 and *Saccharomyces cerevisiae* has been approved at BSL-1.

BSL-1LS is for large scale work (greater than 10 liters or production volumes). BSL-1LS is used for the agents that can be handled at BSL-1 on a small scale. Microbial agents that have been safely used for large scale industrial production for many years may qualify for good large scale practices (GLSP) status. Examples include *Lactobacillus casei*, *Penicillium camembertii*, *Saccharomyces cerevisiae*, *Cephalosporium acremonium*, *Bacillus thuringiensis*, and *Rhizobium mellioti*. The criteria for GLSP were originally developed for the European Economic Community (now known as the European Union) by the Organization for Economic Co-operation and Development (OECD) as "good industrial large scale practices" (GILSP) (Frommer et al, 1989; OECD, 1986) and were slightly revised by the NIH for acceptance and use in the United States (NIH, 1991).

Biosafety level 2 (BSL-2) is used for work with many moderate-risk agents present in the community (indigenous) and associated with human disease of varying degrees of severity. Agents are usually of moderate potential hazard to personnel and the environment. This level is appropriate for clinical, diagnostic, teaching, and other research facilities in which work is done by individuals with a level of competency equal to or greater than one would expect in a college department of microbiology. Workers must be trained in good microbiological techniques in order for the handling of these agents on the open bench to be allowed when the potential for aerosol production is low. Laboratory personnel must have specific training in handling pathogenic agents and must be directed by competent scientists. Workers must be trained in proper use of biological safety cabinets or other appropriate primary containment equipment when the risk of aerosol production is high, as in such tasks as centrifuging, grinding, homogenizing, blending, vigorously shaking or mixing, performing sonic disruption, opening containers with increased internal pressure, inoculating animals intranasally, harvesting infected tissues from animals or eggs, and harvesting human cells from tissues using a cell separator. Access to the laboratory should be limited when work is in progress. Primary hazards to workers include accidental inoculation, exposure of non-intact skin or mucous membranes, and ingestion. Examples of organisms used under BSL-2 conditions are hepatitis B virus, *Salmonella* spp, and *Toxoplasma* spp.

BSL-2LS is for large scale, in vitro work with agents that require BSL-2 containment when work is at small scale. A detailed description of the containment requirements for BSL-2L can be found in Appendix K-IV of the NIH's recombinant DNA guidelines (NIH, 1999).

Biosafety level 3 (BSL-3) is used for work with indigenous or exotic agents where the potential for infection by aerosols is real and the disease may have serious or lethal consequences. Indigenous and exotic agents vary by country, and within regions of some countries, so there must be some flexibility for assignment of containment levels. Biosafety level 3 is appropriate for clinical diagnostic microbiology work when tuberculosis or brucellosis is suspected and also for special teaching and research situations that require the handling of such agents. Partial containment equipment such as Class I or Class II biological safety cabinets is used for all manipulations of infectious material at BSL-3. There are special engineering design criteria and work practices associated with BSL-3 containment. Worker competency must equal or exceed that of college-level microbiologists, and workers must have special training in handling these potentially lethal human pathogens and infectious materials. Supervisors must be competent scientists who are experienced in working with these agents.

Primary routes of exposure of workers to BSL-3 hazards include inhalation, with relatively few infections reported as a result of accidental auto-inoculation or ingestion. The extra personal protective clothing probably serves as a reminder of the hazard level and promotes an awareness that reduces such incidents. Examples of organisms used under BSL-3 conditions are *Mycobacterium tuberculosis*, *Brucella* spp, St. Louis encephalitis virus, *Borna* virus (an exotic agent when used in the United States), and *C. burnetii*.

BSL-3LS: The detailed requirements for BSL-3LS are to be found in Appendix K-V of the NIH recombinant DNA guidelines (NIH, 1999).

Biosafety level 4 (BSL-4) is used for work with dangerous and exotic agents that pose a high individual risk of life-threatening disease. Such an agent has a low infectious dose and poses a danger for the community from person-to-person spread. BSL-4 containment is appropriate for all manipulations of potentially infectious diagnostic materials, isolates, and naturally or experimentally infected animals. Maximum containment equipment, such as a Class III biological safety cabinet, or partial containment equipment in combination with a full-body, air-supplied, positive-pressure personnel suit is used for all procedures and activities. Because of the stringent requirements associated with BSL-4 containment, only a few facilities that meet this standard have been built and are operational.

The main hazard to laboratory or animal care personnel working with agents requiring such extreme caution and containment is respiratory exposure to infectious aerosols. Mucous membrane exposure to infectious droplets and accidental parenteral inoculation also play a role in transmission of infections. Worker competency must equal or exceed that of college-level microbiologists, and workers must receive specific, thorough training in handling extremely hazardous infectious agents. They must understand the function of the primary and secondary containment equipment and the facility design. Supervisors must be competent scientists trained and experienced in such work.

Laboratory access is strictly controlled. The facility is either separated from other buildings or completely isolated from other areas of the building. A separate facility operations manual is required. The maximum containment facility has special design and engineering features that prevent dissemination of microbes to the environment. Some examples of organisms used under these conditions are the agents of viral hemorrhagic fevers (Lassa, Machupo, Marburg, and Ebola), filoviruses, and certain arboviruses.

The requirements for laboratory-scale BSL-4 are described in *BMBL* (CDC/NIH, 1999). Appendix K of the NIH recombinant guidelines (Physical containment for large scale uses of organisms) does not include a description of requirements for BSL-4L because the requirements should be determined on a case-by-case basis if they are requested.

Animal biosafety levels: Other special biosafety precautions described in these guidelines apply to the use of naturally or experimentally infected animals. Animals are restricted from the laboratory unless they are part of the experiment at BSL-2 and higher, and decorative plants are restricted from use at BSL-3 and higher. Animals and plants harbor their own microbial flora, which could infect the worker or contaminate the work, so it is prudent to prohibit their use or presence in microbiology laboratories.

There are intrinsic hazards associated with the use of certain animals (for example, from herpes B virus in macaques), which must be taken into account in assessing the risk to the worker. There are also extrinsic hazards when infectious agents are purposely used to infect animals and vector-host interactions are being studied (in vivo) as opposed to the "controlled work" in culture media (in vitro). These hazards must be addressed.

NIH Guidelines for Research Involving Recombinant DNA Molecules (NIH, 1999 and revisions). The CDC's *Classification of Etiologic Agents on the Basis of Hazard* (1974) was slightly modified and incorporated into Appendix B of the NIH guidelines. The original CDC classification system provided "points to consider" in estimating the degree of hazard, noting that it depended on the etiologic agent and its nature and use. These notes were not included in the NIH document, implying to the user that all members of the groups, species, and strains on that list were pathogenic. Because the NIH guidelines could not take into account all existing and anticipated information on special procedures, users were encouraged to recommend changes to the guidelines. For example, Appendix B has been revised and updated as can be seen in the current guidelines (NIH, 1999).

The NIH guidelines provide the same message as the CDC/NIH guidelines (*BMBL*) that the agent/product rather than the process of recombinant DNA work should be evaluated for worker safety (NRC, 1987). The basic biosafety requirements for work with all microorganisms are the same. However, nonpathogenic, genetically modified organisms are currently registered and regulated at most institutions because of the public's perception of risk, whereas work with true pathogens is often done without internal oversight and review because the public has not been made aware of the risk. For large-scale guidelines, see appendix K (NIH, 1999).

***National Research Council Guidelines* (NRC, 1987, 1989).** *Biosafety in the Laboratory: Prudent Practices for the Handling and Disposal of Infectious Materials* (NRC, 1989): To avoid exposure to infectious agents, the NRC's Committee on Hazardous Biological Substances in the Laboratory recommended seven basic prudent biosafety practices, which are listed later in the chapter. These prudent practices provide barriers against the known routes of exposure for most diseases and are the basic recommendations for working with biohazardous agents. The recommendations are supplemented with additional practices, equipment, and facility design as the severity of the hazard increases. The practices recommended by the NRC, when accompanied by recommendations for facility design and containment equipment, are compatible with the CDC and NIH biosafety levels.

***Introduction of Recombinant DNA-Engineered Organisms into the Environment: Key Issues* (NRC, 1987):** The NRC has concluded that there is no evidence of any unique hazards posed by recombinant DNA techniques. The risks associated with recombinant DNA are the same in kind as those associated with unmodified organisms or organisms modified by other means. The NRC recommended that risk assessments be based on the nature of the organism and the environment into which it is introduced, and not on the method by which it was produced. This recommendation was also accepted by the Office of Science and Technology Policy (OSTP, 1986). Given this conclusion, two sets of guidelines, one for recombinant work and another for work with human pathogens, are redundant. Guidelines for a single code of practice for protection of workers from exposure to biohazardous agents are appropriate and have already been accepted in Europe (*Official Journal of the European Communities*, 1990; OECD, 1986).

INTERPRETATION OF GUIDELINES

Using the CDC/NIH guidelines previously described, decisions on containment levels for work at BSL-1 through BSL-3 at small- and large-scale can be made at the institutional level. BSL-4, because it is limited to so very few facilities, is not considered here. The expertise of an institution's biosafety committee or biosafety officer is needed for risk assessment of pathogenic agents and infectious materials. A professional biosafety consultant may be needed for facilities that do not have such in-house expertise. (The American Biological Safety Association in Mundelein, Ill. can be contacted for a list of certified biosafety professionals.)

Risk assessment for agents to be used at large scale, especially for industrial production, should begin early as an integral part

Table 14–C. ***Summary of Recommended Biosafety Levels for Infectious Agents***

Biosafety Level	*Agents*	*Practices*	*Safety Equipment (Primary Barriers)*	*Facilities (Secondary Barriers)*
1	Not known to consistently cause disease in healthy adults	Standard microbiological practices	None required	Open bench top, sinks required
2	Associated with human disease. Hazard is from percutaneous injury, ingestion, mucous membrane exposure	BSL-1 practice plus —limited access —biohazard warning signs —sharps precautions —biosafety manual defining any needed waste decontamination or medical surveillance policies	Primary barriers - Class I or II BSCs or other physical containment devices used for all manipulations of agents that cause splashes or aerosols of infectious materials; PPEs; laboratory coats; gloves; face protection as needed	BSL-1 plus autoclave available
3	Indigenous or exotic agents with potential for aerosol transmission; disease may have serious or lethal consequences	BSL-2 practice plus —controlled access —decontamination of all waste —decontamination of lab clothing before laundering —baseline serum	Primary barriers - Class I or II BSCs or other physical containment devices used for all open manipulations of agents; PPEs; protective lab clothing; gloves; respiratory protection as needed	BSL-2 facility plus —physical separation from access corridors —self-closing, double-door access —exhausted air not recirculated —negative airflow into laboratory
4	Dangerous/exotic agents which pose high risk of life-threatening disease; aerosol-transmitted lab infections; or related agents with unknown risk of transmission	BSL-3 practices plus —clothing change before entering —shower on exit —all materials decontaminated on exit from facility	Primary barriers - All procedures conducted in Class III BSCs or Class I or II BSCs in combination with full-body, air-supplied, positive pressure personnel suit	BSL-3 facility plus —separate building or isolated zone —dedicated supply and exhaust, vacuum, and decontamination systems —other requirements outlined in the text

Source: CDC, *BMBL*, 1999, p 62.

of the research and development process. The level of pathogenicity should be determined before production of the organism is scaled up, because special large scale containment facilities are too costly to be built and maintained if they are not needed.

The Coordinated Framework for Biotechnology (Office of Science and Technology Policy, 1986) has added the U.S. Environmental Protection Agency (EPA), the U.S. Department of Agriculture, the Food and Drug Administration, and OSHA to the list of federal agencies such as the CDC and NIH who can provide oversight and information on risk assessment. Work with certain agents associated with terrorist activities or biological warfare may require oversight from federal defense agencies as well (Nettleman, 1991). The Department of Commerce also restricts the export of such agents/materials because of their potential use for biological warfare.

HAZARD CONTROL

The process of developing controls to prevent or minimize occupational exposure to infectious agents or other biological agents becomes straightforward once the actual risk of work with the organism or agent is known and the risk category established. Prevention of exposure to potentially infectious agents can be achieved by source control, minimization of accidental release, and protection of the worker. Containment or barriers, used along with the other components of a comprehensive biosafety program, provide the means to work with biological agents without adverse effect.

Containment

Workplace activities involving infectious or biological agents require containment so that workers, the immediate work environment, and the community including those outside the immediate workplace are protected or shielded from exposure. Facility design, safety equipment, and work practices are the building blocks of containment. Varying configurations of these components are used depending on the hazard category of the work.

Protection of workers and the immediate work environment, or primary containment, is achieved through the use of good work practices and appropriate safety equipment. Effective vaccines also decrease worker risk. Protection of personnel in the immediate area outside the laboratory and the community (environment external to the workplace), or secondary containment, is attained by using adequately designed, constructed, and maintained facilities and operational practices.

The CDC and NIH have designated the four biosafety levels (BSLs) previously outlined for work involving infec-

Table 14–D. ***Summary of Recommended Biosafety Levels for Activities in Which Experimentally or Naturally Infected Vertebrate Animals Are Used***

Animal Biosafety Level (ABSL)	*Agents*	*Practices*	*Safety Equipment (Primary Barriers)*	*Facilities (Secondary Barriers)*
1	Not known to consistently cause disease in healthy adults	Standard animal care and management practices, including appropriate medical surveillance programs	As required for normal care of each species	Standard animal facility —no recirculation of exhaust air —directional air flow recommended —handwashing sink recommended
2	Associated with human disease. Hazard: percutaneous exposure, ingestion, mucous membrane exposure	ABSL-1 practice plus —limited access —biohazard warning signs —sharps precautions —biosafety manual —decontamination of all infectious wastes and of animal cages prior to washing	ABSL-1 equipment plus primary barriers; containment equipment appropriate for animal species; PPEs; laboratory coats; gloves; face and respiratory protection as needed	ABSL-1 facility plus —autoclave available —handwashing sink available in the animal room —mechanical cage washer used
3	Indigenous or exotic agents with potential for aerosol transmission; disease may have serious health effects	ABSL-2 practice plus —controlled access —decontamination of clothing before laundering —cages decontaminated before bedding removed —disinfectant foot bath as needed	ABSL-2 equipment plus containment equipment for housing animals and cage dumping activities; Class I or II BSCs available for manipulative procedures (inoculation, necropsy) that may create infectious aerosols, PPEs; appropriate respiratory protection	ABSL-2 facility plus —physical separation from access corridors —self-closing, double-door access —sealed penetrations —sealed windows —autoclave available in facility
4	Dangerous/exotic agents which pose high risk of life-threatening disease, aerosol transmission; or related agents with unknown risk of transmission	ABSL-3 practices plus —entrance through change room where personal clothing is removed and laboratory clothing is put on; shower on exiting —all wastes are decontaminated before removal from the facility	ABSL-3 equipment plus maximum containment equipment (i.e., Class III BSC or partial containment equipment in combination with full body, air-supplied positive-pressure personnel suit) used for all procedures and activities	ABSL-3 facility plus —separate building or isolated zone —dedicated supply/exhaust, vacuum, and decontamination systems —other requirements outlined in the text

tious agents or activities in which experimentally or naturally infected vertebrate animals are manipulated. Each biosafety level consists of a combination of laboratory practices and techniques, standard microbiological and special practices, safety equipment, and facility design. The combination must be specifically appropriate for the operations performed, the documented or suspected routes of transmission of the agent, and the laboratory function or activity. The use of increasingly stringent procedures and more complex laboratory facilities permits microorganisms in higher-risk categories to be handled safely. Tables 14–C and 14–D summarize the recommended biosafety levels for handling different categories of infectious agents and experimentally or naturally infected animals (CDC/NIH, 1999).

FACILITY DESIGN

The laboratory facility provides the shell, or barrier, necessary to protect the community and those outside the immediate work area from exposure to hazardous materials. When agents of increasing hazard are manipulated, facility design plays a more important role in reducing the potential for dissemination of the agent, particularly when an accidental release within the laboratory occurs.

Biosafety level-1 and -2 laboratories have no special design features beyond an ordinary laboratory, except that a handwashing sink is required, doors should be present for access control, and windows opening to the exterior must have fly screens. BSL-2 laboratories may require lockable doors for certain restricted agents and in new facilities directional air

Table 14–E. *Comparison of Biological Safety Cabinets*

Type	*Face Velocity (lfpm)*	*Airflow Pattern*	*Radionuclides/ Toxic Chemicals*	*Biosafety Level(s)*	*Product Protection*
Class I* open front	75	In at front; rear and top through HEPA filter	No	2,3	No
Class II, Type A	75	70% recirculated through HEPA; exhausted through HEPA	No	2,3	Yes
Type B1	100	30% recirculated through HEPA; exhausted through HEPA and hard ducted	Yes (low levels / low volatility)	2,3	Yes
Type B2	100	No recirculation; total exhaust through HEPA and hard ducted	Yes	2,3	Yes
Type B3		Same as IIA, but plena are under negative pressure to room and exhaust air is ducted	Yes	2,3	Yes
Class III	NA	Supply air inlets and exhaust through 2 HEPA filters	Yes	3,4	Yes

* Glove panels may be added and will increase face velocity to 150 lfpm; gloves may be added with an inlet air pressure release that will allow work with chemicals/radionuclides.

flow into the laboratory is encouraged.

The WHO (1993) characterizes agents handled in BSL-1 and BSL-2 laboratories as those having no or very low individual or community risk (BSL-1) or moderate individual risk and low community risk (BSL-2); therefore, the need for special design features to protect the community does not arise in these labs.

The biosafety level-3 laboratory includes design features of BSL-1 and BSL-2 laboratories plus they must be separated from areas of unrestricted traffic flow within the building. In addition, these facilities have controlled access (double-door entry), a specialized ventilation system that creates a directional one-pass airflow into the laboratory from surrounding "clean" areas, special hand-washing controls (elbow, foot, or knee operated), and a means to decontaminate biological waste, preferably within the BSL-3 area. Microorganisms classified at risk level 3 present a high risk to individuals, usually by respiratory exposure, although risk to the community is low.

BSL-3 facility requirements impose additional expense for containment features. In some circumstances where existing facilities do not meet BSL-3 requirements or cannot be made to do so, some accommodation may be made. Work involving routine or repetitive operations (such as diagnostic procedures involving propagation of agents for identification, typing, and susceptibility testing) can be carried out in a BSL-2 facility as long as the work practices and safety equipment associated with BSL-3 containment are used. Exhaust air from the laboratory is also discharged to the outdoors and ventilation to the laboratory is balanced to provide directional air flow into the lab. The decision to alter containment conditions should only be made by the laboratory director. The publication *Biosafety in Microbiological and Biomedical Laboratories* (CDC/NIH, 1999) contains agent summary statements for most microorganisms handled at BSL-3 and identifies those agents where modification of containment conditions may be appropriate.

The biosafety level 4 facility, though rare, draws a great deal of attention, perhaps because it conjures visions of an "Andromeda strain." Agents handled in such a facility have no available vaccines and pose a high risk to both workers and the community, so design criteria must prevent both worker and community exposure. In addition to having the design components of level 3 facilities, a BSL-4 facility is housed in a separate building or in isolated zones that has dedicated ventilation, stringent access requirements, and decontamination systems. For more detailed information, see CDC/NIH (1999).

SAFETY EQUIPMENT

Because most experimental procedures are recognized as having the potential to generate aerosols, safety equipment designed to reduce the likelihood of worker and environmental exposure has become standard in biological laboratories during the last decade.

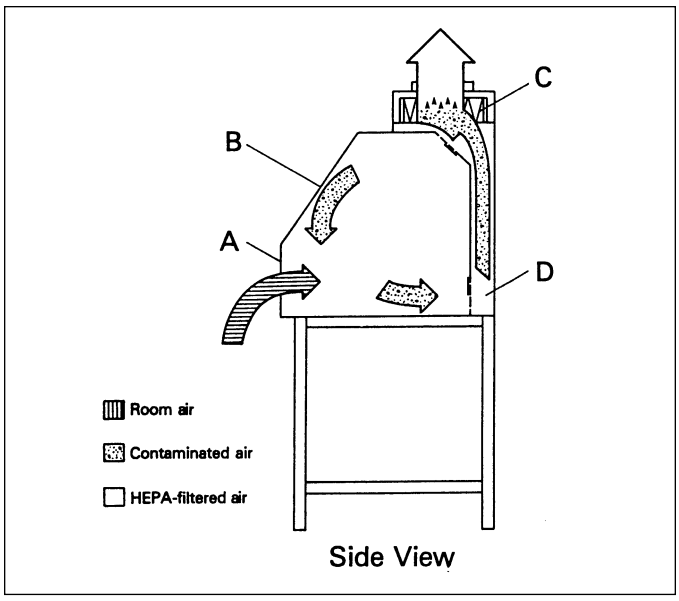

Figure 14–1. Class I biological safety cabinet. A. front-opening, B. sash, C. exhaust HEPA filter, D. exhaust plenum. (Reprinted from *Biosafety in Microbiology and Biomedical Laboratories [BMBL].* CDC, 1999, p 206.)

Biological safety cabinets (BSCs). The most frequently used and effective example of laboratory containment equipment is the biological safety cabinet, which provides a primary barrier to prevent escape of infectious aerosols into the work environment. When used and maintained properly these cabinets provide a combination of worker, product, and environmental protection that varies according to the class and type of cabinet selected.

All three classes of biological safety cabinets (Class I, II, and III) have high-efficiency particulate air (HEPA) filters for exhaust air. Of these, the Class II cabinet is most widely used. Selection of the class and type of cabinet must be based on the hazard level of the microorganism to be manipulated, the nature of the work activity (the potential of a technique to produce aerosols), and the need to protect the worker or the work environment from airborne contamination (see Table 14–E). Class I and II cabinets, when used in conjunction with good microbiological practices, provide an effective means to safely manipulate moderate- and high-risk microorganisms (BSL-2 and BSL-3).

Class I-ventilated cabinets provide personnel and environmental protection (not product protection) by means of a unrecirculated inward airflow away from the operator. The minimum face velocity at the work opening is at least 75 linear feet per minute (lfpm). The cabinet exhaust air is HEPA filtered to protect the environment before it is discharged either to the laboratory or through duct work to the outside atmosphere. In practice this cabinet functions in a manner similar to a chemical fume hood, except for the additional HEPA filtration of exhaust air. The use of Class I cabinets is relatively rare, although they are increasingly used to provide containment for aerosol-producing equipment (or procedures) such as centrifuges, pressurized apparatus, and necropsy of infected animals. Figure 14–1 shows the design and airflow patterns of this cabinet.

Because Class II biosafety cabinets provide protection to workers, experimental materials, and the environment and are easily accessed through a front work opening, they are often used in biological laboratories for manipulation of microorganisms and tissue cultures. Class II cabinets have a face velocity of 75–100 lfpm and are divided into types A and B, with type B cabinets designated as B1, B2, or B3 (see Figures 14–2a through d). Class II, type A cabinets may be used for microbiological activities when volatile or toxic substances and radionuclides are not used. The exhaust air from this cabinet is usually discharged to the work environment, although it may be connected to exhaust ductwork by a thimble connection. The design criteria for this cabinet permit contaminated ducts and plenums under positive pressure.

All Class II, type B cabinets are hard-ducted to the outside atmosphere and have 100 lfpm face velocity, and when contaminated plenums exist, they are under negative pressure or are surrounded by negative-pressure ducts or plenums, depending on the cabinet type. Work associated with minute or small amounts of volatile and toxic chemicals and radionuclides associated with microbiological activities may be handled in a type B cabinet. Whereas the Class II, type B1 cabinet is the basic B design, B2 and B3 have been developed to provide some useful alternatives. Because the B2 cabinet is a "total exhaust" cabinet with no air recirculation, it can be used for cell work involving small amounts of hazardous or toxic chemicals, such as carcinogens and radionuclides. The B3 cabinet, known as the

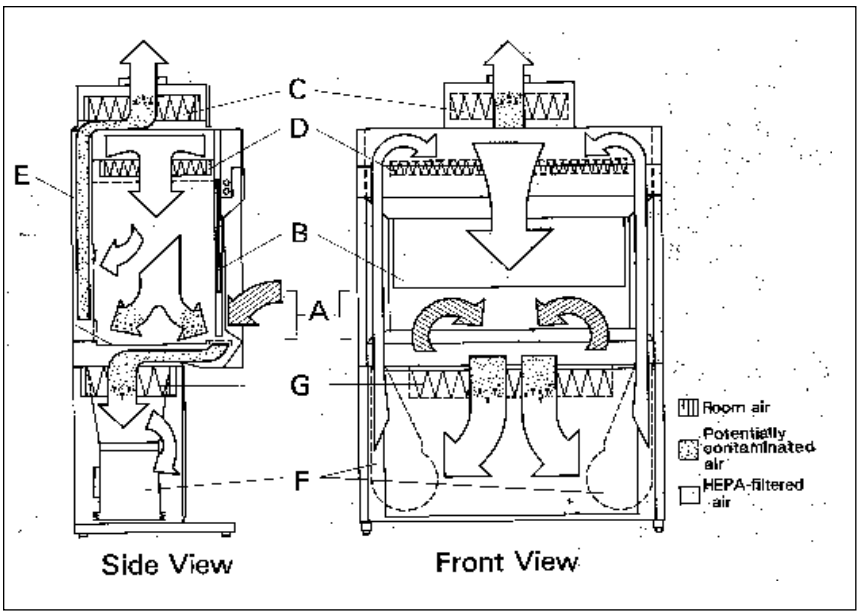

Figure 14–2b. Class II, type B1 biological safety cabinet. A. front-opening, B. sash, C. exhaust HEPA filter, D. supply HEPA filter, E. negative-pressure exhaust plenum, F. blower, G. additional HEPA filter for supply air. Note: The cabinet exhaust needs to be connected to the building exhaust system. (Reprinted from *BMBL*, CDC, 1999, p 208.)

"convertible cabinet," is basically a type A design that can be converted to meet the type B criteria.

The Class III cabinet is a totally enclosed, ventilated, negative-pressure cabinet of gas-tight construction that is used for work requiring the highest level of containment (see Figure 14–3). It offers maximum protection for personnel, the environment, and work materials. Personnel protection equivalent to that provided by the Class III cabinet can also be attained by using a positive-pressure ventilated suit in a maximum containment facility in conjunction with a Class I or II cabinet (CDC/NIH, 1999, p 203).

Certification of biosafety cabinets. The effectiveness of biological safety cabinets depends on a combination of airflow velocity, filter integrity, and location in the laboratory, because ventilation currents and even workers' movements can disrupt cabinet air patterns. It should not be assumed that equipment (or a facility) is providing worker protection merely because it is designed to do so. To be assured that a biological safety cabinet is functioning as designed, it must be certified on a regular basis (prior to initial use, when moved, after a filter change, or at least annually).

The National Sanitation Foundation Standard (NSF) #49 (NSF, 1992) for Class II (laminar-flow) biohazard cabinetry specifies materials, design and construction, and performance criteria for manufacturers. It also outlines recommended field tests for certifiers. Manufacturers must submit new models for NSF testing. Approved models carry the NSF seal. Only approved cabinets should be purchased and

used for work activities involving potentially hazardous biological agents.

Even cabinets with correct design, materials, and construction, rigorous testing, and proper placement may not be enough to prevent workplace and environmental exposures. These features along with well-trained, knowledgeable, and conscientious workers are required for optimal safety conditions. Poor work practices can easily cancel the containment features designed into the cabinet, permitting the release of infectious particles into the environment. It is for this reason that worker training is so critical. The reader can find additional information on the design and use of these cabinets in a variety of excellent references (NRC, 1989; Fleming et al, 1995; Lupo, 1995; CDC/NIH, 1995; CDC/NIH, 1999; WHO, 1993).

Horizontal- or vertical-flow clean benches, which force air out of the front opening into the room, should not be confused with biosafety cabinets. They do not protect workers from exposure; they protect the work product. Therefore, clean benches must not be used for work with materials that are potentially infectious, toxic, allergenic, or irritating.

Centrifugation. Centrifugation can present two serious hazards: mechanical failure and dispersion of aerosols. A mechanical failure such as a broken drive shaft, a faulty bearing, or a damaged rotor can produce not only aerosols but also fast-moving fragments. Even when functioning correctly, a centrifuge is capable of producing hazardous aerosols if improperly operated or when poor laboratory practices are used. Mechanical failure can be minimized by routine maintenance and meticulous observance of the manufacturer's instructions. Generation of aerosols is avoided by using good work practices such as balancing containers and not overfilling them, checking containers for cracks and signs of stress, and checking and greasing O-rings where applicable. Aerosolization is minimized by placing primary containers into centrifuge safety cups and opening rotors and centrifuge containers in a biosafety cabinet.

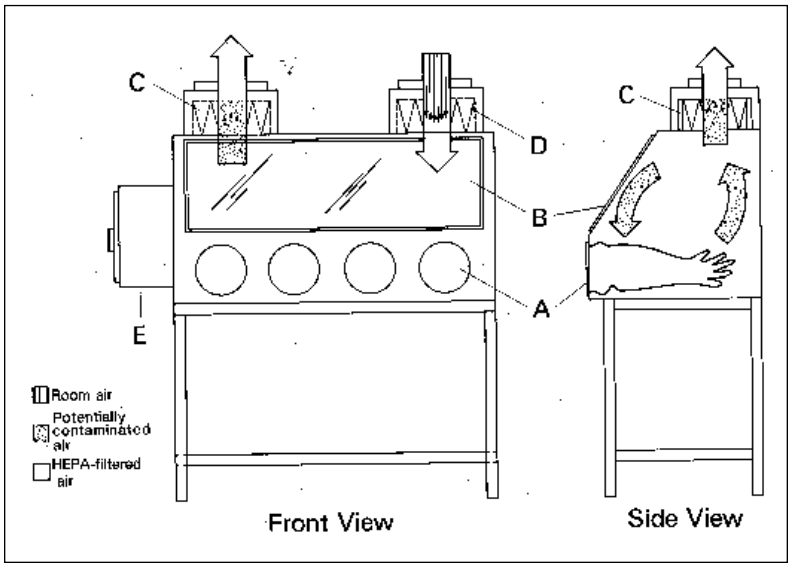

Figure 14–3. Class III biological safety cabinet. A. glove ports, with O-ring for attaching arm-length gloves to cabinet. B. sash, C. exhaust HEPA filter, D. supply HEPA filter, E. double-ended autoclave or pass-through box. Note: A chemical tank may be installed which would be located beneath the work surface of the BSC with access from above. The cabinet exhaust needs to be connected to the building exhaust system. (Reprinted from *BMBL,* CDC, 1999, p 211.)

Laboratory procedures where force or energy act on cell walls or tissue to disrupt them result in the dispersion of aerosols and splatter. Particular attention should be paid to containment when procedures such as homogenization and sonication are planned. Some manufacturers of homogenizers design models that prevent the release of infectious material and specially gasketed blenders are also available. The use of properly designed and maintained containment equipment is essential in minimizing release of infectious aerosols to the environment.

WORK PRACTICES

Work practices—how one actually does the work—are the most important component in preventing occupational exposure. Understanding the concepts of transmission, infectious dose, and route of entry, as well as the potential for various procedures to release infectious material, is critical to the implementation of appropriate containment practices. It becomes straightforward to identify the potential hazard and implement the safeguards necessary to protect workers, when a risk assessment is performed on work activities in advance.

The safeguards known as the seven basic rules of biosafety (NRC, 1989) are summarized here:

- ➢ Do not mouth pipette.
- ➢ Manipulate infectious fluids carefully to avoid spills and the production of aerosols and droplets.
- ➢ Restrict the use of needles and syringes to procedures for which there are no alternatives; use needles, syringes, and other sharps carefully to avoid self-inoculation; and dispose of sharps in leak- and puncture-resistant containers.
- ➢ Use protective laboratory coats and gloves.
- ➢ Wash hands after all laboratory activities, after removing gloves, and immediately following contact with infectious materials.
- ➢ Decontaminate work surfaces before and after use, and immediately after spills.
- ➢ Do not eat, drink, store food, apply cosmetics, or smoke in the laboratory.

Although not a complete listing, these rules represent baseline or minimum practices to be followed. They can be amplified with additional protective clothing such as goggles, full-face shields, or masks when face protection from splatter is needed, and with different types of clothing such as back-fastening gowns, jumpsuits, impervious aprons, sleeve covers, and head and foot covers as suitable. Personal habits such as nail biting and eye and nose rubbing must be avoided because they offer an excellent means for ingesting pathogens and contaminating mucous membranes. The use of good microbiological practices is critical for a worker's own protection and the protection of adjacent colleagues.

DECONTAMINATION

The protection of personnel and the environment from exposure to infectious agents and the prevention of contamination of experimental materials by a variable, persistent, and unwanted background of microorganisms is an integral part of good microbiological procedure. Decontamination, the use of physical or chemical means to render materials safe for further handling by reducing the number of organisms present, must be differentiated from disinfection, a process that kills infectious agents outside the body. Neither of these terms should be confused with sterilization, which implies complete elimination or destruction of all forms of microbial life. In the laboratory setting, the application of heat, either moist or dry, is the most effective method of sterilization. Steam at 250 F (121 C) under pressure in an autoclave is the most widely used and convenient method of rapidly achieving sterilization. However, many variables such as time, temperature, configuration and size of load, and permeability and dimensions of containers must be taken into account in order to successfully sterilize materials.

Chemical disinfectants inactivate microorganisms by one or more of a number of chemical reactions, primarily coagulation and denaturation of protein, lysis, or inactivation of an essential enzyme by either oxidation, binding, or destruction of the enzyme substrate. The level of effectiveness of chemical disinfectants is altered by changes in the concentration of active ingredients, contact duration, temperature, humidity, the concentration of organic matter, and the pH of the material being disinfected. Chemical disinfectants, classified by their active ingredients, include halogens, acids and alkalis, alcohols, heavy-metal salts, quaternary ammonium compounds, phenolics, aldehydes, ketones, and amines.

Specific terminology and classification schemes for chemical disinfectants used by the medical community and licensed by the U.S. EPA can be found in several excellent references and texts (Rutala, 1996; Garner & Favero, 1986; Block, 1991; Favero & Bond, 1991; Klein & Deforest, 1963; NAIN website).

The most frequently used disinfectants in the workplace include sodium hypochlorite (household bleach), isopropyl or ethyl alcohol, iodophors (Wescodyne), and phenolics (Lysol and amphyl). It is essential when choosing a disinfectant to review the manufacturer's literature to determine the disinfectant's efficacy (what microorganisms the disinfectant inactivates) and the recommended application (as an inanimate surface disinfectant, topical disinfectant, surgical scrub, liquid sterilant, or sanitizer). Table 14–F highlights various chemical disinfectants and their uses.

By definition, chemical disinfectants are toxic to viable cells, so it is important that users be familiar with the hazard potential of compounds they use and take necessary precautions to prevent workplace exposure. Compounds such as ethylene oxide, formaldehyde, glutaraldehydes, and concentrated acids and bases require special handling procedures. Consult federal and local OSHA regulations on specific chemical hazards.

INFECTIOUS WASTE

During the past two decades the management of infectious waste has come under scrutiny from regulatory agencies. Pub-

Adapted from: National Research Council. *Biosafety in the Laboratory: Prudent Practices for the Handling and Disposal of Infectious Materials*. 1989, p 40; and Vesley D, Lauer JL. In *Laboratory Safety: Principles and Practices*, 1995, pp 226–227.

lic fear of exposure to AIDS and hepatitis viruses has prompted demands for implementation of rigorous controls for infectious hospital and medical wastes. Most states have promulgated what can only be described as a patchwork of infectious waste regulations. Historically, such wastes were treated by autoclaving before disposal into a sanitary landfill, by incineration, or, in the case of some liquid wastes, by chemical disinfection. Today, these technologies coupled with newer ones (grinding infectious lab wastes in the presence of chemical disinfectants or alkaline hydrolysis at elevated temperature and pressure for disposal of animal carcasses [suitable for large animals]) provide alternate options for waste generators. Local regulations should be consulted for individual state requirements. Federal regulations such as the U.S. DOT Hazardous Materials Regulations, 49 *CFR* 170 series, establish some packaging and volume limitations for the shipment of regulated medical wastes.

Because of the many misconceptions regarding hospital waste, the CDC published the following statement (CDC, 1987b):

> *There is no epidemiologic evidence that most hospital waste is any more infective than residential waste. Moreover, there is no epidemiological evidence that hospital waste has caused disease in the community as the result of improper disposal. Therefore, identifying wastes for which special precautions are indicated is largely a matter of judgment about the relative risk of disease transmission. The most practical approach to the management of infectious waste is to identify those wastes with a reasonable potential to cause infection during handling and disposal, and for which some special precautions appear prudent. Hospital wastes for which special precautions appear prudent include microbiology laboratory waste, pathology waste, and blood specimens and blood products. Although any item that has had contact with blood, exudates, or secretions may be potentially infective, it is not usually considered practical or necessary to treat all such wastes as infective.*

Spill management. The management of spills in the laboratory usually consists of flooding the contaminated area with liquid disinfectant, being careful not to generate aerosols, allowing adequate contact time with disinfectant, cleaning up the spill, reapplying fresh disinfectant, and final cleanup. Protective clothing is always worn. When spills involve large volumes of infectious agents, personnel should leave the area until aerosols have settled before cleanup is begun. Variations of this procedure are used for hospital spills, where emphasis is placed on first absorbing and cleaning the spill and then disinfecting the area. The reason for the difference is the concentration of the microorganisms present in the spill and the likelihood that the general public may be exposed and inadvertently spread contamination elsewhere.

SUMMARY

Containment of microorganisms in laboratories (or other workplaces) is critical to the health of workers and to the community. Engineering controls such as safety equipment and facility design are important because, except for monitoring and appropriate maintenance, they do not require worker input to be effective. Despite this, experience indicates that the use of worker-initiated workplace controls in the form of good work practices and carefully executed techniques is critically important in minimizing biohazardous exposures in the workplace.

Biosafety Program Management

The primary focus of an institutional biosafety program is to ensure that workers, their colleagues, and the community (which includes the general population and the environment) are not adversely affected by potentially hazardous microorganisms or their toxins. Biosafety program components usually include program support, a biosafety officer or specialist, an institutional biosafety committee (IBC), a biosafety manual of written policies and procedures, an occupational health program for relevant employees, and employee training or information communication. Biosafety programs vary markedly depending on the size of the institution and its activities (such as education, industrial research and development, manufacturing, medical patient care, or food service).

PROGRAM SUPPORT

Without strong program support, even the best biosafety program has little chance of succeeding. It is critical to have administrative and financial support. Without support from upper management it is impossible to implement committee decisions and biosafety policies. Inadequate financial support of biosafety activities is equally problematic. Program financing usually comes from one of two general sources: fee for service or institutional overhead. Each method of support has its pros and cons, but it is important to prevent a situation where health and safety services are not accessed because of their cost.

BIOSAFETY SPECIALIST

As institutional activities vary, so do the responsibilities and duties of the biosafety officer/specialist. A strong background in microbiology is imperative so that this person may interact successfully with the scientific and technical community. In addition to microbiology, knowledge in the disciplines of molecular biology, infectious diseases, public health, sanitation, environmental microbiology, and epidemiology is extremely useful. Besides these academic credentials, it is important for a biosafety professional to have worked with microorganisms. An understanding of workplace procedures and equipment becomes invaluable when performing a risk assessment on a work activity or designing workable containment for experiments. Without such experience and an

appropriate academic background, a health and safety professional will find it difficult to interact with scientific and technical staff and provide the biosafety assistance they need.

Because it is often necessary to receive input not only from the scientific staff but also from the biosafety committee and the administration, the biosafety professional must be able to lead diverse groups to a consensus. Biosafety officers work with architects, contractors, facility engineers, medical staff, animal facility personnel, and maintenance and custodial services, to mention only a few groups.

INSTITUTIONAL BIOSAFETY COMMITTEE (IBC)

The original impetus to form these committees is found in the first publication (1976) of the "NIH guidelines for research involving recombinant DNA molecules." NIH mandated that institutions receiving NIH funding conduct recombinant DNA research in compliance with their guidelines. Formation of an IBC was required. Committees were charged to review research activities involving recombinant technology for compliance with the guidelines and to oversee the safe conduct of work. Initially, many institutions chose to have their committees oversee only work activities involving the use of recombinant technology; consequently, work with infectious agents was not scrutinized. Today, most biosafety committees set policy and procedures for all activities involving infectious agents, materials, and animals, in addition to experiments using recombinant technology.

As defined by the NIH, IBCs overseeing recombinant activity must have no fewer than five members selected for their experience and expertise in the technology and their capability to assess the safety of the work and any potential risk to public health and the environment. At least two members must be chosen from outside the institution to represent the interests of the community. As committee responsibilities broaden, in addition to a strong core of microbiologists and molecular biologists, experts in other disciplines (such as animal resources, plant pathology, and gene therapy) are needed.

IBCs must interact with other review bodies within the institution. The use of infectious animals alters the safety considerations to be addressed and the questions that must be answered, so institutional animal care and use committees (IACUCs) also become involved. When research activities involve the development of treatments for human diseases or the use of other hazard materials, IBCs will need to interact with human subject review boards (IRBs), radiation safety committees (RSCs) and radiation safety officers, chemical safety committees (CSCs) and chemical hygiene officers, in order to approve research proposals. In the interest of facilitating the timely review of work, it is imperative that the committees work together effectively.

BIOSAFETY MANUAL

One of the more challenging tasks of a health and safety professional is getting information about health and safety policy, regulations, and safety practices into the workplace. A biosafety manual is one means of handling the communication of information and policy.

At the CDC Third National Symposium on Biosafety in 1994, a workshop was held covering the topic of biosafety manuals and their use and maintenance. Most of the health and safety professionals attending the workshop agreed that it is useful to have some type of biosafety manual. Many participants indicated that their institution had manuals and that these manuals were not used for a variety of reasons. Reasons for this included the fact that the manuals were difficult to use or out of date; employees did not know of their existence; or policies outlined in the manual did not have administrative and supervisory support. To help avoid some of these problems, including spending a great deal of time writing a manual that is destined to be underused, some preparation and planning is helpful. The following series of questions will help define the type of document appropriate for an institution:

- ➢ Why have a manual?
- ➢ What is the manual supposed to accomplish? (What should its scope be?)
- ➢ What support is needed for acceptance?
- ➢ Who should write it?
- ➢ What should be included?
- ➢ Should the manual be printed or available electronically?
- ➢ How should the manual be distributed to users?
- ➢ How can the document be kept current?

No single type of biosafety document is suitable for all work settings; at least five manual formats were identified at the CDC workshop. They included a formal, lengthy, administrative manual that covers all safety topics; a user manual or handbook that has safety information specific to a worksite such as a laboratory; a complete reference document on one subject, such as a bloodborne pathogen exposure control plan; a worksite procedure-specific manual for a defined group of people (waste handlers, glass washers); and a booklet or binder of work practices with all SOPs. Manuals need to be updated frequently and now are usually included on the institution's computer network.

OCCUPATIONAL HEALTH PROGRAM

When setting up an occupational health program for workers potentially exposed to infectious agents or other hazardous materials, decisions must be made regarding the focus of the program and whether it will include acute exposure-related problems and/or disease prevention and wellness programs. The purpose of an occupational health program is fourfold:

- ➢ To provide a mechanism to detect job-related illnesses
- ➢ To determine the adequacy of protective equipment and procedures and verify that hazardous agents are not being released into the general environment
- ➢ To establish baseline pre-exposure status
- ➢ To assess the presence of preexisting conditions that would put an employee at increased risk

Health surveillance programs vary greatly, depending on the microorganisms being handled, the nature of the technical activities being conducted, the volume or concentration of material, and available medical facilities. Exposures to toxic chemicals, radionuclides, physiologically reactive biological and pharmaceutical products, animal allergens, and physical stresses also require consideration.

Some possible components of an occupational health surveillance program include taking medical and occupational histories, conducting physical examinations, laboratory testing, immunization, and serum storage, where indicated. If possible, it is advantageous to include the services of specialists in the fields of occupational health medicine and infectious diseases.

Work with infectious agents requires the evaluation of specific immunizations. Although there is no question that persons working with human blood and related products should receive hepatitis B immunization, there may be reasons to waive immunization with some less effective vaccines. An infectious disease physician should be consulted on such matters. Recommendations for the use of vaccines are included in the agent summary statements in Section VII of the CDC/NIH biosafety document (CDC/NIH, 1999) and a comprehensive listing of immunoprophylaxis for personnel at risk is found in the NRC resource, *Biosafety in the Laboratory* (NRC, 1989, pp 60–62). See also Recommendations of the Advisory Committee on Immunization Practices: adult immunizations (CDC, 1991a), use of vaccines and immune globulins in persons with altered immunocompetence (CDC, 1993b), and immunization of health-care workers (CDC, 1997a).

Serum banking, another component of a medical surveillance program, has less support now than in the past. Although such a resource can provide invaluable information regarding work-related exposures, this benefit must be weighed against such basic considerations as whether adequate facilities and technical support for long-term storage exist. Decisions regarding serum storage and testing should be based on agents handled, availability of reliable tests, likelihood that infection will produce a serological change in exposed persons, and the ability to maintain a secure storage facility. Results of employee medical evaluations must remain confidential, with information being released only with the employee's consent.

Considerations involving host susceptibility must be taken into account, and some of these have been mentioned earlier in the risk assessment section. When decisions regarding employee health issues are made, the decision-making process should include the employee, the physician, and the employer. For additional information on medical surveillance programs for research and biotechnology settings, refer to Goldman (1991, 1995).

INFORMATION AND EDUCATION

All persons whose work involves the handling of infectious organisms or materials must receive adequate information and education to enable them to work safely. Biosafety programs should include a mechanism to provide safety information to employees at all stages of their employment (new, altered work tasks and long-term) as well as periodic safety updates.

In instances where regulations mandate training, such as the OSHA bloodborne pathogen standard, training content may be specified and written control plans required. Many regulations address frequency of training, record-keeping requirements, and qualifications of trainers.

Training materials developed for work with infectious materials must include a description of the biology of the agent(s), including symptoms of the disease; a review of the operations and procedures, with emphasis on potential sources of exposures and means of control; the correct use of containment equipment when applicable; review of acceptable work practices; decontamination methods and waste disposal; and emergency procedures. Equally importantly, personnel need to be made aware of the human factors (such as fatigue, inattentiveness, and haste) that predispose workers to accidents. Employees should understand that although employers must provide appropriate facilities and equipment to conduct work safely, they are responsible for following safety practices and procedures in order to protect themselves, their colleagues, and the community.

One challenge of health and safety training is to provide appropriate and factual information that is geared to the language and educational level of the employees. Clearly information is more readily received when it is presented in an interesting or creative format. Although trainers now have access to an excellent collection of tools such as professionally produced videotapes and interactive computer educational programs, it is critical that training not be a solitary event.

Computers are now making new sources of health and safety information available to the health and safety community. In 1994 the Massachusetts Institute of Technology biosafety group, in conjunction with the American Biological Safety Association (ABSA), initiated an electronic biosafety discussion list (BIOSAFTY). Other useful lists include:

- ➢ University of Vermont's list on environmental health and safety
- ➢ Association for Professionals in Infection Control and Epidemiology (APIC)
- ➢ Duke University's Occupational and Environmental Medicine Web Resources

IDEAL BIOSAFETY PROGRAMS

The ideal biosafety program has strong administrative support from upper management and is funded adequately so that worker safety is not compromised. Depending on the volume of microbiological activity and the hazard associated with the microorganisms handled, a biosafety specialist should become involved in health and safety

considerations. In some cases, it is not feasible to have a dedicated biosafety staff person, because the volume of work is low and the organisms handled are of minimal or low risk. Under these conditions it may be advisable to seek the assistance of a consultant who can work with the existing health and safety staff. When clinical activities are involved, infection control practitioners are an excellent resource for safety departments. In hospital settings, infection control practitioners may oversee clinical laboratory biosafety matters using policies approved by an infection control committee.

To effectively implement institutional biosafety committee (IBC) policies and decisions, institutional administrative support at the highest level must exist. Committee members must be knowledgeable, make informed and realistic decisions, and have credibility among their peers so that committee decisions will be accepted and implemented. Committee business and, ultimately, research activity are facilitated by timely attention to pertinent matters and, where needed, interaction with other institutional bodies such as animal resources, IACUCs, RSCs, CSCs, and IRBs.

No one biosafety manual or training program is appropriate for all work settings. Rather, institutions must strive to prepare material and training that provide their employees with pertinent material in a format that will be understood and utilized. It is the challenge of every safety professional to develop these educational components so that they are not only relevant but interesting.

For the occupational health program to be effective and used, providers must offer services as required by law, be familiar with workplace activities, be responsive to the needs of employees, and interact with the IBC and biosafety specialist. Employees who are indifferent to occupational health programs such as immunization and serum storage are more likely to use them if, where possible and practical, services are performed at the worksite.

ASSESSING COMPLIANCE

Although there is often urgency to develop and implement health and safety programs and controls, the need to assess their efficacy following implementation is sometimes overlooked. Such a review is imperative in order to be assured that the safety practices have been incorporated into work activities and that they are minimizing potential hazards.

Use of Audits to Identify Problem Areas

Self-audits of required safety practices provide a measure of compliance achievement. In work environments where hazardous aerosols are generated, such as agricultural processing facilities, one would begin by monitoring for compliance with personal protective equipment and clothing requirements. In laboratory settings the criteria for the designated biosafety level(s) can be used for the critical elements of the audit.

Routine operating procedures should include a safety check, for example, to determine that equipment (such as a biosafety cabinet or hematocrit centrifuge) is functioning properly or that work surface disinfectants and spill kits are on hand. When agents requiring higher containment are handled, ventilation system function must be checked and actual work practices and techniques reviewed to ensure containment.

Regular safety audits should be carried out quarterly or semiannually by designated safety specialists accompanied by the laboratory supervisor. Deficiencies can be pointed out and abated during the inspection. A written report, suggesting corrective actions, can be sent to the laboratory supervisor, who should report progress on remediation within a designated period of time. Notification of biohazards in use and a list of associated personnel should be obtained from the laboratory supervisor. The inspection program can be used to review information on the facility, work, and workers and serve as a reminder to update the biohazard database.

Annual Biosafety Review

An annual renewal of biohazard registration also helps to remind each responsible supervisor to review the work in progress and keep the information updated. Pathogen or biohazard registration programs used by many institutions provide supervisors with a form to expedite such an update.

Incident/Accident Statistics

Although small statistical changes in incident/accident figures do not usually indicate real deficiencies in a biosafety program, some institutions only judge the status of their safety program by a statistical review of changes in OSHA-recordable incidents.

The positive changes brought about through education and training in preventive methods can be measured with specific outcome audits. For example, in determining the effect of training and safety equipment on the number of needlestick incidents, trends in reports on such injuries show the cost-benefit of the changes. Observations of increases in such injuries, or the reporting of sentinel events (events whose single occurrence is of sufficient concern to trigger systematic response) highlight the need for intervention efforts. Such events can be used as tools for continuous quality improvement if action limits (the criteria for intervention) are defined (Birnbaum, 1993).

Work practices must be assessed for efficacy so that protective practices can be reinforced and unsafe practices altered.

CURRENT TOPICS IN BIOSAFETY

Bloodborne Pathogens

Hepatitis B virus has been the most significant occupational infector of health care and laboratory personnel during the past 50 years. This fact, coupled with the identification of

the human immunodeficiency virus (HIV), the causative agent of acquired immune deficiency syndrome (AIDS), prompted the development and implementation of measures that would promote worker protection. OSHA pioneered the regulation of work environments associated with potentially infectious microorganisms with its publication of a standard regulating occupational exposure to bloodborne pathogens (OSHA, 1991). In addition to the standard, OSHA continues to publish new compliance assistance instructions for their enforcement officers that provide useful information for those covered by the regulation (OSHA, 1999).

The standard applies not only to the health care community but to all occupations (such as emergency responders, law enforcement officers, and morticians) in which there is a potential for exposure to human blood. Bloodborne pathogens are defined as microorganisms that may be present in human blood and body fluids and are capable of causing disease in human beings. While HIV and hepatitis B and hepatitis C viruses are the bloodborne pathogens most frequently associated with occupational infections, other bloodborne microorganisms associated with diseases, such as syphilis and malaria, have also been responsible for work-related infections.

HEPATITIS B VIRUS (HBV)

Epidemiology. Hepatitis B virus infects at a minimum 136,000 persons in the general U.S. population annually, with an estimated 1,012 of these infections attributed to high-risk health care workers, i.e., those having frequent occupational contact with blood (Shapiro, 1995). Among these 1,012 infected health care workers there will be an estimated 250 cases of clinical hepatitis, 50 HBV carriers, 13 cases of chronic hepatitis, and 22 deaths. Prior to licensure of the hepatitis B vaccine in 1981, an estimated 17,000 health care workers were infected annually with HBV. The estimated incidence of HBV among health care workers in 1983 was threefold higher (386/100,000) than the incidence in the general population (122/100,000) (Mahoney et al, 1997). By 1995 the incidence of HBV infections among health care workers decreased by more than 95 percent (9.1/100,000) and was fivefold lower than the incidence of HBV infection in the general population (50/100,000), which had decreased by 60 percent. The periods of greatest decline in infections occurred between 1986–1987, when the recombinant DNA vaccines were licensed, and from 1992–1993 when the OSHA bloodborne pathogen standard was implemented.

Disease. Hepatitis B virus, a DNA virus and member of the *Hepadnaviridiae* family, infects liver cells and has the potential to cause serious liver disease. The incubation period (the time between exposure to the virus and onset of illness) ranges from two to six months, and at least 50 percent of the cases of acute infection are asymptomatic. For the remainder, disease varies from mild to severe or even fatal. Symptoms of clinical illness may include loss of appetite, rash, fever, abdominal discomfort, nausea and vomiting, jaundice, extreme fatigue, anorexia, fever, and joint pain. The majority of infections in adults are self-limited with symptoms lasting several weeks. Most infected persons clear their virus and have lifelong immunity to re-infection; however, 5 to 10 percent of persons with acute HBV infection develop chronic infection and generally remain infected for their lifetime. Some with chronic infection may be asymptomatic carriers, while others develop liver inflammation, cirrhosis, or hepatocellular carcinoma. Persons with chronic HBV infection have an estimated 20 percent lifetime risk of dying of cirrhosis and a 6 percent risk of dying of hepatocellular carcinoma (Beasley & Hwang, 1984; McMahon et al, 1985). A safe effective recombinant vaccine is available and immunization of high risk health care workers is strongly recommended (CDC, 1997a). This same publication also makes recommendations for postexposure prophylaxis for percutaneous and permucosal exposure to HBV.

Transmission. In occupational settings, hepatitis B virus is transmitted by parenteral inoculation and mucous membrane and nonintact skin exposure to human blood, blood products, bloody body fluids, semen, vaginal secretions, and saliva. Airborne transmission has been postulated. But true airborne transmission of HBV probably does not occur, rather transmission occurs due to direct contact with droplet-contaminated surfaces (Favero, 1985). Sexual and perinatal transmission occurs in the general population. Persons exposed to HBV-contaminated needlesticks have a 6 to 30 percent risk of HBV infection (OSHA, 1991, preamble).

HEPATITIS C VIRUS (HCV)

Epidemiology. Hepatitis C virus, an RNA virus in the *Flaviviridae* family, is the primary etiologic agent of parenterally transmitted non-A, non-B hepatitis. HCV is the most common chronic bloodborne infection in the United States. There are an estimated 3.9 million infected persons nationwide with 8,000–10,000 associated deaths each year. The prevalence of HCV among health care workers, including orthopedic, general, and oral surgeons, is no greater than the general population (1–2 %) and is 10-times lower than that of HBV infection (CDC, 1998c).

Disease. Persons with acute HCV infection have either asymptomatic or mild clinical disease: 60–70 percent have no apparent symptoms, 20–30 percent may have jaundice, and 10–20 percent may have nonspecific symptoms such as anorexia, malaise, or abdominal pain (CDC, 1998b). The average incubation period is six to seven weeks.

Following acute infection 15 to 25 percent of persons appear to resolve their infection. However, chronic HCV infection with persistent viremia develops in most persons (75–85%). The course of chronic liver disease is usually insidious, progressing slowly without symptoms or physical

signs in the majority of patients during the first two or more decades after infection. Frequently this status goes unrecognized until the person is identified as HCV-positive during blood-donor screening. Studies indicate that cirrhosis develops in 10 to 20 percent of persons with chronic disease older than 20–30 years, and hepatocellular carcinoma in 1–5 percent (Seeff et al, 1992; Fattovich et al, 1997). An HCV vaccine is currently not available and antiviral therapy is recommended for patients with chronic HCV who are at greatest risk for progression to cirrhosis (NIH, 1997).

Transmission. HCV is transmitted primarily through large and repeated direct percutaneous exposure to blood. Work-related infections have resulted from HCV-contaminated needlesticks or cuts with sharp objects and blood splashed to mucous membranes. The average incidence of anti-HCV seroconversion following needlesticks or sharps exposures from an HCV-positive source is 1.8 percent (range 0–7%) (CDC, 1998c). Risk factors associated with transmission include blood transfusion, injection-drug use, employment in patient care or clinical laboratory work, exposure to a sex partner or household member who has a history of hepatitis, exposure to multiple sex partners, and low socioeconomic level. With the advent of blood screening technologies, transfusion-related infections are now rare (Schreiber et al, 1997). Injection-drug use currently accounts for most of the HCV transmission in the United States (Alter, 1997).

HUMAN IMMUNODEFICIENCY VIRUS (HIV)

Epidemiology. Through Dec. 31, 1998, the CDC had received reports of 188 cases of documented or "possible" occupationally acquired HIV infection among health care workers. A documented means of occupational exposure has been identified in 54 of the cases and 25 of these individuals have developed AIDS (acquired immunodeficiency syndrome). The remaining 134 workers were classified as "possible" occupational HIV exposures because neither the date of infection nor its source could be documented. Forty-six of the documented cases resulted from percutaneous exposures, five from mucocutaneous (mucous membrane and/or skin injury) exposures, two from dual percutaneous and mucocutaneous exposure, and one from an unknown source. Forty-nine of the 54 documented seroconversions resulted from exposure to blood from HIV patients, three to concentrated virus, one to visibly bloody fluid, and one to an unspecified fluid. By occupation, 19 laboratory workers and 22 nurses sustained the greatest number of documented seroconversions (CDC faxline––*AIDS Information Document* #260230).

Disease. HIV is an RNA virus in the family *Retroviridae*, subfamily *Lentivirinea*. Lentiviruses encompass agents able to cause chronic infections with slowly progressive neurological impairment. Persons infected with HIV may remain healthy for years before the virus, which infects the cells of the immune system, ultimately destroys that system. AIDS represents the later clinical stage of HIV infection. Following infection with HIV, persons may be asymptomatic or within several weeks to several months develop an acute self-limited flu-like illness that lasts for one to two weeks. Because symptoms disappear and individuals often remain healthy for a number of years, many infected individuals are unaware of their HIV status. Presently there is no vaccine to prevent infection with HIV nor is there a "cure" for AIDS. A number of anti-retroviral therapies are currently available to help keep HIV replication under control. Guidelines for treatment of exposed health care personnel have been published by the CDC (1998a).

Transmission. HIV is transmitted through exposure to human blood and certain body fluids. In the work setting, infection can result from parenteral, nonintact skin, or mucous membrane (eyes, nose, and mouth) exposure to contaminated materials. Data from needlestick studies indicate that persons exposed to HIV-contaminated needles have a 0.3-percent chance of seroconversion to HIV and a 0.09-percent seroconversion rate as the result of mucous membrane exposures (Short & Bell, 1993).

Epidemiological data on the consequence of parenteral exposure to HIV, HBV, and HCV indicate that one of the most critical workplace controls is the reduction of sharps-related incidents.

OSHA STANDARD
